CHAPTER 44

Hematologic and Coagulation Disorders

Shiv K. Sharma, MD, FRCA • Jill M. Mhyre, MD

CHAPTER OUTLINE

ANEMIA

Normal Hemoglobin Morphology

Normal adult hemoglobin consists of four polypeptides (two alpha and two beta chains) and the iron-containing prosthetic group (heme or ferriprotoporphyrin IX). In the early embryo, theta (θ) and zeta (ζ) chains are present instead of the alpha (α) chains, and epsilon (ε) chains are present instead of the beta (β) chains. After early embryogenesis, pairs of alpha chains are linked with pairs of either beta, gamma (γ), or delta (δ) chains to form adult hemoglobin (Hgb A = $\alpha_2\beta_2$), fetal hemoglobin (Hgb F = $\alpha_2\gamma_2$), or hemoglobin A_2 (Hgb A_2 = $\alpha_2\delta_2$). By term gestation, the ratio of hemoglobin F to hemoglobin A is approximately 1:1. By 1 year of age, hemoglobin F typically constitutes less than 1% of total hemoglobin. Although hemoglobin A_2 is present, it constitutes less than 2.5% of total adult hemoglobin.

The sequence of amino acids (141 amino acids for alpha chains and 146 for beta chains) defines the **primary structure**. The three-dimensional shape of each chain defines the **secondary structure**, and the relationship between the four chains and the heme prosthetic group defines the **tertiary structure** of the hemoglobin molecule. The binding of the ligands 2,3-diphosphoglycerate (2,3-DPG) and oxygen defines the **quaternary structure**. The physiology of oxygen transport in the fetus is described in Chapter 5.

Anemia in Pregnancy

During normal pregnancy, plasma volume increases by approximately 50% but red blood cell (RBC) mass increases by only 30%; this differential increase results in the **physiologic anemia of pregnancy** (see Chapter 2). If the hemoglobin concentration decreases below 10.5 g/dL, the physician should consider other causes of anemia.[1,2]

Iron deficiency is the most common cause of anemia in pregnancy. It becomes more prevalent as pregnancy advances; in a population-based sample of women in the United States, the prevalence increased from 7% in the first trimester to 14% in the second trimester and 30% in the third trimester of pregnancy.[3] Iron-deficiency

anemia during the first two trimesters of pregnancy increases the risk for preterm delivery and low birth weight.[4-6] In addition to reduced hematocrit, iron-deficiency anemia is characterized by low mean corpuscular volume (MCV) and low total serum iron, ferritin, and transferrin saturation. In the United States, the risk for iron deficiency is increased by advanced parity, short interpregnancy interval, Mexican-American ethnicity, and African race.[3,7] Daily oral iron treatment in pregnancy reduces the risk for anemia and low birth weight; a 2013 meta-analysis of randomized controlled trials suggests that there is a clear dose-response relationship for up to a total iron dose of 66 mg/day.[8] Doses greater than 60 mg/day increase side effects, including nausea, vomiting, constipation, and abdominal cramps.[9] Observational data suggest that oral iron therapy can reduce the incidence of preterm birth.[10] Although a 2013 meta-analysis of randomized controlled trials of iron supplementation failed to identify an effect on the incidence of preterm birth or small-for-gestational-age infants, the relative risk confidence intervals were wide.[8] Antepartum anemia is a leading risk factor for postpartum blood transfusion[11]; however, no study has evaluated the impact of antepartum iron supplementation on the risk of postpartum maternal blood transfusion.

Parenteral (intramuscular or intravenous) iron enhances hematologic response compared with oral iron, but formulations that contain dextran may increase risk for venous thrombosis and allergic reactions.[9]

An elevated hemoglobin concentration (≥ 14.5 g/dL) may reflect inadequate volume expansion and has been associated with adverse pregnancy outcomes, including preterm delivery, small-for-gestational-age infants, and stillbirth.[6,12]

Thalassemia

The thalassemias are a group of microcytic, hemolytic anemias that result from the reduced synthesis of one or more of the polypeptide globin chains.[13] This reduced synthesis leads to (1) an imbalance in globin chain ratios, (2) defective hemoglobin, and (3) erythrocyte damage resulting from excess globin subunits. In α-thalassemia, alpha-chain production is reduced, and in β-thalassemia, beta-chain production is reduced.

α-Thalassemia

There are two alpha-chain loci on each chromosome 16; therefore, there are four genes that can produce alpha chains.[14] Because deletions or mutations can affect any or all of these genes, four types of α-thalassemia exist: (1) **silent carrier** (three functioning genes), (2) **α-thalassemia trait** (two functioning genes), (3) **hemoglobin H disease** (one functioning gene), and (4) **α^0-thalassemia** or **Bart's hydrops** (no functioning genes). As the number of functioning genes decreases from three to zero, the ratio of alpha to beta chains decreases from 0.8:1 to 0.6:1 to 0.3:1 to 0:1. The mRNA production from the second alpha gene exceeds that of the first alpha gene by a factor of 1.5 to 3.[14,15] Therefore, deletions of the second alpha gene may produce greater clinical effect. As beta (or beta-like) chains accumulate, they can form tetramers *in utero* (hemoglobin Bart's = γ_4) or after delivery (hemoglobin H = β_4) and appear as Heinz bodies on the peripheral blood smear.

In the United States, 25% to 30% of black women are silent carriers and have slightly smaller (78 to 85 fL) mean corpuscular volume (MCV) than women without thalassemia.[16,17] A chromosome lacking one alpha gene is common in Africa, the Mediterranean basin, the Middle East, India, Southeast Asia, Indonesia, and the South Pacific Islands.[18] Silent carriers are not at increased risk for adverse outcome during pregnancy or surgery.

The **α-thalassemia** trait affects 2% to 3% of black women in the United States[16,17] and is almost exclusively due to homozygous α^+-thalassemia, in which one functional α-globin gene is preserved on each chromosome (α–/α–). These women have an MCV of 70 to 75 fL and mild anemia. They typically are asymptomatic and, beyond the effects of mild anemia, experience no additional risk for adverse outcomes during pregnancy or surgery. Heterozygous α^0-thalassemia trait (––/αα) is common among individuals of Southeast Asian descent. It is phenotypically indistinguishable from homozygous α^+-thalassemia trait but introduces the risk for bearing an offspring with hemoglobin H disease or Bart's hydrops.

Patients with **hemoglobin H disease** experience moderately severe microcytic anemia, splenomegaly, fatigue, and generalized discomfort. Hemoglobin H (β_4) constitutes 2% to 15% of the total hemoglobin in these patients. Affected patients generally do not have a decreased life span, and hospitalization for the treatment of their anemia rarely is required. However, disease severity and prognosis vary, depending on the specific mutations present[19]; some patients require lifelong transfusion and chelation therapy.

Hemoglobin Barts, or **α^0-thalassemia**, is generally incompatible with life. The disease is found predominantly in Southeast Asia, China, and the Philippines. Affected individuals die *in utero* or shortly after birth of hydrops fetalis; mothers carrying these fetuses are prone to develop hypertension or peripartum hemorrhage or both.[20] Intact neonatal survival has been reported with intrauterine transfusion therapy and postnatal hematopoietic stem cell transplantation.[21,22] Antenatal screening for the disease is possible (see later discussion).

β-Thalassemias

In β-thalassemia, the production of beta chains is reduced. There are more than 200 genetic causes for ineffective beta-chain production, including gene deletion, transcription mutations, and RNA-processing mutations.[13] Unlike the alpha chains, which have four genes (two on each chromosome 16), beta chains have only one gene on each chromosome 11. Production of mRNA from the second beta-like gene (i.e., delta) is almost completely suppressed. Therefore, there are only two primary forms of β-thalassemia: (1) **β^0-thalassemia**, in which there is no beta-chain formation, and (2) **β^+-thalassemia**, in which some beta-chain production exists. β^0-Thalassemia also is called **β-thalassemia major** or **Cooley's anemia**. Individuals who receive β-thalassemia genes from both

parents but with mutations of different types often develop a milder form of the disease and require fewer or no transfusions. This condition is known as **thalassemia intermedia**. Finally, **β-thalassemia minor** refers to the heterozygous carrier of β-thalassemia.

β-Thalassemia is found most often in persons from the Mediterranean basin, the Middle East, India, Pakistan, and Southeast Asia and less often among persons from Tajikistan, Turkmenistan, Kyrgyzstan, China, and Africa.[13]

Individuals with β-thalassemia have a relative excess of alpha chains. Excess alpha chains precipitate and form inclusion bodies in red blood cell (RBC) precursors, resulting in anemia secondary to ineffective erythropoiesis and splenic hemolysis.[13] In the fetus, the gamma chain is unaffected; therefore, anemia only develops as gamma-chain production ceases during the first year of life.[13] In some patients, gamma-chain production continues to a variable extent.[13] Thus, the ongoing production of hemoglobin F (even in adults) may minimize the effects of decreased beta-chain production.[13]

β-Thalassemia Major. In patients with β-thalassemia major, progressively severe anemia develops beginning in the first few months of extrauterine life.[13] The anemia results in tissue hypoxia, increased intestinal absorption of iron, and increased erythropoietin production. The resulting expansion of marrow cavities causes skeletal abnormalities and pathologic fractures. Splenomegaly leads to thrombocytopenia and leukopenia.

RBC transfusions are required to maintain life, and the resulting iron load leads to iron accumulation, first in Kupffer's cells (noncirculating macrophages found in the liver), then in liver parenchymal cells, and finally in endocrine and myocardial cells. Deposition of iron in endocrine tissues may result in diabetes mellitus, adrenal insufficiency, and infertility.[23] Myocardial accumulation of iron can lead to conduction abnormalities and intractable heart failure, which are exacerbated by anemia-induced tachycardia. Heart failure and infection are the most common causes of death.

Patients with β-thalassemia major who present when younger than 2 years of age often have hepatomegaly and a hemoglobin concentration as low as 2 g/dL. Patients who present later in life (2 to 12 years of age) typically have a hemoglobin concentration between 4 and 10 g/dL, with marked anisopoikilocytosis and numerous target cells, nucleated RBCs, and inclusion bodies. Levels of hemoglobin F range from 10% to 90% of the total hemoglobin, and hemoglobin A_2 constitutes the remainder of the hemoglobin present.

Treatment includes (1) lifelong transfusion of leukocyte-poor RBCs every 2 to 3 weeks to maintain a hemoglobin concentration greater than 10 g/dL, thus preventing endogenous erythropoiesis; (2) splenectomy; and (3) iron chelation therapy to prevent hemosiderosis.[24] Deferoxamine was the first available chelation agent. It has a long record of successful use, but it requires continuous subcutaneous infusion or intermittent intramuscular injection.[25,26] Deferiprone and deferasirox are alternative oral chelation drugs; deferiprone has emerged as a superior agent for reducing cardiac iron levels and preventing cardiac morbidity and mortality.[25,27] Hematopoietic stem cell transplantation may be curative if a human leukocyte antigen (HLA)-matched family donor without β-thalassemia major is found.[24,28] Research exploring the potential of gene therapy is underway.[29]

It is unusual for patients with β-thalassemia major to become pregnant; nonetheless, transfusion and chelation regimens improve fertility, and assisted reproductive technologies facilitate conception in women with hemosiderosis-related infertility.[30] The metabolic demands of pregnancy increase transfusion requirements. Mordel et al.[31] reviewed reports of these patients and suggested that up to 8 L of transfused RBCs may be required to maintain the hemoglobin concentration above 10 g/dL during pregnancy.[31] It is unclear whether iron-chelation therapy should be continued throughout pregnancy; insufficient evidence is available to refute theoretical concerns about teratogenicity and fetal iron depletion.[32,33] Monitoring for maternal cardiac iron deposition and heart failure may be accomplished using modified magnetic resonance imaging and echocardiography, respectively.[25,34] Historically, these patients had an increased incidence of spontaneous abortion, intrauterine fetal death, and fetal growth restriction (also known as intrauterine growth restriction).[31] Recent case series suggest that among women with normal cardiovascular function, careful transfusion therapy and multidisciplinary care may facilitate uneventful pregnancy.[30,35,36]

A trial of labor is appropriate, and operative delivery should be reserved for obstetric indications.[37] Chronic transfusions increase the risk for alloimmunization, which prolongs the time required to identify compatible allogeneic blood products in the event of peripartum hemorrhage. Intraoperative blood salvage has been safely performed during cesarean delivery in a parturient with thalassemia.[38] Postpartum pharmacologic thromboprophylaxis is indicated.[37]

Extramedullary hematopoiesis can result in vertebral cortical weakening, pathologic fractures, and, rarely, paraplegia. However, in the absence of a major pathologic process of the spine, neuraxial anesthesia can be safely administered.[39] Patients with splenomegaly may develop thrombocytopenia; therefore, anesthesia providers should exclude a history of spontaneous hemorrhage and determine the platelet count before initiating a neuraxial procedure.

β-Thalassemia Minor. The clinical course is usually benign in patients with β-thalassemia minor. The anemia is typically mild (hemoglobin concentration of 9 to 11 g/dL) and is characterized by microcytosis and hypochromatosis. Levels of hemoglobin F range from 1% to 3%, and levels of hemoglobin A_2 range from 3.5% to 7%.

Moderate anemia develops only during periods of stress, such as pregnancy and severe infection. Nonetheless, most patients with β-thalassemia minor tolerate pregnancy well, although the incidence of oligohydramnios and fetal growth restriction are greater than in nonthalassemic women.[40] Because of an increased rate of RBC turnover and an increased risk for neural tube defects, high-dose folate supplementation is recommended in the first trimester. Transfusions are

reserved for patients with hemorrhage or a hemoglobin concentration below 8 g/dL. Infection, which can cause bone marrow suppression, must be treated promptly. β-Thalassemia minor typically does not affect anesthetic management during labor or cesarean delivery.

Antenatal Thalassemia Screening

Among populations at risk for α- or β-thalassemia, antenatal screening can identify couples at increased risk for offspring with a serious hemoglobinopathy. Low maternal and paternal MCV (≤ 80 fL) or mean corpuscular hemoglobin (MCH ≤ 27 pg) with normal serum iron and ferritin should prompt peripheral smear analysis for inclusion bodies or hemoglobin electrophoresis or both.[18] The latter test may reveal elevated hemoglobin A_2 or hemoglobin F, suggesting β-thalassemia or another hemoglobinopathy (sickle cell trait [AS], sickle cell anemia [SS], or hemoglobin C trait [SC]). α-Thalassemia requires α-globin gene testing for diagnosis because hemoglobin electrophoresis will not detect it.[18] Counseling for fetal genetic testing should be offered if both parents carry at least one abnormal hemoglobin gene.[18]

Prenatal diagnosis can be accomplished with the use of fetal cells obtained by means of chorionic villus sampling or amniocentesis and subjected to DNA analysis.[18,37] In the future, cell-free fetal DNA obtained from maternal plasma may provide an alternative source of material for fetal genetic analysis.

Sickle Cell Disease

More than 1000 abnormal α-, β-, γ-, and δ-globin chains have been identified.[41] Structural hemoglobinopathies result when these abnormal chains are used to form hemoglobin molecules. The most common abnormal hemoglobins are hemoglobin S, hemoglobin C, hemoglobin D, and hemoglobin E.[41] Patients can be homozygous for an abnormal hemoglobin (e.g., **hemoglobin SS** or **sickle cell anemia**), heterozygous for an abnormal hemoglobin (e.g., **hemoglobin SA** or **sickle cell trait**), or doubly heterozygous for an abnormal hemoglobin (e.g., **hemoglobin SC** or **sickle cell hemoglobin C disease**).[18,41] The heterozygous state for both the thalassemias and the structural hemoglobinopathies appears to protect against malaria, which may explain their geographic distribution and continued presence in the gene pool.[42]

A **sickle cell disorder** refers to a state in which erythrocytes undergo sickling when they are deoxygenated.[42] Normal erythrocytes have a biconcave shape. Sickle cells are elongated and crescent shaped, with two pointed ends. **Sickle cell disease** refers to disorders in which sickling results in clinical signs and symptoms; it includes hemoglobin SS disease, hemoglobin SC disease, hemoglobin SD disease, and sickle cell β-thalassemia.[18,42]

Sickle Cell Anemia

Epidemiology. Table 44-1 lists the prevalence of sickle cell anemia and the other common hemoglobinopathies in the adult black population in the United States. The current number of individuals with sickle cell disease in the United States may approach 90,000, with 10% of Hispanic origin[43]; however, high-quality surveillance data are not available.[44]

TABLE 44-1 Prevalence of Hemoglobinopathies in the United States in Persons of African Descent

Type	Estimated Prevalence
Traits	
Hemoglobin AS	1:12.5
Hemoglobin AC	1:33
β-Thalassemia minor	1:67
Persistent hemoglobin F	1:1000
Sickling Disorders	
Hemoglobin SS	1:625
Hemoglobin SC	1:833
Hemoglobin S–β-thalassemia	1:1667
Hemoglobin S–persistent hemoglobin F	1:25,000
Hemoglobin CC	1:4444
β-Thalassemia major	1:17,778
Hemoglobin C–β-thalassemia	1:4444

Modified from Motulsky AG. Frequency of sickling disorders in U.S. blacks. N Engl J Med 1973; 288:31-3.

BOX 44-1 Factors That Increase Sickling in Women with Sickle Cell Anemia

- Hemoglobin S concentration more than 50% of the total hemoglobin concentration
- Dehydration leading to increased blood viscosity
- Hypotension causing vascular stasis
- Hypothermia
- Acidosis

Pathophysiology. In hemoglobin S molecules, valine is substituted for glutamic acid as the sixth amino acid in the beta chains.[41] This substitution results in a propensity for hemoglobin molecules to aggregate when the hemoglobin is in the deoxygenated state. The hemoglobin molecules stack on top of one another and form microtubules.

Oxygen tension is the most important determinant in sickling; other factors that affect sickling are listed in Box 44-1. Hemoglobin S begins to aggregate at a Po_2 of less than 50 mm Hg, and all of the hemoglobin S is aggregated at a Po_2 of approximately 23 mm Hg. The formation of hemoglobin S aggregates is time dependent[45]; the proportion of sickled hemoglobin increases with decreasing cardiac output and prolonged venous transit time. If an erythrocyte sickles, it can return to its normal shape once the hemoglobin S becomes oxygenated.[41,45] However, repeated sickling cycles produce erythrocyte metabolic abnormalities and membrane damage, eventually leading

to irreversible sickling regardless of oxygen tension.[41,45] Sickled cells are cleared rapidly from the circulation by the reticuloendothelial system; as a result, the erythrocyte life span is reduced to approximately 12 days.[41,45]

Sickled cells can form aggregates and lead to vaso-occlusive crises and end-organ injury. Repeated cycles of sickling, vaso-occlusion, reperfusion injury, and acute inflammation can lead to chronic inflammation and inflammatory vascular disease. Elevated levels of cell-free hemoglobin deplete nitric oxide, activate the endothelium, and further exacerbate inflammation.[41,42] The reduced erythrocyte life span results in anemia, jaundice, cholecystitis, and a hyperdynamic hemodynamic state.

Marked ventricular hypertrophy can occur in pregnant women with sickle cell disease secondary to increased cardiac output. This may lead to a decrease in ventricular compliance and a deterioration in ventricular diastolic function.[46] Anemia also leads to erythroblastic hyperplasia, expansion of medullary spaces, and a loss of cortex in long bones, vertebral bodies, and the skull.[41] Vaso-occlusive events can give rise to **infarctive crises** (which most often occur in the chest, abdomen, back, and long bones), **cerebrovascular accidents**, and rarely **peripheral neuropathy**.[47] Aggregate formation in the spleen can result in microinfarcts.

Functional asplenia and abnormal neutrophil responses both contribute to susceptibility to infection. Consequently, the incidence of pneumonia and pyelonephritis is higher in pregnant patients with sickle cell disease than healthy pregnant patients. **Aplastic crises** can occur from depression of erythropoiesis secondary to infection (especially parvovirus) or from marrow failure secondary to folate deficiency during pregnancy.[41] During an aplastic crisis, the hemoglobin concentration can decrease rapidly, leading to high-output cardiac failure and death. **Sequestration crises** can result from the massive pooling of erythrocytes, especially in the spleen. This event occurs more frequently in patients with hemoglobin SC disease or sickle cell β-thalassemia than in patients with other forms of sickle cell disease. In general, a major sequestration crisis is one in which the hemoglobin concentration is less than 6 g/dL and has decreased more than 3 g/dL from the baseline measurement.[41]

The long-term clinical course of sickle cell disease is highly variable. Higher fetal hemoglobin expression and coincident α-thalassemia were among the first genetic modulators described.[48] Subsequent work has identified a complex network of single nucleotide polymorphisms associated with specific complications of sickle cell disease, most prominently the transforming growth factor-beta (TGF-β) family of membrane-bound receptors. These receptors play a role in fibrosis, cell proliferation, hematopoiesis, osteogenesis, angiogenesis, nephropathy, wound healing, and immune response.[48]

Diagnosis. In the adult, sickle cell anemia is characterized by (1) a hemoglobin concentration of 6 to 8 g/dL, (2) an elevated reticulocyte count, and (3) the presence of sickle cells on a peripheral blood smear. The diagnosis is confirmed by electrophoresis, thin layer isoelectric focusing, or high-pressure liquid chromatography.[41] Because most hemoglobinopathies are inherited as autosomal recessive conditions, prenatal screening for abnormal hemoglobin is recommended in couples at high risk for sickle cell disease.[18] *In utero*, the diagnosis can be made through the use of restriction endonucleases specific for the sickle mutation applied to fetal cells obtained during amniocentesis or chorionic villus sampling.

Interaction with Pregnancy. Pregnancy typically exacerbates the complications of sickle cell anemia. Maternal mortality from sickle cell disease comprises as many as 1% of all maternal deaths in the United States.[49] Thromboembolic complications, infection, cardiomyopathy, and pulmonary hypertension are the most serious maternal medical complications.[49] Patients with sickle cell anemia have an increased incidence of preterm labor, placental abruption, fetal growth restriction, hypertension, and eclampsia.[49] Intensive fetal surveillance may reduce the risk for intrauterine fetal death.[49]

Medical Management. Sickle cell anemia is a chronic anemia; blood transfusions are given only when they are specifically indicated (e.g., acute anemia, aplastic crisis, pneumonia with hypoxemia, before or during surgery).[41] The goals of transfusion are to achieve a hemoglobin concentration greater than 8 g/dL and to ensure that hemoglobin A represents more than 40% of the total hemoglobin present. Prophylactic blood transfusions do not appear to alter fetal or maternal mortality, although the frequency of maternal pain crises may be reduced.[50,51] If the patient's baseline hemoglobin concentration is less than 6 to 7 g/dL, simple transfusions with buffy-coat-poor, hemoglobin S–free, washed RBCs should be adequate to meet treatment goals. Otherwise, partial exchange transfusions may be necessary.

Hemoglobin F does not form aggregates with hemoglobin S. Administration of hydroxyurea may enhance the production of hemoglobin F, which may decrease the morbidity and mortality of sickle cell anemia. It is unclear whether hydroxyurea is safe in pregnancy; the drug is known to be carcinogenic, mutagenic, and teratogenic in animals.[52] However, among a small series of pregnancies conceived at the time of maternal or paternal hydroxyurea administration, there was no evidence of abnormal pregnancy outcomes or teratogenicity among surviving offspring.[52] Bone marrow transplantation is a potentially curative therapy for individuals with complicated sickle cell disease, although HLA-matched donors can be difficult to locate and the procedure is associated with significant morbidity and mortality.[28,53]

Obstetric Management. During prenatal visits, the obstetrician should monitor maternal weight gain, blood pressure, urine protein content, and uterine and fetal growth. Antepartum fetal surveillance begins at the time of extrauterine viability. Blood transfusions are reserved for specific indications. There is no evidence that preoperative blood transfusion to achieve a hemoglobin concentration of 10 g/dL improves perioperative outcomes for nonobstetric sickle cell patients, but no trial has evaluated prophylactic blood transfusion before cesarean delivery.[42,54] Early preparation of cross-matched blood products should be considered because

alloimmunization, and the antigen crossmatching procedures recommended to prevent its development, can prolong crossmatching procedures.[42] Finally, postpartum pharmacologic thromboprophylaxis is indicated.[55]

Anesthetic Management. Preoperative evaluation should focus on recent sickle cell disease exacerbations, the degree of anemia, and chronic end-organ injury.[42] Pulmonary hypertension and high-output heart failure should be excluded with echocardiography.[55] Pain control during labor is essential; continuous neuraxial analgesia is recommended.[42] Although general anesthesia for cesarean delivery has been associated with postoperative sickling complications, either neuraxial or general anesthesia is acceptable, and the choice of anesthetic technique ultimately depends on the time available to induce anesthesia and the patient's preference and physical status.[56] Principles of anesthetic management include (1) use of crystalloid to maintain intravascular volume, (2) transfusion of RBCs to maintain oxygen-carrying capacity, (3) administration of supplemental oxygen, (4) maintenance of normothermia, (5) prevention of peripheral venous stasis, and (6) provision of appropriate venous thromboembolism prophylaxis.[42,55,56]

Sickle Cell Disease Variants

If a patient carries one sickle cell gene and another gene for a hemoglobin that has a propensity to sickle, that patient is considered to have sickle cell disease. Patients with hemoglobin SD disease tend to have the mildest form, and patients with SC disease or sickle cell β-thalassemia tend to have more severe disease.[41,57]

As with the hemoglobin S gene, hemoglobin C is most prevalent among persons of West African descent, whereas hemoglobin D is more often found among persons of African, northern European, and Indian descent, and hemoglobin E is most prevalent among persons of Southeast Asian descent.[41] Patients with hemoglobin SC and hemoglobin SD disease tend to be asymptomatic during childhood with only mild anemia. Typically, these individuals do not develop symptoms until the second half of pregnancy. During late pregnancy they may have severe anemia (secondary to splenic sequestration) and splenomegaly. Patients with hemoglobin SC disease also have a tendency to develop bone marrow necrosis, which predisposes to fat emboli. The other clinical manifestations are similar to those observed in patients with sickle cell anemia.

Blood transfusion is recommended only when the hemoglobin concentration is less than 7 to 8 g/dL. Obstetric and anesthetic management are similar to the management of patients with sickle cell anemia.

Patients who are homozygous for hemoglobin C, D, or E typically have mild anemia. Target cells often are observed and splenomegaly is common. Patients who are heterozygous (i.e., one gene for hemoglobin C, D, or E and one gene for normal hemoglobin) are asymptomatic. The diagnosis is confirmed with electrophoresis, thin-layer isoelectric focusing, or high-pressure liquid chromatography.[41] Pregnancy typically is well tolerated, and no specific change in obstetric or anesthetic management is required.

Sickle Cell Trait

Sickle cell trait is the most benign form of the sickle cell disorders. It occurs in approximately 8% of black women in the United States. The RBCs of patients with sickle cell trait do not sickle until the Po_2 decreases below 15 mm Hg; therefore, RBC life span is normal.[58] A study of 65,000 patients with sickle cell trait found only a slight increase in the incidence of renal (hematuria) and pulmonary (emboli) complications compared with patients without sickle cell trait.[59] Patients with sickle cell trait are not at increased risk for adverse outcome during surgery.

Autoimmune Hemolytic Anemia

Patients with autoimmune hemolytic anemia produce antibodies to their own RBCs, resulting in hemolysis and varying degrees of anemia. The annual incidence of new cases of autoimmune hemolytic anemia is approximately 1 per 80,000 persons, but the prevalence approaches 1 in 5,000.[60] Table 44-2 lists the characteristics of the four main types of autoimmune hemolytic anemia.[61] Warm antibodies react with RBCs at a temperature of 35° to 40° C, whereas cold antibodies react optimally at a temperature lower than 30° C. Table 44-3 lists the various causes of autoimmune hemolytic anemia.[62]

Patients with **warm-reacting antibodies** typically respond to treatment with corticosteroids; splenectomy and the anti-CD20 antibody rituximab are second-line therapies.[60] After splenectomy, relapses and blood transfusions may lead to the continued requirement for intermittent or continuous corticosteroid therapy. The requirement for extended phenotyping may delay matched blood product availability. In acute hemorrhage, the rapid transfusion of body-temperature, ABO-compatible and Rh-negative blood can be lifesaving, with the expectation that the half-life of transfused red blood cells will be shortened; this practice will allow time to procure compatible blood products.[60]

In patients with **cold-reacting antibodies**, the anemia typically is mild and maintenance of normal body and ambient temperatures typically is all that is required to prevent hemolysis.[61]

COAGULATION

Thrombotic and Thrombolytic Pathways

Hemostasis depends on the normal function of vascular tissue, platelets, and coagulation factors. During the initial response to loss of vessel integrity, platelets adhere to exposed collagen, facilitated by the von Willebrand factor (vWF) (primary hemostasis). Platelet activation results in the release of substances that constrict the injured vessels and cause other platelets to adhere and form a hemostatic plug. The platelet plug is not stable, and initiation of the coagulation cascade, followed by deposition and stabilization of fibrin, is necessary for

TABLE 44-2 Characteristics of Autoimmune Hemolytic Anemias

Disease	Immunoglobulin (Ig)	Complement Involved	Site of Red Blood Cell Destruction	Treatment	Transfusion Requirements
Incomplete warm autoantibodies	Typically IgG Rarely IgA Rarely IgM	No No C4b and C3b	Spleen Spleen Liver	Corticosteroids, splenectomy, immune globulin	Rarely needed; if given, combined with corticosteroids
Complete warm autoantibodies					
Type 1	IgM	C4b and C3b	Liver	Corticosteroids, splenectomy	Rarely needed
Type 2	IgM	C1-9	Intracellular	Plasma exchange, corticosteroids	Frequently needed
Cold autoagglutinins and hemolysins	IgM	No	Intracellular	Corticosteroids, keeping patient warm	Very rarely needed
Biphasic hemolysins:					
Acute	IgG	Yes	Intracellular agglutination	Treatment of underlying infection	Occasionally needed
Chronic	IgG	Yes	Intracellular hemolysis	Plasmapheresis, chlorambucil	Frequently needed

definitive hemostasis (secondary hemostasis). Most coagulation factors circulate in the blood as zymogens, which are converted to active enzymes that in turn convert other zymogens to active enzymes. For example, factor X (a zymogen) is converted to factor Xa (an enzyme), which converts prothrombin (factor II) to thrombin (factor IIa).

In its original conception, the coagulation cascade (Figure 44-1) was believed to propagate within plasma. Subsequent work has located the enzymatic reactions of the **extrinsic system** primarily to the surface of subendothelial cells and those of the **intrinsic system** to the activated platelet surface.[63] Currently, a widely used model divides the coagulation cascade into three phases: (1) an **initiation phase** (classical extrinsic pathway), in which small amounts of active coagulation factors are generated; (2) an **amplification phase**, in which the level of active coagulation factors is boosted; and (3) a **propagation phase**, in which coagulation factors bind to the membrane of activated platelets, leading to the formation of fibrin clots.[63]

In the classical extrinsic pathway, tissue damage activates tissue factor (TF) (also known as factor III or thromboplastin) on the surface of extravascular cells (e.g., fibroblasts, smooth muscle cells), which are exposed to the bloodstream after tissue damage. TF has also been identified on the surfaces of syncytiotrophoblasts,[64] adhered leukocytes, circulating monocytes, and circulating microparticle membrane vesicles released by inflammatory and tumor cells.[63] TF binds factor VII and promotes proteolysis and activation to factor VIIa. On the membrane surface, the TF/VIIa complex converts factor X to Xa and small amounts of factor IX to IXa. Factor Xa amplifies conversion of factor VII to VIIa in the first of many positive feedback loops, and factor Xa forms a complex with factor Va. The membrane-bound prothrombinase complex (i.e., Xa/Va) converts small amounts of soluble prothrombin to thrombin. This thrombin diffuses to the activated platelet surface, where it amplifies the intrinsic coagulation pathway.

In the intrinsic pathway, factor XII binds to a negatively charged substrate (e.g., collagen, platelet phosphatidylserine) and may undergo autolysis to form factor XIIa, or it may be converted to XIIa by trace amounts of XIIa. In addition to activating its own zymogen, factor XIIa converts prekallikrein to kallikrein and factor XI to XIa. High-molecular-weight kininogen can bind factor XI and facilitate its conversion to XIa by XIIa. Kallikrein and high-molecular-weight kininogen also can convert factor XII to XIIa. Factor XIa converts factor IX to IXa, which, with factor VIIIa, converts factor X to Xa. Factor Xa promotes platelet aggregation, and it

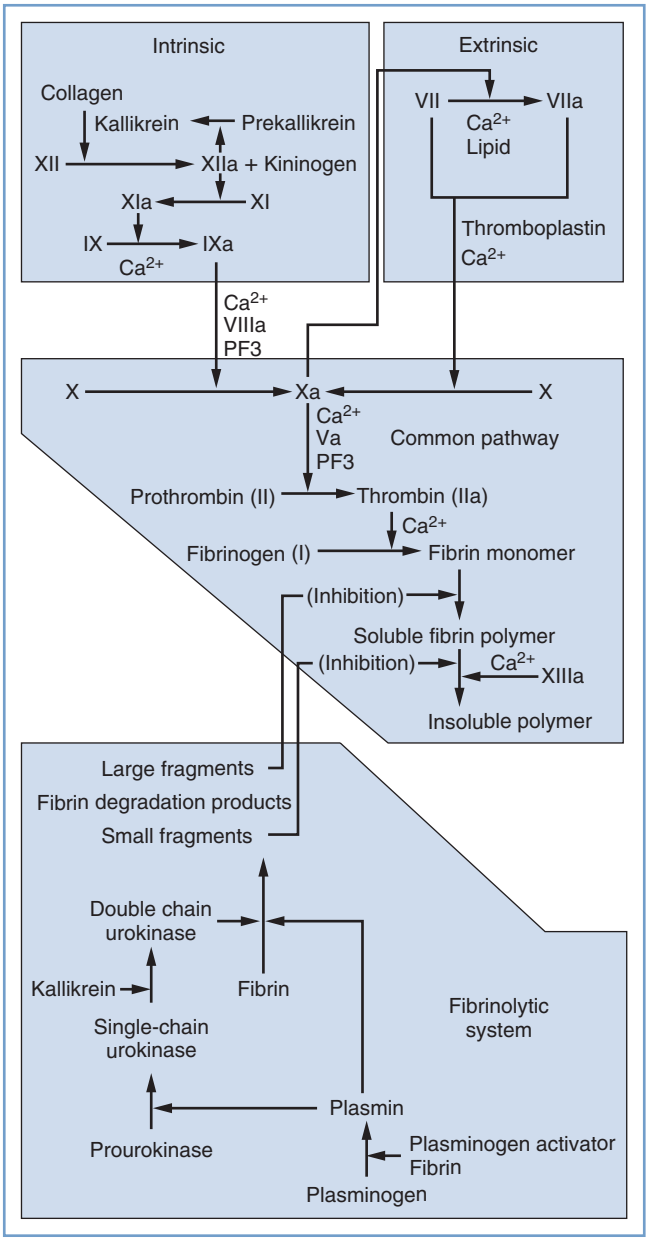

FIGURE 44-1 ■ Components of the extrinsic, intrinsic, and common pathways and the fibrinolytic system. The term *cascade* is a misnomer that stems from the presence of positive and negative feedback loops in both the coagulation and fibrinolytic systems. *PF3,* Platelet factor 3.

converts factors V and VIII to factors Va and VIIIa, respectively. Factor Xa, combined with factor Va, converts factor II (prothrombin) to factor IIa (thrombin), a process termed the *thrombin burst*. Activated platelets provide the primary surface for conversion of factor X to Xa and prothrombin to thrombin. Thrombin converts factors I (fibrinogen), V, VIII, and XIII to factors Ia (fibrin), Va, VIIIa, and XIIIa, respectively. Thrombin also causes platelet activation. Factor XIIIa is required to cross link fibrin strands, which helps form a stable clot.

Clot formation is limited by the natural anticoagulants antithrombin III, proteins C and S, and tissue factor pathway inhibitor (TFPI). Antithrombin III, whose activity is enhanced by heparin, inhibits factor IXa, factor Xa, and thrombin. Protein C is activated by a thrombin-thrombomodulin complex. With protein S as a cofactor, protein C breaks down factors Va and VIIIa. TFPI is produced by endothelial cells and inhibits coagulation by simultaneously binding factor Xa and the TF/factor VIIa complex.

The final component of the coagulation system is the **fibrinolytic system**, in which plasmin breaks down fibrin. Tissue-type plasminogen activator (t-PA) circulates as an active protease; however, its activity increases dramatically when it binds to fibrin, at which time it converts plasminogen to plasmin. Urokinase-like plasminogen activator (u-PA) is secreted as the relatively inactive pro-urokinase; it is converted to the active form (single-chain urokinase) by plasmin. Single-chain urokinase is converted to its most active form (double-chain urokinase) by kallikrein, which is released during activation of the coagulation cascade.

Plasmin-mediated fibrinolysis is confined to the clot by the local availability of fibrin and by plasminogen activator inhibitor-1 (PAI-1), which is secreted by many cells, and by plasminogen activator inhibitor-2 (PAI-2), which is secreted primarily by the placenta. Thrombin-activatable fibrinolysis inhibitor (TAFI) is synthesized in the liver, is activated by the thrombin-thrombomodulin complex, and inhibits fibrinolysis by eliminating the binding sites on fibrin for plasminogen and t-PA. The antifibrinolytic drugs **tranexamic acid** and **epsilon-aminocaproic acid (EACA)** inhibit fibrinolysis by binding to plasminogen and plasmin and preventing their binding to fibrin.

Changes in the concentrations of coagulation factors during pregnancy are outlined in Chapter 2 (see Box 2-2). The levels of most procoagulants increase during pregnancy, while anticoagulant levels remain stable or decrease.[64] Although t-PA levels decrease and antifibrinolytic proteins (i.e., PAI-1, PAI-2, TAFI) increase, plasminogen and fibrin degradation product levels increase, suggesting that fibrinolysis continues unabated during pregnancy.

Placental syncytiotrophoblasts promote coagulation by presenting tissue factor and phospholipids to maternal blood coursing through the intervillous space.[64] The concentrations of the thrombin-antithrombin complex and fibrin degradation products are elevated in blood from the uterine vein compared with peripheral blood, suggesting that many of the hemostatic changes of pregnancy originate in the placental bed.[65]

Deficiencies in procoagulant factors or an increase in fibrinolytic factors cause **hemorrhagic disorders**. Deficiencies in antithrombin III, protein C or S, or the fibrinolytic system cause **thromboembolic disorders**.

Assessment of Coagulation

Routine Hematology

The increase in the concentration of most coagulation factors is associated with a shortening of the prothrombin time (PT) and the activated partial thromboplastin time (aPTT) during normal pregnancy. Similarly, fibrinogen

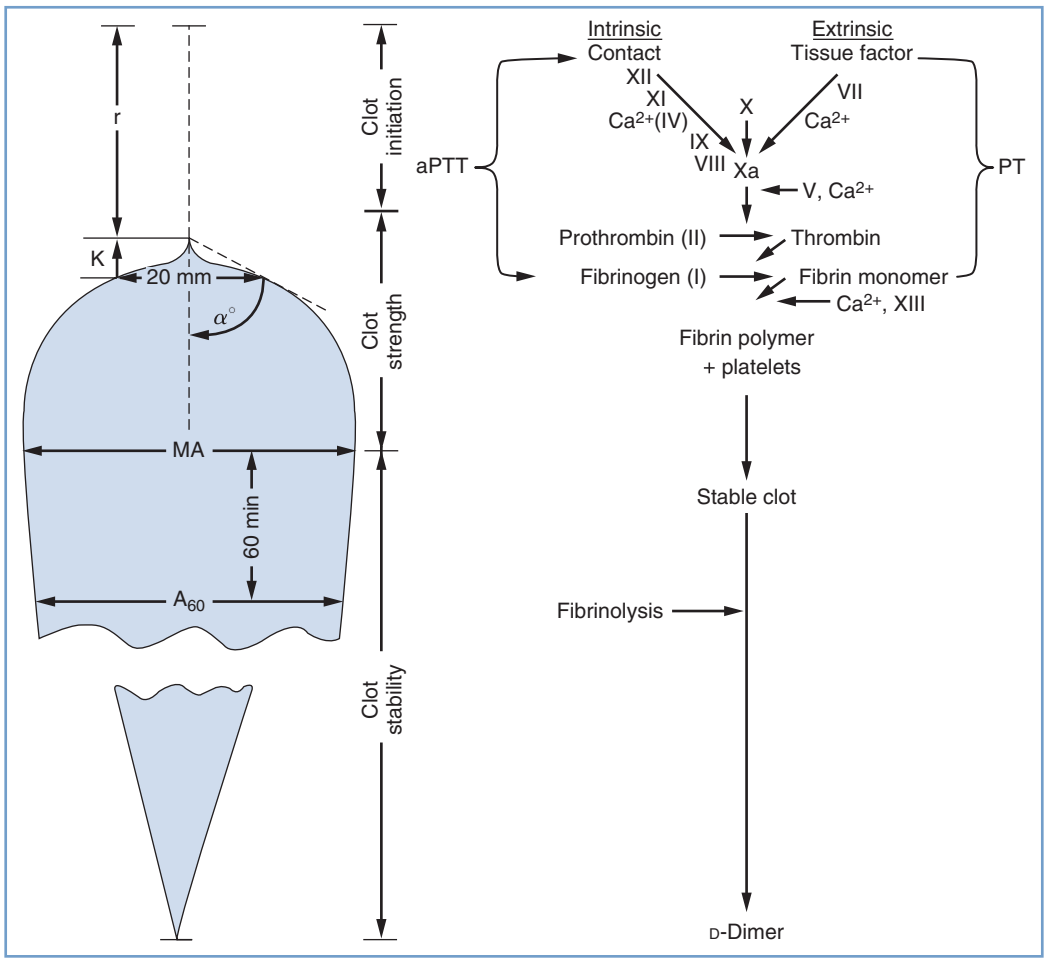

FIGURE 44-2 ■ Simplified side-by-side presentation of thromboelastographic parameters and the routine coagulation profile. *α angle,* clot formation rate; *A60,* amplitude 60 minutes after MA; *aPTT,* activated partial thromboplastin time; *K,* clot formation time; *MA,* maximum amplitude; *PT,* prothrombin time; *r,* reaction time. and fibrin degradation products are increased in normal pregnancy. These changes may mask the early diagnosis of **disseminated intravascular coagulation (DIC)**, so serial laboratory parameters are indicated if the diagnosis is suspected.[64] Thrombocytopenia is a sensitive, but not specific, indicator of DIC. For women with severe preeclampsia, a platelet count is a clinically useful screening test; a result below 100,000/mm^3 suggests the possibility of impaired hemostasis and even DIC.[66,67] In the healthy parturient with no history or clinical signs of bleeding, the routine laboratory assessment of hemostasis parameters, including platelet count, is not indicated.[66] Although used historically, the bleeding time is no longer recommended as a preprocedure screening tool.[68]

Thromboelastography

Thromboelastography (TEG) measures whole blood coagulation and can rapidly provide information about the adequacy of platelet function and other coagulation factors. Thromboelastographic parameters are interrelated and reflect activities of coagulation proteins, platelets, and their interaction (Figure 44-2). TEG has been used to assess coagulation status in normal and high-risk pregnant women,[69] to manage peripartum coagulopathy,[70] and to assess hemostasis before the initiation of neuraxial anesthesia in pregnant patients with thrombocytopenia.[71] In a study of serial coagulation assessment during pregnancy, TEG demonstrated increased coagulability and decreased fibrinolysis during normal pregnancy.[72] However, in another study, TEG was not useful in predicting estimated blood loss during cesarean delivery.[73] Some investigators found a correlation between TEG measurements and low-molecular-weight heparin (LMWH) anticoagulation activity as measured by serum anti–factor Xa (anti-Xa) concentrations. They concluded that TEG might be a useful test to monitor LMWH activity.[74] TEG measurements were also able to detect and quantify the effect of unfractionated heparin on blood coagulation in postcesarean delivery patients.[75]

Thromboelastometry

Thromboelastometry, similar to TEG, is a bedside test that assesses the shear elasticity of whole blood as it clots using a ROTEM® (Pentapharm GmbH, Munich, Germany) monitor. ROTEM thromboelastometry is performed with specific activators, and a real-time graph

provides continuous assessment of the coagulation time, clot formation time, and maximal clot firmness to evaluate the extrinsic and intrinsic coagulation systems, and the fibrinogen and platelet contributions to clotting within 15 to 30 minutes of initiating the test.[76] Further research is needed to establish the clinical value of thromboelastometry in the obstetric population.

Platelet Function Analyzer

The PFA-100® (Siemens Healthcare Diagnostics, Deerfield, IL) measures platelet function *in vitro*, especially platelet activation and aggregation. This simple test evaluates the capacity of a sodium-citrated whole blood sample to form a platelet plug at the aperture situated on a collagen/adenosine phosphate or collagen/epinephrine surface under high-shear conditions. The time required for full occlusion of the aperture by the platelet plug is designated as the *closure time*. Some investigators have found this test equally sensitive to platelet aggregometry and more sensitive than the bleeding time in detecting both congenital and acetylsalicylic acid–induced platelet defects.[77] PFA-100 measurements do not correlate with platelet counts in healthy parturients,[78] but they may demonstrate impairment in platelet function with severe preeclampsia.[79]

THROMBOCYTOPENIC COAGULOPATHIES

Autoimmune Thrombocytopenic Purpura

Several terms have been used to describe autoimmune thrombocytopenic purpura. *Idiopathic thrombocytopenic purpura* was used first, but the name was changed to *immune thrombocytopenic purpura* when it was discovered that immunoglobulin G (IgG) antibodies were responsible for the increased platelet destruction.[80] Currently the preferred term is **autoimmune thrombocytopenic purpura (ATP)**. This disease should not be confused with neonatal alloimmune thrombocytopenia, in which maternal antibodies to a fetal platelet antigen cause fetal and neonatal thrombocytopenia.

The incidence of mild thrombocytopenia during pregnancy is 5% to 8%,[81] but the incidence of ATP is 0.01% to 0.1%.[81,82] Antibodies directed against platelet antigens are produced primarily in the spleen, where phagocytosis by macrophages occurs. Antibody production and phagocytosis also can occur in the liver and bone marrow. The binding of complement to platelets can facilitate their clearance, and antibody binding to megakaryocytes can result in ineffective production of platelets.[83]

Diagnosis

The diagnosis of ATP must be considered if the platelet count is less than 100,000/mm^3 and normal or higher numbers of megakaryocytes are present in the bone marrow. Moreover, the blood smear often reveals the presence of higher platelet volume and greater platelet diameter.[81] Other *nonimmunologic* conditions that must be considered include (1) **gestational or essential thrombocytopenia**, (2) **preeclampsia**, (3) **DIC**, (4) **thrombotic thrombocytopenic purpura**, and (5) **acute fatty liver of pregnancy**.[81,82] Other *immunologic* conditions that must be considered include (1) **drug-induced thrombocytopenia**, (2) **post-transfusion purpura**[84] (in individuals who have received a blood transfusion in the previous 1 to 2 weeks), and (3) **pseudothrombocytopenia**. Pseudothrombocytopenia is a laboratory artifact in which chelation of calcium ion by ethylenediaminetetraacetic acid (EDTA) exposes antigenic sites that react with antibodies, causing clumping that artificially lowers the platelet count.[85] In these cases, the automated platelet count is normal if citrate anticoagulant is used.

Interaction with Pregnancy

Conservative management is typically sufficient if ATP is diagnosed during pregnancy. Corticosteroids are administered if the platelet count is less than 20,000 to 30,000/mm^3 before the onset of labor or less than 50,000/mm^3 at the time of delivery.[82,86] High-dose intravenous immune globulin (IVIG) produces a rapid but transient increase in the platelet count and is administered if there is no response to corticosteroid therapy.[82,86] In some women with preexisting ATP who become pregnant, thrombocytopenia becomes sufficiently severe that administration of high-dose corticosteroids and immune globulin is inadequate. Splenectomy may be necessary and, if so, is best performed in the second trimester.[82,87]

Some obstetricians have observed significant hemorrhage during the immediate postpartum period in as many as 33% of women with a platelet count of less than 100,000/mm^3.[88] In contrast, others have noted no increase in peripartum blood loss in women with a platelet count between 60,000/mm^3 and 100,000/mm^3.[89]

Obstetric Management

Maternal IgG can cross the placenta and cause fetal thrombocytopenia, which increases the risk for neonatal hemorrhage. Although there is a correlation between maternal platelet-associated IgG and fetal thrombocytopenia,[90] it is not possible to predict the degree of fetal thrombocytopenia based on maternal platelet count[91] or serology.[81,82,92] No study has demonstrated a correlation between the fetal platelet count and intrapartum fetal risk. There are no definitive reports of fetal intracranial hemorrhage secondary to ATP. Neonatal intracranial hemorrhage is rare and is not related to the method of delivery.[93] Thus, current guidelines recommend that cesarean delivery should be reserved for obstetric indications.[82,93] Percutaneous umbilical cord blood sampling at 38 weeks' gestation has been suggested.[94] However, it is likely that the risk of the procedure is greater than the risk for intrapartum fetal hemorrhage. Fetal scalp blood sampling during labor can cause significant hemorrhage and can generate misleading results if the sample is exposed to vernix or amniotic fluid. Current guidelines do not recommend attempts to measure the fetal platelet count before delivery.[82]

Because episiotomies and perineal lacerations pose the greatest potential for peripartum bleeding, it is preferable to avoid performing an episiotomy in thrombocytopenic women, if possible. Bleeding occurs less often from the placental implantation site.[90] (Contraction of the uterus represents the primary mechanism for postpartum hemostasis.) After delivery, the platelet count often returns to normal in these patients.[95]

Thrombotic Thrombocytopenic Purpura

The classic pentad that defines the syndrome of thrombotic thrombocytopenic purpura (TTP) includes (1) thrombocytopenia (platelet count as low as 20,000/mm^3), (2) microangiopathic hemolytic anemia, (3) fever, (4) neurologic signs such as photophobia, headache, and seizures, and (5) renal failure. Only the first two elements are essential for diagnosis.[96] Disseminated platelet aggregation is a hallmark of TTP.[96,97] Neurologic and renal changes result from the deposition of platelet emboli and may be of variable intensity in the acute presentation and during recurrences. Diseases that share some of the clinical findings of TTP include DIC, preeclampsia, and hemolytic-uremic syndrome.

TTP is associated with either a congenital or acquired deficiency of enzyme ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13). ADAMTS13 is responsible for cleaving vWF multimers. These multimers promote systemic platelet aggregates and microemboli.[96] Decreased levels of the large multimeric forms of vWF are seen in the acute phase of TTP[98] but return to normal during remission. In contrast, in hemolytic-uremic syndrome the large multimeric forms of vWF are present in normal amounts.[99] The affinity of vWF for platelet membrane glycoprotein IIb/IIIa is also increased in TTP.[97] The presence of vWF (but not fibrinogen) in platelet aggregates helps to differentiate TTP from DIC.[100] (In patients with DIC, fibrinogen but not vWF is found in platelet aggregates.)

Approximately 40% of patients who achieve remission have at least one recurrence, but relapse is rare in patients without severe ADAMTS13 deficiency.[101] Pregnancy appears to be a precipitating event for both initial and recurrent episodes of TTP, particularly among women with congenital ADAMTS13 deficiency.[101] ADAMTS13 activity declines progressively through normal pregnancy, while vWF levels increase.[102]

Prompt diagnosis and effective treatment for TTP appear to improve both maternal and fetal survival,[86,103] although perinatal loss remains significant if the disease develops in the first and second trimesters.[103] Diagnosis of TTP may be delayed because of a misdiagnosis with the hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome; concurrent diagnoses have been reported.[103] Clinical signs that suggest TTP include microangiopathic anemia with thrombocytopenia in the first half of pregnancy, concomitant fever or neurologic signs, and a high ratio of lactate dehydrogenase to aspartate aminotransferase.[103]

Plasma exchange is the mainstay of therapy for TTP, with an exchange volume of 1.0 to 1.5 times the predicted plasma volume of the patient.[96,103,104] Corticosteroids are recommended for second-line therapy.[105] Additional treatments include rituximab, intravenous immunoglobin, and prostacyclin.[105-107] Termination of pregnancy may be beneficial if medical treatment is ineffective[108] but has not been shown to improve maternal outcomes. Platelet transfusions are usually avoided but may be safe if administered immediately before or after plasma exchange therapy begins.[105] Because of the coagulopathy present in patients with TTP, neuraxial anesthesia is not recommended. One case report described spinal anesthesia administered for cesarean delivery in a woman with familial ADAMTS13 deficiency treated with fresh frozen plasma.[109]

Inherited Platelet Disorders

Bernard-Soulier syndrome is a rare autosomal recessive disorder characterized by (1) thrombocytopenia, (2) large platelets on the peripheral blood smear, and (3) defects of the platelet membrane glycoprotein Ib-IX-V complex.[110] Laboratory diagnosis includes prolonged bleeding time and prolonged closure time on PFA-100. Treatment during labor and delivery may require tranexamic acid or administration of recombinant factor VIIa (rFVIIa).[110] Other therapies include human leukocyte antigen (HLA)– and platelet antigen–matched platelet transfusion, if available, or unmatched platelet transfusion, if necessary.

Patients with **Glanzmann thrombasthenia** have a deficiency in platelet surface glycoprotein IIb/IIIa receptors, the major receptor for fibrinogen; this deficiency results in abnormal platelet aggregation.[111] These patients have a normal platelet count, but bleeding time and closure time on PFA-100 are prolonged. The treatment of Glanzmann thrombasthenia during labor and delivery is similar to that for Bernard-Soulier syndrome.[111]

Drug-Induced Platelet Disorders

Drugs can accelerate platelet destruction through an immunologic mechanism[112]; however, drugs that are likely to result in this complication are not often used in obstetric patients (e.g., quinidine, quinine, gold salts).[113] Heparin is an exception; it can cause thrombocytopenia via a nonimmunologic or an immunologic mechanism.[114] The risk for heparin-induced thrombocytopenia (HIT) is lower with LMWH than unfractionated heparin.[115]

Drugs that *impair* platelet function are often used in obstetric patients (Table 44-4). Aspirin irreversibly inactivates cyclooxygenase.[116] The bleeding time is prolonged for 1 to 4 days after the ingestion of aspirin,[117] and *in vitro* platelet function tests can remain abnormal for as long as 1 week.[116] However, low-dose aspirin (i.e., 60 to 70 mg) does not significantly prolong the bleeding time in pregnant women.[118] Moreover, a large number of women receiving low-dose aspirin therapy for the prevention or treatment of preeclampsia have received neuraxial analgesia for labor and delivery without complications.[119] Therefore, in the absence of a coadministered anticoagulant (e.g., LMWH) or preexisting hemostatic defect

TABLE 44-4 Drugs That Affect Platelet Function

Category	Drug(s)
Inhibitors of cyclooxygenase	Aspirin, nonsteroidal anti-inflammatory drugs
Stimulators of adenyl cyclase	Prostaglandin E_1, prostacyclin
Inhibitors of phosphodiesterase	Caffeine, theophylline
Antibiotics	Penicillins, cephalosporins
Anticoagulant	Heparin
Volume expanders	Dextran, hydroxyethyl starch

TABLE 44-5 Classification of von Willebrand's Disease

Type	Description
1	Partial quantitative deficiency of VWF
2	Qualitative VWF defects
2A	Decreased VWF-dependent platelet adhesion and a selective deficiency of high-molecular-weight VWF multimers
2B	Increased affinity for platelet glycoprotein Ib
2M	Decreased VWF-dependent platelet adhesion without a selective deficiency of high-molecular-weight VWF multimers
2N	Markedly decreased binding affinity for factor VIII
3	Virtually complete deficiency of VWF

VWF, von Willebrand factor.
From Sadler JE, Budde U, Eikenboom JC, et al. Update on the pathophysiology and classification of von Willebrand disease: a report of the Subcommittee on von Willebrand Factor. J Thromb Haemost 2006; 4:2103-14.

(e.g., von Willebrand's disease, hemophilia A, uremia) in which aspirin's effect is more pronounced,[120,121] recent ingestion of aspirin does not contraindicate the administration of neuraxial anesthesia.[122]

Other nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen, indomethacin, naproxen) reversibly inhibit cyclooxygenase.[123] These drugs have only a transient effect on the bleeding time[117,124] and have been given to patients with hemostatic diseases (e.g., hemophilia A) without deleterious effect.[125] Maternal ingestion of these drugs should not affect anesthetic management for delivery.

Drugs that increase platelet cyclic adenosine monophosphate (cAMP) levels decrease platelet responsiveness.[123] This increase in cAMP levels can occur after the administration of prostaglandin E_1 or prostacyclin (which stimulates adenyl cyclase)[126] or after the administration of drugs that decrease the destruction of cAMP (e.g., caffeine, theophylline).

Most penicillins and some cephalosporins impair platelet activity.[123,127] In addition to its effect on the coagulation system, heparin impairs platelet function by reducing the production of thrombin, a potent platelet activator.[123] Dextran, which is absorbed onto platelet membranes, can reduce platelet aggregation, secretion, and procoagulant activity.[123] Because platelet membranes are a substrate for steps in the coagulation system, clot formation may also be impaired by dextran. Hydroxyethyl starch also appears to worsen platelet function.[123] A diet rich in omega-3 fatty acids or fish oil can reduce the platelet concentration of arachidonic acid and prolong bleeding time.[123] Herbal therapies including garlic, gingko, and ginseng can similarly impact hemostasis.[122]

CONGENITAL COAGULOPATHIES

von Willebrand's Disease

The hemostatic disorder, von Willebrand's disease, was named for Erich von Willebrand, who first described it in 1926.[128] vWF is synthesized by endothelial cells and megakaryocytes.[129] The vWF subunit is 260 to 275 kDa. A dimer is formed by a combination of two subunits, and variable numbers of the dimers are combined to form multimers that range from 500 to 200,000 kDa. vWF plays two primary roles in coagulation: (1) it forms a complex with factor VIII, which decreases the excretion of factor VIII; and (2) it mediates platelet adhesion by binding to platelets (a reaction enhanced by ristocetin) and collagen.[129]

von Willebrand's disease can be divided into several subtypes based on quantitative and qualitative defects in vWF (Table 44-5).[129-131] **Type 1 von Willebrand's disease** is the most common congenital bleeding disorder, which typically is inherited as an autosomal dominant trait[132]; its incidence ranges from 1:100 to 1:2500.[129,132,133] In this subtype, vWF functions normally but its levels are reduced. Both vWF and factor VIII increase in normal pregnancy, so antenatal bleeding is rare in women with type 1 disease. **Type 2 von Willebrand's disease** is less common and includes a family of disorders characterized by qualitative dysfunction of vWF, with normal plasma concentrations.[129] Although types 2A and 2M lead to decreased platelet aggregation, type 2B results from a gain-of-function mutation in which vWF increases binding between platelets, leading to accelerated platelet turnover and thrombocytopenia.[129] Finally, **type 3 von Willebrand's disease** is caused by a severe quantitative deficiency in vWF and is inherited in an autosomal recessive pattern; the estimated incidence is between 1:200,000 and 1:2,000,000.[134,135]

Patients with von Willebrand's disease have variable levels of both vWF and factor VIII. Thus, some patients with von Willebrand's disease are asymptomatic. Because vWF aids in platelet binding to sites of vascular damage, symptoms of von Willebrand's disease (e.g., bleeding from skin and mucosae) can mimic those of platelet disorders.[129] vWF slows the clearance of factor VIII; therefore, a deficiency can result in decreased factor VIII levels, and patients with severe disease can present with hemorrhages into muscles and joints similar to those seen in patients with classic hemophilia.[129]

Patients with von Willebrand's disease usually have decreased platelet aggregation in response to ristocetin. Levels of factor VIII and vWF ristocetin cofactor should

be determined during pregnancy, at least during the third trimester. Prophylactic treatment is reserved for patients with a factor VIII level below 50 IU/dL.[129] For patients with von Willebrand's disease type I or IIA, 0.3 μg/kg of desmopressin (l-desamino-8-D-arginine vasopressin [DDAVP]) is administered intravenously as labor begins, and the dose is repeated every 12 to 24 hours.[129] For patients who are unresponsive to desmopressin, commercial preparations of plasma concentrates that contain both vWF and factor VIII are administered.[129] The usual dose is 40 to 60 IU/kg. For acute bleeding, fresh frozen plasma (FFP) or cryoprecipitate (500 to 1500 units of factor VIII activity) may be administered; however, large volumes of FFP are needed for factor replacement.

During labor, factor VIII and vWF ristocetin cofactor levels should be maintained at greater than 50% of normal.[130] When considering anesthetic and analgesic options, the balance between risks and benefits of a neuraxial procedure should be evaluated for each patient.[136] Postpartum hemorrhage rates are increased for up to 1 month after delivery.[130] The factor VIII level should be checked daily during the postpartum period, and treatment should be initiated if the factor VIII level decreases below 50% of normal levels or if significant bleeding occurs.[129,137]

Other Coagulation Factor Deficiencies

In males, the two most common coagulation factor deficiencies are factor VIII (**hemophilia A**) and factor IX (**hemophilia B**). Both occur as X-linked traits. It is possible for a female to have hemophilia if her father is a hemophiliac and her mother is a carrier for hemophilia and passes the abnormal X chromosome to her daughter.[138] A female can also have hemophilia if she is a carrier (i.e., she received one abnormal gene from a carrier mother or an affected father) and she has either a new mutation of the other gene for factor VIII or IX or another X-chromosome abnormality.[138]

In early embryogenesis, half of the X chromosomes are inactivated.[139] Of the gene population, half of the abnormal genes and half of the normal genes are inactivated in females who are heterozygous for hemophilia A or B. On average, these women have half of the normal concentration of factor VIII or IX, which typically is adequate for coagulation. Because the chromosome inactivation is random, more abnormal genes are inactivated in a certain percentage of carriers, and these women have a normal concentration of factor VIII or IX. However, if most of the normal genes are inactivated, the individual can have severely depressed levels of factor VIII or IX. If such a patient becomes pregnant, factor supplementation with pooled human plasma concentrate (antihemophilic factor/vWF concentrate [hemophilia A] or prothrombin complex concentrate [PCC] [hemophilia B]) may be necessary before or during delivery.

On average, half of the male children of heterozygous carriers for hemophilia A or B will have hemophilia. These infants have an increased incidence of excessive bleeding after circumcision, but the incidence of cephalohematoma does not appear to be increased.[140] It is not clear whether the mode of delivery affects the incidence of cephalohematoma. Women who are heterozygous carriers may undergo a trial of labor and vaginal delivery, but the following procedures should be avoided: (1) placement of a fetal scalp electrode, (2) fetal scalp blood pH determination, (3) vacuum extraction, and (4) difficult forceps delivery.[141] One report has described the administration of epidural analgesia during labor in a patient with severe hemophilia A after factor replacement.[142]

Acquired hemophilia is an autoimmune disease resulting from antibodies to factor VIII and is associated with pregnancy and the postpartum period.[143] Both rFVIIa and factor eight inhibitor bypassing activity (FEIBA) have been used to treat bleeding in patients with acquired hemophilia, but both agents are associated with thromboembolism.[143] Immunosuppression is necessary to treat the underlying cause of the disease.

Other congenital factor deficiencies occur as autosomal recessive traits and cause symptoms only in the homozygous state. Table 44-6 lists the plasma concentrations of coagulation factors that are required for hemostasis. The patient whose liver disease or vitamin K deficiency is responsible for the coagulopathy may benefit from intramuscular administration of vitamin K. In an emergency, factors may be rapidly replaced by administration of the appropriate pooled human plasma product or FFP (10 to 20 mL/kg).

TABLE 44-6 Minimum Coagulation Factor Levels

Coagulation Factor	Plasma Concentration Required for Hemostasis (U/dL)
I	10-25
II	40
V	10-15
VII	5-10
VIII	10-40
IX	10-40
X	10-15
XI	20-30
XIII	1-5

ACQUIRED COAGULOPATHIES

Disseminated Intravascular Coagulation

DIC results from an abnormal activation of the coagulation system, which leads to (1) formation of large amounts of thrombin, (2) activation of the fibrinolytic system, (3) depletion of coagulation factors, and (4) hemorrhage. In severe cases, diffuse microvascular thrombosis can lead to end-organ injury.[144] In the obstetric population, the most frequent causes of DIC are preeclampsia, placental abruption, sepsis, retained dead fetus syndrome, postpartum hemorrhage, acute fatty liver of pregnancy, and amniotic fluid embolism.[64]

Laboratory findings consistent with DIC include (1) a decreased platelet count; (2) decreased fibrinogen and

antithrombin III concentrations; (3) variable increases in PT, aPTT, and thrombin and reptilase times; and (4) higher concentrations of D-dimer, fibrin monomer, and fibrin degradation products than are normal during pregnancy.[64]

Therapeutic goals for these patients are to (1) treat or remove the precipitating cause, (2) replace depleted coagulation factors, (3) stop ongoing proteolytic activity (i.e., both the coagulation and fibrinolytic pathways), and (4) provide multisystem support as required.[145] In obstetric patients, evacuation of the uterine contents often results in removal of the precipitating cause.[146] A vaginal delivery can be attempted if the mother is stable and delivery can be achieved in a timely manner. If delivery cannot be achieved quickly, cesarean delivery may be required. Rarely, cesarean delivery may be necessary to deliver a dead fetus.

Considerable controversy exists regarding the medical management of patients with DIC.[144,146] Management may vary according to the etiology of the disorder.[144] In the presence of active bleeding or when an invasive procedure is required, the physician should transfuse FFP (15 to 30 mL/kg) to maintain the PT and aPTT within 1.5 times normal values, cryoprecipitate or fibrinogen concentrate to maintain the fibrinogen concentration above 150 to 200 mg/dL, and platelets to maintain a platelet count above 50,000/mm^3.[64,145]

The use of heparin is controversial. No trials have demonstrated improved clinical outcomes with heparin treatment,[145] but experts suggest that heparin at therapeutic doses may be helpful in cases of DIC complicated by thromboembolism or extensive fibrin deposition.[145,147,148] Both unfractionated heparin and LMWH are effective only in the presence of an adequate concentration of antithrombin III.[147] Patients with DIC may have a depleted concentration of antithrombin III,[147] and administration of FFP, lyophilized antithrombin III, or both may be necessary.[64,149] Several reports have described the use of rFVIIa in massive obstetric hemorrhage with DIC (see Chapter 38).[64]

Patients with DIC often have multiorgan system failure and require mechanical ventilatory support and care in the intensive care unit. DIC almost always mandates administration of general anesthesia in patients who require cesarean delivery. Given the increased risk for venous thromboembolism among patients with DIC, thromboprophylaxis with unfractionated heparin or LMWH, mechanical methods, or a combination of multiple methods is indicated.[145,148]

Therapeutic Anticoagulation

Most pregnant women who require long-term anticoagulation receive LMWH throughout pregnancy.[150] If warfarin is administered during pregnancy, it is typically discontinued in favor of unfractionated heparin or LMWH before the onset of labor. If a patient begins to labor while she is still taking warfarin, the effects can be reversed by oral or intravenous administration of vitamin K and intravenous PCC.[151,152] Although in emergency situations warfarin has traditionally been reversed with the rapid administration of FFP, PCC is increasingly used for this indication.[152] In 2013, a four-factor PCC (Kcentra) was approved by the U.S. Food and Drug Administration (FDA) for warfarin reversal. The dose of PCC depends on the patient's INR.[152]

Unfractionated heparin therapy should be discontinued and normalization of coagulation can be monitored by regular assessment of the aPTT or the activated coagulation time (ACT). If conditions require immediate reversal of anticoagulation, intravenous protamine 12.5 to 50 mg can be administered,[151] with additional doses administered as determined by the aPTT or the ACT. Protamine reversal of heparin therapy to allow administration of neuraxial anesthesia is not recommended. Further, protamine is unpredictable in reversing the anti–factor Xa activity caused by LMWH.[151] Therefore, protamine reversal of LMWH is not recommended.

If the coagulation status is deemed adequate for cesarean delivery, a neuraxial anesthetic technique can be considered. The anesthesia provider should weigh the risks and benefits of neuraxial and general anesthesia for the individual patient. It is preferable not to administer neuraxial anesthesia to a patient with a persistent laboratory coagulation abnormality. However, in selected circumstances, neuraxial anesthesia may be offered to a patient who has an isolated laboratory abnormality and no clinical evidence of coagulopathy. In such patients, frequent neurologic examinations are performed to facilitate the early detection of an epidural hematoma during the postpartum period.

Other Acquired Coagulopathies

Coagulopathies associated with hypertensive disorders of pregnancy and obstetric hemorrhage are discussed in Chapters 36 and 38, respectively.

NEURAXIAL ANESTHESIA IN THE PATIENT WITH ONGOING COAGULOPATHY OR PHARMACOLOGIC ANTICOAGULATION

Concern exists that an epidural hematoma may develop after the administration of neuraxial anesthesia in patients with coagulopathy (see Chapter 32). There are only a few published case reports of epidural or spinal subdural hematoma after the administration of neuraxial anesthesia in pregnant patients.[122] Similarly, multicenter survey studies have not reported this complication in obstetric patients.[153,154] However, in view of the serious consequences of an epidural hematoma, the risks and benefits of performing neuraxial anesthesia should be carefully assessed in a patient with either clinical or laboratory evidence of coagulopathy.

Frank coagulopathy represents an absolute contraindication to the administration of neuraxial anesthesia. The anesthesia provider can use PT/INR, aPTT, and ACT measurements or TEG to assess the extent of anticoagulation and the effectiveness of reversal therapy in patients receiving unfractionated heparin or oral anticoagulation therapy. If use of a neuraxial

anesthetic technique is considered in a patient with a congenital coagulopathy, results of relevant factor assays should be within the normal range before neuraxial needle placement.[130,142,155,156]

Professional societies have developed evidence-based guidelines to improve the safety of neuraxial anesthesia/analgesia in anticoagulated patients. The American Society of Regional Anesthesia and Pain Medicine (ASRA) Third Consensus Conference on Neuraxial Anesthesia and Anticoagulation concluded that *thromboprophylaxis* with twice-daily dosing of **unfractionated heparin** does not contraindicate the use of neuraxial anesthetic techniques as long as the total daily dose is not greater than 10,000 units (see Table 39-4).[122] However, the safety of neuraxial procedures in patients receiving daily heparin doses greater than 10,000 units or more than twice-daily dosing has not been established.[122] The platelet count should be assessed before the administration of neuraxial anesthesia or catheter removal in patients who have received unfractionated heparin therapy for more than 4 days.[122]

LMWH is considered to be more efficacious for thromboprophylaxis than unfractionated heparin.[115,150] However, a significant increase in the incidence of epidural and spinal hematoma after neuraxial anesthesia in *nonobstetric* patients receiving LMWH was recorded by the FDA between 1993 and 1998.[122,157] In December 1997, the FDA issued a warning that called attention to the risk for epidural or spinal hematoma in the setting of LMWH therapy. The apparent increase in the risk for an epidural hematoma after concurrent administration of neuraxial anesthesia and prophylactic LMWH may be related to the use of higher doses of LMWH and the relatively greater bioavailability and longer biologic half-life of LMWH than unfractionated heparin.[157] Recent reports have identified very few cases of epidural hematoma among nonobstetric patients who received care fully compliant with the ASRA guidelines.[153] No case of neuraxial hematoma in an obstetric patient has been attributed to antithrombotic or antiplatelet therapy.[122] Studies suggest that the risk for epidural hematoma is lower in obstetric patients than elderly nonobstetric patients.[153,154]

In patients receiving LMWH for *thromboprophylaxis*, the ASRA guidelines recommend an interval of at least 10 hours after the last LMWH dose before initiation of a neuraxial procedure (see Table 39-4).[122] In patients receiving higher doses of LMWH (e.g., enoxaparin 1 mg/kg every 12 hours, enoxaparin 1.5 mg/kg daily, dalteparin 120 U/kg every 12 hours, dalteparin 200 U/kg daily, tinzaparin 175 U/kg daily), neuraxial needle placement should not occur until at least 24 hours after the last dose of LMWH.[122] Concomitant administration of medications affecting hemostasis (e.g., administration of both LMWH and an antiplatelet drug) further increases the risk for hemorrhagic complications.[122]

In patients receiving a single daily dose of LMWH thromboprophylaxis, the first postoperative LMWH dose should be administered 6 to 8 hours after surgery.[122] An indwelling epidural catheter may be safely maintained in these patients; however, it should be removed at least 10 to 12 hours after the last dose of LMWH, and the next dose of LMWH should be administered at least 2 hours* *after* catheter removal. In patients receiving higher (e.g., twice-daily) doses of LMWH, the first dose of LMWH should be delayed for 24 hours postoperatively, and an indwelling catheter should be removed at least 2 hours* *before* initiation of LMWH therapy. The anti-Xa level is not predictive of the risk for bleeding during or after administration of neuraxial anesthesia.

Fondaparinux is a newer antithrombotic drug that inhibits factor Xa activity. Its use has been reported in pregnant women who developed HIT.[158] The American College of Chest Physicians (ACCP) recommends limiting the use of fondaparinux to those with severe allergic reactions to heparin (e.g., HIT).[150] The risk for spinal hematoma with fondaparinux is not known.[122]

In patients receiving long-term **warfarin** therapy, the anticoagulation therapy should be stopped at least 4 to 5 days before the planned procedure and the INR should be normalized before needle placement, with catheter removal deferred until the INR is 1.5 or less.[122]

Aspirin or **NSAID** therapy is not a contraindication for neuraxial anesthesia. The use of **herbal medications** such as garlic, ginkgo, or ginseng alone may not increase the risk for spinal hematoma; however, concurrent use of an oral anticoagulant or heparin may increase the risk for bleeding complications in these patients.[122]

The assessment of risk is more problematic in patients with isolated laboratory evidence of thrombocytopenia. **Thrombocytopenia** (defined as a platelet count $< 100{,}000/mm^3$) develops in up to 1 in 20 healthy women by the end of pregnancy, normally with little clinical consequence.[81] However, the combination of both quantitative and qualitative platelet deficits presents a more serious risk for epidural hematoma and may develop in the context of severe preeclampsia (see Chapter 36), ATP, and congenital platelet disorders. A number of groups have reported the safe administration of epidural anesthesia—without any neurologic complications—in healthy pregnant women with thrombocytopenia, preeclamptic women, and women with ATP.[156,159,160] Published studies of neuraxial anesthesia in thrombocytopenic patients are small and retrospective and do not exclude the possibility that modest thrombocytopenia increases the risk for epidural hematoma.[156] However, no published evidence suggests that a specific platelet count predicts the risk for epidural hematoma in obstetric patients.

Although there is no widespread consensus about the minimum platelet count needed to ensure safe neuraxial procedures, several experts have reviewed the available evidence and concluded that a minimum platelet count of $80{,}000/mm^3$ is usually sufficient for the safe initiation of neuraxial analgesia/anesthesia and removal of a neuraxial catheter.[159,160] Under selected circumstances, neuraxial procedures may be appropriate in a

*The U.S. Food and Drug Administration recommends waiting at least 4 hours after removal of a neuraxial catheter before administering a postprocedure dose of LMWH. (U.S. Food and Drug Administration. Low molecular weight heparins: drug safety communication—recommendations to decrease risk of spinal column bleeding and paralysis. November 6, 2013. Available at http://www.fda.gov/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm373918.htm. Accessed November 2013.)

well-counseled patient with a platelet count between 50,000 and 80,000/mm^3.[159] When determining whether neuraxial anesthesia is safe in a thrombocytopenic patient, the anesthesia provider should consider the following factors: (1) clinical evidence of bleeding, (2) time interval since the platelet count was measured, (3) any recent change in the platelet count (e.g., downward trending), (4) quality of platelet function, (5) adequacy of coagulation factor level and function, and, perhaps most importantly, (6) the risk versus benefit of performing neuraxial anesthesia. The bleeding time measurement is *not* helpful in determining the risk for epidural hematoma. Although TEG shows some promise, its usefulness in predicting the risk for epidural hematoma is unproven. The use of single-shot spinal anesthesia may be associated with a lower risk for epidural vein trauma than epidural catheter insertion and removal.

Clinical judgment represents the most important means of assessing the risk for epidural hematoma in an individual patient. Clearly, the anesthesia provider would not want to perform neuraxial anesthesia in a patient with clinical evidence of coagulopathy (e.g., bleeding from nasal or oral mucosae or venipuncture sites, presence of petechiae or ecchymoses). In contrast, a patient with severe preeclampsia, severe upper airway edema, a stable platelet count of 95,000/mm^3, and no clinical evidence of coagulopathy may be an appropriate candidate for neuraxial anesthesia. The risk for a failed tracheal intubation is greater than the risk for an epidural hematoma in such a patient. Neuraxial analgesia may be offered to such a patient after a thorough discussion of the risks and benefits. However, some anesthesia providers advocate a more conservative approach in such cases and recommend alternative methods of analgesia during labor, followed by awake laryngoscopy and tracheal intubation if cesarean delivery should become necessary.

Several modifications of the neuraxial technique may decrease the risk for venous injury during the administration of epidural analgesia: (1) administration of epidural analgesia early in labor before the platelet count or platelet function declines, (2) needle and catheter placement with the patient in the lateral rather than sitting position, (3) the use of a wire-embedded polyurethane rather than polyamide epidural catheter, (4) limiting catheter insertion length to 6 cm or less, and (5) administration of saline through the needle to distend the epidural space before insertion of the catheter.[161] The epidural catheter may be sited several hours before the patient requires analgesia. This interval allows the anesthesia provider to observe for symptoms and signs of epidural hematoma formation (e.g., back pain, radicular pain, leg weakness) before the administration of an analgesic or anesthetic solution. This last recommendation is impractical in most circumstances. Furthermore, it is unclear that any of these recommendations reduces the likelihood of epidural hematoma in patients with platelet dysfunction or coagulopathy.

During the administration of epidural analgesia, the anesthesia provider can minimize motor blockade, which might confuse the diagnosis of epidural hematoma, by administering a dilute solution of local anesthetic with an opioid. A neurologic examination should be performed at 1- to 2-hour intervals to look for evidence of an epidural hematoma. In addition, all clinical staff should be aware of the signs and symptoms of epidural hematoma, including (1) severe, unremitting backache; (2) neurologic deficit, including bowel or bladder dysfunction or radiculopathy; (3) tenderness over the spinous or paraspinous area; and (4) unexplained fever.[162] If clinical findings raise concern for epidural hematoma, immediate steps should be taken to obtain appropriate diagnostic imaging and to consult a neurosurgeon (see Chapter 32).

In some cases, severe thrombocytopenia and coagulopathy may develop *after* the placement of an epidural catheter. Epidural hematomas have been reported after epidural catheter removal in obstetric patients with coagulopathy.[122] It is possible that movement or removal of the catheter may dislodge a clot, resulting in fresh bleeding and an epidural hematoma. As such, recommended hemostatic conditions for epidural catheter removal parallel those recommended for neuraxial block administration.[122,159]

HYPERCOAGULABLE STATES

Effective hemostasis is maintained by an appropriate balance of procoagulant and anticoagulant activity. A congenital deficiency in anticoagulant activity occurs in more than 50% of women with pregnancy-related venous thrombosis.[163,164] Factor V Leiden mutation, prothrombin mutation, protein C deficiency, protein S deficiency, and antithrombin III deficiency are the most common thrombophilias diagnosed in pregnancy.[164] Venous thromboses are more common than arterial thromboses[165]; the incidence increases with surgery, pregnancy, oral contraceptive use, and immobilization. Although the results of small case-control studies have suggested that patients with thrombophilias may have an increased incidence of fetal growth restriction, intrauterine fetal death, preeclampsia, and placental abruption, these associations have not been replicated in large prospective cohorts.[164,166] There is insufficient evidence that screening for thrombophilias improves birth outcomes for women with a history of pregnancy complications.[150]

Commonly used anticoagulation regimens during pregnancy are listed in Table 39-3. The American College of Obstetricians and Gynecologists (ACOG) and the ACCP has recommended thromboprophylaxis regimens for pregnancies complicated by inherited thrombophilias.[150,164,167] Additionally, the ACCP recommends LMWH during pregnancy for the prevention and treatment of venous thromboembolism, rather than unfractionated heparin or warfarin.[150]

For women receiving long-term thromboprophylaxis with LMWH or vitamin K antagonists during pregnancy, consideration should be given toward transitioning the patient to a shorter-acting agent in anticipation of delivery to facilitate initiation of neuraxial procedures and peripartum hemostasis.[150] Intermediate- and therapeutic-dose LMWH heparin should be discontinued at least 24 hours before the induction of labor or cesarean delivery.[150]

Factor V Leiden Mutation

Factor V Leiden is a genetic disorder attributable to genetic mutation resulting in a single amino acid substitution in the factor V protein. The mutant protein persists longer in the circulation owing to its slower degradation by activated protein C, leading to a hypercoagulable state.[164] The incidence of heterozygous factor V Leiden is 5% to 8%; the risk for thrombosis is increased 4- to 8-fold.[163,168] A homozygous state is found in 1 in 1600 individuals, and these patients have at least a 25-fold higher risk for thrombosis.[163,168]

Prothrombin Gene Mutation

The prothrombin *G20210A* gene mutation results in elevated circulating prothrombin levels.[163] This gene mutation is present in 2% to 3% of the general population and accounts for up to 17% of cases of venous thromboembolism in pregnancy.[163,164] For women who are heterozygous for the prothrombin mutation, a personal or family history of venous thrombosis increases risk for a subsequent venous thromboembolism in pregnancy from less than 0.5% to approximately 10%.[164] Further, the combination of factor V Leiden and prothrombin mutations has synergistic hypercoagulable effects.[164]

Protein C Deficiency

Protein C is produced in the liver and acts by inhibiting activated factors V and VIII. Deficiency is defined by an activity level less than 50%. The incidence of protein C deficiency is approximately 0.3% in the general population; the risk for thrombosis in pregnancy is increased up to fivefold.[163,168] Protein C levels normally increase by 35% during pregnancy, but this increase is attenuated in patients with protein C deficiency.[169] Among women with protein C deficiency, the risk for venous thromboembolism during pregnancy increases from less than 1% among those without previous thrombosis to between 2% and 17% for those with a previous thrombosis.[164]

Protein C is a vitamin K–dependent protein with a short half-life (8 hours). If warfarin is administered without prior heparin anticoagulation, protein C levels decrease before the levels of factors II, VII, IX, and X decrease. Thrombosis with skin necrosis can result.[170]

Protein S Deficiency

Protein S acts as a cofactor for protein C. In contrast to protein C, the plasma levels of protein S normally *decrease* during pregnancy.[169] The prevalence of protein S deficiency is approximately 0.2 % in the general population; the risk of venous thromboembolism during pregnancy is increased up to 2- to 4-fold.[163,168] Protein S is also produced in the liver and depends on vitamin K for its synthesis.[170] Circulating protein S binds to C4b-binding protein (a protein of the complement system), but it is the free fraction of protein S that acts as a cofactor for protein C.[170] Immunologic assays measure total protein S concentration; therefore, a diagnosis of protein S deficiency is made either by using a functional assay (< 50% activity) or by calculating the percent of protein S bound to C4b-binding protein.[170] The risk of antepartum and postpartum venous thromboembolism is low in patients with protein C or protein S deficiency; hence thromboprophylaxis is not indicated unless the patient has a history of venous thromboembolism or additional risk factors are present.[167]

Antithrombin III Deficiency

Antithrombin III is synthesized in the liver and endothelial cells. It inactivates thrombin and factors IXa, Xa, XIa, and XIIa[171]; its activity is potentiated by heparin. Deficiency of antithrombin III occurs in 0.02% to 0.4% of the general population[164,172]; the risk for thrombosis in pregnancy is increased up to fivefold.[163,168,172] The risk for thrombosis during pregnancy increases from 3% to 7% among those with antithrombin III deficiency and no prior thromboembolism to more than 40% among those with a prior venous thromboembolism.[164] Quantitative (type I) and qualitative (type II) deficiencies exist[170]; thus, both immunologic and functional assays are required to detect abnormalities.[173]

Heparin acts by potentiating the activity of antithrombin III. If antithrombin III levels are decreased, heparin may not ensure effective thromboprophylaxis. Antithrombin III replacement, with or without coadministration of heparin, has been proposed for perioperative or peripartum therapy for patients with antithrombin III deficiency and a history of venous thromboembolism.[171] Although long-term antithrombin III replacement is expensive, its use may be indicated for women who experience venous thrombosis despite thromboprophylaxis with LMWH.[174] Warfarin is an alternative option for women in the second or third trimester of pregnancy, remote from delivery.[174]

Lupus Anticoagulant

The term *lupus anticoagulant* is a misnomer. Patients with lupus anticoagulant do *not* have a coagulopathy; rather, they are at risk for thromboembolic events. The hypercoagulable state associated with lupus anticoagulant is discussed in Chapter 41.

KEY POINTS

- Neuraxial anesthetic techniques can be used safely during labor and delivery in patients with a hemoglobinopathy.
- Routine laboratory assessment of the platelet count and coagulation status is not indicated before the initiation of neuraxial procedures in healthy parturients.
- The first goal in the treatment of disseminated intravascular coagulation is to treat or remove the precipitating cause. In pregnant patients, evacuation of the uterine contents often results in removal of the precipitating cause.

- Uncorrected, frank coagulopathy represents an absolute contraindication to the administration of neuraxial anesthesia.
- In a patient with an isolated laboratory abnormality and no clinical evidence of coagulopathy, the anesthesiologist should assess the risks and benefits of performing neuraxial anesthesia.
- Prophylactic and therapeutic anticoagulation regimens exist for patients with venous thromboembolism or those at increased risk for thromboembolism; anesthesia providers should be aware of the safety implications of anticoagulation therapy on the timing of initiation of neuraxial anesthesia and neuraxial catheter removal.

CHAPTER 50

Obesity

Ashraf S. Habib, MBBCh, MSc, MHSc, FRCA • Robert D'Angelo, MD

CHAPTER OUTLINE

Obesity is a worldwide health problem, with the prevalence in the general population growing at an alarming rate and reaching epidemic proportions. Data from the National Center for Health Statistics show that in 2010, 69% of Americans were overweight and 36% were obese; 56% of women of reproductive age (20 to 39 years old) were overweight, and 32% were obese.[1] Although no definition of obesity specific to pregnancy exists, a pregnant woman is generally considered overweight when her body mass index (BMI) is 25.0 to 29.9 kg/m^2, and obese when her BMI is 30 kg/m^2 or greater. The World Health Organization defines three grades of obesity: class I (BMI 30.0 to 34.9 kg/m^2), class II (BMI 35.0 to 39.9 kg/m^2), and class III (BMI 40 kg/m^2 or greater).

Obesity is associated with an increased risk for maternal morbidity and mortality. The care of obese parturients poses significant challenges to the anesthesia provider as a result of common comorbidities, an increased cesarean delivery rate, and technical difficulties associated with both neuraxial and general anesthesia. Understanding the pathophysiologic changes and comorbidities associated with obesity and pregnancy is crucial for the safe conduct of anesthesia in these high-risk patients.

PHYSIOLOGIC CHANGES OF OBESITY

Pulmonary Changes

Obesity increases the demands on the pulmonary system. As energy expenditure increases proportionate to the increase in body mass,[2] oxygen consumption and carbon dioxide (CO_2) production also increase proportionate to the increase in work performed.[3] Minute ventilation is increased owing to the elevated respiratory demand, except in the 5% to 10% of patients with Pickwickian syndrome, who display a reduced sensitivity to CO_2.[4] Obesity affects the body's ability to meet these demands by changing pulmonary mechanics, altering lung volumes, and impairing oxygen consumption. The combined effects of obesity and pregnancy on the respiratory system are summarized in Table 50-1.

Pulmonary Mechanics

Obesity increases the weight of the chest wall; thus, greater energy expenditure is required during ventilation to move this greater mass. Several prospective studies have demonstrated that morbidly obese patients, in comparison with controls, expend a disproportionately high percentage of total oxygen consumption on respiratory work, even during quiet breathing.[5] The weight gain associated with pregnancy further increases the work of breathing in obese patients. In obese individuals, frequent shallow respirations may represent a more efficient breathing pattern than a pattern characterized by large tidal volumes. This pattern of frequent shallow respirations contrasts to the increased tidal volumes that typically accompany pregnancy. Although the $Paco_2$ in most morbidly obese pregnant women is not different from that in nonobese pregnant women, pulmonary reserve is reduced.

Lung Volumes

Greater abdominal weight restricts diaphragm movement, especially in the supine or Trendelenburg position,

thus encouraging smaller tidal volumes. Functional residual capacity (FRC) decreases at the expense of expiratory reserve volume and may be less than closing capacity. In morbidly obese patients, this difference can result in airway closure during tidal ventilation. Similarly, expiratory reserve volume, vital capacity, inspiratory capacity, total lung capacity, and maximum minute ventilation all decrease in morbidly obese patients. Both chest wall and lung compliance decrease, but airway resistance increases.[6,7]

Pregnancy also alters lung volumes, and these changes may modify some of the normal effects of obesity on respiratory function. In nonobese pregnant women, expiratory reserve volume and FRC both decline 20% to 25% by term. Eng et al.,[8] examining a series of pregnant women whose estimated prepregnancy weights ranged from 50% to 140% above normal, measured lung volumes during the third trimester and again at 2 months postpartum. With the exception of FRC, the lung volume changes resembled those that occur in nonobese pregnant women. However, FRC decreased less in obese pregnant women than in nonobese pregnant women.

Oxygenation

Pulmonary diffusion typically remains normal in most women with morbid obesity. Decreased chest wall compliance and greater abdominal weight promote airway closure in the dependent portion of the lung.[9] Ventilation preferentially occurs in the more compliant, nondependent portion of the lung. In contrast, pulmonary blood flow preferentially occurs in the dependent portion of the lung, resulting in ventilation-perfusion mismatch and hypoxemia.[9]

Consistent with the positional deterioration of lung volumes, oxygenation worsens in obese persons in the supine and Trendelenburg positions. Both term pregnant and obese patients are prone to rapid oxygen desaturation during induction of general anesthesia.[10] Although oxygenation does not necessarily correlate linearly with weight,[11] massive weight loss improves Pao_2 and expiratory reserve volume. Weight loss does not, however, improve forced expiratory volume in 1 second, forced vital capacity, or maximum mid-expiratory flow.[12]

Cardiovascular Changes

Cardiovascular changes associated with pregnancy and obesity are summarized in Table 50-2. Both obesity and pregnancy increase blood volume and cardiac output. The latter increases by 30 to 50 mL/min for every 100 g of fat.[13] This change occurs as a result of increases in both stroke volume and heart rate. In addition to the elevated preload observed in obese parturients, left ventricular afterload is also increased owing to the high peripheral resistance and greater arterial wall stiffness. These changes result in both eccentric and concentric left ventricular hypertrophy. Messerli et al.[14] documented a 30-fold increase in premature ventricular contractions in obese patients with eccentric left ventricular hypertrophy in comparison with lean subjects. The increase in heart rate limits the time available for diastolic filling. Diastolic relaxation is impaired, leading to diastolic dysfunction.[15] In contrast, ventricular systolic function is usually normal in obese individuals.[16]

Pulmonary blood volume increases in proportion to increases in cardiac output and total blood volume. Pulmonary hypertension can occur and may be position

dependent. Paul et al.[17] observed an 11% increase in oxygen consumption and a 44% increase in pulmonary capillary wedge pressure when morbidly obese patients were placed in a supine position. Hypoxemia, if present, increases pulmonary vascular resistance. Airway obstruction may also increase pulmonary artery pressure.

Hypertension occurs more frequently among obese pregnant women than lean women. A BMI of 30 kg/m^2 or more is associated with a threefold higher incidence of hypertension during pregnancy than a BMI less than 30 kg/m^2.[18] BMI and left ventricular mass are directly related, even after controlling for age and blood pressure, especially in patients with a BMI greater than 30 kg/m^2.[19] Among morbidly obese pregnant women, left atrial size, left ventricular thickness, interventricular septal thickness, and left ventricular mass are increased compared with nonobese pregnant women.[13] Fatty infiltration of the heart can occur, especially in the right ventricle and perhaps in the conduction system.[20]

Aortocaval compression of the great vessels in the supine position may be greater in obese parturients, particularly those with a large fat panniculus.[21] Tsueda et al.[22] reported two cases of cardiac arrest in morbidly obese patients who had been placed in the supine position. The authors speculated that the sudden circulatory changes associated with this change in position accounted for the sudden death of these patients.

Gastrointestinal Changes

It is unclear whether obesity in pregnancy is associated with an increase in gastric volume and a decrease in gastric pH. Vaughan et al.[23] observed that 88% of obese nonpregnant patients presenting for surgery had a gastric pH less than 2.5 and 86% had a gastric volume exceeding 25 mL. These findings resemble those in a cohort of healthy pregnant women who presented for elective cesarean delivery.[24] Roberts and Shirley[25] reported that gastric volumes aspirated from obese laboring women undergoing cesarean delivery were significantly higher than those obtained from lean controls.

Other studies, however, did not confirm these findings and reported conflicting evidence regarding gastric volume and pH in obese patients.[26,27] Similarly, studies have reported conflicting data regarding gastric emptying in the obese population; studies have reported delayed, unchanged, or more rapid rates of gastric emptying in obese subjects compared with lean subjects.[28] In a nonobstetric obese population, Maltby et al.[29] reported that drinking 300 mL of clear fluid 2 hours before surgery had no effect on gastric fluid volume and pH compared with fasting after midnight. Similarly, Wong et al.[30] found that gastric emptying in obese, nonlaboring term pregnant volunteers was not delayed after ingestion of 300 mL of water compared with ingestion of 50 mL of water. The gastric volume was similar to baseline 60 minutes after ingestion of water. It should be remembered, however, that obesity is a risk factor for diabetes,[18] which may cause delayed gastric emptying.

Both gastroesophageal reflux and hiatal hernia are more common in obese than in nonobese patients.[31] Obesity is also associated with a higher risk for difficult airway management, which is a known risk factor for aspiration.[32] Therefore, it seems likely that morbidly obese patients are at higher risk for pulmonary aspiration of gastric contents.

Coagulation Changes

Obesity is associated with a higher risk for thromboembolic complications.[33] Venous thromboembolism was the leading cause of direct maternal mortality in the United Kingdom from 1985 to 2005.[34] Although the most recent report of the *Confidential Enquiries into Maternal Deaths in the United Kingdom* covering the triennium 2006 to 2008 showed a reduction in deaths from venous thromboembolism, 12 of the 16 women who died were obese.[34] Obesity is associated with changes in coagulation, venous stasis, and endothelial injury that contribute to the pathogenesis of venous thromboembolism. For instance, adipose tissue secretes the following: (1) adipokines such as plasminogen activator inhibitor-1 (PAI-1), which results in impaired fibrinolysis; (2) leptin, which promotes platelet aggregation; and (3) interleukin-6, which stimulates the liver to produce coagulation factors.[35,36] C-reactive protein levels are also elevated in obese women, leading to platelet activation.[37] Venous stasis is compounded in obese women by increased intra-abdominal pressure, which leads to increased iliofemoral venous pressure.[38] Endothelial injury may also be increased in obese patients; obesity was shown to be associated with endothelial dysfunction in the nonpregnant population.[39] Therefore, all risk factors that contribute to the pathogenesis of thromboembolic complications are likely to be exacerbated by obesity.

Endocrine Changes

Gestational diabetes and diabetes mellitus occur more frequently in obese patients.[18] The pathologic process is attributed to the following: (1) peripheral insulin resistance as a result of augmentation of free fatty acids by visceral obesity,[40] (2) increased proinflammatory cytokine levels,[41] (3) relative gonadotropin resistance, and (4) a low sex hormone–binding globulin concentration, which leads to hyperandrogenism and decreased insulin sensitivity.[42] The concentration of adiponectin, an adipokine with insulin-sensitizing properties, is also decreased in obesity, which leads to decreased insulin sensitivity.[43]

COMORBIDITIES ASSOCIATED WITH OBESITY

Sleep Apnea

Obesity is a significant risk factor for obstructive sleep apnea (OSA), which is characterized by repeated episodes of complete or partial upper airway collapse, leading to hypoxemia and hypercarbia. Those repeated periods of hypoxemia and reoxygenation lead to significant endocrine and metabolic disturbances, which result in an increased risk for hypertension, myocardial infarction, stroke, diabetes, and metabolic syndrome.[44] There is no

consensus on the definition of OSA in pregnancy, and therefore the prevalence is unknown.

The changes of pregnancy may both worsen and protect against OSA. For instance, weight gain[45] and estrogen-induced hyperemia and edema of nasal mucosa[46] might promote OSA, whereas sleeping in the lateral position,[47] reduced rapid eye movement (REM) sleep, and the progesterone-induced increase in minute ventilation might protect against it. Obesity does not seem to be as strongly correlated with OSA in pregnancy as in the nonpregnant population.[45]

The risks for gestational hypertension, preeclampsia, and gestational diabetes are increased with OSA.[48,49] Some studies have examined the potential impact of maternal OSA on poor perinatal outcomes, but most of the studies have been small with conflicting results. For instance, Sahin et al.[50] simultaneously performed polysomnography and a nonstress test to assess the impact of hypoxemia due to OSA on the fetus. OSA was found in 4 of the 35 women evaluated; in 3 of these women fetal heart rate (FHR) decelerations accompanied maternal oxyhemoglobin desaturation. Olivarez et al.[51] performed simultaneous polysomnography and at least 3 hours of continuous FHR monitoring on 100 pregnant women (including 19 with a diagnosis of OSA), and they found no association between FHR abnormalities and OSA parameters. Louis et al.[52] reported an increased risk for preeclampsia (odds ratio [OR], 3.54; 95% confidence interval [CI], 1.26 to 9.92), neonatal intensive care unit admission (OR, 3.39; 95% CI, 1.23 to 9.32), and cesarean delivery (OR, 3.04; 95% CI, 1.14 to 8.1) among obese pregnant women with OSA compared with those with no OSA after adjusting for age, race, and BMI.

Other Comorbidities

Obesity is associated with an increased risk for a number of disease states compared with lean controls (Table 50-3).[31,33,53] These comorbidities complicate the care of obese parturients.

TABLE 50-3 Relative Risk or Odds Ratio of Comorbidities in Obese Women

IMPACT OF OBESITY ON PREGNANCY

Maternal and Fetal Complications

Obesity results in greater use of health care resources. Chu et al.[54] reported that obese pregnant women receive significantly more prenatal tests, ultrasonographic examinations, medications, and prenatal visits with a physician, and they are at greater risk for having a high-risk pregnancy, cesarean delivery, and prolonged hospitalization than pregnant women of normal weight.

Obesity is associated with a significantly increased incidence of maternal, fetal, and neonatal complications. These include a higher risk for spontaneous abortion (miscarriage), thromboembolic complications, gestational diabetes, hypertensive disorders of pregnancy, dysfunctional labor, shoulder dystocia, operative vaginal delivery, cesarean delivery, postpartum hemorrhage, wound infection, fetal macrosomia, fetal congenital anomalies, stillbirth, and neonatal death.[18,55,56] In a prospective multicenter cohort study of more than 16,000 unselected pregnant women in the United States, Weiss et al.[18] assessed obstetric complications in 1473 obese women (BMI 30.0 to 34.9 kg/m^2), 877 morbidly obese women (BMI ≥ 35 kg/m^2), and 3752 lean controls (BMI < 30.0 kg/m^2). The odds of gestational diabetes, gestational hypertension, preeclampsia, macrosomia, preterm delivery, and operative vaginal and cesarean delivery were all greater in morbidly obese pregnant women compared with lean women (Table 50-4).

Most importantly, obesity increases the risk for death during pregnancy. The latest report of *Confidential Enquiries into Maternal Deaths in the United Kingdom* for the 2006 through 2008 triennium showed that 49% of women who died were overweight or obese.[34] Similarly, in the previous report that covered the 2003-2005 triennium, 52% of the mothers who died were overweight or obese.[57] The impact of obesity on maternal mortality was even greater among women who died of thromboembolism or cardiac disease; of the mothers who died of these two disease entities, 78% and 61%, respectively, were overweight or obese.[34] Because of the high risk for thromboembolism in obese pregnant women and the significant probability of subtherapeutic anticoagulation with fixed-dose low-molecular-weight heparin regimens, the Royal College of Obstetricians and Gynaecologists (RCOG) added weight-based recommendations for thromboprophylaxis to their 2009 guidelines.[58]

Obesity has also been identified as a risk factor for anesthesia-related maternal mortality. Six of the 13 direct

TABLE 50-4 Obstetric Complications in Obese and Morbidly Obese Women

Outcome	Odds Ratio (95% Confidence Interval)	
	OBESE VERSUS CONTROL	MORBIDLY OBESE VERSUS CONTROL

Data from Weiss JL, Malone FD, Emig D, et al. Obesity, obstetric complications and cesarean delivery rate—a population-based screening study. Am J Obstet Gynecol 2004; 190:1091-7.

maternal deaths attributed to anesthesia in the last two triennial reports from the United Kingdom occurred in obese parturients.[34,57] In the United States, Mhyre et al.[59] reported that six of eight pregnant women who died of anesthesia-related deaths in Michigan between 1985 and 2003 were obese. Because of the increased risk for complications, in 2010 the United Kingdom Centre for Maternal and Child Enquiries (CMACE) and the RCOG published joint guidelines on the management of women with obesity in pregnancy.[60] Both these guidelines and the American College of Obstetricians and Gynecologists (ACOG) guidelines[61] recommend a multidisciplinary approach to the care and treatment of obese pregnant women, including (1) evaluation of all women for obesity by calculating BMI, (2) offering preconception counseling to obese women, (3) screening for gestational diabetes, (4) providing guidelines for prenatal weight gain, and (5) referring obese women for antepartum consultation with an anesthesiologist.

Progress of Labor and Method of Delivery

The progress of labor appears to be impacted by BMI. A large multicenter study involving 118,978 patients, whose labor management reflected current practice in the United States, reported that labor progressed more slowly with increasing BMI for both nulliparous and parous women.[62] The median time to progress from 4 to 10 cm cervical dilation increased from 5.4 hours to 7.7 hours for lean and morbidly obese *nulliparous* women, respectively, and from 4.6 hours to 5.4 hours for lean and morbidly obese *parous* women, respectively. These findings were independent of gestational age and induction of labor. Entry into the active phase of labor was also delayed in parous women as a function of BMI. Possible explanations include increased fetal size, higher induction rates, and/or decreased responsiveness to oxytocin.[62] Poor uterine contractility has also been demonstrated in obese parturients. Zhang et al.[63] found that myometrium obtained from obese women at cesarean delivery contracted with less force and frequency and had less calcium flux than that from normal-weight women. This observation may be attributable to the inhibitory effect of cholesterol[63] and/or adipokines (e.g., leptin, ghrelin, apelin), which were shown to inhibit human uterine contractility *in vitro*.[64]

Obesity is also associated with a higher risk for failed medical induction of labor. In a secondary analysis of data from a large labor induction trial involving 1273 patients (in which patients were stratified according to BMI), the duration of labor, oxytocin requirements, and cesarean delivery rates were significantly higher in women with a greater BMI.[65] In a large series from Sweden involving 233,887 deliveries, Cedergren[66] found a fourfold increase in the risk for cesarean delivery in parturients with a BMI greater than 40 kg/m^2, primarily because of failed or obstructed labor, despite attempts at augmentation.

Operative vaginal delivery, with its associated maternal and fetal morbidity, is more likely in the obese parturient.[18] One study examining maternal anthropometric parameters associated with shoulder dystocia reported a 2.7-fold increase in risk for shoulder dystocia in obese compared with lean parturients after adjustment for potential confounders such as macrosomia and diabetes.[67] Risk for fetal macrosomia is also higher with obesity, which, in addition to increasing the risk for shoulder dystocia and its associated birth trauma, predisposes to perineal lacerations, newborn infant injury, and postpartum hemorrhage.[18,67,68]

Higher BMI, increased prepregnancy weight, and excessive maternal weight gain increase the risk for both elective and emergency cesarean delivery.[69,70] This risk is further increased by obesity-related pregnancy complications such as macrosomia, fetal growth restriction (also known as intrauterine growth restriction), diabetes mellitus, and hypertensive disorders of pregnancy.[55,71] In a meta-analysis of 33 trials,[56] the unadjusted odds ratios (95% CI) of cesarean delivery were 1.46 (1.34 to 1.60), 2.05 (1.86 to 2.27), and 2.89 (2.28 to 3.79) among overweight, obese, and severely obese women, respectively, compared with normal-weight pregnant women.

ANESTHETIC MANAGEMENT

The high incidence of comorbid conditions among obese pregnant women necessitates early, careful preanesthetic assessment. There are also a number of technical matters that should be considered when caring for an obese parturient.

An appropriate-sized blood pressure cuff must be used for noninvasive blood pressure measurements. Unless the length of the sphygmomanometer cuff exceeds the circumference of the arm by 20%, systolic and diastolic blood pressure measurements may overestimate true maternal blood pressure. Forearm blood pressure measurement is sometimes used if an appropriate-sized blood pressure cuff is not available or if the upper arm cuff continues to slide from its position owing to the shape of the obese patient's upper arm. There is a good correlation

between upper arm and forearm noninvasive measurements, but forearm pressures exceed upper arm pressures by 10 ± 10 mm Hg (mean ± SD).[72] In selected cases, invasive monitoring of blood pressure with an intra-arterial catheter may be desirable.[57]

Intravenous access may be difficult in some obese patients. Ultrasonographic guidance may be useful; however, if peripheral intravenous access remains unsuccessful, central venous cannulation may be necessary.

Appropriately sized labor beds, transportation gurneys, and operating tables, and sufficient personnel to assist with patient transport, are imperative. Although standard operating tables are generally rated for persons weighing up to 500 pounds (227 kg), this rating may be insufficient for morbidly obese patients, especially when the table is articulated. Regardless of the weight rating of the table, it is critical that the obese patient be centered over the operating table pedestal at all times. Special equipment for positioning the patient, and longer spinal/epidural needles, may be needed (see later discussion).

Labor and Vaginal Delivery

Options for analgesia are the same as those for nonobese patients. Using the McGill pain questionnaire, Melzack[73] reported a positive correlation between BMI and the severity of labor pain. A later study, however, did not confirm these findings.[74]

Many of the options for labor analgesia have limitations in the obese parturient. For example, obese parturients with OSA may be more susceptible to the respiratory depressant effect of systemic opioids, leading to episodes of apnea and oxyhemoglobin desaturation. Pudendal nerve block may be more difficult technically in obese patients. Inhalation analgesia is useful in some patients; however, nitrous oxide has limited effectiveness and is not available in many birthing rooms. Further, inhalation analgesia may lead to loss of consciousness, which can be very dangerous in an obese woman with a difficult airway.

Neuraxial analgesia represents the best option for pain relief and is particularly desirable in the obese parturient. Given the greater risks for fetal macrosomia and shoulder dystocia in obese patients, adequate analgesia is often needed to facilitate an atraumatic vaginal delivery. The use of epidural analgesia during labor allows the anesthesia provider to extend epidural analgesia to surgical anesthesia for cesarean delivery and thus avoid the need for general anesthesia with its associated risks. Given the increased likelihood for cesarean delivery and the greater risks of general anesthesia in the obese parturient, the early administration of neuraxial labor analgesia is recommended in the obese parturient.

When performing a neuraxial anesthetic technique in the obese parturient, technical difficulties may include (1) inability to palpate the spinous processes or identify the midline[75]; (2) greater depth of the epidural space,[76] which may exaggerate minor needle directional errors and increase the likelihood of identifying a lateral portion of the epidural space[77]; and (3) the presence of fat pockets as well as hormonal softening of the ligaments, which may result in a false loss of resistance and/or a higher risk for unintentional dural puncture.[78] In the majority of obese parturients, however, the epidural space can be identified with a standard-length epidural needle.[79] Therefore, it seems prudent to use a standard-length needle first, which allows the provider better control, before switching to a longer needle.

Observing the prominence of the seventh cervical vertebra and the gluteal cleft can facilitate identification of the midline. Asking the parturient about the perceived location of the needle during block placement (relative to the midline) can also facilitate identification of the midline. Marroquin et al.[80] reported that 77% of morbidly obese parturients who were questioned about the position of the needle during a difficult labor epidural needle placement provided useful feedback to the anesthesia provider. Probing the subcutaneous tissue with a needle can also help identify the spinous processes and help identify a lumbar interspace.[81] More objectively, ultrasonographic guidance can be used to identify the midline, image the epidural space, and measure the distance from the skin to the epidural space. Grau et al.[82] reported that prepuncture ultrasonographic imaging significantly reduced the number of puncture sites and attempts and facilitated the performance of labor epidural analgesia. Similarly, Vallejo et al.[83] reported that prepuncture ultrasonography (performed to determine the midline, correct needle direction, and distance from the skin to the epidural space) reduced the number of attempts and need for catheter replacements when inexperienced trainees performed the blocks. Balki et al.[84] found a strong correlation between the depth of the epidural space measured by ultrasonography and that measured by the epidural needle in obese parturients. However, ultrasonographic imaging is more difficult in obese individuals; the same group of investigators reported that they were able to identify the midline but not measure the depth of the epidural space in a morbidly obese parturient with a BMI of 70 kg/m^2.[78] Furthermore, not all anesthesia providers are proficient in this technique.

Placing the patient in the sitting position facilitates identification of the midline and is preferred by many anesthesia providers when initiating a neuraxial anesthetic procedure in obese parturients. In the lateral position, gravity may cause lateral fat to sag down and obscure the midline. Bahar et al.[85] reported that the risk for epidural venous cannulation was lower in the lateral head-down position than in the sitting position and that there was no difference between the two positions in the number of attempts required to locate the epidural space. However, the average BMI of subjects in their study was approximately 37 kg/m^2.[85] Further, the distance from the skin to the epidural space is minimized when the patient is in the sitting flexed position.[86,87]

Care is needed to avoid dislodgement of the epidural catheter after insertion. Hamilton et al.[87] demonstrated that patient movement from the sitting-flexed to the lateral decubitus position causes redistribution of the soft tissue of the back. The distance from the skin to the epidural space increases, and an unsecured catheter will appear to be drawn inward by as much as 1.0 to 2.5 cm.[87] An epidural catheter secured with tape to the back of a patient in the sitting flexed position can be

unintentionally dislodged from the epidural space when the patient moves from the sitting to the lateral decubitus position. Movement of the epidural catheter relative to the skin is most striking in obese patients. Therefore, these investigators recommended that the patient assume the lateral position before the epidural catheter is secured to the skin.

Numerous authors have documented technical difficulties with neuraxial techniques in obese parturients. Hood and Dewan[88] reported that 94% of patients who weighed more than 300 lb (136.4 kg) experienced adequate analgesia for delivery, compared with 98% of controls. More attempts were required to identify the epidural space in obese women, there was a significantly higher initial failure rate (42% versus 6%), and placement of a second or third epidural catheter was more often required. Similarly, Dresner et al.[89] reported an increased risk for labor epidural block failure and need for catheter replacement with increasing BMI (2.4% for BMI < 25 kg/m^2 versus 6.6 % for BMI > 40 kg/m^2). Perlow et al.[90] reported that 74.4% of morbidly obese parturients needed more than one attempt and 14% needed more than three attempts for successful epidural catheter placement. In contrast, Bamgdade et al.[91] reported a significantly higher number of attempts to perform neuraxial anesthesia in obese parturients, but they observed no difference in the rate of failure of neuraxial anesthetic techniques for cesarean delivery in obese parturients. Although some investigators have reported a higher incidence of unintentional dural puncture in morbidly obese parturients than in lean parturients,[92] others did not confirm those findings.[74]

It is not known if epidural local anesthetic dose requirements are altered in morbidly obese parturients. In 1980, Hodgkinson and Husain[93] administered 20 mL of 0.75% epidural bupivacaine at the L3 to L4 interspace to women undergoing elective or emergency cesarean delivery over a period of 40 seconds. The patients remained supine for 40 minutes after drug injection. Twenty-seven percent of the patients with a BMI less than 28 kg/m^2 needed supplementation of the block at 30 minutes, whereas none of the patients whose BMI exceeded 28 kg/m^2 required additional local anesthetic to achieve surgical anesthesia. The cephalad extent of neuroblockade was associated with patient BMI and weight but not with height. Similarly, using an up-down sequential allocation study design to estimate the median effective epidural bupivacaine dose (administered in a volume of 20 mL), Panni and Columb[94] found that obese women required significantly less epidural bupivacaine for initiation of labor analgesia than lean parturients.[94] In contrast, Milligan et al.[95] observed that neither patient position nor obesity affected the extent of sensory blockade when 12 mL of 0.25% bupivacaine was administered for epidural analgesia during labor.[95] Duggan et al.[96] found that obesity had only a weak effect in enhancing the spread of epidural local anesthetics; this effect was only observed with the largest volume and concentration used in the study (15 mL of bupivacaine 0.75%), but not with a lower volume (10 mL) and concentration (0.5%) of bupivacaine.

The goals of epidural labor analgesia should be the provision of excellent pain relief with minimal motor block. Epidural administration of a dilute solution of bupivacaine with fentanyl provides analgesia for labor while minimizing adverse effects such as hypotension and motor blockade. The neuroblockade provided to obese parturients in labor should be bilateral and *near perfect*. Otherwise, the epidural catheter should be removed and replaced because an inadequate block with a frequent need for top-up doses may lead to failure of extending the block for cesarean delivery.[97] Regular evaluation of the parturient's neuraxial block is essential. In a study of morbidly obese parturients, the initial administration of local anesthetic through the epidural catheter resulted in failure of analgesia/anesthesia in 42% of the women, a rate that was seven times higher than that in control parturients.[88] However, careful evaluation of the epidural block and early replacement of a malpositioned catheter resulted in a high rate of success, so that only 1 of 55 cesarean deliveries attempted with epidural anesthesia required conversion to general anesthesia because of inadequate anesthesia.

The combined-spinal epidural (CSE) technique provides a rapid onset of excellent pain relief. However, the epidural catheter remains untested until the spinal block has worn off, and therefore it might fail to provide adequate anesthesia if it is malpositioned and a need for emergency cesarean delivery arises. For this reason, some anesthesia providers prefer to use a standard epidural technique when providing labor analgesia in morbidly obese parturients. On the other hand, a number of studies have reported a higher success rate for epidural catheters inserted as part of a CSE technique compared with those inserted as part of a standard epidural technique[98,99]; presumably, obtaining backflow of cerebrospinal fluid (CSF) through the spinal needle indirectly confirms correct epidural needle position.

In cases of unintentional dural puncture, continuous spinal analgesia can be used to provide labor analgesia. In addition to providing reliable labor analgesia, continuous spinal analgesia may be converted to spinal anesthesia for emergency cesarean delivery. It is crucial, however, that the catheter be clearly labeled and all personnel are made aware of its intrathecal location because unintentional administration of an epidural dose of a local anesthetic through the spinal catheter markedly increases the risk for high spinal block and subsequent respiratory arrest. The risk for post–dural puncture headache may be lower in the obese parturient. The higher intra-abdominal pressure that results from a large abdominal panniculus may contribute to reduced CSF leak through the dural puncture site.[92]

Cesarean Delivery

A thorough preanesthetic evaluation is critical to the safe care of the obese parturient. Of particular importance is a thorough airway assessment. Large breasts, the greater anteroposterior diameter of the chest, airway edema, and reduced chin-to-chest distance increase the likelihood of difficult laryngoscopy and failed tracheal intubation in obstetric patients.[100] Obesity exaggerates many of the anatomic changes of pregnancy. Increased fat in the neck and shoulders increases the difficulty of positioning the

patient for laryngoscopy and tracheal intubation. Excess fat deposition may also cause distorted anatomy, such as an enlarged tongue and redundant pharyngeal and palatal soft tissue. Further, the fat pads on the back of the shoulders often restrict the range of motion of the neck, exacerbating the difficulty of mask ventilation, laryngoscopy, and tracheal intubation.

All morbidly obese parturients undergoing cesarean delivery should be placed in a ramped position with left uterine displacement, regardless of the planned anesthetic technique. This position was shown to improve laryngoscopic view in morbidly obese patients undergoing elective bariatric surgery.[101] Folded blankets or a padded ramp designed for this purpose are placed under the chest and head to achieve horizontal alignment between the external auditory meatus and the sternal notch (Figure 50-1).[102] This position aligns the oral, pharyngeal, and tracheal axes to facilitate tracheal intubation and has been shown to improve hemodynamic and respiratory parameters during laparoscopic gastric bypass surgery.[103] Modern surgical tables can also be flexed at a number of angles, and this feature can be used to optimize the patient position for laryngoscopy and tracheal intubation.

It may be difficult to position the obese patient appropriately and safely. The protuberant abdomen may shift markedly with left uterine displacement. The patient must be secured to the operating table before the table is tilted leftward; however, it is important to initiate left uterine displacement as soon as possible. Tsueda et al.[22] described two obese patients who experienced acute cardiovascular collapse after assuming the supine position.

The anesthesia provider should confirm that the patient's weight does not exceed the weight limits of the operating table, consider use of lateral table extenders, and use foam or blankets to ensure that the shoulders and arms are positioned in a horizontal plane. Correct arm position will maximize patient comfort, improve stability, and avoid neurologic injury to the upper extremity.[104]

The anesthesia care team may be asked to participate in cephalad retraction of the large panniculus by tethering retractors to an object such as the ether screen. Both the obstetrician and the anesthesia provider must remain cognizant of the risks of hypotension, difficulty with ventilation, and fetal compromise during cephalad retraction of the panniculus in morbidly obese patients. Hodgkinson and Husain[105] reported an intraoperative fetal death in a morbidly obese patient who had received epidural anesthesia for cesarean delivery. The death was attributed to prolonged hypotension associated with cephalad retraction of a large panniculus. A vertical and cephalad suspension of the panniculus has been suggested to avoid maternal hypotension and hypoxemia.[78]

Pharmacologic aspiration prophylaxis is crucial in this patient population. Oral administration of 30 mL of a 0.3 M solution of sodium citrate effectively increases gastric pH within 5 minutes.[106] Administration of a histamine-2 (H_2)-receptor antagonist and metoclopramide provide additional protection.[107] The anesthesia provider must be aware that the patient remains at risk for aspiration at the end of surgery; the efficacy of sodium citrate wanes 45 to 60 minutes after administration.[24]

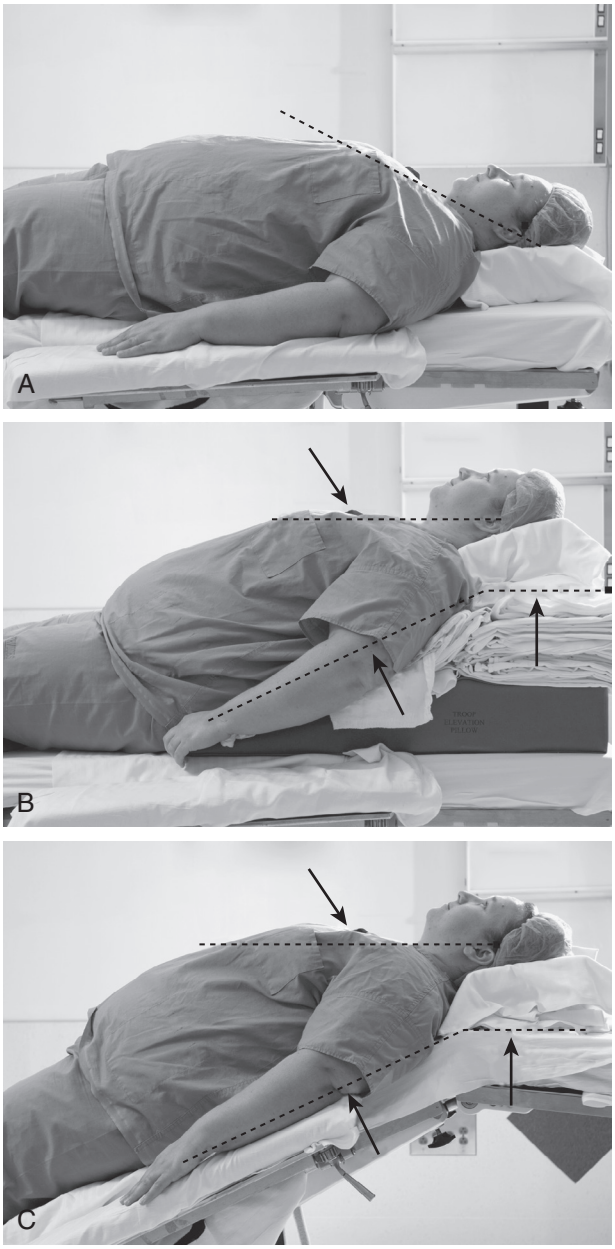

FIGURE 50-1 ■ Positioning the obese patient to facilitate intubation of the trachea. **A,** Patient in the supine position using standard head support. Note that the *dashed line* (compare with **B**) is not parallel to the floor. **B,** Elevating the patient's head with neck and shoulder supports so that an imaginary line drawn through the external auditory meatus and the sternal notch (*upper dashed line*) is parallel to the floor may facilitate tracheal intubation. **C,** Similar positioning achieved by repositioning the operating table. Note the similarity of the *upper* and *lower dashed lines* with use of the second and third positioning techniques.

Neuraxial Techniques

Neuraxial anesthesia is the anesthetic technique of choice in the obese parturient. Single-shot spinal anesthesia provides a reliable, fast onset and dense neuroblockade, and it is a common anesthetic technique in nonobese parturients undergoing planned cesarean delivery. However,

concerns about the use of single-shot spinal anesthesia in obese patients include technical difficulties, appropriate dosing, and insufficient duration of anesthesia.

Spinal anesthesia is technically feasible in morbidly obese pregnant women, although a longer spinal needle may be required. The distribution of adipose tissue varies among obese patients. Spinal needle placement can be uneventful in women who do not have excessive adipose tissue over the midline of the back. However, in others with excessive adipose tissue at the needle placement site, identification of the intrathecal space with a small-gauge spinal needle can be very challenging. Identification of the epidural space with a large-gauge epidural needle is often technically easier, and a needle-through-needle CSE technique may be easier to perform than a single-shot spinal technique in the morbidly obese parturient. Furthermore, the duration of surgery is often prolonged in the obese parturient.[108] Therefore, single-shot spinal anesthesia may not have sufficient duration. Because intraoperative induction of general anesthesia is undesirable and potentially hazardous in morbidly obese pregnant women, a continuous neuraxial technique such as a CSE or epidural technique that allows the maintenance of neuraxial anesthesia with the epidural catheter is preferable to a single-shot spinal technique. Epidural anesthesia is preferred if the patient has a well-functioning epidural catheter *in situ*. Otherwise, a CSE technique may be preferable because it combines the reliability of the spinal block and the flexibility of epidural anesthesia. Anesthesia can be initiated with a low dose of intrathecal local anesthetic combined with an opioid (see Chapter 26). Insufficient extent of cephalad neuroblockade can be treated by administering additional local anesthetic via the epidural catheter. Continuous spinal anesthesia with a spinal catheter is also an option. Some anesthesiologists have suggested that this technique should be considered in the setting of emergency cesarean delivery for obese parturients because it may be technically easier to rapidly identify the spinal space with a large-gauge epidural needle than with a spinal needle.[79]

Local Anesthetic Dosing for Neuraxial Techniques. The choice of local anesthetic dose in morbidly obese parturients in controversial. It has been a long-held belief that neuraxial local anesthetic doses should be reduced in obese patients because of fear of an unpredictable and exaggerated spread of local anesthetic, resulting in a high block. Magnetic resonance imaging (MRI) has confirmed that obese patients have a reduced lumbar CSF volume.[109] Engorgement of the epidural veins secondary to compression of the inferior vena cava by the gravid uterus and abdominal panniculus, as well as inward movement of soft tissue through the intervertebral foramina as a result of increased abdominal pressure, may be responsible for the reduced CSF volume in these patients. A separate study using MRI demonstrated an inverse correlation between the cephalad extent of neuroblockade and lumbar CSF volume[110]; this finding suggests that reduced CSF volume in obese patients increases the risk for a high spinal block. Additionally, Greene[111] has suggested that excess adipose tissue in the buttocks may result in relative Trendelenburg positioning of the vertebral column in the patient in the supine position, which can lead to an exaggerated cephalad spread of anesthesia.

A number of studies, however, do not seem to support the concerns of exaggerated cephalad spread of spinal anesthesia in morbidly obese women undergoing cesarean delivery. Norris[112] and Hartwell et al.[113] administered hyperbaric bupivacaine 12 mg intrathecally and found no correlation between height, weight, BMI, and the extent of spinal anesthesia. However, morbidly obese patients were not specifically studied, so these results may not be applicable to heavier parturients. In an up-down sequential allocation dose-finding study, Lee et al.[114] reported that the estimated ED_{95} (effective dose in 95% of patients) for hyperbaric bupivacaine was similar between obese and nonobese patients; no patient had an excessively high cephalad block with bupivacaine doses up to 12 mg. More recently, Carvalho et al.[115] estimated the ED_{50} (median effective dose) and ED_{95} for hyperbaric spinal bupivacaine for cesarean delivery in 42 morbidly obese parturients who were randomized to receive doses that ranged from 5 to 11 mg as part of a CSE technique. They reported that the ED_{50} and ED_{95} in these morbidly obese parturients were similar to those in nonobese parturients enrolled in a previous study performed by the same authors using similar methodology. Although it was common to obtain a satisfactory initial sensory level even with the lowest doses studied, few of the low-dose blocks were adequate for surgery and many required supplementation via the epidural catheter. Thus, the findings of these studies suggest that reducing the dose of intrathecal bupivacaine is not justified in morbidly obese patients and might increase the risk for inadequate anesthesia.

Results of studies of epidural local anesthetic dosing in morbidly obese parturients are also inconsistent (see earlier discussion). Unlike single-shot spinal anesthesia in which titration of the dose is not possible, careful titration of epidural anesthesia is recommended to achieve the desired dermatomal level of neuroblockade.

General Anesthesia

Difficult mask ventilation and tracheal intubation may be associated with more rapid oxyhemoglobin desaturation during apnea in obese patients than in lean individuals. The association between obesity and a short neck can make tracheal intubation difficult in this population.[116] In a series of patients who received general anesthesia for cesarean delivery, the incidence of difficult tracheal intubation was 33% among women who weighed more than 300 lb (136.4 kg).[88] Lee et al.[117] reported their experience with difficult tracheal intubation in 284 morbidly obese patients who underwent gastric bypass surgery. The incidence of difficult tracheal intubation was 2.4% among patients between 1.5 and 1.75 times the ideal weight and tripled to 7.3% in patients whose weight was 1.75 to 2.0 times the ideal. In a meta-analysis of 35 studies (with 50,760 patients), Shiga et al.[118] reported that obese patients had a threefold higher risk for difficult tracheal intubation than nonobese patients. In an analysis of 91,332 patients undergoing general anesthesia and direct laryngoscopy, a BMI of 35 kg/m^2 or more was associated

with a greater risk for difficult tracheal intubation (OR, 1.34; 95% CI, 1.19 to 1.51).[119]

The potential for failed tracheal intubation and difficult mask ventilation in the obese patient underscores the need for an experienced assistant during induction of general anesthesia. The primary anesthesia provider may fatigue rapidly with attempted mask ventilation of an obese patient. Further, the jaw-thrust maneuver may require the use of both hands, and additional personnel will be required to provide positive-pressure ventilation and cricoid pressure. A short-handled laryngoscope, assorted laryngoscope blades, various sizes of endotracheal tubes and supraglottic airway devices (e.g., laryngeal mask airways), a video laryngoscope, a fiberoptic intubation device, and equipment for percutaneous cricothyrotomy and transtracheal jet ventilation should be readily available.[120] A failed tracheal intubation algorithm should be initiated and help should be called immediately in the event of failed tracheal intubation (see Chapter 30). Supraglottic airway devices may be lifesaving in these situations.

Awake tracheal intubation, via either video laryngoscopy or direct fiberoptic laryngoscopy, is an alternative method of securing the anticipated difficult airway. However, women requiring urgent performance of cesarean delivery may not be ideal candidates for awake tracheal intubation because of the lack of adequate time to optimally prepare the patient's airway.

When preanesthetic assessment suggests that tracheal intubation will not be difficult, a rapid-sequence induction is indicated. The administration of general anesthesia begins with effective pulmonary denitrogenation (so-called *preoxygenation*). During apnea, pregnant women become hypoxemic more rapidly than nonpregnant women.[121] Similarly, during apnea, obese patients become hypoxemic more rapidly than nonobese patients.[122] Therefore, adequate denitrogenation is essential before the administration of general anesthesia in obese pregnant women.

One study demonstrated that four maximal inspirations of 100% oxygen within 30 seconds provide benefit similar to that provided by 3 minutes of tidal-volume breathing of 100% oxygen before rapid-sequence induction of general anesthesia for cesarean delivery.[123] However, another study reported a more rapid onset of hypoxemia in patients who underwent four maximal inspirations of 100% oxygen than in similar patients who underwent 3 minutes of tidal-volume breathing of 100% oxygen.[124] Goldberg et al.[107] evaluated the use of both techniques in morbidly obese nonpregnant patients undergoing gastric bypass surgery. The techniques provided similar increases in Pao_2, but patients who used the 3-minute technique showed evidence of a slight retention of CO_2. The investigators speculated that a blunted ventilatory response to CO_2 contributed to the increase in $Paco_2$. In contrast, other studies have suggested that obese patients have a normal ventilatory response to CO_2.[4] Later data from a study in 20 pregnant volunteers (at 36 to 38 weeks' gestation) compared 3 minutes of tidal-volume breathing with four deep breaths in 30 seconds (4 DB) or eight deep breaths in 1 minute (8 DB) of 100% oxygen by measuring end-tidal fractional oxygen concentration ($FETO_2$) after preoxygenation.[125] An $FETO_2$ value of 90% or greater was achieved in 76% of women after either the 3-minute or the 8-DB method, compared with only 18% of women after the 4-DB method of preoxygenation.[125] The investigators concluded that for emergency cesarean delivery using general anesthesia, the 8-DB method was as effective as the 3-minute tidal volume method of preoxygenation and was more quickly performed.

It is wise to apply a tight-fitting face mask and administer 100% oxygen as soon as the patient is moved onto the operating table; this maneuver helps achieve denitrogenation while other preparations are being made. It then seems reasonable to let circumstances dictate the selected method of denitrogenation. When the 3-minute tidal volume breathing technique is selected, the anesthesia provider should encourage the patient to take several deep breaths. In urgent situations, such as emergency cesarean delivery for maternal hemorrhage, the patient should be instructed to take eight deep breaths (the 8-DB method) to extend the safe interval before oxyhemoglobin desaturation occurs. When time allows, the 8-DB method is preferred over the 4-DB method.

The dose of intravenous induction agents should not be based on total body weight. Rather, the induction dose of propofol or thiopental in the obese parturient should be based on the lean body weight.[126] This practice will avoid excessive doses of drug with subsequent adverse effects. Propofol 2 to 2.8 mg/kg, thiopental 4 to 5 mg/kg, or other induction agents can be used according to the clinical circumstances and the anesthesia provider preference. All these agents will cross the placenta and can affect the neonate.

Succinylcholine remains the muscle relaxant of choice for rapid-sequence induction, and doses of 1.0 to 1.5 mg/kg are commonly used for general anesthesia and tracheal intubation in obese parturients. Lemmens et al.[127] compared the efficacy of succinylcholine in dosing regimens of 1 mg/kg based on ideal body weight, lean body weight, and total body weight in morbidly obese nonpregnant patients. The third regimen (1 mg/kg total body weight) was superior for providing complete neuromuscular paralysis and predictable laryngoscopic conditions in almost every patient, whereas intubating conditions were poor in one third of the patients dosed according to ideal body weight. The investigators also noted that "none of these dosing regimens will provide… a safe (short) duration of apnea."

Rocuronium at a dose of 1 to 1.2 mg/kg provides equivalent intubating conditions to succinylcholine 1 mg/kg. However, this dose range is associated with a significantly prolonged duration of neuromuscular blockade.[128] In obese patients, the dose of rocuronium should be based on ideal body weight.[129] Sugammadex is a cyclodextrin molecule that has been available in Europe since 2008. Sugammadex will effectively reverse high-dose rocuronium (1.2 mg/kg) in 2 minutes when used in a dose of 12 mg/kg in surgical patients.[130] Recent small series in obstetric patients have reported the use of sugammadex after rocuronium doses of 0.6 mg/kg,[131] 1 mg/kg,[132] and 1.2 mg/kg,[133] with no major adverse maternal or neonatal effects. Two studies in nonpregnant obese patients

suggested that sugammadex dosing can be based on ideal body weight plus 40%[134] or on corrected body weight (ideal body weight + 0.4[total body weight – ideal body weight]).[135] However, its use has not been specifically studied in obese parturients and its safety in this patient population remains to be confirmed.

Maintenance of anesthesia is usually achieved with a volatile halogenated agent with or without nitrous oxide. No evidence suggests that obesity alters the minimum alveolar concentration (MAC) of volatile halogenated anesthetic agents in pregnant women. In theory, increased body fat serves as a reservoir for inhalational and intravenous agents. Likewise, the body fat reservoir could increase the threat of biotransformation of volatile halogenated agents, which would increase the risk for organ toxicity. Isoflurane is an appropriate choice for morbidly obese parturients owing to its limited biotransformation.[136] Desflurane and sevoflurane are associated with a shorter time to extubation than isoflurane in obese patients, although the difference may not be clinically relevant.[137,138]

Morbidly obese patients may require administration of a higher inspired oxygen concentration and may not tolerate usual concentrations of nitrous oxide. Moreover, general anesthesia reduces FRC. The supine and Trendelenburg positions further decrease FRC, thus increasing the risk for intraoperative hypoxemia. The following strategies have been recommended to reduce the risk for small airway closure, atelectasis, and hypoxemia in obese patients: (1) use of inspired oxygen concentration of less than 0.8, (2) ventilation with tidal volumes ranging from 6 to 10 mL/kg ideal body weight, (3) increasing the respiratory rate to maintain physiologic $Paco_2$, (4) use of manual or automated periodic lung inflation (i.e., a recruitment maneuver), and (5) application of positive end-expiratory pressure.[139]

Emergence from general anesthesia is a critical period. Indeed, maternal deaths from hypoventilation and airway obstruction have been reported during emergence and recovery from general anesthesia.[59] It is imperative that the patient is fully awake with complete reversal of neuromuscular blockade before tracheal extubation, which preferably should be performed in the semi-upright position to minimize diaphragmatic compression by abdominal viscera. Trained personnel should provide postoperative care before the discharge of the patient to the ward.

POSTOPERATIVE COMPLICATIONS

Obesity increases the risk for postoperative complications such as endometritis, urinary tract infection, wound infection, wound dehiscence, peripheral nerve injury, hemorrhage, deep vein thrombosis, pulmonary thromboembolism, atelectasis, pneumonia, respiratory depression, hypoxemia, tracheal reintubation, sleep apnea, myocardial infarction, cardiac arrest, and maternal death.[79,140]

The combination of obesity, OSA, general anesthesia, and opioid administration may increase the risk for opioid-induced respiratory depression. In a report on maternal mortality in Michigan, Mhyre et al.[59] found that all anesthesia-related maternal deaths from airway obstruction or hypoventilation occurred during emergence and recovery, with obesity being identified as a significant risk factor for these complications. The American Society of Anesthesiologists (ASA) has issued Practice Guidelines for the Perioperative Management of Patients with Obstructive Sleep Apnea, which include recommendations for the preoperative, intraoperative, and postoperative management of these patients.[141] Although the published literature is often insufficient to establish definite relationships between interventions and outcomes, the Task Force consultants made the recommendations listed in Box 50-1. These recommendations are not intended specifically for pregnant women, but they do provide some guidance for the care of the obese parturient with OSA undergoing cesarean delivery. Morbidly obese patients at risk for OSA who have undergone cesarean delivery should be monitored with continuous pulse oximetry after being discharged from the postanesthesia care unit.

POSTOPERATIVE CARE

Postoperative Analgesia

Adequate postoperative analgesia is crucial to facilitate early mobilization, thereby reducing the risk for thromboembolic and pulmonary complications. However, the ideal analgesic regimen in the obese parturient remains unclear. Neuraxial morphine has been shown to provide superior analgesia to that provided by parenteral and oral opioids after cesarean delivery, at the expense of increased opioid-related side effects such as pruritus and nausea.[142,143] There is a concern, however, that morbidly obese patients might be at higher risk for respiratory depression after neuraxial opioid administration, although there are few data addressing this issue. In a series of 856 patients who received intrathecal morphine 0.2 mg added to hyperbaric bupivacaine for cesarean delivery, Abouleish[144] reported that respiratory depression, defined as an Sao_2 of 85% or less and/or a respiratory rate of 10 breaths per minute or less, occurred in 8 patients, all of whom were obese. In patients who have received general anesthesia, postoperative opioids are best administered using an intravenous patient-controlled analgesia (PCA) system. With all routes of opioid administration, vigilance and appropriate postoperative monitoring are essential in the obese patient who might have undiagnosed OSA and may be at a higher risk for opioid-induced respiratory depression.

A multimodal analgesic regimen including regular administration of a nonsteroidal anti-inflammatory drug and acetaminophen may contribute to opioid sparing and improve postoperative analgesia (see Chapter 27). Local anesthetic techniques including wound infiltration and transversus abdominis plane (TAP) block may also be valuable for postoperative analgesia. A systematic review of randomized controlled trials (including both obstetric and nonobstetric patients) found that continuous infusion of local anesthetic through catheters placed at the incisional site led to an improvement in analgesia and

BOX 50-1 American Society of Anesthesiologists Practice Guidelines for Perioperative Management of Patients with Obstructive Sleep Apnea

Preoperative

- Preoperative initiation of continuous positive airway pressure (CPAP) should be considered, particularly if obstructive sleep apnea (OSA) is severe.
- Patients with known or suspected OSA may have a difficult airway and therefore should be managed according to the ASA Practice Guidelines for Management of the Difficult Airway* or other similar airway management guidelines.

Intraoperative

- The potential for postoperative respiratory compromise should be considered.
- Patients at increased perioperative risk from OSA should be extubated while awake.
- Full reversal of neuromuscular blockade should be verified before extubation.
- When possible, extubation and recovery should be carried out in the lateral, semi-upright position.

Postoperative

- Postoperative analgesia: regional analgesic techniques should be considered to reduce or eliminate the requirement for systemic opioids in patients at increased perioperative risk from OSA.
- If neuraxial analgesia is planned, the anesthesiologist should weigh the benefits (improved analgesia, decreased need for systemic opioids) and risks (respiratory depression from rostral spread) of using an opioid or opioid–local anesthetic mixture as compared with a local anesthetic alone.
- If a patient-controlled systemic opioid analgesic technique is used, a continuous background infusion should be used with extreme caution or avoided entirely.
- Nonsteroidal anti-inflammatory agents and other modalities should be considered if appropriate to reduce opioid requirements.
- Supplemental oxygen should be administered continuously to all patients who are at increased perioperative risk from OSA until they are able to maintain their baseline oxygen saturation while breathing room air.
- Hospitalized patients at increased risk for respiratory compromise from OSA should be monitored with continuous pulse oximetry after discharge from the post–anesthesia care unit.

patient satisfaction as well as a reduction in opioid use, side effects, and duration of hospital stay, in comparison with administration of systemic opioids alone.[145] However, the value of this technique combined with neuraxial administration of a long-acting opioid is unclear.

Similarly, TAP block was found to produce opioid sparing and reduce pain scores and opioid-related side effects in women who received general anesthesia or did not receive neuraxial morphine as part of their neuraxial anesthetic technique. However, it did not enhance analgesia in patients who received neuraxial morphine and produced analgesia inferior to that produced by neuraxial morphine.[146] Further, performance of TAP block may be technically challenging in the obese parturient with a large abdominal panniculus. Patient-controlled epidural analgesia (PCEA) with ropivacaine provides analgesia comparable to that provided by epidural morphine,[147] but with more motor block, thus delaying patient mobilization.[147] PCEA techniques have not been specifically studied in obese parturients.

Thromboprophylaxis

The American College of Chest Physicians published guidelines for antithrombotic therapy in the parturient.[148] They used major and minor risk factors to identify women at increased risk for venous thromboembolism after cesarean delivery, and they classified obesity (BMI > 30 kg/m^2) as a minor risk factor. Thromboprophylaxis was recommended in the presence of one major risk factor (risk for thromboembolism > 3%) or two minor risk factors (combined risk > 3%) (see Box 39-4). In the setting of emergency cesarean delivery, one minor risk factor results in a risk greater than 3%, and, therefore, mechanical or pharmacologic thromboprophylaxis is recommended. In the United Kingdom, the RCOG guidelines[58] recommend thromboprophylaxis with low-molecular-weight heparin for all obese parturients undergoing either emergency or elective cesarean delivery. Further, the RCOG guidelines[58] recommend thromboprophylaxis after vaginal delivery in all morbidly obese women.

KEY POINTS

- The presence of coexisting disease(s) complicates obstetric and anesthetic management of the morbidly obese pregnant woman.
- The obese pregnant woman is at increased risk for obstetric, anesthetic, neonatal, surgical, and postoperative complications.
- The obese pregnant woman should be referred to an anesthesiologist for preanesthesia consultation.
- Airway complications, which can occur during the postoperative period as well as during the induction and emergence from general anesthesia, constitute the most common cause of anesthesia-related maternal death.
- The anesthesia provider should perform a careful, thorough assessment of the airway in every obese pregnant woman and should consider securing the airway before induction

of general anesthesia when a difficult airway is anticipated.

- Early labor administration of neuraxial analgesia is advised in obese parturients; anesthesia providers should critically evaluate the quality of the epidural block and replace any catheter that does not provide excellent analgesia.
- Continuous spinal anesthesia should be considered in emergency settings involving potentially difficult tracheal intubation and in cases of unintentional dural puncture in morbidly obese patients.
- Morbidly obese parturients may be at significant risk for obstructive sleep apnea; therefore, they should be carefully monitored with continuous pulse oximetry for postoperative hypoxemia resulting from airway obstruction and/or respiratory depression after discharge from the postanesthesia care unit.

CHAPTER 45

Human Immunodeficiency Virus

David J. Wlody, MD

CHAPTER OUTLINE

In 1981, a cluster of cases of an unusual disorder, *Pneumocystis carinii* pneumonia (PCP), in five otherwise healthy men, initiated a search that culminated in the characterization of a new disease, acquired immunodeficiency syndrome (AIDS), and the identification of its causative agent, the human immunodeficiency virus (HIV). Subsequently, there has been an explosion of this disease in the United States. Geographically, a disease that once was limited to two or three urban areas is now found throughout the country. Further, the number of cases of HIV infection has reached epidemic levels. At the end of 2008, an estimated 1,178,000 persons were living with HIV in the United States, including more than 236,000 whose infection was undiagnosed.[1] As of December 2011, more than 1,155,000 cases of AIDS had been reported to the U.S. Centers for Disease Control and Prevention (CDC). Some 636,000 people were reported to have died of AIDS and its complications by December 2010.[2] HIV infection has exploded demographically from its initial isolation among homosexual men to its current endemic status among intravenous drug users, their sexual partners, and children born to women infected with HIV.

The impact of HIV infection in the developing world has been nothing less than catastrophic. As of 2012, the Joint United Nations Programme on HIV/AIDS (UNAIDS) estimated that approximately 34 million people worldwide were infected with HIV (Figures 45-1 and 45-2). More than two thirds of these infections have occurred in sub-Saharan Africa, where nearly 5% of adults are infected with HIV and where 70% of all new infections that occurred worldwide during 2011 originated. It is encouraging that the number of new cases of HIV infection in sub-Saharan Africa has decreased by 25% between 2001 and 2011. Unfortunately, in at least nine countries, the number of new infections has increased by more than 25% in the same period.[3]

In the United States, although the rate of new infection in women appears to be decreasing, 21% of all new diagnoses of HIV infection identified in 2008 through 2011 occurred in women.[2] Minority populations are disproportionately affected; 47% and 20% of all newly diagnosed infections in 2011 were seen in African-American and Hispanic populations, respectively.[2] In 2009, HIV was the third leading cause of death in African-American women aged 35 to 44 years.[4] Clearly, anyone providing anesthesia to pregnant women in the United States in the 21st century will care for patients who are infected with HIV. Neither medicolegal concerns nor fear of infection with HIV should prevent anesthesia providers from providing effective intrapartum analgesia and anesthesia to HIV-infected women.

PATHOPHYSIOLOGY

HIV, previously known as lymphadenopathy-associated virus (LAV) and human T-cell lymphotropic virus type III (HTLV-III), is a member of the lentivirus subfamily of human retroviruses. The lentiviruses typically cause indolent infections in their hosts. These infections are notable for central nervous system (CNS) involvement, long periods of clinical latency, and persistent viremia caused by an impaired humoral immune response.[5] HIV

is a retrovirus (i.e., it carries the enzyme reverse transcriptase). This enzyme converts the single-stranded viral RNA into double-stranded DNA, which subsequently can be integrated into the DNA of the infected cell. This process is error prone, leading to rapid mutation of the virus, which significantly complicates drug therapy. HIV displays similarity to human immunodeficiency virus type 2 (HIV-II), a virus that is endemic in western Africa and that produces a similar syndrome. HIV-II is even more closely related to the simian immunodeficiency virus (SIV). It has been suggested that HIV arose in human populations through transmission of SIV via infected "bush meat," the meat of chimpanzees and other primates consumed as food.[6]

For infection of the host cell to occur, HIV must bind to a cell-surface receptor, the $CD4^+$ antigen complex.[7] This protein molecule was first detected on helper T cells, and it subsequently was identified on B cells, macrophages, and monocytes.[8] It also is found on placental cells[9] and may provide a route of vertical transmission to the fetus during early pregnancy. The interaction between HIV and host cells requires an interaction with an additional cell-surface protein; binding with either the CCR5 or CXCR4 co-receptor is required for infection to occur. A number of therapeutic agents target this interaction.[10]

Infection of helper T cells is the key to immune suppression in HIV disease. These cells play a major role in the initial recognition of foreign antigen as well as in the activation of other immune system components.[11] $CD4^+$ monocytes and macrophages are also targeted by HIV. In addition to these T cell–mediated effects, both neutropenia and disturbances of neutrophil function are common in the later stages of HIV infection.[12] Abnormalities of these elements of the immune system render the HIV patient vulnerable to bacterial, viral, fungal, parasitic, and mycobacterial infection. In addition, for reasons that are not entirely clear, patients infected with HIV are susceptible to several malignancies (e.g., Kaposi's sarcoma, B-cell lymphoma, invasive cervical carcinoma). AIDS-associated Kaposi's sarcoma is almost exclusively limited to homosexual men with HIV or to women whose male sexual partners are bisexual; this fact suggests that the malignancy is related to another sexually transmitted disease. In fact, DNA sequences from human herpesvirus-8 have been identified in AIDS-associated Kaposi's sarcoma.[13,14]

DIAGNOSIS

The techniques for diagnosing HIV infection include viral culture, p24 antigen detection tests, nucleic acid amplification tests such as viral polymerase chain reaction (PCR), and immune function tests. Most often, the diagnosis is made on the basis of results of one of two antibody detection tests: enzyme immunoassay (EIA) and the Western blot technique. EIA measures the binding of anti-HIV antibody from the patient's serum to a mixture of antigens that typically have been obtained through recombinant DNA techniques (third-generation tests). The use of third-generation tests has improved the reliability of EIA, but false-positive results (caused by autoimmune disorders, influenza or hepatitis B immunization, and/or high parity) and false-negative results (caused by immunosuppressive therapy and various malignancies) can occur.[11] For these reasons, a Western blot test usually is performed after a positive EIA result is obtained. False-positive Western blot tests can also occur, but they are less common than false-positive EIA tests. The Western blot technique allows the identification of antibodies to nine specific HIV antigens. Different organizations have different criteria for a positive Western blot test, but a positive Western blot test generally requires the presence of antibody to at least three different antigens. If there is no detectable antibody to any of these antigens, the result is negative.[11] Identification of any combination of antibodies that does not meet the criteria for a positive result is considered an indeterminate result and an indication for retesting in 4 to 8 weeks.

Nucleic acid amplification tests can detect extremely low levels of infection. This technique can detect viremia as early as 1 to 2 weeks after exposure, during the period of primary symptomatic infection.[11] Although this technique can be used to diagnose acute HIV infection, it is typically used to monitor the response to ongoing antiretroviral therapy.

Both the EIA and the Western blot tests rely on the detection of antibody to HIV antigens. Unfortunately, there may be an interval of several weeks to months after the initial infection before detectable levels of antibody

BOX 45-1 Acquired Immunodeficiency Syndrome—Indicator Conditions

- Candidiasis of bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (greater than 1 month's duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, human immunodeficiency virus–related
- Herpes simplex: chronic ulcer(s) (longer than 1 month's duration); or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (longer than 1 month's duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt's (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site (pulmonary or extrapulmonary)
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jiroveci* pneumonia
- Pneumonia, recurrent
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome due to human immunodeficiency virus
- CD4 T lymphocyte count < 200 cells/μL

Modified from 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR Recomm Rep 1992; 41(RR-17):1-19.

are present. A patient infected with HIV who is tested during this "window period" has a negative test result but is fully capable of infecting others. In fact, exceptionally high levels of viremia are present during the initial period of infection, and transmission after needle-stick injury or other occupational exposure is more likely.[15] This is a strong argument for instituting universal precautions. If barrier precautions are instituted only for patients with positive test results, health care workers will be exposed unnecessarily to seronegative but infectious patients.

Patients may be chronically infected with HIV for many years yet appear clinically well or have only minor evidence of immune suppression, such as oral candidiasis or recurrent herpes zoster. The diagnosis of AIDS is made when any one of a number of AIDS-indicator conditions develops (Box 45-1).

CLINICAL MANIFESTATIONS

In the early years of the AIDS epidemic, the predominant symptoms were those of immune suppression (e.g., opportunistic infections, unusual malignancies). Disturbances of gastrointestinal function were also prominent. As improvements in prophylaxis and treatment of opportunistic infections have increased longevity, it has become apparent that HIV eventually affects multiple organ systems. The aggressive use of highly active antiretroviral therapy (HAART) can significantly prolong the symptom-free interval, and it is highly unusual for a pregnant patient to have significant organ system involvement due to HIV.

BOX 45-2 Neurologic Manifestations of Human Immunodeficiency Virus Infection

Early (Initial Infection)

- Headache
- Photophobia
- Meningoencephalitis
- Cognitive and affective changes
- Cranial neuropathy
- Peripheral neuropathy

Latent Phase

- Demyelinating neuropathy
- Cerebrospinal fluid abnormalities, even in asymptomatic patients

Late (Clinical Acquired Immunodeficiency Syndrome)

- Meningitis
- Diffuse encephalopathy
- Focal brain lesions
- Myelopathy (segmental or diffuse)
- Peripheral neuropathy
- Myopathy

Neurologic Abnormalities

Neurologic involvement can occur at any time during HIV infection (Box 45-2). Viral particles can be isolated from the cerebrospinal fluid (CSF) at the time of primary infection.[16] The manifestations of nervous system involvement vary with the stage of the disease.

During **initial systemic HIV infection,** a variety of CNS disorders may occur. Headache, photophobia, and retro-orbital pain are common. Cranial and peripheral neuropathies, demyelinating polyneuropathy, and septic meningoencephalitis have been reported.[17] Cognitive and affective changes (e.g., depression, irritability) may be noted. Most of these disorders are self-limited, but persistent neurologic dysfunction may occur.[17]

A subset of patients remains neurologically asymptomatic during the **latent phase of HIV infection.** Nevertheless, these patients typically have CSF abnormalities, including the local synthesis of HIV antibody and the presence of HIV particles or viral nucleic acid.[18] This is an important consideration when one is determining the risk for introducing virus into the CNS during the performance of neuraxial anesthesia in an asymptomatic patient. It is almost certain that CNS infection has already occurred.

Finally, the **late stages of HIV infection** are marked by significant neurologic deterioration in almost all patients. **Meningitis** is common, and its causes include tuberculosis, infection with *Cryptococcus*, metastatic lymphoma, and direct infection of the meninges by HIV. **Diffuse encephalopathy** can occur; cytomegalovirus (CMV), herpes simplex virus (HSV), and toxoplasmosis typically produce a simultaneous impairment of both cognition and alertness. Diffuse encephalopathy may also be seen as a consequence of systemic disease, such as sepsis or hypoxemia secondary to respiratory disease. Patients with the **AIDS dementia complex** also have a diffuse encephalitic picture; however, unlike other forms of encephalitis in which cognitive function is diminished, the level of alertness remains unimpaired. In addition, the complex is associated with impairment of motor function and behavioral changes (apathy, agitation). **Focal brain disorders** can occur secondary to toxoplasmosis, primary CNS lymphoma, and progressive multifocal leukoencephalopathy, an opportunistic viral infection that causes selective destruction of white matter tracts. **Myelopathy** is common; it can manifest in an acute, segmental form, as in the transverse myelitis produced by varicella infection, or as a more progressive and diffuse disorder—vacuolar myelopathy—which is marked by a progressive, painless gait disturbance and spasticity. A distal, predominantly sensory **peripheral neuropathy** is quite common in late HIV infection. The etiology is unknown; it has been suggested to occur as a result of cytokine-mediated neurotoxicity.[19] Sensory and motor dysfunction typically are minimal, but pain can be severe enough to prevent walking. CMV infection can also lead to a polyradiculopathy that usually responds to anti-CMV therapy. **Autonomic neuropathy** can manifest as mild postural hypotension or severe cardiovascular instability during invasive procedures. Autonomic dysfunction also can contribute to the chronic diarrhea that occurs in some patients with AIDS. An inflammatory myopathy resembling dermatomyositis has been reported, although this disorder is less common than the neuropathies.[19] Finally, neurologic side effects of antiretroviral and other therapies also may occur (see later discussion).

Pulmonary Abnormalities

The pulmonary manifestations of HIV disease are caused not by a direct effect of the virus but, rather, by the opportunistic infections associated with the disease. The most prominent of these is *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii)*, a fungal organism that is seen in a wide variety of mammals and appears to be carried asymptomatically by many humans.[20] Despite this evidence of widespread exposure to the organism, symptomatic *Pneumocystis* pneumonia (PCP) is typically seen only in patients with severe immune suppression. The clinical picture is similar to the adult respiratory distress syndrome, consisting of severe hypoxemia and a pattern of diffuse interstitial infiltrates on chest radiography. The mortality rate of patients with PCP who require tracheal intubation may be as high as 75%.[21] Early initiation of corticosteroid therapy decreases the likelihood of progression to respiratory failure.[22] Patients who survive the disease are at risk for the development of pneumatoceles; subsequent rupture leading to pneumothorax is common. Survivors of PCP also are at risk for developing chronic airway disease, including chronic bronchitis and bronchiectasis.[23]

Reactivation of latent **tuberculosis** is common in patients with HIV infection because of the impairment of cellular immunity that ordinarily keeps the disease in a quiescent state; HIV-infected individuals also may be more susceptible to acquiring tuberculosis when they are exposed to an infectious individual.[24] The impairment of humoral immunity is responsible for a higher incidence of bacterial pneumonia caused by encapsulated organisms (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*).[25] Finally, although less common than PCP, pneumonia secondary to other fungal organisms (e.g., *Aspergillus*, *Cryptococcus*, *Coccidioides*) is much more common in patients infected with HIV than in the general population.[25]

Gastrointestinal Abnormalities

Gastrointestinal disturbances occur at some time in almost all patients with HIV infection (Box 45-3). Painful or difficult swallowing is common and is typically caused by herpetic, CMV, or candidal **esophagitis;** the contribution of these disorders to gastroesophageal reflux is unclear.[26] **Severe diarrhea** resulting from infection with CMV, HSV, *Shigella*, *Salmonella*, *Candida*, *Cryptosporidia*, *Giardia*, *Mycobacterium avium* complex (MAC), or HIV itself can lead to significant cachexia and electrolyte abnormalities. Finally, **hepatobiliary disease** is common. Causes of parenchymal liver disease include hepatitis B and C, CMV, mycobacterial infection (both *Mycobacterium tuberculosis* and MAC), and *Cryptococcus*. Kaposi's sarcoma and non-Hodgkin's lymphoma may involve the liver. Biliary tract disease can develop in patients with advanced HIV infection; although several pathogens have been associated with this disorder (cryptosporidium, CMV), treatment of those pathogens is seldom effective.[27] Endoscopic retrograde cholangiopancreatography (ERCP)–guided stenting has been successfully used to treat this disorder.[28]

Hematologic Abnormalities

HIV infection is associated with hematologic abnormalities that affect each of the peripheral cell lines.[12] **Leukopenia** is a hallmark of the disease, especially the depletion

BOX 45-3 Gastrointestinal Manifestations of Human Immunodeficiency Virus (HIV) Infection

- Esophagitis and dysphagia
- Hepatitis (opportunistic organisms, coexisting hepatitis B)
- Biliary disease (acalculous cholecystitis, sclerosing cholangitis)
- Wasting ("slim disease")
- Chronic diarrhea (HIV infection of bowel, superinfection with bacterial or parasitic pathogens)

of $CD4^+$ lymphocytes; qualitative alterations in the functions of neutrophils and macrophages also occur. **Anemia** is quite common. Causes include direct HIV infection of erythroid precursors, suppression of erythropoiesis due to inappropriate release of tumor necrosis factor, infiltration of bone marrow with MAC or malignancy, and occult gastrointestinal blood loss.

Coagulation disturbances are common in patients with HIV. **Immune thrombocytopenia** is common and typically is only mildly symptomatic. Platelet production may be impaired because of direct infection of megakaryocytes with HIV. Thrombocytopenia frequently responds to the initiation of antiretroviral therapy. The response to corticosteroid therapy is variable. Intravenous immune globulin produces a rapid but transient effect, and it may be indicated in patients with life-threatening hemorrhage. The activated partial thromboplastin time may be prolonged because of the presence of the lupus anticoagulant; this finding is linked to a higher incidence of major thromboembolic events in HIV-infected patients. Finally, many of the antiretroviral agents and other drugs used in these patients have hematologic toxicity.

Cardiovascular Abnormalities

When echocardiography and autopsy evidence of lymphocytic infiltration of the myocardium are used as evidence of cardiovascular involvement in patients with HIV, the prevalence of such involvement is as high as 50%.[29] Nevertheless, clinically significant cardiovascular disease is rare in patients with HIV. **Pericarditis** has been reported to be the most prevalent cardiovascular disorder seen in HIV-infected patients. The most common etiology appears to be mycobacterial infection; CMV, HSV, Kaposi's sarcoma, malignant lymphoma, and HIV itself have also been implicated.[30] **Pulmonary hypertension** can develop secondary to repeated episodes of PCP and can also be a consequence of cytokine-mediated endothelial injury.[29] Direct **myocardial involvement**—typically, focal myocarditis—is identified in 15% to 50% of autopsy studies, but clinical myocarditis or cardiomyopathy is rare.[29] **Infective endocarditis** among patients with HIV occurs almost exclusively in intravenous drug users. Finally, the elevations in serum cholesterol and triglyceride concentrations produced by antiretroviral agents appear to increase the risk for coronary artery disease in patients receiving these drugs.[31]

Endocrine Abnormalities

Endocrine dysfunction can result from HIV infection, opportunistic infections, or drug therapy.[32] There is a relatively high incidence of pathologic findings in the adrenal gland at autopsy, yet clinical evidence of glucocorticoid insufficiency is rare. Patients with AIDS frequently have abnormal thyroid function test results, similar to the findings in patients with other chronic illnesses, yet clinical hypothyroidism is unusual. Insulin resistance and diabetes are increasingly recognized as consequences of HIV infection and antiretroviral treatment.[33]

Renal Abnormalities

Patients with HIV are at risk for acute renal failure secondary to sepsis, dehydration, and drug toxicity.[34] A common cause of chronic renal insufficiency is proliferative glomerulonephritis secondary to deposition of immune complexes containing HIV antigen within the glomeruli. Renal failure may also occur because of a specific disorder, **HIV-associated nephropathy.**[35] This entity, seen almost exclusively in African-American patients, is characterized by a focal segmental glomerulosclerosis. Hypertension is uncommon, deterioration of renal function is extremely rapid, and the long-term prognosis is worse than that seen in renal failure from other causes. The underlying cause appears to be direct infection of renal cells by HIV. Antiretroviral therapy appears to modify the course of the disease.[35]

INTERACTION WITH PREGNANCY

In 1991 and in 1995, the nationwide seroprevalence rate of HIV during pregnancy was reported to be 1.5 and 1.7 per 1000 pregnant women, respectively.[36,37] There was considerable geographic variation in these figures; the highest rates of seroprevalence were found in New York (5.8 per 1000), Washington, DC (5.5 per 1000), and New Jersey (4.9 per 1000). In 1991, seropositive women were identified in all but 2 of the 39 reporting areas.[36] In New York City, the prevalence of HIV infection among pregnant women was 6.2 per 1000 in 1999-2000, having declined by 49% over the previous decade. This decrease was markedly greater in white women than in African-American women.[38] According to the CDC, the number of HIV-infected women giving birth in the United States increased from 6000 to 7000 in 2000 to 8700 in 2006, an increase of approximately 30%.[39]

The diagnosis of HIV infection in the offspring of HIV-infected mothers has been hampered by the persistence of passively acquired maternal antibody in the infant for as long as 18 months. Until 18 months of age, an infant's HIV status must be confirmed by viral culture or DNA polymerase chain reaction (PCR). Measurement of circulating p24 antigen has been used for rapid diagnosis of neonatal HIV infection,[40] but this test is no longer recommended because it is less sensitive than PCR and is associated with false-positive results.[41]

There is intense interest in the identification of factors that promote perinatal transmission of HIV from mother to the newborn (i.e., vertical transmission) (Box 45-4).[42] Clinical severity of maternal disease is associated with an increased risk for transmission, as reflected by a higher rate of infection in newborns of women with symptomatic AIDS.[43] Maternal viral burden correlates with transmission. In one study, 13 of 13 women with more than 80,000 viral RNA copies per mL of plasma transmitted the disease, but none of the 63 women with less than 20,000 copies per mL transmitted HIV.[44] Other factors that have been implicated in vertical transmission are the presence of ruptured membranes for more than 4 hours,[45] coexisting sexually transmitted diseases,[46] chorioamnionitis,[47] and invasive procedures such as amniocentesis and

BOX 45-4 Risk Factors for Vertical Transmission of Human Immunodeficiency Virus

- Severity of maternal disease
- Maternal viral burden
- Viral genotype
- Sexually transmitted disease
- Substance abuse
- Lack of maternal antiviral therapy
- Chorioamnionitis
- Prolonged ruptured membranes
- Invasive fetal monitoring
- Vaginal delivery
- Forceps delivery
- Breast-feeding
- Prematurity

cerclage.[46] At least one study has demonstrated that fetal scalp blood sampling and the use of fetal scalp electrodes do not increase vertical transmission[48]; however, the documented presence of HIV in maternal cervical secretions has made some clinicians reluctant to use this monitoring technique.[49] Finally, there is considerable evidence that breast-feeding may double the rate of perinatal transmission in women with established HIV infection.[50] Thus, breast-feeding should be discouraged unless bottle-feeding is not a safe alternative, as is true in many developing countries.

In addition to identifying risk factors for vertical transmission, there is a significant effort to determine which active interventions might decrease the transmission of HIV. The first such intervention that was identified is the administration of zidovudine (ZDV, formerly azidothymidine [AZT]). In a study known as the AIDS Clinical Trial Group (ACTG) Protocol 076, administration of ZDV orally during pregnancy, intravenously during labor, and orally to the infant for the first 6 weeks of life decreased the transmission rate from 25.5% to 8.3%. No significant adverse effects were noted in these infants.[51] Because of the success of HAART in reducing perinatal transmission to 1% to 2%—compared with 10% for ZDV monotherapy[52]—it has been suggested that all HIV-infected pregnant women should receive an aggressive treatment regimen, regardless of viral load.[42]

Because neonatal infection rates are low when the time interval between rupture of membranes and delivery is shortened, it has been suggested that cesarean delivery might decrease vertical transmission. At least four studies have suggested that elective cesarean delivery may decrease the rate of transmission by as much as 80%.[53] The American College of Obstetricians and Gynecologists (ACOG) has recommended that HIV-infected women be offered the option of elective cesarean delivery to decrease the rate of transmission below the rate that would be expected with ZDV therapy alone.[54] Although the ACOG acknowledged that the data were insufficient to demonstrate a benefit for women with viral loads less than 1000 viral copies per milliliter of plasma, there is some evidence that abdominal delivery may be beneficial even in the setting of viral loads below that threshold[55]; thus, it has been suggested that elective cesarean delivery be offered to patients in this group as well.[53]

A number of studies have assessed the effect of HIV infection on pregnancy outcome. Alger et al.[56] followed 97 seronegative and 101 seropositive but asymptomatic women throughout pregnancy. There was no difference between groups in the incidence of low-birth-weight (LBW) (< 2500 g), small-for-gestational-age (SGA) infants, or low 5-minute Apgar scores.[56] However, in a study of 315 seropositive and 311 seronegative women in Kenya, HIV seropositivity was associated with an increased risk for preterm delivery and LBW infants but not with an increased incidence of SGA infants.[57] These different results may reflect the higher incidence of symptomatic HIV disease in the Kenyan patients. Another study noted that the incidence of serious infectious complications (e.g., PCP, CNS toxoplasmosis) is greater than 30% in pregnant women with advanced HIV infection ($CD4^+$ lymphocyte counts < 300 cells/mm^3).[58] The fetal implications of such infections are obvious. Drug therapy *per se* does not seem to affect pregnancy outcome; specifically, evidence suggests that there is no higher incidence of preterm delivery, LBW infants, low Apgar scores, or stillbirth in women receiving therapy than in controls.[59]

There also is concern that pregnancy itself may have an adverse effect on the progression of HIV infection. However, no evidence suggests that pregnancy accelerates clinical deterioration in the HIV-infected patient or that viral RNA load changes significantly during pregnancy.[56,60,61]

DRUG THERAPY

There is an ever-increasing number of medications used to treat HIV infection, administered in innumerable multidrug regimens; in addition to HIV medications, patients may receive a number of other drugs to treat or prevent opportunistic infections. The side effects of the most commonly used antiretroviral agents and medications used for prophylaxis and treatment of opportunistic infections are listed in Tables 45-1 and 45-2, respectively.

Fetal Side Effects

There are few published data regarding the use of HIV medications in pregnant women. Fortunately, clinical experience suggests that fetal risk is minimal. This is best demonstrated by ACTG Protocol 076, which showed a significant reduction of vertical transmission of HIV with maternal ZDV therapy.[51] There was no difference between the ZDV and placebo groups in the number and type of birth defects. The only apparent difference in neonatal outcome was a mild transient anemia (which required no treatment) in the ZDV group. Ongoing observation of these infants is planned, but no difference in growth or neurodevelopmental status has been identified in the ZDV group. As of July 2012, the Antiretroviral Pregnancy Registry[62] had collected records of more than 14,000 women who had received these agents during pregnancy in the United States; the data indicate no

TABLE 45-1 Side Effects of Antiretroviral Agents

Drug	Side Effects
Zidovudine (ZDV, AZT, Retrovir)	Headache, N&V, bone marrow suppression
Didanosine (ddI, Videx)	N&V, peripheral neuropathy, pancreatitis, lactic acidosis
Zalcitabine (ddC, HIVID)	Peripheral neuropathy, pancreatitis
Stavudine (d4T, Sterit)	Peripheral neuropathy, pancreatitis, lactic acidosis
Lamivudine (3TC, Epivir)	N&V, headache, pancreatitis (children)
Emtricitabine (FTC, Emtriva)	Headache, N&V
Abacavir (ABC, Ziagen)	Systemic hypersensitivity reaction, headache, N&V
Delavirdine (Rescriptor)	Rash, elevated liver function test results
Nevirapine (NVP, Viramune)	Rash, hepatotoxicity
Efavirenz (EFV, Sustiva)	Dizziness, lightheadedness, vivid dreams, rash
Saquinavir (SQV, Invirase)	N&V, diarrhea, abdominal pain, hyperglycemia, increased triglycerides, fat redistribution
Ritonavir (RTV, Norvir)	N&V, diarrhea, abdominal pain, hyperglycemia, increased triglycerides, fat redistribution
Indinavir (IDV, Crixivan)	Nephrolithiasis, gastrointestinal intolerance, hyperglycemia, increased triglycerides, fat redistribution
Nelfinavir (NFV, Viracept)	N&V, diarrhea, hyperglycemia, increased triglycerides, fat redistribution
Amprenavir (APV, Agenerase)	Headache, N&V, hyperglycemia, increased triglycerides, fat redistribution
Lopinavir/ritonavir (LPV/RTV, Kaletra)	N&V, diarrhea, hyperglycemia, increased triglycerides, fat redistribution
Atazanavir (ATV, Reyataz)	N&V, headache, smaller increase in triglycerides than with other protease inhibitors
Tenofovir (TDF, Viread)	N&V, headache
Enfuvirtide (T20, Fuzeon)	Injection site reaction

N&V, Nausea and vomiting.

TABLE 45-2 Side Effects of Agents Used for Prophylaxis/Treatment of Opportunistic Infections

Opportunistic Infection	Drug	Side Effects
Pneumocystis jiroveci	Trimethoprim-sulfamethoxazole	Nausea, vomiting, anorexia, rash
	Dapsone	Fever, rash, hepatitis
	Pentamidine	*Intravenous:* nephrotoxicity, leukopenia, hypoglycemia, hyperglycemia *Inhaled:* cough, dyspnea, dizziness
Cytomegalovirus	Ganciclovir	Neutropenia, thrombocytopenia, central nervous system disturbances
	Foscarnet	Nephrotoxicity, electrolyte disturbances
Mycobacterium avium complex	Clarithromycin	Nausea, vomiting, diarrhea
Fungal infections: cryptococcosis, histoplasmosis, coccidiomycosis	Amphotericin	Nephrotoxicity, fever, hypotension
	Fluconazole	Nausea, headache, rash
Herpes simplex virus	Acyclovir	Nephrotoxicity, neurotoxicity

From Pau AK, Robertson S. AIDS-related medications. In Dolin R, Masur H, Saag MS, editors. AIDS Therapy. 3rd edition. St. Louis, Churchill Livingstone, 2008:1407-40.

increase in overall risk for birth defects or risk for specific defects for the overall population exposed to antiretroviral drugs. However, exposure to didanosine or nelfinavir was associated with a modest but statistically significant increase in overall rates of birth defects. The clinical relevance of this finding is unclear, and no pattern of birth defects has been observed with either drug.[62]

Historically, physicians have been concerned that the use of trimethoprim-sulfamethoxazole during the third trimester might increase the risk for neonatal kernicterus. This complication has not been reported, and trimethoprim-sulfamethoxazole should be continued until delivery in women who tolerate the drug.[63]

None of the antiretroviral agents or drugs used to treat opportunistic infections during pregnancy are listed in U.S. Food and Drug Administration pregnancy category A, which signifies a lack of fetal effect in controlled human trials.[42] Despite the reassuring findings of the Antiretroviral Pregnancy Registry, the use of these drugs requires a full discussion of the risks and benefits with the mother.[64] Minkoff and DeHovitz [63] concluded, "The guiding principle in the use of medications by HIV-infected women who become pregnant is to adhere strictly to standards promulgated for nonpregnant women, unless there are documented and compelling fetal concerns that would justify a modification of those standards."

ANESTHETIC MANAGEMENT

Coexisting Diseases

Many pregnant women infected with HIV have health problems that are related to the behaviors that led to their infection with HIV. The most significant of these is substance abuse. A significant proportion of women with HIV contract the disease through intravenous drug use. It can be expected that many of these patients also abuse alcohol and crack cocaine.

The HIV-positive parturient is at high risk for harboring other sexually transmitted diseases. From the anesthesia provider's perspective, the most significant of these diseases is syphilis, because of its neurologic effects in later stages. If neuraxial anesthesia is performed, a careful neurologic examination should be completed and documented. Hepatitis B also is a sexually transmitted disease, and it should be investigated in HIV-positive parturients. Severe hepatic impairment affects anesthetic management. Of equal importance are the infectivity of hepatitis B and the high likelihood of its transmission after needlestick injury. For this reason, it is unacceptable for health care workers to remain unvaccinated against hepatitis B.

Choice of Anesthetic Technique

There are concerns with the use of either general or neuraxial anesthesia. Overall, both techniques are safe, keeping in mind the precautions outlined in this chapter.[65]

Neuraxial Anesthesia

Whether HIV-infected pregnant women are more prone to the occurrence of infection after administration of neuraxial anesthesia is an important concern. Hughes et al.[66] performed a study of 30 HIV-positive parturients, of whom 18 received neuraxial anesthesia and 12 did not; there was no evidence of accelerated disease progression in either group, and there were no neurologic or infectious complications in either group immediately after delivery and at 4 to 6 months postpartum.[66] A later study demonstrated no postoperative changes in viral load or $CD4^+/CD8^+$ lymphocyte ratio and no increased hemodynamic instability or blood loss in HIV-infected patients undergoing elective cesarean delivery with spinal anesthesia.[67] The prevention of infectious complications of neuraxial anesthesia depends on the maintenance of strict aseptic technique, which should include careful hand washing and wearing a face mask (see Chapter 12). Although the American Society of Anesthesiologists (ASA) practice advisory[68] does not specifically recommend that anesthesia providers wear a sterile gown during initiation of neuraxial anesthesia, the U.S. CDC has recommended that a gown should be worn to prevent the transmission of HIV to the health care worker "during invasive procedures likely to result in the splashing of blood or other bodily fluids."[69]

Some physicians may question whether it is prudent to administer neuraxial anesthesia to a patient who almost certainly will develop neurologic deficits at some time in the future and whether these deficits might be ascribed to the neuraxial anesthetic technique. Because such deficits are unlikely to be temporally related to the anesthesia, this does not seem to be a significant concern. Further, it seems cruel to deny the most effective intrapartum analgesic techniques to HIV-positive women simply because of fear of future litigation.

Another question is whether an anesthesia provider can ethically or legally refuse to provide care to an HIV-positive patient. Specifically, can an anesthesia provider refuse to provide epidural analgesia during labor? The American Medical Association has taken the position that physicians have an ethical duty to treat HIV-positive patients. Refusing to treat a patient with HIV also places the physician at legal risk, because numerous federal, state, and local statutes prohibit discrimination against patients with HIV disease. Any physician who refuses to provide care for patients with HIV must participate in a referral system ensuring that such patients receive prompt medical care.[70]

Despite the use of small-gauge, pencil-point spinal needles, and despite careful technique during administration of epidural anesthesia, post–dural puncture headache (PDPH) remains a problem in pregnant patients (see Chapter 31). Clearly, the onset of headache and photophobia in an immunosuppressed patient who has recently received a major neuraxial anesthetic can be worrisome, but the typical postural nature of a PDPH should allay fears of bacterial meningitis. Once the diagnosis of PDPH is made, an initial course of conservative therapy is indicated. It typically consists of bed rest, analgesics, and oral hydration. Although dehydration can worsen PDPH, there is no evidence that forced oral or intravenous overhydration has any beneficial effect.

Should conservative therapy for PDPH fail, a number of additional pharmacologic interventions have been proposed, including intravenous or oral caffeine, adrenocorticotropic hormone, and the $5\text{-}HT_3$ receptor agonist sumatriptan; all have varying degrees of success. However, the "gold standard" for treatment of PDPH is an autologous epidural blood patch. Such treatment can be expected to produce permanent and complete pain relief in the great majority of patients; a second epidural blood patch typically produces relief in most patients for whom the initial procedure fails.

Some physicians have expressed concern that the introduction of HIV-infected blood into the neuraxis might lead to the introduction of HIV into a previously uninfected CNS.[71] Demonstration of subarachnoid extension of an epidural blood patch on magnetic resonance imaging heightens these concerns.[72] However, it is likely that CNS infection occurs quite early in the course of HIV disease, even in asymptomatic patients. Nevertheless, it seems prudent to acknowledge the possibility that an epidural blood patch could accelerate the CNS manifestations of the disease. This question was addressed in a study of six seropositive patients who experienced PDPH after diagnostic lumbar puncture and who subsequently received an epidural blood patch.[73] These patients subsequently underwent serial neuropsychological testing for as long as 2 years. The investigators stated that "none of these six subjects had a decline in neurocognitive performance or other adverse neurologic or infectious

sequelae" during the period of the study. Although these numbers are small and this study has never been repeated, it provides the best evidence to date of the safety of epidural blood patch in an HIV-infected patient.

An alternative to autologous epidural blood patch is the epidural infusion of normal saline or colloidal solutions such as hetastarch. Unfortunately, the relief obtained from this technique is often transient, lasting only as long as the infusion continues. Further, the safety of epidural colloid infusion has not been established. Another proposed alternative is an epidural blood patch with fresh allogeneic whole blood; however, there are no published data on this technique.

General Anesthesia

As with neuraxial anesthesia, it is appropriate to ask whether patients with HIV might be more susceptible to the infectious (e.g., pulmonary) complications of general anesthesia. No published study has addressed this question. However, it seems appropriate to handle the endotracheal tube in as sterile a manner as possible and to minimize the duration of postoperative ventilation.

Another question involves the effect of general anesthesia on immune function. Several published studies suggest that general anesthesia can transiently depress immune function, but this depression appears to be clinically insignificant in healthy patients.[74] It is appropriate to ask whether this effect might be exaggerated to the point of clinical significance in patients with HIV disease. Studies on this issue are lacking. At present, it would be inappropriate to recommend one anesthetic technique over another on the basis of their effects on immune function.[75]

STRATEGIES TO MINIMIZE TRANSMISSION OF HUMAN IMMUNODEFICIENCY VIRUS

To the Uninfected Patient

Any survey of HIV and anesthesia must include a discussion of those measures that can decrease the risk for HIV transmission to the uninfected patient. The most common iatrogenic cause of such transmission is the transfusion of infected blood. The use of nucleic acid amplification techniques to test donor blood should reduce the risk for transfusing HIV-infected blood. Nonetheless, the most significant impact that anesthesia providers can have on disease transmission is to minimize the transfusion of allogeneic blood.

In healthy patients, oxygen delivery is satisfactorily maintained at hemoglobin levels much lower than the historical transfusion threshold of 10 g/dL. The Consensus Development Conference on Perioperative Red Blood Cell Transfusion concluded that healthy patients tolerate a hemoglobin concentration as low as 7 g/dL.[76] Patients with chronic anemia have a higher concentration of 2,3-diphosphoglycerate, which allows effective oxygen delivery at low hemoglobin concentrations. ASA guidelines[77] state the following:

> *The information needed to precisely define when a blood transfusion should be given is not available….Red blood cells should usually be administered when the hemoglobin concentration is low (e.g., less than 6 g/dL in a young, healthy patient), especially when the anemia is acute. Red blood cells are usually unnecessary when the hemoglobin concentration is more than 10 g/dL….The determination of whether intermediate hemoglobin concentrations (i.e., 6 to 10 g/dL) justify or require RBC transfusion should be based on any ongoing indication of organ ischemia, potential or actual ongoing bleeding (rate and magnitude), the patient's intravascular volume status, and the patient's risk factors for complications of inadequate oxygenation. These risk factors include a low cardiopulmonary reserve and high oxygen consumption.*

It is not clear how these guidelines should be applied to pregnant women. An association between preterm delivery and hemoglobin concentrations of less than 10 g/dL has been reported,[78] as has a similar association between LBW infants and hemoglobin concentrations lower than 9 g/dL.[79] However, whether this is a causal relationship or whether anemia serves as a marker of poor nutrition or lower socioeconomic status that may independently lead to perinatal morbidity is unknown. Although it is impossible to designate a minimum acceptable hemoglobin level during pregnancy, anemia is clearly undesirable. Once a cause is determined, appropriate therapy should be initiated, including transfusion if the anemia is life threatening for the mother or fetus.

Patients often want to use blood specifically donated by friends or relatives for their use (**directed donation**). There are disadvantages of directed donation. First, a directed unit is unavailable to another patient who may need it more urgently. Second, directed donation may discourage the routine voluntary donation of blood. Third, the directed donor sacrifices anonymity and legal protection. More pertinent to the issue of HIV transmission, there is no evidence that blood from designated donors is safer than anonymously donated bank blood[80]; this finding may be related to the slightly higher rate of HIV seropositivity among first-time donors.[81] Further, fatal graft-versus-host disease has been reported in patients receiving blood from first-degree relatives.[82]

Another approach is the use of **autologous blood donation** during pregnancy in patients at high risk for peripartum hemorrhage, such as those with placenta previa or suspected placenta accreta. Several studies have demonstrated the safety of autologous donation in pregnant women with a hematocrit of at least 34%.[83,84] However, it may be impossible to identify the patients who are more likely to require transfusion. In one study, only 4 (1.6%) of 251 high-risk patients eventually required transfusion. Further, only 2 of 13 patients who did receive blood during the peripartum period had identifiable risk factors. These results cast doubt on the benefits and cost-effectiveness of autologous blood donation during pregnancy.[85]

In patients at risk for hemorrhage during cesarean delivery, the use of **acute normovolemic hemodilution** may reduce the need for transfusion. This approach involves the collection of blood immediately before

surgery with the simultaneous infusion of an appropriate volume of crystalloid or colloid to maintain normovolemia. In one study of 38 patients at risk for hemorrhage, 750 to 1000 mL of blood was removed with the simultaneous infusion of an equal volume of pentastarch. The hemoglobin concentration dropped from 10.9 to 8.3 g/dL; fetal monitoring revealed no change in the fetal heart rate pattern. The blood was reinfused during surgery. Neonatal outcome was satisfactory, and only one patient required allogeneic blood.[86] In contrast, a meta-analysis in nonpregnant patients did not support the use of normovolemic hemodilution as an effective strategy for avoiding allogeneic transfusion.[87]

A final option for minimizing allogeneic transfusion is **intraoperative blood salvage** through the use of a cell salvage device (see Chapter 38). In the past, the use of intraoperative blood salvage in obstetric patients has been limited, in part by concern that transfusion of salvaged blood might precipitate amniotic fluid embolism. Waters[88] and others have argued that this rare but devastating complication is not an embolic disease but rather an anaphylactoid reaction that would occur with or without transfusion of cell-salvaged blood, given that amniotic fluid is routinely entrained into the maternal circulation at the time of delivery.

Published experience with intraoperative blood salvage suggests that it is safe in obstetric patients.[89,90] Allam et al.[89] reviewed the use of intraoperative blood salvage in obstetric patients; at the time of their review in 2008, approximately 400 published cases had been reported. (In most published cases, the total volume of transfused salvaged blood was small.) These investigators concluded that "no single serious complication leading to poor maternal outcome has been directly attributed to its use." They suggested that large prospective studies are needed to evaluate the efficacy and safety of cell salvage in obstetric patients.[89] Arguments against use of intraoperative blood salvage in obstetric patients include (1) because of the low use of blood salvage procedures in obstetrics, ongoing operator (user) competency may be problematic and the risk for error may be increased; and (2) the number of patients studied to date is not sufficient to detect rare adverse events.[91] Uncertainty remains about the cause of the syndrome of amniotic fluid embolism (including uncertainty as to which agent[s] trigger[s] the syndrome and which patients are at risk). Also, the blood salvage procedure does not eliminate fetal red blood cells, so the Rh-negative mother is at risk for isoimmunization from transfusion of salvaged blood.

The revised ASA Practice Guidelines for Obstetric Anesthesia[92] recommend that "in cases of intractable hemorrhage when banked blood is not available or the patient refuses banked blood, intraoperative cell salvage should be considered if available." And a 2012 ACOG committee opinion[93] concluded that "autologous blood salvage devices have proved safe and the use of these devices may be a valuable adjunct during…surgery [for placenta accreta]." At best, however, intraoperative blood salvage will reduce or eliminate exposure to allogeneic blood in a minority of parturients who require transfusion[94] (see Chapter 38 for a more complete discussion of intraoperative blood salvage).

Standards for Equipment Disinfection

The ASA Subcommittee on Infection Control Policy[95] has made specific recommendations about the disinfection of reusable anesthesia equipment that comes in contact with mucous membranes. In practice, this equipment consists of laryngoscope blades, endoscopes, and face masks. The ASA Subcommittee recommends that such items be washed as soon as possible to remove gross contamination, followed by either high-level disinfection or sterilization. Functionally, each of these procedures kills fungi, viruses, and vegetative bacteria (including mycobacteria). In addition, sterilization kills larger numbers of endospores.[95]

In many institutions, disposable carbon dioxide absorbers and unidirectional valves are used for the anesthetizing of HIV-infected patients. However, no evidence suggests that HIV is transmitted in respiratory aerosols.[96] This practice is unnecessary and is not recommended by the ASA subcommittee. An exception involves the HIV patient with active pulmonary tuberculosis; if a disposable absorber is not used for such a patient, the entire assembly distal to the fresh gas source must be disassembled and sterilized.

The rate of nosocomial transmission of HIV is negligible, and the only documented cases of such transmission apparently occurred in a setting in which disinfection procedures were notably lax.[96] Commonsense measures should effectively reduce the rate of nosocomial transmission to zero.

To the Health Care Worker

The primary means of preventing the transmission of HIV to health care workers is the mandatory use of universal blood and body fluid barrier precautions. This policy has three crucial components. First, it must be universal. Establishing a higher level of concern for dealing with known HIV-positive patients implies a lower level of concern in the care of patients not known to be HIV positive. Unfortunately, a patient who is infected with HIV may be living within the window between the acquisition of infection and seroconversion. Further, all care providers should be equally concerned with the transmission of other bloodborne infections of higher infectivity and sometimes equal deadliness, such as hepatitis B and C.

Second, this policy must be followed whenever contact with infectious material is anticipated. Blood obviously is the primary source of exposure, but other potentially infectious body fluids include amniotic fluid, CSF, synovial fluid, pleural fluid, and pericardial fluid. Saliva is not believed to be infectious, but manipulations of the oral mucosa (e.g., laryngoscopy, tracheal intubation) probably lead to the contamination of saliva with blood.

Third, barrier precautions must be effective. Barriers include gloves, mask, and eye shields. The use of gloves prevents 98% of an anesthesia provider's contact with patient blood.[97] When gross contamination is likely (e.g., during neonatal resuscitation), full-length gowns are indicated.

An additional component of universal precautions is the avoidance of needle-stick injuries. The recapping of

needles is the most common cause of needle-stick injuries. Contaminated needles, including needles that have been injected into intravenous tubing, should not be recapped by hand. If recapping is necessary, a mechanical protective device should be used. The use of needleless systems can be expected to significantly decrease the risk for injury, and the use of such systems should be encouraged.[98]

Postexposure Prophylaxis for Health Care Workers

Occupational exposure to HIV is perhaps the most frightening work-related injury that an anesthesia provider can sustain. The risk for seroconversion after percutaneous exposure to HIV-infected blood is approximately 0.3%,[99] but this statistic provides little reassurance to the exposed health care worker in view of the presumed 100% fatality rate of HIV infection. As of June 2000, the CDC had received voluntary reports of 56 U.S. health care providers with documented HIV seroconversion temporally related to occupational exposure, and an additional 138 reports of seroconversion that were considered possibly a result of occupational exposure.[100] There have been no confirmed cases of occupational transmission since 1999.[101]

Certain measures should be taken after any parenteral exposure to potentially infectious body fluids, even those of the HIV-negative patient (Box 45-5). Although it is of unclear efficacy in preventing HIV seroconversion, local wound care with an antiseptic solution is indicated.[102] In view of the exceedingly high transmission rate of hepatitis B infection, it is mandatory to determine the health care worker's antibody status after parenteral exposure to body fluids from a patient known to have or to be at high risk for hepatitis B. A previously vaccinated health care worker with absence or insufficiency of antibodies to hepatitis B should receive a booster dose of vaccine and hepatitis B immune globulin to provide protection until an adequate antibody response develops. A health care worker with no history of vaccination and an absence of antibodies should undergo primary immunization and should receive hepatitis B immune globulin.[99]

Several primate studies have demonstrated that the administration of antiretroviral drugs shortly after inoculation with SIV or HIV-2 can prevent seroconversion.[103,104] Further, although prospective data are lacking, a retrospective case-control study demonstrated an 81% reduction in transmission of HIV to exposed health care workers who received ZDV prophylaxis.[105] Finally, the reduction of vertical transmission by ZDV therapy demonstrated by ACTG Protocol 076 was only partly a result of the reduction of maternal viral load; inhibition of viral replication clearly played some role.[99] Altogether, these results suggest that postexposure prophylaxis may play a significant role in preventing seroconversion.

The U.S. Public Health Service has issued postexposure prophylaxis guidelines for health care workers who have experienced either percutaneous or permucosal exposure to HIV.[99] These recommendations attempt to determine the relative risk of transmission on the basis of (1) the nature of the material to which the worker was exposed, (2) the size of the inoculum, (3) the route of exposure, and (4) the presumed viral titer in the inoculum. Although encouraging results have been obtained, the primary strategy for the prevention of occupational transmission should focus on the prevention of exposure, especially the prevention of needle-stick injuries.

BOX 45-5 Treatment of Occupational Exposure to Human Immunodeficiency Virus

- Local wound care
- Administration of tetanus toxoid
- Determination of worker's hepatitis B antibody titers
- Risk stratification
- Chemoprophylaxis as indicated

KEY POINTS

- Over two thirds of all new cases of HIV infection in the United States occur in minority populations.
- More than 20% of all new HIV infections in the United States occur in women.
- HIV infection eventually can be expected to involve every organ system. Central nervous system involvement occurs as early as the period of initial infection and seroconversion.
- Highly active antiretroviral therapy during pregnancy can reduce the rate of vertical transmission of HIV infection to the fetus to 1% to 2%.
- Elective cesarean delivery can provide further protection in women with more than 1000 copies of viral RNA per mL of plasma and may benefit women with lower viral loads.
- HIV-infected patients often are treated with multiple medications, each of which has side effects that are relevant to anesthetic management.
- Neuraxial anesthesia is safe in the HIV-infected parturient.
- Autologous epidural blood patch is safe in the HIV-infected patient.
- Our greatest contribution to minimizing the spread of HIV to uninfected patients is the minimization of homologous blood transfusion.
- The most effective method of minimizing HIV transmission to health care workers is strict adherence to universal blood and body fluid barrier precautions.
- Postexposure prophylaxis is indicated for all health care workers who experience high-risk exposures to potentially infectious materials.

CHAPTER 46

Liver Disease

David B. Wax, MD • Yaakov Beilin, MD • Michael Frölich, MD, MS

CHAPTER OUTLINE

LIVER DISEASES

Liver diseases can be either incidental or unique to pregnancy and complicate as many as 3% of all pregnancies. The more common conditions are addressed in this chapter, and the hepatic aspects of preeclampsia/eclampsia and HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome are discussed in Chapter 36.

Liver Diseases Incidental to Pregnancy

Viral Hepatitis

The presentation of viral hepatitides ranges from mild, nonclinical illness to fulminant hepatic necrosis. Viral hepatitis is the most common cause of jaundice and most frequent reason for gastroenterology consultation during pregnancy.[1] Six types—hepatitis A, B, C, D, E, and G—have been identified and are associated with specific viruses. Types A, B, and C are the most common. Infrequently, hepatitis can also be caused by herpes simplex virus (HSV), yellow fever virus, rubella virus, Epstein-Barr virus (EBV), or cytomegalovirus (CMV).

Hepatitis A (**HAV**) and **hepatitis E** (**HEV**) are viral infections of hepatocytes that typically spread by oral ingestion of food or water contaminated with feces from infected individuals. Although endemic in other countries, the current all-time low incidence of 1.3 per 100,000 in the United States is attributed to good sanitation.[2] The incidence of HAV infection has been reduced by vaccination for preexposure prophylaxis; immune globulin is available for postexposure prophylaxis to prevent or attenuate infection. Clinically, a preicteric phase typically occurs with nonspecific viral symptoms, followed by an icteric phase with jaundice and acholic stools. Acute treatment is supportive. Chronic HAV infection does not occur, but a prolonged or relapsing course occurs in up to 20% of patients and an acute fulminant course occurs in less than 1% of patients.[3] Vertical transmission to the fetus has been reported rarely.[4]

HEV infection may be largely asymptomatic. In symptomatic patients, the disease is usually self-limited. Pregnant women and patients already infected with another hepatitis virus, however, are more likely to develop fulminant hepatic failure. Chronic HEV infection may occur in immunosuppressed patients, and vertical transmission can occur.[5] Pegylated interferon and/or ribavirin treatment for chronic HEV infection has shown moderate success, and HEV vaccines are under development.[6]

Hepatitis B (**HBV**) and **hepatitis D** (**HDV**) are usually transmitted via percutaneous or permucosal exposure to infected body fluids. In high-prevalence areas, HBV infection is most commonly acquired perinatally or in early childhood. In low-prevalence areas, infection is primarily acquired in adulthood through sexual contact or intravenous drug abuse. The incidence is decreasing after widespread vaccination and safety precautions in health care settings. Postexposure prophylaxis with HBV vaccination alone or a combination of vaccination with HBV immunoglobulin is highly effective in preventing HBV transmission in adults as well as in infants of HBV-infected mothers and may prevent perinatal transmission in 90% of cases. The majority of acute infections are asymptomatic, with only 30% of adults developing typical symptoms of hepatitis, and less than 0.5% developing fulminant hepatitis. Most cases can be managed with supportive treatment, although nucleoside analogue therapy may improve prognosis in severe cases. Chronic

HBV develops in less than 5% of adults but in more than 20% of children, and exacerbations of chronic HBV may occur in the postpartum period. The 5-year cumulative incidence of cirrhosis in those with chronic HBV may be as high as 20%, and once cirrhosis has developed the annual risk for hepatocellular carcinoma may be as high as 5%. Treatment of chronic HBV, therefore, is aimed at clearance of virus to prevent the development of cirrhosis and cancer. Vertical transmission to the fetus from hepatitis Be antigen (HBeAg)-positive mothers can be as high as 90% without attempts to prevent transmission.[7] Nucleoside analogue antiviral therapy with lamivudine has a favorable side-effect and safety profile and may be used during pregnancy to reduce vertical transmission, but there is significant risk for viral resistance.[8] In contrast, interferon therapy has a finite course of treatment and an increased chance of viral clearance and significantly reduces the risk for cirrhosis and liver cancer; however, it has more side effects and is contraindicated during pregnancy.[9] Current recommendations are to administer HBV vaccination to *all* neonates, and to administer hepatitis B immune globulin (HBIG) to all offspring of infected mothers.[10]

HDV is dependent on HBV co-infection to replicate. Acute co-infection with both viruses can be more severe than acute HBV infection alone and may result in acute liver failure. HDV superinfection in the setting of chronic HBV results in chronic HDV infection in most patients, and these patients have more rapid progression to cirrhosis.[11]

Hepatitis C (HCV) transmission most commonly occurs from transfusion of infected blood products or injection of contaminated drugs (both illicit and iatrogenic). Maternal-fetal and sexual transmission are less common routes of transmission. Initial infection is generally asymptomatic, but up to 30% of patients develop acute hepatitis. In patients with acute HCV infection that has not cleared spontaneously within 12 weeks, treatment with pegylated interferon may be used to prevent chronic infection, with treatment success in up to 98% of patients. In most asymptomatic and untreated cases, infection persists for over 6 months and leads to chronic infection with progression to cirrhosis in up to 30% of patients within 30 years. Thus, HCV is the leading cause of chronic hepatitis, cirrhosis, and liver cancer (which develops in up to 3% of patients per year) and a primary indication for liver transplantation in the developed world. Depending on the severity of liver fibrosis, therapy may be warranted to prevent these complications. Combination treatment with pegylated interferon, ribavirin, and a protease inhibitor can result in a sustained virologic response in up to 80% of patients, but is contraindicated during pregnancy.[12,13]

Hepatitis G (HGV) is transmitted parenterally, sexually, or vertically. In the United States, nearly 20% of all blood preparations are infected with HGV. Although there have been reports of acute, fulminant, and chronic hepatitis and hepatic fibrosis, HGV replicates predominantly in the hematopoietic system rather than in hepatocytes. Clinical significance is mostly for those co-infected with HCV or human immunodeficiency virus (HIV) or for individuals with hematologic cancers.[14]

Cholecystitis

Pregnancy may promote gallstone formation. Cholelithiasis is present in up to 3% of pregnant women, although acute cholecystitis occurs in only 0.1% of pregnancies.[15] Patients may have right upper quadrant pain, fever, and leukocytosis, and diagnosis is generally made by ultrasonography. Serious complications include **cholangitis, pancreatitis, gangrenous cholecystitis,** and **perforation.** To avoid surgery, conservative treatment may be considered in mild cases and includes intravenous hydration, antibiotics, opioid analgesia, bowel rest, and possibly percutaneous cholecystostomy. There is some evidence, however, that there is greater risk for fetal demise among patients treated conservatively.[16] When surgical intervention is required, both laparoscopic and open cholecystectomy have been safely used during pregnancy.[15]

Liver Abscess

Liver abscess can develop from infection by a range of organisms with various sites of entry. Organisms with a predilection for the liver include parasites such as ***Entamoeba***, ***Echinococcus***, ***Clonorchis***, and ***Ascaris***. Direct inoculation during medical instrumentation or hematogenous spread from intravenous drug abuse or endocarditis can occur. Appendicitis, diverticulitis, or other intra-abdominal infections may spread to the liver. **Fungal infections** are also possible in immunocompromised patients. Management of liver abscess includes antimicrobial agents, percutaneous or open drainage, and possibly surgical resection.[17] The condition is rare during pregnancy, but treatment modalities are similar to those described for the nonpregnant woman.[18]

Autoimmune Diseases

Autoimmune hepatitis, primary biliary cirrhosis, and **primary sclerosing cholangitis** are conditions that may overlap and may also be associated with other extrahepatic autoimmune disorders.[19,20] All may lead to end-stage liver disease, and treatment with corticosteroids, other immunosuppressants, and/or ursodeoxycholic acid is aimed at preventing this progression. For advanced and intractable disease, liver transplantation may be necessary. Pregnancy is associated with a 33% incidence of disease flares (mostly in the postpartum period), and an 11% incidence of serious maternal adverse events associated with hepatic decompensation, as well as increased neonatal intensive care requirement. Immunosuppressive therapy during pregnancy is reportedly safe and effective in reducing disease flares.

Vascular Syndromes

Budd-Chiari syndrome involves thrombosis of the hepatic vein or suprahepatic inferior vena cava and may be associated with pregnancy or other hypercoagulable states.[21] Hepatic venous congestion can also result from right-sided heart failure or other cardiopulmonary diseases that increase central venous pressure or from

mechanical compression or compartment syndrome that impedes hepatic venous outflow. This congestive hepatopathy can ultimately lead to fibrosis, portal hypertension, and liver failure. **Portal vein thrombosis** may also occur and cause portal hypertension without cirrhosis. Initial therapy is anticoagulation, and liver transplantation may ultimately be required in chronic cases. Disruption of hepatic arterial and/or portal venous inflow can result in acute ischemic/hypoxic hepatitis, especially in the setting of other coexisting liver disease. This "shock liver" syndrome can occur in the setting of perioperative hypotension, critical illness with septic shock or cardiac arrest, pulmonary embolus, heart failure, or heatstroke.[22,23]

Metabolic Diseases

Wilson's disease is a condition of reduced copper excretion. Gradual copper accumulation in the liver can lead to cirrhosis, while rapid accumulation may result in acute liver failure. Patients may also develop neurologic, ophthalmologic, and renal dysfunction. Fertility is generally reduced in women, but treatment with copper-chelating agents during pregnancy can result in positive outcomes for both the mother and fetus.[24] **Hemochromatosis** is a condition of iron accumulation that results in arthropathy, skin pigmentation, diabetes, hypopituitarism, hypogonadism, heart failure, and liver cirrhosis. Phlebotomy (with or without a chelating agent) to deplete iron stores markedly improves survival and prevents most of the complications.[25] **α_1-Antitrypsin deficiency** results in uncontrolled tissue degradation, with effects predominantly in the lungs and liver. This leads to emphysematous changes in the lung as well as liver cirrhosis.[26] Pregnancy can be complicated by fetal growth restriction (also known as intrauterine growth restriction), preterm labor, and pneumothorax or other respiratory decompensation.[27]

Hepatotoxicity

Hepatotoxicity can result from a variety of exposures. **Acetaminophen (paracetamol),** involved in 20% of drug overdoses during pregnancy, is metabolized by the liver into highly reactive oxides. If their formation exceeds the binding capacity of glutathione, maternal and fetal hepatic injury occurs. Treatment with *N*-acetylcysteine within 16 hours of acetaminophen ingestion may bind toxic metabolites in both the mother and the fetus and improve outcomes.[28] **Alcoholic hepatitis** can result from the acute ingestion of large amounts of alcohol, and chronic alcohol ingestion may lead to cirrhosis.[29] Other agents that have potential to cause hepatotoxicity during pregnancy are **antiretroviral drugs** for HIV infection, **propylthiouracil** for hyperthyroidism, **alpha-methyldopa** for hypertension, **isoniazid** for tuberculosis, **statins** for antiphospholipid syndrome or hyperlipidemia, **mushrooms** and **herbal supplements**, and **industrial agents**.[30-32] In one report, liver transplantation was successfully accomplished during pregnancy to treat acquired propylthiouracil-induced hepatotoxicity.[33]

Liver Diseases Specific to Pregnancy

Liver diseases specific to pregnancy are summarized in Table 46-1.

Hyperemesis Gravidarum

Hyperemesis gravidarum occurs in 0.3% of pregnancies and is characterized by a severe and persistent form of nausea and vomiting that can lead to dehydration and electrolyte imbalances, as well as elevated liver transaminases, mild jaundice, and transient hyperthyroidism (see Chapter 16).[34] The possible etiologies include hormonal, infectious (e.g., *Helicobacter pylori*), mechanical (e.g., gastroesophageal reflux), genetic, and psychogenic causes. Treatment with vitamin supplementation and antiemetics (e.g., doxylamine, metoclopramide, ondansetron) may be indicated, and severe cases may require enteral or parenteral nutrition and rehydration. Adverse pregnancy outcomes are rare but may occur in women who fail to gain adequate weight during pregnancy.

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy occurs in less than 0.3% of pregnancies overall in the United States but in up to 6% in some (e.g., Hispanic) subpopulations. It is more common in nulliparous women with multiple gestation.[35] Proposed causes include genetic mutations that alter phospholipid or bile salt transport across hepatocyte membranes, as well as abnormal steroid hormone profiles, resulting in pruritus and elevated serum bile acid levels during the second or third trimester. Pruritus is primarily on the palms and soles, is more severe at night, and may lead to excoriations resulting from scratching. Jaundice may also be present.

Intrahepatic cholestasis of pregnancy has minimal impact on maternal health during gestation. However, failure to correct vitamin K malabsorption may lead to clinical coagulopathy. Fisk et al.[36] reported an 11% incidence of postpartum hemorrhage among women with intrahepatic cholestasis of pregnancy. Although maternal outcome is generally good, the fetus is at increased risk. A study of 693 women with a diagnosis of intrahepatic cholestasis of pregnancy showed an increased risk for preterm delivery (4.3%), asphyxia events (7.1%), and meconium staining.[37] Fetal complications were increased when bile acid levels were greater than 40 μmol/L.

Ursodeoxycholic acid is currently the treatment of choice until fetal lung maturity allows for early delivery.[38] Antihistamines may also be used to relieve pruritus. Delivery at 37 weeks' gestation is recommended because most fetal demise occurs with longer gestations; even earlier delivery may be warranted in cases of intolerable pruritus or previous fetal demise. Recurrence of the disease is common in subsequent pregnancies.[39-41]

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP), or reversible peripartum liver failure, occurs in up to 1 per 7,000 pregnancies and is more common in twin gestations. Maternal

TABLE 46-1 **Liver Diseases Specific to Pregnancy**

	Hyperemesis Gravidarum	Intrahepatic Cholestasis of Pregnancy	Preeclampsia/ Eclampsia	HELLP Syndrome	AFLP
Incidence	< 0.3%	0.3%-6%	2%-8%	0.1%-0.6%	<0.01%
Presentation	1st trimester	2nd or 3rd trimester	2nd or 3rd trimester, or after delivery	2nd or 3rd trimester, or after delivery	3rd trimester
Symptoms, Signs, and Complications	Nausea/vomiting Ketosis	Pruritus Jaundice	Hypertension Proteinuria Edema Seizures Renal failure Pulmonary edema Hepatic hematoma/ rupture	Abdominal pain Renal dysfunction Hypertension Hepatic hematoma/ rupture Liver infarction	Nausea/vomiting Abdominal pain Jaundice Hepatic failure
Laboratory Findings	Elevated aminotransferase levels	Increased serum bile acid levels Hyperbilirubinemia Mild abnormalities of liver function tests	Low platelet count Proteinuria Increased uric acid level Mildly elevated aminotransferase levels	Low platelet count Hemolysis Markedly elevated aminotransferase levels	Low platelet count Hypoglycemia Mildly/moderately elevated aminotransferase levels
Treatment	Supportive management	Delivery at fetal maturity Ursodeoxycholic acid	Blood pressure control Seizure control Delivery	Prompt delivery	Prompt delivery
Outcome	Benign for mother and fetus	No increase in maternal death rate Increased risk for preterm delivery and fetal loss May recur with subsequent pregnancies Increased risk for subsequent liver and biliary tract disease	Increased risk for maternal morbidity and mortality Increased risk for perinatal morbidity	Maternal death rate 1%-4% Fetal death rate 1%-30%	Maternal death rate < 12% Fetal death rate < 66%

AFLP, acute fatty liver of pregnancy; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count.
Adapted from Schutt VA, Minuk GY. Liver diseases unique to pregnancy. Best Pract Res Clin Gastroenterol 2007; 21:771-92.

mortality up to 12% and fetal mortality up to 66% have been reported, but with prompt and aggressive care the mortality rates can be significantly decreased.[42] The disease is characterized by microvesicular fatty infiltration of the liver (and possibly kidney) believed to be due to defective beta oxidation of fat, usually in the third trimester. To date, AFLP has been documented in 30% to 80% of pregnancies in which the fetus was found to have a long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD) deficiency. It remains unclear why only some mothers who give birth to a child with fatty acid oxidation defects develop AFLP. Multiple gestation may further stress the fatty acid oxidation capacity in susceptible pregnant women. Davidson et al.[43] reported three cases of AFLP in parturients with triplet gestation.

Early symptoms are nonspecific and include anorexia, nausea, emesis, malaise, fatigue, and headache. Jaundice, edema, hypertension, hypoglycemia, diabetes insipidus, and encephalopathy may develop. Progression to fulminant hepatic and renal failure can be rapid. AFLP is commonly misdiagnosed as preeclampsia or HELLP syndrome because of a similar constellation of presenting symptoms. Similarities between AFLP and preeclampsia or eclampsia are intriguing. Both disorders primarily occur near term and are associated with nulliparity and multiple gestation.

AFLP is a medical emergency that demands rapid evaluation and treatment. Hepatic failure and fetal death may occur within days. Management includes control of hypertension, seizure prophylaxis, and immediate delivery of the fetus or termination of the pregnancy. Mode of delivery is not as critical as is doing so expeditiously.[44] Liver transplantation may be indicated in severe cases. The anesthesiologist should anticipate postpartum hemorrhage, establish adequate intravenous access, and ensure that crossmatched blood is immediately available for any parturient with AFLP.[45] There is often a worsening of liver function, renal function, and coagulopathy for 48 hours after delivery, followed by improvement during the subsequent weeks.[39,40,44] Survivors experience no

hepatic residua, and subsequent liver biopsy specimens show no evidence of fibrosis.[42] Episiotomy is avoided if possible, and abdominal delivery may be complicated by wound dehiscence related to coagulopathy; delayed wound closure may be indicated.[44]

Spontaneous Hepatic Rupture of Pregnancy

In 2003, 150 cases of hepatic rupture in pregnancy had been published.[46] Hepatic rupture may also complicate preeclampsia, eclampsia, HELLP syndrome, and AFLP. By definition, spontaneous hepatic rupture of pregnancy occurs in the absence of antecedent trauma. Instead, rupture is preceded by an intraparenchymal hepatic hematoma. The strong association with preeclampsia suggests that periportal hemorrhagic necrosis, hypertension, and coagulopathy may lead to hematoma formation. With expansion of the hematoma, the hepatic capsule is progressively distended and dissected from the parenchyma, leading to rupture.[47] **Primary hepatic pregnancy** with embryonic implantation on the liver is another rare condition that can result in liver hemorrhage and shock. In the early postpartum period, growth of hepatic hemangiomas, adenomas, or other potentially hemorrhagic masses may occur.

The mortality rate from hepatic rupture in pregnancy is greater than 60% but may be reduced by greater awareness and improved diagnostic modalities.[48] Ultrasonography, computed tomography, magnetic resonance imaging, angiography, technetium scintigraphy, and exploratory laparotomy may demonstrate the expanding hematoma before rupture.[49] Hematomas that are contained within the liver may be conservatively managed with intravenous fluids and blood products. More aggressive treatment options include open laparotomy, hepatic artery ligation or embolization, and compression of bleeding points with hepatic packing. Recombinant factor VIIa may be considered in the presence of intractable hemorrhage,[50] and liver transplantation can be considered as a last resort.[51]

LIVER FUNCTION AND DYSFUNCTION

Regardless of the disease state and whether it is incidental or unique to pregnancy, the signs and symptoms of acute and chronic liver diseases are similar.

Markers of Liver Dysfunction

The liver performs a variety of physiologic functions, derangements of which are characteristic of liver diseases (Box 46-1). Amino acid metabolism in the liver uses enzymes that include alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Levels of these enzymes are generally normal in pregnancy, but hepatocyte injury leads to their release (commonly called "transaminitis") into the blood where abnormal serum levels can be detected. The liver also removes bilirubin produced from heme metabolism in the blood. Thus, liver dysfunction can lead to accumulation of bilirubin that becomes symptomatic as jaundice. Gluconeogenesis can be impaired by liver dysfunction leading to hypoglycemia and accumulation of lactate. Synthetic functions of the liver include production of albumin and coagulation factors. Although albumin concentration normally decreases during pregnancy secondary to increased maternal plasma volume, prothrombin time (PT) is unchanged during normal pregnancy; therefore, an increase in PT is an indicator of possible liver disease. Decreased thrombopoietin production in the liver, along with hypersplenism from portal hypertension, may lead to thrombocytopenia. Alkaline phosphatase (ALP) and gamma glutamyl transferase (GGT) are found in biliary tract cells. ALP is normally increased during pregnancy because of fetal and placental production, but an elevated level of GGT is suggestive of biliary disease. Detoxification functions of the liver are responsible for clearance of many toxic metabolites and drugs. Failure of conversion of ammonia to urea in the liver results in accumulation of ammonia and consequent encephalopathy. Decreased clearance of estrogen and progesterone with liver disease may cause hyperventilation, and other signs of a hyperestrogenic state such as telangiectases and palmar erythema, although this may occur even in normal pregnancies because of increased production by the placenta. Various antigens and antibodies also show characteristic patterns of abnormalities in autoimmune and infectious forms of hepatitis and can be used for diagnosis and treatment monitoring.[22,52]

BOX 46-1 Signs and Symptoms of Liver Disease

Laboratory Findings

- Increased
  - Alanine aminotransferase (ALT)
  - Aspartate aminotransferase (AST)
  - Gamma glutamyl transferase (GGT)
  - Bilirubin
  - Lactate
  - Prothrombin time/international normalized ratio (PT/INR)
  - Ammonia
- Thrombocytopenia
- Hypoglycemia
- Hypoalbuminemia
- Metabolic acidosis
- Respiratory alkalosis
- Immune dysfunction
- Renal dysfunction
- Decreased systemic vascular resistance
- Portal hypertension and varices
- Pulmonary hypertension

Symptoms and Physical Findings

- Jaundice
- Pruritus
- Abdominal pain
- Decreased appetite
- Telangiectases
- Palmar erythema
- Easy bruising
- Gastrointestinal bleeding
- Ascites
- Encephalopathy

Acute Liver Failure

Acute (or fulminant) liver failure is an extreme complication of liver disease specific or incidental to pregnancy. Because the liver is responsible for many physiologic processes, liver failure manifests in profound ways that may be life threatening. A patient's condition can deteriorate in an unpredictable and rapid manner, and the patient may require management in a critical care setting. Treatment is mostly supportive, except in cases with specific anecdotal or proven therapies (e.g., immediate delivery for pregnancy-related causes,[53] *N*-acetylcysteine therapy for acetaminophen toxicity, lamivudine for acute HBV infection, penicillin therapy in *Amanita phalloides* intoxication, chelating agents in Wilson's disease, and steroid therapy for autoimmune hepatitis). Advances in critical care medicine and management strategies have improved 1-year survival to approximately 25% without a liver transplant and to 60% to 80% with a liver transplant.[54]

Encephalopathy results from reduced hepatic ammonia metabolism that leads to astrocytic glutamine accumulation and cerebral edema. Subtle mental status changes are followed by somnolence and disorientation, then by incoherence, and finally by coma. Use of invasive intracranial pressure (ICP) monitoring to determine cerebral perfusion pressure (CPP) is controversial because of questionable usefulness and concerns about intracranial bleeding from the procedure. If monitored, ICP should be maintained below 25 mm Hg and CPP should be maintained above 50 mm Hg. Jugular bulb oxygen saturation can provide information about cerebral oxygen use, with levels below 55% indicative of cerebral hypoperfusion and levels above 85% suggestive of cerebral hyperemia or inadequate neuronal metabolism.[55]

Patients should be kept in a quiet room with the head of the bed elevated more than 30 degrees. Mannitol or hypertonic saline infusion may be used to manage intracranial hypertension. Tracheal intubation should be considered once encephalopathy progresses, to prevent pulmonary aspiration, allow for sedation, prevent agitation that can contribute to increased ICP, and facilitate hyperventilation to treat refractory intracranial hypertension. High levels of positive end-expiratory pressure, hypercarbia, and frequent suctioning should be avoided. Other options to consider include thiopental or pentobarbital coma, mild hypothermia (35°C to 36°C [95°F to 96.8°F]), or moderate hypothermia (with a paralytic agent to prevent reflex shivering) to reduce brain oxygen requirement. Phenytoin or propofol can effectively decrease the risk for seizure activity. For patients whose ICP and CPP have been refractory to therapy, a technetium-99m albumin scan can document the absence of cerebral blood flow so that these patients can be removed from the liver transplant waiting list.

Immune dysfunction is related to loss of Kupffer and other immune cell function, and complications of bacterial or fungal infections are a leading cause of mortality. Prophylactic treatment with intravenous antibiotics and antifungal agents significantly reduces the risk for sepsis, decreases the risk for progression to high-grade encephalopathy, and increases the potential for successful transplantation.

Coagulopathy results from impaired synthesis of coagulation factors, most of which are produced in the liver, and from thrombocytopenia, which may be caused by reduced hepatic thrombopoietin production, acute portal hypertension with splenic sequestration, and reduced marrow production. Disseminated intravascular coagulation may also develop. Mucocutaneous, gastrointestinal, and iatrogenic bleeding can all occur in this setting. Cholestasis leads to malabsorption of vitamin K, an important cofactor required for the synthesis of factors II, VII, IX, and X. A therapeutic trial of vitamin K may be attempted if malabsorption is the primary defect, but women with impaired hepatic synthesis do not respond. Routine use of fresh frozen plasma or platelet transfusion is not recommended except when there is evidence of active bleeding or an invasive procedure is planned. Proton-pump inhibitors may help prevent gastric stress ulcers and bleeding. Although liver failure is generally thought to be a hypocoagulable state, it can also be a hypercoagulable state, with clinical manifestations that are difficult to predict and cannot be effectively prevented by prophylactic treatment with blood product transfusions.[56]

Circulatory dysfunction is common because of low systemic vascular resistance, and subclinical myocardial injury is common. Fluid resuscitation is the initial treatment for hypotension, but fluid overload can increase the risk for cerebral edema and acute lung injury. Dopamine or norepinephrine may be used to maintain CPP. Vasopressin and epinephrine are not first-line agents because they may have deleterious effects on splanchnic blood flow, acid-base status, and ICP. Corticosteroids may be considered for patients unresponsive to vasopressors.

Increased production and reduced hepatic uptake of lactate results in metabolic acidosis. In addition, renal function is impaired in up to 40% of patients. Renal failure, acidemia, electrolyte disturbances, or volume overload necessitate renal replacement therapy with continuous venovenous hemofiltration with dialysis. Decreased gluconeogenesis can lead to hypoglycemia, whereas hyperglycemia may worsen neurologic outcome. Enteral feeding is preferred to parenteral nutrition, although parenteral nutrition with hypocaloric, low-glutamine, and normal protein formula appears to be safe.

For patients who are not expected to recover liver function necessary for survival, liver transplantation may be planned. In patients with toxicity from massive liver necrosis, total hepatectomy and temporary portocaval shunting can be done in the interim, while awaiting a donor organ. Auxiliary partial orthotopic liver transplantation has also been performed where only half the native liver is resected and transplanted, allowing the native liver time to recover/regenerate and eventually allowing the donor liver to be rejected, avoiding lifelong immunosuppression. Artificial and bioartificial liver-support devices are also under development.[28,53,54,57,58]

Cirrhosis and Chronic Liver Failure

Any chronic liver disease can progress to cirrhosis, which is characterized by diffuse hepatic fibrosis. Cirrhosis may be asymptomatic until up to 90% of the hepatic parenchyma is destroyed or until a comorbidity causes

decompensation. Many manifestations are similar to those of acute liver failure, although gradual in onset and of lesser severity, whereas others are unique to cirrhosis. Pregnancy is rare in patients with cirrhosis because cirrhosis is uncommon in women of reproductive age and because hormonal changes can cause anovulation and infertility in those who are cirrhotic during childbearing age. Spontaneous abortion rates, risk for prematurity, and perinatal death rates are all greater than those for noncirrhotic parturients.[59]

Hepatic fibrosis causes increased resistance to portal blood flow, resulting in portal hypertension that promotes blood flow through portosystemic anastomoses such as esophageal, hemorrhoidal, and other intra-abdominal veins. Congestion and dilation of these collateral vessels increases the risk for spontaneous or iatrogenic bleeding. In addition, coagulopathy of cirrhosis resulting from decreased clotting factor production and thrombocytopenia can exacerbate bleeding from many causes. **Esophageal variceal bleeding** has been reported in up to 32% of pregnant women with cirrhosis, 50% of those with known portal hypertension, and 78% of those with preexisting varices, with a mortality rate up to 50%. It most commonly occurs later in pregnancy when maternal blood volume is expanded and fetal growth causes compression of collateral vessels. Risk increases during labor because of the repetitive intra-abdominal pressure increases, especially from pushing during the second stage. Elective cesarean delivery or forceps delivery to shorten the second stage of labor and avoid the need for the Valsalva maneuver may decrease this risk.[60] Prophylaxis against variceal bleeding may be considered but is of unproven benefit during pregnancy. Nonselective beta-adrenergeic receptor antagonists can decrease the risk for variceal bleeding by reducing portal pressure through reduction of cardiac output and splanchnic vasoconstriction, but they may cause fetal complications. Prophylactic endoscopic band ligation or surgical portocaval shunting may also be considered in high-risk parturients. For acute esophageal variceal hemorrhage, endoscopic band ligation (after tracheal intubation for airway protection) is the first-line management. Octreotide infusion may also be considered, although its safety has not been proven in pregnant patients. Transjugular intrahepatic portosystemic shunting may be considered for refractory variceal bleeding (see later discussion).[61] Surgical shunt procedures may also be considered in extreme cases.

Splenic artery aneurysms may also develop in cirrhotic parturients, and rupture in late pregnancy carries high maternal and fetal mortality rates. Management options include splenectomy, transcatheter embolization, and stent-graft placement. Postpartum uterine hemorrhage is another potential source of maternal morbidity and mortality, occurring in up to 10% of pregnancies in patients with cirrhosis. In patients with portal hypertension, cesarean delivery can also lead to additional bleeding from intra-abdominal collateral vessels.

Encephalopathy secondary to ammonia accumulation may occur in cirrhotic patients and may be precipitated or exacerbated by sedative medications, infection, hypoglycemia, gastrointestinal hemorrhage, hypotension, or hypoxemia. Management includes correction of precipitating factors and reducing the nitrogenous load from gastrointestinal tract with oral, nonabsorbed antimicrobial agents such as lactulose and neomycin. Flumazenil may also improve mental status transiently, and bromocriptine may improve extrapyramidal symptoms, although these have not been studied extensively in cirrhotic parturients.

Massive **ascites** appears to be uncommon in pregnancy, possibly because the increased intra-abdominal pressure from the gravid uterus opposes extravasation of fluid from splanchnic vessels and organs. If therapy is required, sodium restriction and diuretics can be used. Symptomatic ascites refractory to medical treatment may require paracentesis for drainage, although this could potentially increase the risk for bacterial peritonitis and pregnancy complications.

Cardiovascular manifestations of cirrhosis include systemic vasodilation due to reduced hepatic clearance of endogenous substances regulating vascular tone. Cardiac output is thereby increased, assuming cardiomyopathy is not present as may occur in the settings of alcoholic cirrhosis or hemochromatosis. **Portopulmonary hypertension,** a progressive disease characterized by increased pulmonary vascular resistance due to arteriolar medial hyperplasia, thrombosis, or fibrosis, and eventually right-sided heart failure, has been reported as a complication during pregnancy resulting in postpartum maternal death.[62] **Hepatorenal syndrome,** renal dysfunction secondary to splanchnic and systemic vasodilation of cirrhosis, does not appear to be a common complication in cirrhotic parturients. Similarly, **hepatopulmonary syndrome** due to intrapulmonary vasodilation and shunting resulting in hypoxemia appears to be rare during pregnancy.[62-68]

LIVER SURGERY

Liver Transplantation during Pregnancy

Liver transplantation during pregnancy and successful maternal and fetal outcomes have been reported.[69] Severe fulminant hepatic failure of any cause during pregnancy may necessitate liver transplantation, if a suitable living or deceased donor can be found. For second-trimester transplants, maternal outcomes are excellent but fetal outcomes are poor as a result of elective abortions due to concerns over teratogenicity of therapy, spontaneous abortions, fetal demise, and neonatal death. The literature is inadequate to recommend choice of surgical technique, use of venovenous bypass, or other therapies during the transplantation surgery. In patients for whom a matching organ cannot be found, artificial support systems have been used temporarily while awaiting an organ or spontaneous recovery of liver function.[70-72]

Pregnancy after Liver Transplantation

In 1978, the first pregnancy in a liver transplant recipient was reported.[73] Subsequently, hundreds of such pregnancies have been reported worldwide. Hormonal changes of chronic liver disease can disrupt menstruation, but

liver transplantation restores menstrual function in most female recipients of childbearing age. Despite transplantation and immunosuppression, pregnancy in these patients results in a live birth rate comparable to that in nontransplanted parturients. Successful pregnancy outcome has even been achieved after triple organ transplantation (small intestine, liver, and pancreas).[74] A systematic review and meta-analysis of articles that reported pregnancy outcomes in liver transplant recipients between 2000 and 2011 reported data on 450 pregnancies in 306 recipients.[75] Overall, the pregnancy outcomes of liver transplant recipients appear to be favorable, but pregnancy complications are more common in transplant recipients, with hypertension being the greatest risk to the mother and preterm delivery the greatest risk to the infant. Data from one study suggest that use of the immunosuppressant drug tacrolimus in pregnant women is associated with a lower incidence of new-onset hypertension and preeclampsia than the use of cyclosporine.[76] Based on data from kidney transplants, it is recommended that transplant recipients wait 1 to 2 years before becoming pregnant to allow for stabilization of graft function and immunosuppression and ensure the best maternal and fetal outcomes.[77]

Liver Resection

Benign and malignant liver tumors may occur during pregnancy in patients with or without chronic underlying liver disease. Surgical resection, where feasible, is the definitive treatment.[78] Partial hepatectomy has been reported during pregnancy with good maternal outcomes. Management of the pregnancy has ranged from termination,[79] to simultaneous cesarean delivery,[80] to later spontaneous vaginal delivery.[81] There are inadequate data to make specific recommendations about the intraoperative management of liver resection during pregnancy, including the role of vascular clamping and maintenance of low central venous pressure to reduce blood loss.[82]

Transjugular Intrahepatic Portosystemic Shunt

Indications for a transjugular intrahepatic portosystemic shunt include variceal bleeding and massive ascites refractory to other therapies. Contraindications include right-sided heart failure, polycystic liver disease, severe hepatic failure, systemic infection, hepatic encephalopathy, hepatic tumors, and portal vein thrombosis. The procedure involves accessing a jugular vein, fluoroscopically guiding an endovascular needle into a hepatic vein, and then perforating the liver parenchyma until the needle tip reaches an intrahepatic portal vein. An endovascular stent is then placed across the liver parenchyma to maintain the shunt. The communication created between the portal and systemic venous systems decompresses the portal system, thereby decreasing the pressure that was causing bleeding and formation of ascites.[83] This procedure has been successfully performed during pregnancy and can be done with radiation-limiting techniques that minimize exposure to the fetus and allow the pregnancy to continue.[61,84]

ANESTHETIC CONSIDERATIONS

Anesthetic management is influenced by the extent of hepatic impairment. If hepatic synthetic and metabolic functions are intact, the patient may be managed in the same manner as healthy parturients. In contrast, the parturient with evidence of severe hepatic impairment presents the anesthesiologist with many challenges (Box 46-2).

For patients with underlying liver disease, ischemic or other hepatic insults have the potential to exacerbate liver dysfunction. Many retrospective analyses of various types of hepatic and nonhepatic surgery and anesthesia have focused on perioperative outcomes in patients with liver disease, although not specifically during pregnancy. Most studies have shown an association between preoperative liver disease (and its severity) and postoperative morbidity and mortality, suggesting that abdominal surgery should be avoided or deferred, if possible, until full evaluation and optimal treatment has been completed.[85-93] Other studies, however, found no such association.[94-96] The timing of delivery should be based on maternal and fetal considerations. If possible, it is best to fully evaluate the liver disease before delivery, although sometimes this may not be practical. Early delivery should be considered if the liver disease is exacerbated by the pregnancy (e.g., acute fatty liver of pregnancy or cholestasis of pregnancy) or if the pregnancy is limiting the ability to perform a full liver evaluation. Neuraxial techniques have been used safely in asymptomatic chronic hepatitis patients, as well as after liver transplantation, although data specifically on pregnant patients are lacking.[27,96-99]

Hepatic Effects of Anesthesia

Various studies have examined the effects of anesthetics on hepatic blood flow, although these investigations were not in the setting of pregnancy. Volatile anesthetics appear to decrease hepatic blood flow, with **enflurane**

BOX 46-2 Anesthetic Guidelines for the Parturient with Liver Disease

- Evaluate the extent of hepatic impairment.
- Recognize and evaluate underlying systemic abnormalities, including coagulation and volume status.
- Assist the obstetric team with stabilization of maternal condition before delivery.
- Plan preferentially for neuraxial analgesia/anesthesia for labor, delivery, and cesarean delivery in the absence of contraindications.
- Exclude coagulopathy before administration of neuraxial anesthesia.
- Prevent further hepatic injury by optimizing hepatic blood flow and oxygenation.
- Recognize altered pharmacokinetics and pharmacodynamics.
- Prevent transmission of viral hepatitis to the health care team.
- Monitor the patient for evidence of postoperative hepatic dysfunction.

and **halothane** causing significantly more reduction (> 20%) than **isoflurane**, **sevoflurane**, or **desflurane** (< 20%). Additionally, halothane is thought to cause two distinct forms of drug-induced hepatitis. **Nitrous oxide** may further decrease hepatic blood flow, whereas propofol or ketamine anesthesia may maintain hepatic blood flow better than inhalational anesthesia.[100-107] **Neuraxial anesthesia** also may reduce hepatic blood flow via the effects of systemic arterial hypotension secondary to sympathetic blockade.[108-110] In one study,[110] this reduction persisted during lumbar epidural anesthesia despite maintenance of normotension by infusion of colloid, but the decrease in hepatic blood flow was reversed by dopamine infusion. These findings suggest that reduced cardiac output, secondary to sympathetic blockade, may be responsible for the observed decrease in hepatic blood flow rather than hypotension. Nevertheless, judicious hydration and avoidance of systemic hypotension should minimize the chances of a clinically significant reduction in hepatic blood flow.

Pharmacokinetic Effects of Liver Failure

The liver's numerous metabolic functions include clearance of drugs as well as synthesis of plasma proteins that bind drugs. Liver disease, therefore, can alter the normal pharmacokinetics of anesthetics and other drugs. Drug clearance may be decreased by hepatocyte dysfunction or reductions in liver blood flow. Impaired hepatic synthesis of plasma proteins can lead to decreased drug binding and increased free fraction of drugs. This makes more drug available for clearance by the liver, but at the same time increases tissue availability and effective volume of distribution, which can alter drug effects and clearance. Overall, severe liver disease can decrease clearance of various agents, and repeated or continuous administration can lead to drug accumulation and adverse effects. Additionally, compared with their effects in healthy individuals, anesthetic agents at any concentration may cause increased sedation or decompensation in patients already compromised by hepatic encephalopathy.

Clearance of some opioids, including **morphine**, **meperidine**, and **alfentanil** may be decreased in patients with advanced liver disease. Other opioids, including **fentanyl** and **sufentanil**, do not appear to have significantly impaired clearance, although repeated or continuous dosing may be problematic. **Remifentanil** undergoes breakdown by plasma and tissue esterases, and so its pharmacokinetics are not significantly changed. **Methadone** also appears to have nearly normal disposition. **Codeine**, which requires hepatic conversion to morphine for analgesia and clearance, may not be safe or effective, and similar uncertainty exists regarding tramadol.[111-114] Prolonged effects can also be seen with **etomidate** and benzodiazepines including **midazolam** and **diazepam**, whereas **propofol**, **methohexital**, and **thiopental** clearances are unchanged after anesthesia induction doses.[115-119] Neuromuscular blocking agents normally cleared by the liver (**vecuronium**, **rocuronium**) or by liver-synthesized enzymes (**succinylcholine**), or that may be present in a larger volume of distribution (**pancuronium**), may have longer durations of action, whereas agents not dependent on liver function (**atracurium**, **cisatracurium**) should have normal durations of action.[120-124] The half-lives of amide local anesthetics (**lidocaine**, **bupivacaine**, **ropivacaine**) may be prolonged and potential for toxicity increased because of decreased liver clearance, whereas ester local anesthetics (**2-chloroprocaine**) have potentially prolonged half-lives because of decreased hepatic pseudocholinesterase synthesis.[125-127] **Acetaminophen** can be safely administered in routine doses for acute pain in patients with cirrhosis, but chronic administration can provoke hepatic injury. Although **ketorolac** metabolism may be normal, **nonsteroidal anti-inflammatory drugs** (**NSAIDs**) can precipitate renal dysfunction and should be avoided.[67,128]

Neuraxial Anesthesia

Neuraxial analgesia/anesthesia is the preferred technique for labor, vaginal delivery, and cesarean delivery and can be offered to patients with liver disease in the absence of significant intravascular volume depletion and a coagulopathy. Prior to administration of a neuraxial technique, a full coagulation profile and platelet count should be obtained and intravascular volume assessed. Epidural techniques in particular may have added risk in patients with portal hypertension because the epidural venous plexus is engorged even beyond that of normal pregnancy and could predispose to intravascular needle/catheter placement or epidural hematoma.[129] The potential for impaired clearance of local anesthetics and opioids described earlier should also be considered, especially when repeated boluses or continuous infusions are used. There are no data indicating that one local anesthetic is clearly superior to another for epidural analgesia, and we use our standard epidural infusion of bupivacaine with fentanyl for labor analgesia. Single-shot spinal techniques with small-gauge needles may minimize the issues of drug metabolism and bleeding, although with possibly increased risk for acute hypotension and reduced liver blood flow.

General Anesthesia

Coagulopathy, obstetric hemorrhage, altered mental status, and severe fetal compromise may necessitate the use of general anesthesia for cesarean delivery. Intravascular volume should be evaluated before induction. Invasive blood pressure monitoring and pulmonary artery catheterization may be useful in the patient with cardiovascular compromise or portopulmonary hypertension. Large-bore intravenous access should be established and blood products should be available. Gastric acid neutralization should precede rapid-sequence induction and tracheal intubation. All standard induction agents are safe, and the dose should not be altered. Liver disease and reduced pseudocholinesterase concentrations may delay the metabolism of succinylcholine, but the delay is of negligible clinical importance. Succinylcholine thus remains the muscle relaxant of choice during rapid-sequence induction of general anesthesia, and it should be administered in the same dose as for healthy parturients. Careful gastric tube placement may be considered even in the presence of esophageal varices.[130] For maintenance of

anesthesia, agents that do not undergo significant hepatic metabolism (e.g., isoflurane, desflurane, atracurium, cisatracurium, remifentanil, and nitrous oxide) may be preferable to other inhalational agents that further reduce liver blood flow or intravenous agents that may accumulate before clearance. Reversal of neuromuscular blockade must be ensured before tracheal extubation.

Postoperative Care

Although clearance is delayed in patients with severe liver disease, intravenous opioids may be administered judiciously to provide postoperative analgesia. Neuraxial opioids, especially a single dose of morphine, may obviate any accumulation issues. Advanced liver disease can lead to hepatic encephalopathy. Neurologic deterioration in the postoperative period may result from the residual effects of anesthetic agents, acute liver decompensation, or an intracranial process. Neurologic observation and liver function monitoring is essential to the proper postoperative management of pregnant women with advanced liver disease.

KEY POINTS

- Liver disease can be either incidental or unique to pregnancy and complicates as many as 3% of all pregnancies.
- Viral hepatitides are the most common cause of jaundice during pregnancy.
- All pregnant women should be screened for hepatitis B virus, and all neonates should be vaccinated against it.
- Acute fatty liver of pregnancy (AFLP) is a rare but life-threatening complication of pregnancy that demands rapid evaluation and prompt delivery.
- AFLP is commonly misdiagnosed as preeclampsia or hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome because of a similar constellation of presenting symptoms.
- Hepatic rupture may complicate preeclampsia/eclampsia, HELLP syndrome, or AFLP; and the mortality rate can be greater than 60%.
- Encephalopathy may result from reduced hepatic ammonia metabolism.
- Coagulopathy may result from impaired liver synthesis of coagulation factors and from thrombocytopenia.
- Renal failure and cardiovascular, renal, pulmonary, and immune dysfunction may accompany liver failure.
- Women with portal hypertension may develop esophageal varices that are prone to bleed during the third trimester of pregnancy, and this risk increases during labor.
- Successful pregnancy is common after liver transplantation, and pregnancy does not affect the long-term survival of hepatic allografts.
- Pregnancy complications are more common; hypertension is the greatest risk to the mother, and preterm delivery is the greatest risk to the infant.
- Liver disease can alter the normal pharmacokinetics of anesthetics and other drugs.
- Both neuraxial and general anesthesia can be administered safely to the parturient with liver disease, with close attention to hemodynamics to preserve hepatic blood flow.
- Neuraxial analgesia/anesthesia is the preferred technique for labor, vaginal delivery, and cesarean delivery and can be offered to patients with liver disease provided significant intravascular volume depletion and coagulopathy have been excluded.
- Neurologic observation and liver function monitoring should continue into the postoperative period.

CHAPTER 51

Psychiatric Disorders

Warwick D. Ngan Kee, BHB, MBChB, MD, FANZCA, FHKCA, FHKAM

CHAPTER OUTLINE

Psychiatric disorders occur commonly during pregnancy, but their prevalence is often underestimated and underappreciated. Women have higher rates than men of many psychiatric disorders, such as anxiety, feeding and eating disorders, and depression; the reproductive years coincide with the greatest period of risk.[1] Management can be difficult and may be complicated by variable presentation of symptoms, social stigmas, confusion with normal symptoms of pregnancy, and inconsistent published treatment recommendations. Further, pregnant women with psychiatric disorders may resist drug treatment because of their desire to avoid fetal harm. Psychiatric disorders during pregnancy may be associated with other aspects of poor maternal health and deficient prenatal care, which may have an impact on anesthesia care.[2] Women with a history of previous psychiatric hospitalization or an identified mental illness are at increased risk for cesarean delivery.[3]

CLASSIFICATION

Internationally, psychiatric disorders are most commonly classified according to the *International Statistical Classification of Diseases and Related Health Problems (ICD)*, produced by the World Health Organization; the current version is *ICD-10* and is available on the Internet.* In the United States, a clinical modification of *ICD* is used; the latest version, *ICD-10-CM*, is due for implementation on October 1, 2014, and is also available on the Internet.† Although in the United States *ICD* is the official diagnostic system for mental disorders, the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*, published by the American Psychiatric Association (APA), is widely used; the current version is *DSM-5*.[4] These classification systems provide standardized language and criteria for diagnosis and classification of mental disorders, but it should be noted that definitions may not have precise boundaries and may not cover all situations, and there may be considerable overlap between "mental" and "physical" disorders.[4]

EPIDEMIOLOGY

Estimates of the prevalence of psychiatric disease in pregnancy vary. It has been estimated that more than 500,000 pregnancies each year in the United States involve women who have a psychiatric illness that either predates or emerges during pregnancy[1] and that 14% to 23% of pregnant women will experience a depressive disorder during pregnancy.[5] Importantly, data from the *Confidential Enquiries into Maternal Deaths in the United Kingdom*[6]

*http://apps.who.int/classifications/icd10/browse/2010/en#/V

†http://www.cdc.gov/nchs/icd/icd10cm.htm#icd2014

have consistently highlighted suicide as a major indirect cause of maternal death.

Pregnancy is widely considered a time of increased vulnerability to psychiatric disorders. However, a large national epidemiologic survey in the United States found that although the prevalence of disorders was high among pregnant women, pregnancy itself was not associated with an increased risk; the results were thought to reflect a general increase in risk for psychiatric disorders in women during the childbearing years.[2] A conspicuous exception was the risk for major depressive disorder, which appears to be increased during the postpartum period. Identified risk factors for developing psychiatric disorders during pregnancy include younger age, unmarried status, exposure to traumatic or stressful life events, pregnancy complications, and poor overall health. The survey also noted that treatment rates among pregnant women with psychiatric disorders were very low.

MOOD DISORDERS

Mood disorders include depressive disorders and bipolar disorders ("manic-depressive disorders").[4]

Major Depressive Disorder

Box 51-1 includes diagnostic criteria for major depressive disorder. Although depression is recognized as being relatively common during pregnancy, many of its symptoms (e.g., weight gain, appetite changes, sleep disturbances, fatigue) must be differentiated from symptoms that may occur during normal pregnancy. Risk factors for depression during pregnancy include a history of depression or bipolar disorder, childhood mistreatment, being a single mother or having more than three children, marital problems, unwanted pregnancy, smoking, low income, age younger than 20 years, poor social support, and domestic violence.[7,8] The risk for major depressive illness is increased in women who have a miscarriage (i.e., spontaneous abortion); this most frequently occurs in the first month after miscarriage and is more likely to occur in women who are childless or who have a prior history of major depressive disorder.[9] Depression during pregnancy is associated with an increased risk for poor obstetric outcomes such as miscarriage, preterm birth, and low birth weight.[10]

Bipolar (Manic-Depressive) Disorder

Patients with bipolar disorder (BPD) have episodes of major depression with other distinct periods of mania or hypomania. A strong familial association exists. Diagnostic criteria for mania are summarized in Box 51-2. BPD in pregnancy is particularly important because there is a strong link between discontinuation of medication and relapse of BPD and a relatively high suicide rate among patients. Treatment of BPD typically consists of mood stabilizer and antipsychotic medication, with psychotherapy as an adjunct.[11] Electroconvulsive therapy (ECT) is very effective for patients with BPD and severe depression.

BOX 51-1 Diagnostic Criteria for Major Depressive Episode

- Five or more of the following symptoms present in the same 2-week period, representing a change from previous functioning, and including at least either number 1 or 2:
  1. Depressed mood most of the day, nearly every day
  2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day
  3. Significant weight loss when not dieting, or weight gain, or a decrease or increase in appetite nearly every day
  4. Insomnia or hypersomnia nearly every day
  5. Psychomotor agitation or retardation nearly every day
  6. Fatigue or loss of energy nearly every day
  7. Feelings of worthlessness or excessive or inappropriate guilt nearly every day
  8. Diminished ability to think or concentrate, or indecisiveness, nearly every day
  9. Recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide
- In addition, symptoms should cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, and should not be a result of the physiologic effects of a substance. The episode should not be better explained by schizoaffective disorder, schizophrenia, or schizophrenia-related or other psychotic disorders, and there should never have been a manic or hypomanic episode.

Modified from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition. Arlington, VA, American Psychiatric Association, 2013.

Postpartum Depression

Postpartum depression describes a major depressive episode that occurs in the first 4 to 6 weeks after birth. Symptoms do not differ from those of depression occurring at other times. There may be accompanying psychotic features, which are thought to be more common in nulliparous women,[4,12] and there is a high risk for recurrence in subsequent pregnancies. It is important to differentiate postpartum depression from the "baby blues," which affects up to 70% of women in the first 10 days after delivery and is transient without functional impairment. It is also important to differentiate postpartum depression from delirium that arises from physical causes.[4] In a systematic review, Robertson et al.[13] showed that the strongest predictors of postpartum depression were (1) depression, anxiety, or stressful life events occurring during pregnancy or the early puerperium; (2) low levels of social support; and (3) previous history of depression. Biologic effects such as hormonal changes and psychologic and social role changes that occur with childbirth may increase the risk for postpartum depression.[14]

BOX 51-2 Diagnostic Criteria for Manic Episode

- A distinct period when there is abnormally and persistently elevated, expansive, or irritable mood and persistently increased goal-directed activity or energy, that lasts at least 1 week and is present most of nearly every day, or requires hospitalization
- Concurrent occurrence of three or more of the following symptoms:
  1. Inflated self-esteem or grandiosity
  2. Decreased need for sleep
  3. More talkative than usual (pressured speech)
  4. Flight of ideas or racing thoughts
  5. Distractibility
  6. Increased goal-directed activity or psychomotor agitation
  7. Excessive involvement in pleasurable activities with a high potential for painful or negative consequences
- Symptoms should be severe enough to cause marked impairment in occupational functioning, social activities, and interpersonal relationships and necessitate hospitalization or have psychotic features. Symptoms should not meet criteria for mixed episode and should not be caused by substance abuse or general medical conditions (e.g., hyperthyroidism).

From American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition. Arlington, VA, American Psychiatric Association, 2013.

Postpartum Psychosis

Postpartum psychosis occurs within 2 weeks of approximately 1 to 2 per 1000 live births; a relatively high risk continues for the first 3 months postpartum.[15] The risk is higher in patients with a history of BPD or a history of previous postpartum psychosis,[16] as well as in women with major depression and schizophrenia. Typical features include prominence of cognitive symptoms such as disorganization, confusion, impaired sensorium, disorientation, and distractibility.[15] Infanticide may be associated with command hallucinations to kill the infant or delusions that the infant is possessed.[12]

ANXIETY DISORDERS

Anxiety disorders affect women twice as often as men and are the most common psychiatric disorders during pregnancy and the postpartum period.[17] There is a wide range of anxiety disorders, including **panic disorder**, **separation anxiety disorder**, **selective mutism**, **specific phobia**, **social anxiety disorder**, **agoraphobia**, **generalized anxiety disorder**, **substance /medication-induced anxiety disorder**, **anxiety disorder due to another medical condition**, **other specified anxiety disorder**, and **unspecified anxiety disorder**. Closely related to anxiety disorders are **trauma- and stressor-related disorders**, which includes **post-traumatic stress disorder**, and **obsessive-compulsive disorder**.[4] Clinical features of anxiety disorders in pregnant women are similar to those in nonpregnant women, but concern about the pregnancy and the fetus may be the predominant feature.[18]

Panic Disorder

Panic disorder is characterized by the occurrence of recurrent, unexpected panic attacks. Affected women experience discrete episodes of intense fear or discomfort in the absence of a true danger; these episodes are accompanied by somatic or cognitive symptoms such as palpitations, sweating, shaking, dyspnea, choking, chest pain, nausea, paresthesias, chills, and/or flushes. Typically there is a rapid onset and peak of symptoms that may be accompanied by an urge to escape.[4] It is important to be aware of the possibility that panic attacks may occur during preparation of a patient for cesarean delivery. Panic attacks with hyperventilation may mimic systemic local anesthetic toxicity.[19] A possible role of lactated Ringer's solution as a trigger has been refuted.[20] Patients with panic disorder often have co-morbid major depression.[17]

Post-traumatic Stress Disorder

Post-traumatic stress disorder (PTSD) occurs after the experience of a traumatic event that evokes intense fear or helplessness.[1] Pregnancy and childbirth may exacerbate symptoms of PTSD. Symptoms of PTSD are more common after emergency cesarean delivery than after other modes of delivery,[21] and PTSD has resulted from (1) awareness during general anesthesia,[22] (2) inadequate regional anesthesia for cesarean delivery,[23] and (3) inadequate pain control during vaginal delivery.[23] The risk for PTSD may be increased if the pregnancy has resulted from rape or if memories of sexual trauma are triggered. It has been suggested that the childbirth experience itself can precipitate PTSD with a resulting fear of pregnancy termed *tocophobia*.[1] Fear of vaginal delivery may be a factor that contributes to maternal request for cesarean delivery.[21]

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is characterized by the presence of obsessions (intrusive thoughts or images) and compulsions (repetitive or ritualistic behaviors or thought patterns).[17] Pregnancy is a potential trigger of the onset of symptoms.[1] Classically, pregnant women with OCD may focus on protection of the fetus, which may manifest as cleaning and checking compulsions.[18] Care should be taken to identify infanticidal ideation.[17]

FEEDING AND EATING DISORDERS

There are conflicting data on the effect of pregnancy in patients with feeding and eating disorders, which include **anorexia nervosa** and **bulimia nervosa** as well as **pica**, **rumination disorder**, **avoidant/restrictive food intake disorder**, **binge-eating disorder**, **other specified feeding or eating disorder**, and **unspecified**

feeding or eating disorder.[4] Improvement in symptoms during pregnancy has been described, but conversely, pregnancy may result in body image preoccupations and unfavorable eating habits that may develop into a frank eating disorder.[15] Although fertility is reduced in patients with anorexia nervosa, patients may still conceive. Patients with eating disorders have a higher risk for psychiatric comorbidity, including anxiety and postpartum depression,[1] and are at greater risk for cesarean delivery.[15]

SCHIZOPHRENIA SPECTRUM AND OTHER PSYCHOTIC DISORDERS

These disorders include schizophrenia, other psychotic disorders, and schizotypal (personality) disorder. Defining features include abnormalities in one or more of the following areas: hallucinations, disorganized thinking, grossly disorganized or abnormal motor behavior, and negative symptoms.[4] In **schizophrenia**, the disorder lasts for at least six months, with at least one month of active symptoms.[4]

Limited data are available on the course of psychotic disorders in pregnancy; both deterioration and improvement have been reported. The postpartum period is thought to be a high-risk period for relapse.[15] Compared with women without psychotic disorders, pregnant women who have psychotic disorders often receive less prenatal care; have poorer nutrition; exhibit greater use of tobacco, alcohol, and illicit drugs; and have higher rates of obstetric interventions and obstetric complications.[1,15] Fear of loss of child custody may result in underreporting of symptoms.[15]

OTHER DISORDERS

Personality Disorders

Personality disorders have high prevalence rates of approximately 10% in the general population and up to 40% among psychiatric patients.[24] The *DSM 5* lists 10 specific personality disorders that are grouped into three clusters based on descriptive similarities. Patients in cluster A **(paranoid, schizoid, schizotypal)** appear odd or eccentric; patients in cluster B **(antisocial, borderline, histrionic, narcissistic)** appear dramatic, emotional, or erratic; and patients in cluster C **(avoidant, dependent, obsessive-compulsive)** appear anxious and fearful.[4] There is also one further category, **personality disorder not otherwise specified**. The *DSM-5* also provides an alternative dimensional model for personality disorders based on both personality functioning and pathologic personality traits that takes the perspective that personality disorders represent maladaptive variants of personality traits that merge into normality and into one another.[4] This accounts for the observation that patients who meet criteria for a specific personality disorder frequently also meet criteria for other personality disorders.[4]

Pseudocyesis

Pseudocyesis is a clinical syndrome in which a woman firmly believes that she is pregnant in the absence of a true gestation. Patients may develop convincing signs and symptoms suggestive of pregnancy, including abdominal enlargement and menstrual disturbance.[25] Diagnosis can be made using a pregnancy test and ultrasonography. Physical diagnoses should be excluded. For example, tumors such as bronchogenic carcinoma may produce hormones (e.g., human chorionic gonadotrophin [hCG]) that can cause secondary amenorrhea, which may be confused with pregnancy.[26]

Denial of Pregnancy

In contrast to pseudocyesis, denial of pregnancy is more common, with an estimated incidence of 1 in 400 to 516 pregnancies.[27] It may be associated with adverse outcomes, including psychological stress, unassisted delivery, and infanticide. Patients who are identified should be referred for psychiatric assessment.[27]

Substance Abuse

Substance abuse during pregnancy is covered in Chapter 54.

MANAGEMENT OF PSYCHIATRIC DISORDERS IN PREGNANCY

General Considerations

Treatment options for different psychiatric disorders overlap. Data are limited on pregnancy-specific efficacy, but, in general, response in pregnant patients is thought to be similar to that in nonpregnant patients.[1] There is often concern about potential harmful effects of psychotropic drugs given during pregnancy and lactation, particularly the potential for teratogenicity, perinatal syndromes, neonatal toxicity, and abnormal postnatal behavioral development.[12] Because of the difficulties of performing experimental studies in this area, inadequate data are available from randomized controlled trials, and much of the available information is based on observational studies, which provide a less-than-optimal level of evidence. Because many patients with psychiatric disorders also smoke or abuse illicit substances, it can be difficult to separate the effects of psychiatric drugs on the fetus from the effects of these other substances and other behavioral factors.[8] Further, because women who take medication for their psychiatric disorders are likely to have more severe disease than women who do not, some of the risks associated with psychiatric drugs may be attributable to factors associated with the more severe disease (i.e., confounding by indication).[7] These considerations are important because the risks of withholding psychiatric drugs in pregnancy must always be balanced against the risks and potential harm of exacerbation of psychiatric disorders that can result from cessation or withholding of treatment.

General recommendations for the management of women with psychiatric disorders include the following[6]: (1) a psychiatric history should be identified prenatally, and even if affected patients are well, they should be frequently monitored and supported during pregnancy and the first few weeks postpartum; (2) psychiatric services should have priority-care pathways for pregnant and postpartum women; and (3) care by multiple psychiatric teams should be avoided. Conversely, care should be taken to avoid misattribution of physical symptoms to psychological causes in patients with no psychiatric history and other concurrent disease. Consensus guidelines for the treatment of depression during pregnancy are available from the APA and the American College of Obstetricians and Gynecologists (ACOG).[14] The National Institute for Health and Clinical Excellence (NICE) in the United Kingdom has also published guidelines for antenatal and postnatal mental health.[28] All patients with psychiatric disorders, particularly those with acute or postpartum psychosis, should be carefully screened for thoughts of harm to themselves and/or their infants.

A multidisciplinary approach is essential in the management of pregnant patients with psychiatric disorders, especially because many anesthesia providers may not be familiar with management of these patients. Patients who are noncooperative or violent may be challenging and require patience, compassion, and emotional support. Flexibility in management is important. For example, general anesthesia may sometimes be required if neuraxial anesthesia is considered not practical or unsafe. Consent and medicolegal issues are covered in Chapter 33.

Psychotherapy and Light Therapy

These nonpharmacologic options are effective particularly for treatment of anxiety disorders and depression but are underinvestigated.[1] They have the advantage of nonexposure to potentially teratogenic drugs. Psychotherapy techniques include cognitive-behavioral therapy and interpersonal psychotherapy. A randomized controlled trial demonstrated that light therapy (fluorescent white light for 1 hour per morning for 5 weeks) improved antenatal depression compared with placebo.[29]

Psychotropic Drugs

Box 51-3 includes principles related to the use of psychiatric medications during pregnancy. The use of nonanesthetic drugs during pregnancy and lactation is discussed in Chapter 14.

Selective serotonin uptake inhibitors (SSRIs), which include **sertraline** (Zoloft), **paroxetine** (Paxil), **fluoxetine** (Prozac), and **citalopram** (Celexa) are a mainstay therapy for depression and anxiety. Some concerns have been raised about a possible association between their use in pregnancy and an increased risk for birth defects, although data are conflicting. In a large multicenter evaluation, Louik et al.[30] found no overall association between first-trimester maternal use of SSRIs and birth defects; however, analysis of individual drugs showed small but significant associations between the use of sertraline and omphalocele and cardiac septal defects and between the use of paroxetine and right ventricular outflow tract obstruction. Other studies have also found associations between use of SSRIs and these and other birth defects, including craniosynostosis, anencephaly, and persistent pulmonary hypertension of the newborn.[7] Exposure to SSRIs in the third trimester has been associated with an increased risk for perinatal complications, including preterm delivery, admission to the special care nursery, poor neonatal adaptation, and lower birth weight and length.[31] Of note, the absolute risk of exposure to SSRIs during pregnancy is considered to be small, and overall these drugs are not considered major teratogens.[12] However, the ACOG[12] has recommended that paroxetine should be avoided by pregnant women and women planning pregnancy, if possible, and fetal echocardiography should be considered for women who are exposed to paroxetine in early pregnancy. Serotonin syndrome (i.e., agitation, restlessness, hallucinations, increased body temperature, vomiting) may occur with an overdose or a combination of serotonergic drugs.[32]

Serotonin-norepinephrine reuptake inhibitors (SNRIs) are a class of drugs related to SSRIs that are also considered relatively safe in pregnancy, although fewer reassuring data are available for this class of drug than for SSRIs.[7]

Tricyclic antidepressants have a long history of use and have generally been considered safe to use in pregnancy. However, a large review of data from the Swedish Medical Birth Registry reported that these drugs were associated with a greater risk for congenital malformations compared with other antidepressants.[33] Tricyclic antidepressants may have anticholinergic side effects,

BOX 51-3 General Principles Related to the Use of Psychiatric Drugs in Pregnancy

- All psychotropic drugs cross the placenta and pass into breast milk.
- The major time of risk for teratogenesis occurs during embryogenesis (i.e., 3 to 8 weeks' gestation).
- Use of a single medication at a higher dose (monotherapy) is preferred to use of multiple medications.
- Medications with fewer metabolites, higher protein binding, and fewer drug interactions are preferred.
- Discontinuing medication exchanges the fetal and neonatal risks of drug exposure for the risks of untreated maternal illness.
- Changing medication increases fetal drug exposure.
- Major concerns about use of psychotropic drugs in pregnancy include risks for morphologic teratogenicity, behavioral teratogenicity, and perinatal syndromes.
- Drug doses may need adjustment during pregnancy because of alteration in pharmacokinetics.

Modified from American College of Obstetrics and Gynecologists. Use of psychiatric medications during pregnancy and lactation. ACOG Practice Bulletin No. 92. Washington, DC, April 2008. (Obstet Gynecol 2008; 111:1001-20); and Levey L, Ragan K, Hower-Hartley A, et al. Psychiatric disorders in pregnancy. Neurol Clin 2004; 22:863-93.

especially after overdose; clinical features include dilated pupils, agitation, seizures, delirium, hyperthermia, and arrhythmias. The fatality risk after overdose is greater with most tricyclic antidepressants than with SSRIs. Tricyclic antidepressants have been largely replaced by SSRIs and SNRIs as first-line therapy for depression.

Routine prescription of **benzodiazepines** for pregnant women is typically avoided, except for short-term treatment of extreme anxiety and agitation, because of concern for risks including oral clefts, floppy baby syndrome, and neonatal withdrawal syndrome.[12,28] The risk for oral clefts is a matter of dispute.[12] If benzodiazepine use is discontinued during pregnancy, this should not be done abruptly.[12]

Lithium is a foundation therapy for management of BPD. Early studies reported that use of lithium in early pregnancy was associated with an increased risk for congenital malformations, with particular concern for cardiac abnormalities, especially Ebstein's anomaly. Although the risk now appears to be less than initially thought, it has been recommended that women who are exposed to lithium in the first trimester undergo fetal echocardiography. Exposure in later gestation has been associated with fetal and neonatal diabetes insipidus, polyhydramnios (thought to occur from fetal diabetes insipidus), thyroid dysfunction, cardiac arrhythmias, hypoglycemia, preterm delivery, and floppy baby syndrome.[12] Renal clearance of lithium is increased in pregnancy, and a reduced serum lithium concentration may result in a relapse of symptoms; therefore, serum levels should be closely monitored in pregnant women who are taking lithium. Discontinuation of lithium is associated with a high risk for recurrent illness, particularly in the postpartum period.

Anticonvulsant drugs are often used as mood stabilizers in patients with BPD. **Valproate** use in pregnancy is associated with an increased risk for many congenital anomalies (e.g., craniofacial, limb, cardiovascular abnormalities) and a variable risk for cognitive impairment.[1] A meta-analysis showed that the risk for neural tube defects in infants of mothers taking valproate was 3.8% and that the risk for major congenital malformations was dose-related, with the risk particularly high when the daily dose exceeded 1000 mg.[34] **Fetal valproate syndrome**, which includes fetal growth restriction (also known as intrauterine growth restriction), facial dysmorphology, and limb and heart defects, has been described.[12] **Carbamazepine** has also been associated with congenital abnormalities, although with less frequency or severity compared with valproate.[1] **Fetal carbamazepine syndrome**, which includes facial dysmorphism and fingernail hypoplasia, has been described.[12] **Lamotrigine** appears to be associated with less fetal risk than occurs with valproate and carbamazepine.[1,12] Folate supplementation is sometimes offered to patients taking anticonvulsants to reduce the risk for neural tube defects.

Typical antipsychotic drugs (e.g., **haloperidol, thioridazine, fluphenazine, perphenazine, chlorpromazine, trifluoperazine**) have a long history of use in pregnant patients and generally have minimal teratogenic effects.[12] The phenothiazines are also used for their antiemetic effects. Fetal and neonatal toxicity after maternal exposure can include dyskinesia, extrapyramidal side effects, neonatal jaundice, and postnatal intestinal obstruction. The **neuroleptic malignant syndrome** is of particular interest to anesthesia providers because of its similarity to malignant hyperthermia. Features include hyperthermia, rigidity, mental status alteration, creatine kinase elevation, sympathetic nervous system lability, tachycardia, and tachypnea.[35] Treatment is largely supportive and includes discontinuation of triggering agents, antipyretics, cooling, rehydration, and management of autonomic instability. Use of dantrolene, bromocriptine, and amantadine has been described.[32]

Atypical antipsychotic drugs (e.g., **clozapine, olanzapine, quetiapine, risperidone, ziprasidone, aripiprazole**) are now commonly used for schizophrenia and also for BPD, OCD, and resistant depression. Although these drugs are well tolerated, fewer data about reproductive safety are available, when compared with older drugs.

Drug Interactions

A number of drug interactions involving psychiatric drugs are relevant to anesthesia providers. The most important of these involve monoamine oxidase inhibitors (MAOIs), which include older irreversible drugs (e.g., phenelzine, tranylcypromine) and newer reversible drugs (e.g., selegiline, moclobemide). Potential interactions include (1) hypertension after administration of an indirect-acting vasopressor (e.g., ephedrine, metaraminol), which results from increased norepinephrine concentration in sympathetic nerve endings, and (2) excitatory interactions associated with serotonin toxicity. The latter are characterized by clonus, hyperreflexia, hyperthermia, and agitation and may be precipitated by co-administration of an MAOI and a serotonin uptake inhibitor. Of note, phenylpiperidine opioids, especially meperidine (pethidine), but also tramadol, methadone, and dextromethorphan, are weak serotonin uptake inhibitors and have been implicated in toxic reactions associated with MAOIs, including hyperpyrexic coma. Irreversible MAOIs should be stopped 2 weeks before administration of anesthesia to allow regeneration of MAO and restoration of normal monoamine metabolism, and reversible MAOIs should be stopped for 24 hours before administration of anesthesia.[36]

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is considered an important treatment option in the pregnant patient with psychiatric disease, especially when balancing the risk for morbidity from psychiatric illness and the potential adverse effects of psychiatric drugs. The APA has endorsed the use of ECT in all three trimesters of pregnancy.[37] Indications include major unipolar or bipolar depressive episodes, mania, and certain acute schizophrenia exacerbations. Acute suicide risk, poor response to medications, and patient preference may also affect the decision to use ECT.[38] Contraindications include anticipated intolerance of associated physiologic

BOX 51-4 Suggested Guidelines for Electroconvulsive Therapy during Pregnancy

- Obtain preoperative obstetric consultation.
- Monitor fetal heart rate and check for uterine contractions before and after the procedure.
- Ensure adequate hydration.
- Maintain left uterine displacement after 18 to 20 weeks' gestation.
- Consider pharmacologic aspiration prophylaxis and tracheal intubation in patients with symptoms of gastroesophageal reflux.
- Observe for vaginal bleeding after the procedure.

Modified from Miller LJ. Use of electroconvulsive therapy during pregnancy. Hosp Community Psychiatry 1994; 45:444-50.

changes that result from autonomic activation during ECT (e.g., increased intracranial pressure). Relative contraindications include hypertensive disease and impaired uteroplacental perfusion.

There is a paucity of controlled data evaluating the use of ECT in pregnancy, with most information coming from case series. In a series of 300 published cases of ECT in pregnancy between 1942 and 1991, Miller[39] reported complications in 28 (9.3%) cases, which included self-limited fetal heart rate abnormalities (five cases), vaginal bleeding, uterine contractions, abdominal pain, spontaneous abortion, preterm labor, stillbirth, and neonatal death. The overall incidence of spontaneous abortion was 1.6%—a rate much lower than that in the general population—suggesting that ECT is not a significant risk factor for spontaneous abortion. There were five cases of congenital anomalies, but neither the pattern nor the number of anomalies suggested that ECT was a determining factor. The author concluded that ECT was effective and that the risks to both mother and fetus are low. However, Pinette et al.[40] reported a case of deep cerebral interhemispheric infarcts in a neonate whose mother had received ECT during pregnancy. After a review of fetal and neonatal risks, the authors recommended that ECT in pregnancy should be performed specifically according to APA guidelines and only after medical therapy has failed.

ECT for pregnant patients should be administered in a facility that can handle fetal emergencies. Anesthetic agents commonly used during ECT include barbiturates, succinylcholine, and anticholinergics (e.g., glycopyrrolate); these agents have a long history of use during pregnancy. Suggested guidelines for ECT during pregnancy are summarized in Box 51-4. These guidelines include left uterine displacement and both fetal heart rate and uterine monitoring. Pharmacologic aspiration prophylaxis and tracheal intubation should be considered in patients with symptoms of gastroesophageal reflux. Some anesthesia providers contend that tracheal intubation should be performed after 20 weeks' gestation, when the enlarging uterus has arisen out of the pelvis.

KEY POINTS

- Psychiatric disorders occur commonly during pregnancy, but their prevalence is often underestimated and underappreciated.
- The risk for major depressive disorder is increased during the postpartum period.
- Anxiety disorders are the most common psychiatric disorders in pregnant women.
- When managing pregnant patients with psychiatric disorders, the risks of withholding psychiatric drugs because of concerns for teratogenic or other harmful effects on the fetus must be balanced against the risks and potential harm for exacerbation of psychiatric disorders.
- Patients with a previous psychiatric history should be identified prenatally and frequently monitored and supported during pregnancy and the first few weeks postpartum. Psychiatric services should have priority-care pathways for pregnant and postpartum women, and care by multiple psychiatric teams should be avoided.
- A multidisciplinary approach is essential in the management of pregnant patients with psychiatric disorders.
- Awareness during general anesthesia for cesarean delivery, inadequate neuraxial anesthesia for cesarean delivery, and poor pain control during vaginal delivery may result in post-traumatic stress disorder in susceptible patients.
- Anesthesiologists should be aware of potential drug interactions with psychotropic drugs.
- The use of electroconvulsive therapy has been endorsed for selected psychiatric conditions in all three trimesters of pregnancy.

CHAPTER 47

Malignant Hyperthermia

M. Joanne Douglas, MD, FRCPC

CHAPTER OUTLINE

Malignant hyperthermia (MH) is an inherited disorder of skeletal muscle. On exposure to triggering agents (e.g., succinylcholine, volatile halogenated anesthetic agents), affected individuals demonstrate a hypermetabolic syndrome characterized by hypercapnia, acidosis, muscle rigidity, arrhythmias, and hyperthermia. MH was first described in 1960 by Denborough and Lovell,[1] but may have been responsible for some of the earlier deaths attributed to ether and chloroform anesthesia.[2]

EPIDEMIOLOGY

Ørding,[3] reviewing the incidence of MH in Denmark, noted that the incidence of the fulminant syndrome (e.g., muscle rigidity, acidosis, hyperkalemia, arrhythmias, hyperthermia, increased creatine kinase [CK] levels, myoglobinuria) was 1 in 220,000 patients who received general anesthesia and 1 in 62,000 patients in whom succinylcholine was combined with a volatile halogenated agent. MH (either mild or fulminant) was suspected in 1 in 16,000 patients who received anesthesia of any type. The male-to-female ratio was 1.4:1.[3] There is some geographic variation in the incidence of MH.[4]

There are few reports of development of MH during pregnancy and parturition.[5-12] The infrequent occurrence during pregnancy probably reflects both the low frequency of this disorder in the general population and the widespread use of local and neuraxial anesthetic techniques in obstetric patients.

PATHOPHYSIOLOGY

MH is the result of a disorder in the regulation of intracellular calcium in skeletal muscle. The precise mechanism by which volatile anesthetics and depolarizing muscle relaxants cause an MH crisis is still unknown.[13] In muscle the sarcoplasmic reticulum is responsible for controlling calcium release and reuptake during muscle contraction.[14] During skeletal muscle excitation-contraction coupling, calcium is released from the terminal sarcoplasmic reticulum via the **ryanodine receptor** (RYR1). Dihydropyridine receptors in the T-tubule membrane also participate in the excitation-contraction coupling. In humans, mutations in both the dihydropyridine receptor and the ryanodine receptor can result in clinical MH. Dantrolene inhibits excitation-contraction coupling, and succinylcholine, caffeine, and volatile halogenated agents increase it.

GENETICS

MH is a heterogeneous disorder, meaning that more than one gene defect is responsible for expression of the clinical syndrome.[15] It is inherited in an autosomal dominant fashion with variable penetrance, although this pattern has been questioned in some families.[16] Porcine MH is transmitted as a recessive gene. The defective gene in MH-susceptible pigs has been localized to a single point

mutation in the ryanodine receptor gene (*RYR1*) responsible for the calcium release channel.[17]

Investigators have found the corresponding point mutation on the human ryanodine receptor gene (*RYR1*) in some families with MH (chromosome 19q12.1-13.2; locus MHS-1), and other mutations in *RYR1* have been linked to MH susceptibility.[18] Other point mutations in *RYR1* are found in patients with central core disease, a myopathy associated with MH.[19] As of 2011, more than 200 *RYR1* mutations associated with MH had been identified.[15] Mutations responsible for MH in some families are located on chromosomes 5p, 17, 7q, 3q, and 1q.[20] Other myopathies may be characterized by a hyperthermic state with muscle damage and metabolic derangements similar to those seen in MH, but their chromosomal abnormality has not been mapped to the same area.[15]

TRIGGERS

Known triggers of MH include the depolarizing muscle relaxants (e.g., succinylcholine) and all the volatile halogenated anesthetic agents (i.e., sevoflurane, desflurane, isoflurane, halothane, enflurane) (Box 47-1). The dose and duration of exposure to the triggering agent may influence the onset and severity of a reaction. Previous uneventful administration of general anesthesia with triggering anesthetic agents does not rule out the diagnosis of MH.[21]

In contrast to the porcine model, reports of stress-induced MH in humans are rare.[22-28] In one report two cases of fatal, stress-induced MH occurred in unrelated families[26]; both children had a known *RYR1* mutation and one had a second mutation, possibly suggesting an additive effect.[29] The sympathetic nervous system is active during an episode of acute MH, but there is insufficient evidence to implicate increased sympathetic activity as a cause in humans. Although muscle biopsy testing may help distinguish MH from exercise-induced myolysis, exertional heat stroke, and other myopathies, there is some evidence of a link between some cases of heat stroke and exercise-induced rhabdomyolysis and MH susceptibility.[30]

Investigators have explored other possible triggers of MH both in the porcine model and in humans. No evidence suggests that exogenous calcium, digoxin, hypercarbia, potassium,[31] or norepinephrine[32] triggers MH. Exercise[33] and environmental temperature[34-36] may intensify an existing reaction or modify a developing reaction. Sodium thiopental and pancuronium delay the onset in pigs and may modify the reaction in humans.[37] Duke et al.[38] postulated that hypomagnesemia may increase the probability and severity of an MH event in MH-susceptible humans.

There are case reports of the occurrence of MH during regional anesthesia and during general anesthesia with nontriggering agents.[39-43] The cases that occurred during regional anesthesia appeared mild and responded readily to treatment. In some cases, however, the diagnosis was not confirmed with muscle biopsy or appropriate laboratory investigation at the time of the event.

CLINICAL PRESENTATION

Individuals who are MH-susceptible may demonstrate the fulminant syndrome when anesthetized with a triggering agent. During an acute episode, the diagnosis is based on the finding of an elevated end-tidal CO_2 concentration, muscle rigidity (generalized and/or masseter), respiratory and metabolic acidosis, rhabdomyolysis, hyperkalemia, elevated CK concentration, and myoglobinuria (Box 47-2). Hypoxemia, unstable blood pressure, and evidence of sympathetic hyperactivity (e.g., tachycardia, hypertension, arrhythmias) are other signs. Hyperthermia may occur early, but often it is a late sign. Perioperative rhabdomyolysis, without any of the previously mentioned clinical signs, also may indicate MH susceptibility.[44,45]

With the advent of routine end-tidal CO_2 monitoring, MH may be detected early, often before the development of rhabdomyolysis and hyperthermia.[46] This situation may lead to uncertainty about the clinical diagnosis of MH, given that many of the confirmatory signs and laboratory abnormalities may be absent during the early phase of MH. Thus, early treatment of possible MH could present a dilemma as to whether the patient should undergo diagnostic muscle biopsy or should be assumed to be MH susceptible.

Masseter Muscle Rigidity

Masseter muscle rigidity is one of the early signs of MH.[46] The masseter muscles are sensitive to the action of succinylcholine and respond with increased tension in normal individuals.[47,48] Often this tension is imperceptible, but in some patients it is impossible to open the mouth for laryngoscopy and intubation. The duration of rigidity parallels the duration of action of succinylcholine. Typically there is no difficulty with mask ventilation. Masseter muscle rigidity rarely occurs after the use of nondepolarizing muscle relaxants such as rocuronium and vecuronium.[49] Patients with myopathies and other neuromuscular disorders also may have masseter muscle rigidity after the administration of succinylcholine.[50]

If masseter muscle rigidity is accompanied by generalized rigidity, anesthesia should be discontinued, dantrolene should be administered, and the patient should be monitored closely.[51] However, there is controversy regarding the management of isolated masseter muscle rigidity.[52] Options include (1) discontinuation of the anesthetic agents and administration of dantrolene; (2) continuation of anesthesia with nontriggering, "safe" agents and close attention to the end-tidal CO_2 concentration; and (3) continuation of anesthesia with triggering agents and careful monitoring. In my judgment, the anesthesia provider should either discontinue anesthesia altogether or continue anesthesia with nontriggering agents. If the anesthesia is continued, the minute ventilation, end-tidal CO_2 concentration, electrocardiogram (ECG), temperature, and arterial blood gas measurements should be monitored. The anesthesia provider also should look for evidence of rhabdomyolysis by monitoring CK levels and looking for myoglobinuria, and should recommend that the patient undergo muscle biopsy and caffeine-halothane contracture test (see later discussion).[53]

DIAGNOSIS

Investigators have correlated clinical presentation (i.e., evidence of metabolic and muscle derangements) with abnormal contracture on the caffeine-halothane contracture test.[54-56] The greater the number of clinical signs or abnormal laboratory findings, the greater the risk for MH (Table 47-1).[54] An early assessment of the risk for MH allows the anesthesia provider to initiate appropriate treatment. The mortality rate for MH is as high as 80% without dantrolene therapy.[56] Early administration of dantrolene lowers the mortality rate to 4%.[57]

An international group of experts has developed a clinical grading scale to predict MH susceptibility.[58] This scale consists of six processes (rigidity, muscle breakdown, respiratory acidosis, temperature increase, cardiac involvement, family history) and their clinical indicators. Points are assigned for each indicator present in a patient, and the total represents a raw score. A rank is subsequently assigned to this score, which indicates the likelihood of development of MH in the patient.

TABLE 47-1 Risk for Malignant Hyperthermia (MH) with Associated Signs and Symptoms

Type	Symptoms/Signs	Risk
Fulminant/classic	Metabolic acidosis Muscle rigidity Hyperthermia (> 38.5° C) Arrhythmias Hyperkalemia Myoglobinuria Increased creatine kinase level	0.96
Moderate	Inconclusive signs of MH involving metabolic and muscle abnormalities, with MH the probable diagnosis	0.88
Mild	Signs of metabolic derangement (pH > 7.3, body core temperature < 38.5° C)	0.14
Masseter spasm with rhabdomyolysis	Creatine kinase level > 1500 U/L, myoglobinuria	0.76
Masseter spasm with signs of metabolic disturbance	Arrhythmias, rising core temperature	0.57
Masseter spasm only		0.28
Unexplained perioperative death or cardiac arrest		0.66
Other	Postoperative pyrexia or rhabdomyolysis	0.07

Data from Ellis FR, Halsall PJ, Christian AS. Clinical presentation of suspected malignant hyperthermia during anaesthesia in 402 probands. Anaesthesia 1990; 45:838-41.

TESTING

Susceptibility to MH is determined by a positive caffeine-halothane contracture test result. During this test, fresh muscle is exposed to halothane and caffeine, and the extent of contraction is measured. The caffeine-halothane contracture test has been standardized in MH testing centers throughout North America (the North American protocol)[59] and Europe (the European protocol is called the *in vitro* contracture test).[60] This test is the "gold standard" for the diagnosis of MH. The sensitivity and specificity of the North American protocol are 97% and 78%, respectively.[61] Some false-positive results may occur.[62] Patients with a negative caffeine-halothane contracture test result subsequently have received anesthesia with triggering agents without incident.[63-66]

Testing for the known genetic mutations associated with MH is now available. However, because all the genetic mutations responsible for MH have yet to be identified, genetic testing is still not sensitive enough to use for routine screening.[67] In the future, MH may be detected in most MH-susceptible patients without the need for an invasive muscle biopsy.[67] In the absence of muscle biopsy results, a parturient with a positive family history should be treated as if she were MH susceptible.

PREGNANCY AND MALIGNANT HYPERTHERMIA

In 1972, Crawford[68] wondered "whether or not there was a record of a pregnant or newly born patient or animal having developed hyperpyrexia and … whether hyperpyrexia has been encountered in a patient undergoing an operation under regional block anesthesia." Subsequently there have been few reports of MH during parturition and fewer reports of maternal mortality attributable to MH. Wadhwa[5] reported the death of a woman with a known family history of MH in whom muscle rigidity developed during twilight sleep for parturition. Douglas et al.[6] reported one fatal case of MH in a parturient undergoing general anesthesia for cesarean delivery.

There are three published reports[7-9] of nonfatal MH during cesarean delivery and one report of MH after cesarean hysterectomy performed because of postpartum hemorrhage.[12] The triggering agents were succinylcholine and halothane,[7] succinylcholine and isoflurane,[12] cyclopropane,[8] and succinylcholine alone (without a volatile halogenated agent).[9] There are several reports of the successful administration of epidural and spinal anesthesia during labor and cesarean delivery in MH-susceptible parturients.[5,12,69-76]

Although it is unclear whether pregnancy alters susceptibility to MH, the rarity of MH events during pregnancy suggests that pregnancy protects against the occurrence of MH. However, it also may reflect the widespread use of neuraxial anesthesia for labor, vaginal delivery, and cesarean delivery.

Maternal Physiology

Basal metabolic rate, oxygen consumption, and minute ventilation increase during pregnancy (see Chapter 2). Serum bicarbonate, buffer base, and base excess decrease to maintain normal pH. Thus, the pregnant patient typically has a compensated respiratory alkalosis. The reduced buffering capacity could adversely affect the pregnant woman during an episode of MH.

Oxygen consumption and minute ventilation increase further during labor. Maternal lactate and pyruvate concentrations increase steadily during labor, indicating an increase in both aerobic and anaerobic metabolism. Hyperventilation during contractions may result in periods of hypoventilation between contractions, which may adversely affect the Pao_2 of both the mother and the fetus. These metabolic and physiologic responses to pain are similar to the metabolic and physiologic changes that are observed during acute MH. Effective epidural analgesia decreases oxygen consumption and minute ventilation. If tachycardia and hyperventilation occur despite effective analgesia, they are more likely to signal an episode of MH.

Aortocaval compression from the pregnant uterus results in decreased cardiac output, hypotension, and reduced uteroplacental perfusion. Thus, aortocaval compression may accelerate the occurrence of acidosis during an episode of MH. Aortocaval compression hinders resuscitative efforts during cardiac arrest, and evacuation of the uterus (i.e., delivery of the fetus) facilitates maternal resuscitation.[77] The obstetrician may need to deliver the fetus to facilitate maternal resuscitation during a fulminant case of MH.

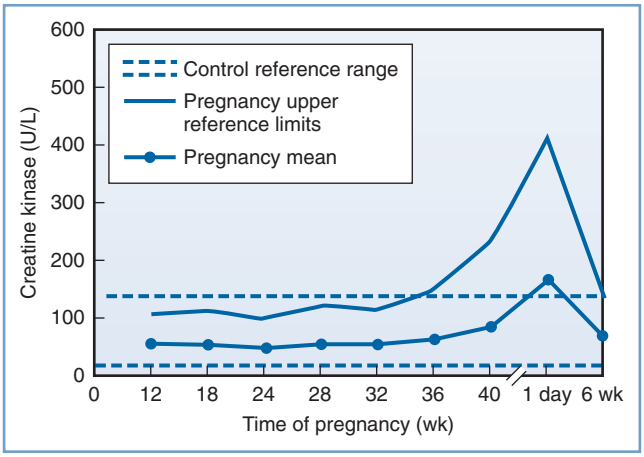

FIGURE 47-1 ■ Changes in creatine kinase activity during and after pregnancy. (Modified from Lockitch G, editor. Handbook of Diagnostic Biochemistry and Hematology in Normal Pregnancy. Boca Raton, FL, CRC Press, 1993:59.)

CK concentrations are not diagnostic of MH. During pregnancy, there is a slight decrease in CK levels during the first trimester. CK levels remain stable until term, when they increase by approximately 50%. At delivery, there is an abrupt rise in the CK concentration, followed by a return to normal by 6 weeks postpartum (Figure 47-1).[78] The increased CK concentration results from increases in both the CK-M fraction (skeletal muscle) and the CK-B fraction (myometrium, placenta, and fetal blood). Postpartum CK levels are higher in nulliparous women regardless of differences in duration of labor.[79] Mean plasma CK activity is approximately 50% higher in African-Americans than in Caucasians or Asians.[78]

Acute cocaine toxicity may mimic MH. Although cocaine does not induce contractures in MH-susceptible muscle,[80] elevated CK concentrations and myoglobinemia can occur secondary to rhabdomyolysis and renal failure from cocaine intoxication.[81] Umbilical cord blood CK and myoglobin levels are elevated when cocaine metabolites are present in maternal urine.[82]

Effects on the Fetus and Newborn

MH often is inherited as an autosomal dominant gene. In these cases there is a 50% chance that the infant of an MH-susceptible parent will also be MH susceptible. All anesthetic agents cross the placenta. Small quantities of succinylcholine also cross the placenta. This knowledge should prompt the anesthesia provider to question the choice of anesthetic agents for an MH-negative mother whose fetus has an MH-susceptible father. In this situation, the anesthesia provider should avoid the use of triggering agents until after delivery.[83]

There is only one published report of suspected MH in a newborn.[84] The condition is rare in infancy, and some

TABLE 47-2 **Common Anesthetic Drugs and Their Safety in Malignant Hyperthermia–Susceptible (MHS) Women**

Drug	Route	Use	Safe in MHS Women
Local Anesthetic Agents			
Bupivacaine	Neuraxial	Analgesia/anesthesia	Yes
Lidocaine	Neuraxial	Analgesia/anesthesia	Yes
	Intravenous	Arrhythmia	Yes

Sevoflurane, desflurane, isoflurane, halothane, enflurane	Inhalation	Anesthesia, uterine relaxation	No
Nitrous oxide	Inhalation	Analgesia/anesthesia	Yes

reports of infant MH may represent undiagnosed myopathy.[50,85,86]

MANAGEMENT OF THE MALIGNANT HYPERTHERMIA–SUSCEPTIBLE PARTURIENT

Ideally, an anesthesiologist will evaluate every MH-susceptible pregnant patient before she is hospitalized for labor and delivery. Clearly, the obstetrician should consult an anesthesia provider immediately after the admission of each MH-susceptible patient. All hospitals and birthing facilities should be prepared to provide care for MH-susceptible patients. Adequate supplies of dantrolene (at least 36 vials), sterile water, and sodium bicarbonate should be immediately available.

Analgesia for Labor

Soon after admission, a large-gauge intravenous catheter should be placed in each MH-susceptible patient. Maternal temperature, heart rate, and blood pressure should be monitored throughout labor. During early labor, it may be acceptable to monitor temperature and heart rate intermittently to facilitate maternal ambulation, if desired. Once active labor is established, frequent monitoring of the maternal heart rate and temperature should be initiated. Continuous ECG and axillary temperature monitoring are ideal once the parturient is confined to bed. (Measurement of axillary temperature allows placement of a temperature probe in close proximity to large muscle groups.) Of course, aortocaval compression should be avoided throughout labor and delivery.

Most agents used for intrapartum analgesia are considered safe in the MH-susceptible parturient (Table 47-2). Both the obstetrician and the anesthesia provider should encourage the early administration of neuraxial analgesia. Relief of pain reduces maternal stress (as reflected by decreased catecholamine,[87] cortisol,[88] and adrenocorticotropic hormone [ACTH] concentrations), and decreases maternal metabolism and oxygen consumption.[89] Although experts continue to debate the role of stress in human MH,[90,91] it is best to diminish stress when possible. Further, the anesthesia provider may extend epidural analgesia for vaginal or cesarean delivery if necessary, thus avoiding administration of general anesthesia.

All local anesthetic agents appear safe for MH-susceptible patients. Epinephrine can be safely added to the local anesthetic agent to improve the quality and duration of analgesia, if clinically appropriate.

Anesthesia for Cesarean Delivery

General anesthesia should be avoided for operative delivery if possible. Spinal or epidural anesthesia using either

amide or ester local anesthetic agents can be given safely. Epidural anesthesia may be preferred because slow induction of anesthesia may decrease the risk for hypotension. Phenylephrine is probably the preferred agent for the treatment of hypotension. Ephedrine may exacerbate the catecholamine response during an acute episode of MH. In doses greater than those used clinically, ephedrine exacerbates halothane-induced muscle contractures *in vitro*.[92]

Rarely, the mother may refuse neuraxial anesthesia. In other cases, neuraxial anesthesia may be contraindicated (e.g., maternal hemorrhage, coagulopathy, prolonged fetal bradycardia). When the anesthesia provider encounters an MH-susceptible parturient, the anesthesia machine and delivery circuit should be flushed of volatile agents. Preparation consists of replacing the carbon dioxide absorbent and the delivery tubing, disabling the vaporizers, and purging the machine of residual anesthetic agent with a 10 L/min flow of oxygen through the circuit (including the ventilator).[93] The time required to purge the anesthesia machine is dependent on the specific machine.[93] Activated charcoal filters appear to be an effective alternative to the prolonged flushing required to reduce the volatile anesthetic concentration in new-model anesthesia machines.[94]

In cases of general anesthesia, the anesthesia provider should administer a nonparticulate antacid and perform adequate denitrogenation. Nontriggering agents should be administered for induction and maintenance of general anesthesia (Box 47-3, see also Table 47-2). Unless a difficult intubation is expected, rapid-sequence induction should be performed with a sedative-hypnotic drug and a nondepolarizing neuromuscular blocking agent. All commonly used induction agents (e.g., propofol, thiopental, ketamine, etomidate) are safe in MH-susceptible patients. Succinylcholine and the volatile halogenated agents (sevoflurane, desflurane, isoflurane, halothane, enflurane) are contraindicated. For intubation, rapid onset (approximately 60 to 90 seconds) of muscle relaxation can be achieved with rocuronium (0.6 to 0.9 mg/kg, which is two to three times the effective dose in 95% of patients [ED_{95}])[95] or vecuronium[96] (0.25 mg/kg). Nitrous oxide (delivered via a prepared anesthesia machine), opioids, and propofol are safe agents for the maintenance of anesthesia. Midazolam administered after delivery provides amnesia. It is safe to reverse neuromuscular blockade with glycopyrrolate and neostigmine or edrophonium. Atropine may cause an increase in temperature, which could cause a diagnostic dilemma.

At delivery, determination of maternal and umbilical cord blood gas and pH measurements may provide information about an impending reaction in either the mother or the neonate. As well, if the MH-susceptible mother has a known genetic mutation, umbilical cord blood may be used to assess MH susceptibility in the neonate.[97] If uterine relaxation (tocolysis) is required to assist with delivery of the baby or to facilitate the removal of a retained placenta, I prefer to give 100-μg bolus doses of nitroglycerin intravenously[98]; the action of this agent is brief and easily reversed with oxytocin. Clearly, a volatile halogenated agent should *never* be given to effect uterine relaxation in an MH-susceptible patient.

Concern has been raised about administering triggering agents to a non–MH-susceptible mother who is carrying a fetus whose father is MH susceptible.[99] In this situation the Malignant Hyperthermia Association of the United States recommends that the mother be treated as if she were MH susceptible to avoid a possible MH reaction in the neonate.[83]

BOX 47-3 General Anesthesia for Cesarean Delivery in the Malignant Hyperthermia–Susceptible Patient

Monitoring
- End-tidal CO_2
- Pulse oximeter
- Electrocardiogram
- Automatic blood pressure monitoring
- Peripheral nerve stimulator
- Temperature (central)

Induction of Anesthesia
- Denitrogenation
- Rapid-sequence induction (propofol 2.0 to 2.8 mg/kg, thiopental 4 mg/kg, ketamine 1 mg/kg)

Muscle Relaxant
- Intubation: rocuronium 0.6 to 0.9 mg/kg
- Maintenance: rocuronium

Maintenance of Anesthesia
- Nitrous oxide/oxygen, propofol, opioid

Amnestic Agent
- Midazolam

Reversal of Neuromuscular Blockade
- Glycopyrrolate and neostigmine

Obstetric Drugs in Malignant Hyperthermia–Susceptible Parturients

Information on use of obstetric drugs in MH-susceptible patients is scant (Table 47-3). The beta-sympathomimetic tocolytic agents (e.g., terbutaline) produce anxiety and tachycardia in normal parturients. Such side effects may be confused with MH, although these agents most likely are safe in the MH-susceptible parturient.

Magnesium sulfate attenuates but does not prevent MH in MH-susceptible swine.[100] There is one report of a fatal adverse interaction between dantrolene and the calcium entry–blocking agent diltiazem,[101] and hyperkalemia has been described after the co-administration of dantrolene and verapamil.[102] Administration of calcium entry–blocking agents should be avoided during an episode of MH. These agents do not prevent the development of MH.[103]

Oxytocin is safe. Some of the commercial preparations of oxytocin contain a preservative (chlorbutol) that has been shown to reverse the development of MH in susceptible pigs *in vitro*.[104] The ergot alkaloids cause

TABLE 47-3 Drugs Commonly Used for Labor and Delivery and Their Safety in Malignant Hyperthermia–Susceptible (MHS) Women

Drug	Route	Use	Safe in MHS Women

NSAIDs, nonsteroidal anti-inflammatory drugs.
*Do not use during an MH crisis (see text).
†May exacerbate the catecholamine response during an MH crisis (see text).

vasoconstriction, which may lead to decreased muscle perfusion and a greater tendency toward lactic acidosis. The prostaglandins may be associated with changes in blood pressure and maternal oxygen desaturation.[105] Prostaglandin E_2 and misoprostol may cause pyrexia, which may lead to confusion in the diagnosis of an MH episode.[106] The routine postpartum administration of ergot alkaloids, prostaglandins, or misoprostol probably should not be performed in MH-susceptible patients. However, persistent uterine atony and postpartum hemorrhage may warrant the administration of these agents.

ASSESSMENT OF HYPERTHERMIA AND TACHYCARDIA

The hallmark signs of MH may be present during normal labor (Boxes 47-4 and 47-5). Other causes of fever and tachycardia in the MH-susceptible parturient should be excluded. Tachycardia and tachypnea are normal responses to pain, anxiety, and fever. Fever may be a sign of dehydration and infection. Pain and infection (e.g., chorioamnionitis, urinary tract infection) are much more common during parturition than MH. Some healthy parturients may have a gradual increase in

BOX 47-4 Differential Diagnosis of Fever during Parturition

- Infection: chorioamnionitis, urinary tract infection, other infections (e.g., influenza, viral illness)
- Environmental temperature
- Labor epidural analgesia
- Dehydration/labor
- Malignant hyperthermia
- Drug reactions: cocaine, atropine, tricyclic antidepressants, monoamine oxidase (MAO) inhibitors, neuroleptic malignant syndrome, prostaglandins (misoprostol)

temperature during epidural analgesia.[107] The fever may be accompanied by corresponding increases in maternal and fetal heart rates.

The butyrophenones, phenothiazines, thioxanthenes, and other miscellaneous antipsychotic agents may produce tachycardia, fever, and rigidity (i.e., neuroleptic malignant syndrome).[108] There is one published report of neuroleptic malignant syndrome in a pregnant woman.[109] Drugs capable of increasing serotonin in the central nervous system (i.e., serotonin reuptake inhibitors) also can produce a hypermetabolic reaction. Cocaine intoxication causes severe vasoconstriction, fever, and rhabdomyolysis.[110]

TREATMENT

Box 47-6 summarizes the treatment of MH; a more detailed protocol for the management of an MH episode is available online from the Malignant Hyperthermia Association of the United States (http://www.mhaus.org). The anesthesia provider should call for help, obtain dantrolene, and notify the surgeon. All triggering agents must be stopped immediately, and the patient should be hyperventilated with 100% oxygen at 10 L or more per minute. The level of volatile agent decreases rapidly with flushing of the machine with 100% oxygen. Therefore, substitution with a vapor-free machine is not an immediate priority. Insertion of an activated charcoal filter into the breathing circuit, if available, may also be helpful, but administration of dantrolene is the first priority.[111]

The anesthesia provider should give dantrolene intravenously in a dose of 2.5 mg/kg, until the signs and symptoms (e.g., tachycardia, hypercarbia, rigidity, fever) have subsided.[112] Although the maximum dantrolene dose is often listed as 10 mg/kg, there are case reports in which higher doses of dantrolene were required to control an MH reaction. Oxygen saturation, end-tidal CO_2, ECG, blood pressure, arterial and venous blood gas measurements, core temperature, potassium levels, lactate concentration, CK levels, coagulation profile, urine output, and urine myoglobin should be monitored.

The anesthesia provider must initiate treatment of acidosis, hyperkalemia, arrhythmias, and hyperthermia. Metabolic acidosis is treated by giving sodium bicarbonate in 1- to 2-mEq/kg increments as guided by blood gas and pH measurements. Hyperkalemia is treated by administration of bicarbonate, glucose, and insulin. Calcium administration may also be indicated.

Early administration of dantrolene often prevents or successfully treats arrhythmias. If arrhythmias persist, one should follow standard advanced cardiac life support (ACLS) protocols. Amiodarone, lidocaine, procainamide, and adenosine may be used safely. Calcium entry–blocking agents should be avoided because simultaneous administration of dantrolene and a calcium entry–blocking agent may precipitate cardiovascular collapse.[102]

The operating room care team should actively cool the patient. Options for doing so include (1) intravenous administration of cold saline; (2) surface cooling with ice and/or a hypothermia blanket; and (3) lavage of stomach, bladder, rectal, peritoneal, and thoracic cavities with iced saline.

Myoglobin is excreted in the urine. Thus, diuresis should be maintained by giving adequate volumes of crystalloid and furosemide 1 mg/kg and/or mannitol 0.25 g/kg. Mannitol is present in dantrolene, and separate administration of a diuretic agent may not be necessary. Sedation should be administered as necessary.

After an acute episode of MH, postoperative administration of dantrolene (1 mg/kg or more intravenously every 4 to 6 hours for 24 to 48 hours) is recommended. In addition, the patient should be monitored closely in an intensive care unit for at least 24 to 48 hours. In a retrospective analysis of data from the North American Malignant Hyperthermia Registry, 20% of patients had recrudescence of MH after the initial MH episode.[113] Recrudescence was associated with increased muscle mass and a longer interval between anesthesia induction and intraoperative reaction. Counseling and diagnostic muscle biopsy should be performed after recovery from the acute episode. The Malignant Hyperthermia Association of the United States provides a registry and an informative newsletter for MH-susceptible patients. An MH hotline (800-MH-HYPER [800-644-9737] or, outside the United States, +1-209-417-3722) is available 24 hours a day to assist physicians with questions on treatment, diagnosis, and follow-up.

BOX 47-6 Management of Malignant Hyperthermia Crisis

1. Call for help and obtain dantrolene.
2. Notify the surgeon.
3. Discontinue all triggering agents.
4. Hyperventilate with 100% oxygen at high gas flows (≥10 L/min).
5. Administer dantrolene 2.5 mg/kg intravenously. Repeat until signs and symptoms resolve.
6. Perform serial blood gas measurements. Treat acidosis with sodium bicarbonate 1 to 2 mEq/kg.
7. Treat hyperkalemia with sodium bicarbonate, glucose, insulin, and calcium.
8. Treat arrhythmias with amiodarone or lidocaine.
9. Cool patient (external cooling blanket, ice packs, cold intravenous solutions, lavage of body cavities with cold solutions).
10. Maintain urine output with fluids, mannitol, and/or furosemide.
11. Call the Malignant Hyperthermia Hotline for assistance (1-800-MH-HYPER).
12. Postoperatively, monitor patient in intensive care unit for 24 to 48 hours. Administer maintenance dantrolene.
13. Counsel patient and family, and refer for caffeine-halothane contracture test.

Modified from Malignant Hyperthermia Association of the United States. Emergency Therapy of Malignant Hyperthermia. September 2011. Available at http://www.mhaus.org/healthcare-professionals/#.T6rV3VI2cTY. Accessed December, 2012.

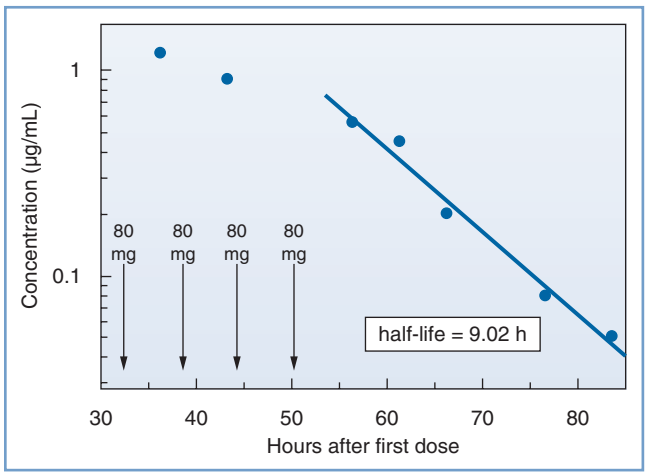

FIGURE 47-2 ■ Estimation of the half-life of dantrolene in breast milk by log-linear fitting of the terminal elimination phase (dantrolene measured in breast milk by high-pressure liquid chromatography, reverse-phase high-pressure liquid chromatographic column, by in-line ultraviolet absorption spectrometer; detection limit, 0.02 µg/mL). (From Fricker RM, Hoerauf KH, Drewe J, Kress HG. Secretion of dantrolene into breast milk after acute therapy of a suspected malignant hyperthermia crisis during cesarean section. Anesthesiology 1998; 89:1023-5.)

DANTROLENE IN PREGNANCY

Dantrolene is the drug of choice for the treatment of an MH crisis. Dantrolene works by blocking the release of calcium from the sarcoplasmic reticulum of skeletal muscle cells.[114] It crosses the placenta and can be detected in the fetus after maternal administration.[115] Clinical doses do not adversely affect maternal or fetal cardiovascular and acid-base measurements in gravid ewes. Morison[74] reported a fetal-to-maternal serum dantrolene concentration ratio of approximately 0.4 after prophylactic oral administration of dantrolene. Theoretically, dantrolene may cause neonatal hypotonia if it is administered before delivery.

There is one published report of postpartum uterine atony after the administration of dantrolene.[10] Laboratory testing of the effects of dantrolene sodium on pregnant uterine muscle suggests that the relaxant effect is secondary to the mannitol.[116]

There is no benefit to dantrolene prophylaxis in the MH-susceptible patient when all triggering agents are avoided.[114] However, the anesthesia provider should give dantrolene promptly when an MH crisis is suspected.

Fricker et al.[117] reported serial measurements of dantrolene concentrations in breast milk after administration of dantrolene in a patient with suspected MH during cesarean delivery (Figure 47-2). They estimated that the half-life of dantrolene in breast milk is approximately 9 hours. They concluded that "breast-feeding can be expected to be safe for the newborn 2 days after discontinuation of intravenous dantrolene administration in the mother."[117]

KEY POINTS

- Malignant hyperthermia is a heterogeneous disorder of skeletal muscle with variable clinical penetrance.
- Affected individuals develop a hypermetabolic syndrome on exposure to triggering agents (succinylcholine, volatile halogenated agents).
- The current diagnostic test is the caffeine-halothane contracture test.
- Current genetic testing has low sensitivity.
- It is unclear whether pregnancy alters susceptibility to MH.
- Both the obstetrician and the anesthesia provider should encourage early administration of neuraxial analgesia during labor in MH-susceptible patients.
- The anesthesia provider may convert epidural *analgesia* to epidural *anesthesia* for emergency cesarean delivery and thus avoid administration of general anesthesia.
- All local anesthetic agents are safe in MH-susceptible patients.
- Intravenous administration of dantrolene is life-saving treatment for an MH crisis.
- Dantrolene crosses the placenta and may result in neonatal hypotonia.
- Dantrolene may cause uterine atony.
- The anesthesia provider need not administer dantrolene prophylactically to MH-susceptible parturients.

CHAPTER 48

Musculoskeletal Disorders

Roanne Preston, MD, FRCPC

CHAPTER OUTLINE

Pregnancy commonly results in musculoskeletal complaints. Although they typically are benign and self-limited, symptoms may be disabling in some women. In addition, preexisting musculoskeletal disorders interact with pregnancy to a variable extent. These interactions range from an ameliorating effect of pregnancy on the course of the disease (e.g., rheumatoid arthritis) to the potential for a significant and possibly life-threatening deterioration in maternal condition (e.g., uncorrected severe thoracic scoliosis). The purpose of this chapter is to discuss the most common musculoskeletal disorders encountered in pregnant women and their implications for obstetric and anesthesia providers.

LUMBOPELVIC PAIN OF PREGNANCY

Lumbopelvic pain is the most common musculoskeletal complaint during pregnancy; it comprises two distinct areas of discomfort: (1) the lumbar spine area (low back pain) and (2) the posterior pelvic girdle area (from the sacroiliac joints radiating down into the posterior thighs), which has been termed *pelvic girdle pain*.[1-3] Lumbopelvic pain of pregnancy occurs at some time during gestation in more than 50% of pregnant women and impairs at least one normal activity of daily life, including sleep. Although originally it seemed to be a more significant problem in Scandinavian countries than elsewhere, it is now recognized as a universal issue, with the prevalence ranging from 25% to 70%. It is the most common reason for sick leave during pregnancy.[2] Women with mainly pelvic girdle pain report more disability during pregnancy than those with lumbar pain alone.[3,4] Differentiation between pelvic girdle pain and low back pain is important because the management differs and the disability of pelvic girdle pain is more likely to extend into the postpartum period for up to 1 to 2 years.[2] Risk factors for lumbopelvic pain of pregnancy include a history of low back pain, young age, hypermobile joints, low socioeconomic class, multiparity, and spondylolisthesis; however, the strongest factors are prior history of lumbopelvic pain of pregnancy, previous non–pregnancy-related low back pain, and strenuous work.[3-7] Unfortunately, women who suffer from lumbopelvic pain in one pregnancy have a very high risk for experiencing it during subsequent pregnancies.

The etiology includes hormonal and mechanical factors. The corpus luteum synthesizes and releases relaxin, and maternal blood concentrations of this peptide hormone increase 10-fold during gestation. Relaxin induces ligamentous softening and peripheral and pelvic joint laxity, which cause instability of the symphysis pubis and sacroiliac joints; the extent of instability and disability may be related to the maternal concentration of

relaxin. There is a correlation between mean serum levels of relaxin and the occurrence of back pain during pregnancy, and women with incapacitating symptoms have the greatest serum concentrations of relaxin.[8]

Mechanical changes have a later onset than hormonal changes. Women with pelvic girdle pain have increased pelvic joint motion, which increases sheer forces across the joints and likely results in pain.[2] In all pregnant women uterine enlargement results in a forward rotation of the sacrum and an increase in the lumbar lordotic curve, which tends to close the lumbar interlaminar space (Figure 48-1). This change exaggerates the mechanical load borne by both the facet joints and the posterior aspect of the intervertebral discs. These mechanical changes also may compromise nerve root foramina. Sciatica occurs in 1% of pregnant women, and most cases occur late in pregnancy.[9] Sciatica is distinguished from pelvic girdle pain by its extension to the ankle or involvement of the foot, and it may be associated with neurologic changes.[9] Disc herniation is rare in pregnancy but does occur.[10] Incapacitating pain that radiates below the knee, typically accompanied by progressive neurologic deficits or bowel and bladder dysfunction, distinguishes disc herniation from the more common and benign lumbopelvic pain of pregnancy.[3,10]

In summary, hormonal changes cause sacroiliac joint dysfunction, which is responsible for the lumbopelvic pain that occurs early in pregnancy. Mechanical changes are primarily responsible for the pain that manifests during late gestation, although symphysis pubis and sacroiliac joint instability may also continue to cause pain.

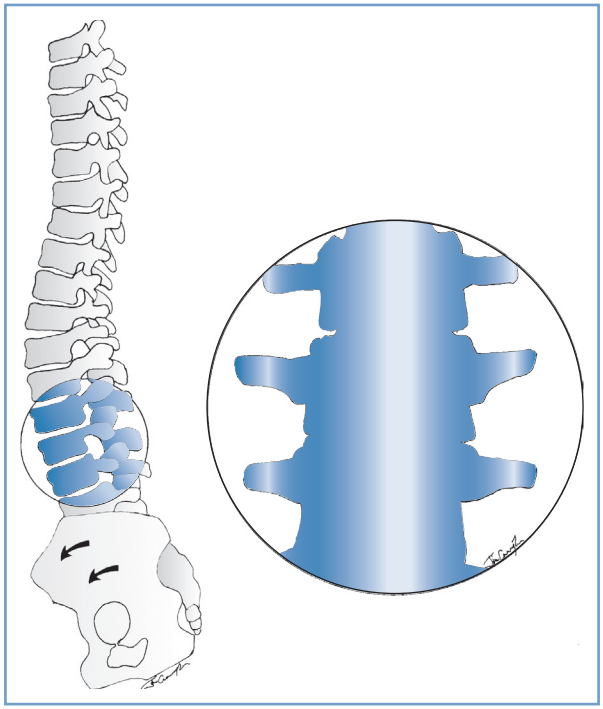

FIGURE 48-1 ■ Musculoskeletal changes of pregnancy. Forward rotation of the pelvis and greater lumbar lordosis increase the load borne by the posterior vertebral elements and tend to close the lumbar interlaminar spaces. *Inset,* Lumbar vertebrae L2 to L4.

Disc herniation is uncommon and is characterized by the presence of neurologic findings.

Obstetric Management

Treatment is conservative in the absence of neurologic compromise. Structured exercise programs, acetaminophen, transcutaneous electrical nerve stimulation (TENS), and acupuncture have been shown to be beneficial for women suffering from lumbopelvic pain during pregnancy.[11,12] Bed rest is reserved for patients with neurologic symptoms or disability secondary to pelvic instability. Patients with severe neurologic signs or symptoms of disc herniation should be assessed by a consultant neurosurgeon who can provide recommendations for intrapartum and postpartum care. Surgical intervention may be required in women with incapacitating pain or progressive neurologic deficits.[13] In a woman with severe symptoms, the obstetrician may choose to perform elective instrumental vaginal delivery to decrease maternal work and back stress during the second stage of labor. Because the disability associated with lumbopelvic pain of pregnancy, especially pelvic girdle pain, can impair the woman's ability to function postpartum, it is important to diagnose lumbopelvic pain of pregnancy and treat it appropriately.[2]

Anesthetic Management

No evidence suggests that epidural or spinal anesthesia is contraindicated in patients with lumbopelvic pain. The anesthesia provider may administer neuraxial anesthesia, even to patients with sciatica. However, neurologic signs and symptoms should be first identified, delineated, and recorded. It seems prudent to administer a dilute solution of local anesthetic, with or without an opioid, to minimize motor block associated with epidural analgesia during labor to reduce any further stress on relaxed sacroiliac joints. Women with lumbopelvic pain of pregnancy may be reluctant to have neuraxial anesthesia because of concern that it may aggravate symptoms. The literature does not support this fear, and reassurance may be required.

All members of the obstetric care team must pay careful attention to the positioning of the patient with back complaints. The patient must not be placed in a position that she could not tolerate before the administration of neuraxial anesthesia. The lithotomy position puts significant stress on the lower back and should be avoided whenever possible. If it is used, care must be taken to raise and lower both legs simultaneously to prevent injury to the lumbar spine and to avoid extremes when positioning the legs. Finally, caregivers should avoid rotational movements of the spine during transfer of the patient between the bed and the operating table.[2]

CHRONIC LOW BACK PAIN

Approximately 50% of pregnant women with a previous history of back pain or those with chronic low back pain experience a recurrence or exacerbation of their

symptoms during pregnancy.[6] Neuraxial anesthesia is more likely to fail in patients with chronic low back pain and in those who have had back surgery.[14-16] Benzon et al.[14] reported a delayed onset of epidural anesthesia in patients with back pain or sciatica; the affected roots were blocked 10 to 70 minutes later than the contralateral roots at the same level. The delay in block onset most likely results from the inability of the local anesthetic agent to diffuse into the area of the injured root. Luyendijk and van Voorthuisen[17] evaluated 600 epidurograms and confirmed that contrast material failed to reach the nerve root in 33% of patients with uncomplicated disc prolapse and did not move beyond the affected disc space in 5% of cases. This may be due to epidural scarring and adhesions that may develop during healing after disc injury. During epidurography, they noted that contrast material did not diffuse past the level of an injured disc and exited through the foramina below the abnormal disc. Prolapse of an intervertebral disc may result in relative or total obstruction of the flow of local anesthetic agent within the epidural space. The unblocked area includes the affected segment but also may include all segments (either ipsilateral or bilateral) distal to the affected level.

Sharrock et al.[15] reported a high rate (91%) of successful epidural anesthesia in patients with a history of limited spinal surgery. However, the success rate was lower than that achieved by the same group of anesthesiologists in a population with no history of back surgery (98.7%). They attributed the greater rate of failure to the distortion of surface anatomy and the tethering of the dura to the ligamentum flavum by scar formation, which rendered the epidural space discontinuous or obliterated it entirely. Support for this hypothesis is provided by LaRocca and MacNab's[18] description of the post-laminectomy membrane. They noted the post-laminectomy formation of organized fibrous tissue surrounding the dura and, at times, binding of the nerves to the posterior aspect of the disc and adjacent vertebral body. The fibrous response was proportional to the extent of surgical trauma and was more marked with greater operative exposures. Consequently, a local anesthetic agent injected into the epidural space may not diffuse beyond the area of scarring and an inadequate or unexpectedly high block may result.[16] Post-laminectomy spinal stenosis also may lead to attenuation or obliteration of the epidural space, and the most common site of obstructive stenosis is immediately above the fusion mass.[19]

Obstetric Management

It is not uncommon for obstetricians to offer pregnant women who have had persistent chronic low back pain the option of cesarean delivery to decrease the potential for further back injury during labor. There are no data to either encourage or discourage this option.

Anesthetic Management

The anesthesia provider may offer epidural or spinal anesthesia to patients with previous lumbar spine pathology or surgery after an appropriate history and screening examination to identify any neurologic deficits.[10] A decreased incidence of successful epidural anesthesia may be expected, especially in patients who have had extensive surgery. Nonetheless, the experienced anesthesia provider will likely administer epidural anesthesia successfully in the majority of patients. Sharrock et al.[15] recommended administration of epidural anesthesia one or two interspaces above the operated segment to improve the likelihood of a successful block. Subarachnoid anesthesia is likely to be more reliable than epidural anesthesia in this patient population.

POSTPARTUM BACKACHE

Postpartum backache is a common complaint worldwide, occurring in at least 25% of women, with 5% to 7% of women seeking medical help.[3] MacArthur et al.,[20,21] citing data obtained from a postal survey of 11,701 women who had delivered 1 to 9 years previously, reported that postpartum backache, starting within 3 months of delivery and persisting for 6 weeks or longer, occurred in 23% of women. Approximately 25% of these women had experienced backache before delivery, but 14% reported new-onset backache. In many women, the pain was persistent; 70% had experienced it for more than 2 years, and 65% had pain at the time of questioning 1 to 9 years later. Back pain was more common in women who delivered vaginally with epidural analgesia than in those who did not have epidural analgesia (18.9% versus 10.5%, respectively). Women who had epidural analgesia also were more likely to have had induced labor, an abnormal fetal position, a multiple pregnancy, a prolonged first or second stage of labor, forceps delivery, episiotomy, cesarean delivery, postpartum hemorrhage, or a large infant.

MacLeod et al.[22] also performed a postal survey of 2065 patients 1 year postpartum and reported a 26.2% incidence of postpartum backache in women who had received epidural analgesia, compared with a 1.7% incidence in those who had not; the latter incidence of postpartum backache (1.7%) is the lowest, by far, reported by any investigator in a postpartum population in the first year after delivery. Orlikowski et al.,[23] who examined data from 992 women as a secondary analysis of a prospective randomized study on epidural analgesia versus continuous midwifery support, found no relationship between back pain at 6 months postpartum and the use of epidural analgesia. Mogren[24] sent a questionnaire to 639 women who had completed an earlier postpartum survey in which they indicated that they had suffered from lumbopelvic pain during pregnancy. Mogren explored the relationship between persistent lumbopelvic pain at 6 months postpartum, mode of delivery, and the use of epidural or spinal anesthesia. She concluded that use of epidural or spinal anesthesia was not associated with persistent lumbopelvic pain.

A number of investigators have carried out prospective evaluations to eliminate the potential for reporting bias that may confound retrospective surveys. Breen et al.[25] assessed 1042 women at 6 months postpartum. Although 44% of women experienced postpartum backache, there was no difference between those who had received

epidural analgesia and those who had not. The most significant predictor of postpartum backache was antenatal back pain. Weight gain was greater in patients with postpartum and new-onset back pain.

Macarthur et al.[26] also prospectively studied the association between epidural analgesia and early, new-onset postpartum backache in 329 women. In patients who labored without epidural analgesia, the incidence of postpartum backache was 43% at 1 day, 23% at 7 days, and 7% at 6 weeks. The incidence of symptoms in patients who had received epidural analgesia was greater on the first postpartum day (53%), but this increase was not persistent. At 1 year postpartum, 12% of the patients had back pain (9.9% in the epidural group and 13.8% in the control group). Howell et al.[27] performed a randomized controlled trial comparing epidural with nonepidural analgesia during labor in 369 nulliparous women. There was no difference in the incidence or characteristics of postpartum backache at 3 and 12 months postpartum. In a follow-up study, there was no difference between the two groups in the incidence of back pain, disability, or movement restriction more than 2 years after delivery.[28]

The type of epidural analgesia provided has also been reviewed to determine whether alteration of the technique affects postpartum backache. Wilson et al.[29] reported the incidence of postpartum backache in 1054 nulliparous women enrolled in the Comparative Obstetric Mobile Epidural Trial (COMET). The women had received either high-dose labor epidural analgesia (bupivacaine 0.25% administered with intermittent bolus injections) or low-dose mobile analgesia (either combined spinal-epidural [CSE] analgesia followed by intermittent epidural bolus injections of 0.1% bupivacaine with fentanyl or a low-dose epidural infusion of 0.1% bupivacaine with fentanyl). The incidence of backache that started within 3 months and lasted for at least 6 weeks did not differ between the three groups: 46.9% (high dose), 41.7% (CSE), and 45.8% (low-dose infusion). These findings are similar to results of previous studies of this issue.

Both transient and more persistent postpartum backaches are common, but there is little evidence that they are related to the provision of epidural analgesia during labor. Similarly, no evidence suggests that denying a parturient epidural analgesia results in a lower incidence of back problems during the postpartum period. Factors associated with more persistent postpartum backache include the presence of back pain before pregnancy, the presence of lumbopelvic pain of pregnancy, cesarean delivery, and performance of physically demanding work.[3,24]

SCOLIOSIS

Scoliosis is a lateral deviation in the vertical axis of the spine. The severity of scoliosis is determined by measurement of the angle of the spinal curve, the Cobb angle, which is expressed in degrees (Figure 48-2). The incidence of minor curves is 4 per 1000 in the North American population; larger curves occur less frequently, predominantly in females. Severe scoliosis is relatively rare in pregnant women, occurring in 0.03% of pregnancies.[30] Although women with moderate to severe scoliosis constitute a small population of obstetric patients, pregnancy within this population is common.[31] Most cases of scoliosis are idiopathic, although some are associated with other conditions, most commonly neuromuscular disorders (Box 48-1).

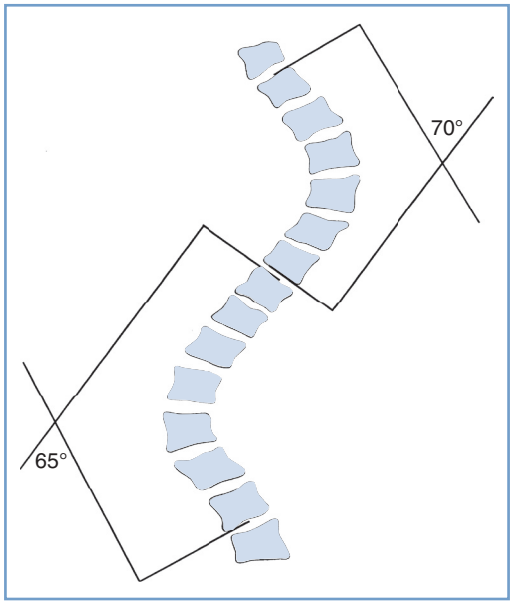

FIGURE 48-2 ■ Schematic representation of the Cobb angle. A line is drawn parallel to the superior cortical plate of the proximal end vertebrae and another line parallel to the inferior cortical plate of the distal end vertebrae. A perpendicular line is drawn to each of these lines. The angle of intersection is the Cobb angle of the curve.

BOX 48-1 Conditions Associated with Scoliosis

Congenital (Vertebral) Anomalies
- Hemivertebra
- Spina bifida

Neurologic Disorders
- Cerebral palsy
- Polio
- Neurofibromatosis

Myopathic Disorders
- Myotonic dystrophy
- Muscular dystrophy

Connective Tissue Disorders
- Marfan syndrome
- Rheumatoid disease

Osteochondrodystrophies
- Achondroplasia/hypochondroplasia
- Osteogenesis imperfecta

Infection
- Tuberculosis

Previous Trauma

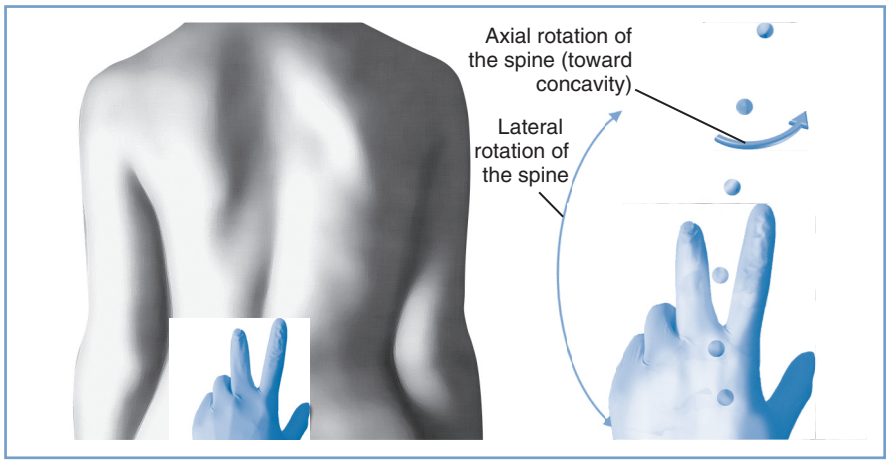

FIGURE 48-3 ■ Spinal rotation with scoliosis. *Left,* View of the lumbar spine in a patient with a scoliotic curve to the left demonstrating surface landmark palpation. *Right,* Skeletal anatomy at the same level in the same patient. There is a reduction in the dimensions of the interlaminar space on the concave side of the curve (to the right) and an expansion on the convex side. These changes are enhanced with greater severity of the curve. As the curve increases, the spinous processes rotate into the concavity of the curve, further altering the local anatomy. Surface landmark palpation from the view at left superimposed on the skeleton reveals how the palpated midline (*indicated by the white X*) is to the right of the true midline. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

Scoliotic curves can be divided into structural and nonstructural varieties. **Nonstructural curves** are those seen with postural scoliosis, sciatica, and leg-length discrepancies. They do not affect the mobility of the spine and are nonprogressive. **Structural curves** are seen in patients with idiopathic scoliosis and with scoliosis resulting from the conditions listed in Box 48-1. Structural curves lead to reduced spinal mobility, and affected patients typically have a fixed prominence (rib hump) on the convex side of the curve. There is also a rotatory component associated with the structural scoliotic curve. The axial rotation of the vertebral body is such that the spinous processes rotate away from the convexity of the curve and back toward the midline of the patient (Figures 48-3 and 48-4).[32] Deformation of the vertebral bodies results in shorter, thinner pedicles and laminae and a more narrow vertebral canal on the concave side. Vertebral deformation is unusual in patients with a Cobb angle less than 40 degrees.

Scoliosis interferes with the formation, growth, and development of the lungs; the occurrence of scoliosis before lung maturity may reduce the number of alveoli that ultimately form. The pulmonary vasculature develops in parallel with the alveoli; early-onset scoliosis and severe scoliosis may result in greater pulmonary vascular resistance and eventually lead to pulmonary hypertension. Musculoskeletal deformities also affect the mechanical function of the lungs; anatomic findings in scoliosis that are most commonly associated with respiratory compromise include the presence of a thoracic curve, thoracic lordosis, and a rib cage deformity. The most common pulmonary function abnormality is a restrictive pattern with decreases in vital capacity, total lung capacity, and lung compliance. This pattern occurs in all patients with a thoracic curve greater than 65 degrees. The functional residual capacity (FRC) is reduced, and airways may close during normal tidal breathing. If the FRC is reduced to the extent that it falls below the closing capacity, atelectasis may occur in basal alveoli. The most common blood gas abnormality is an increased alveolar-to-arterial oxygen gradient, with reduced Pao_2 and a normal $Paco_2$. It results from both venoarterial shunting and altered regional perfusion. Venous admixture may lead to arterial hypoxemia.

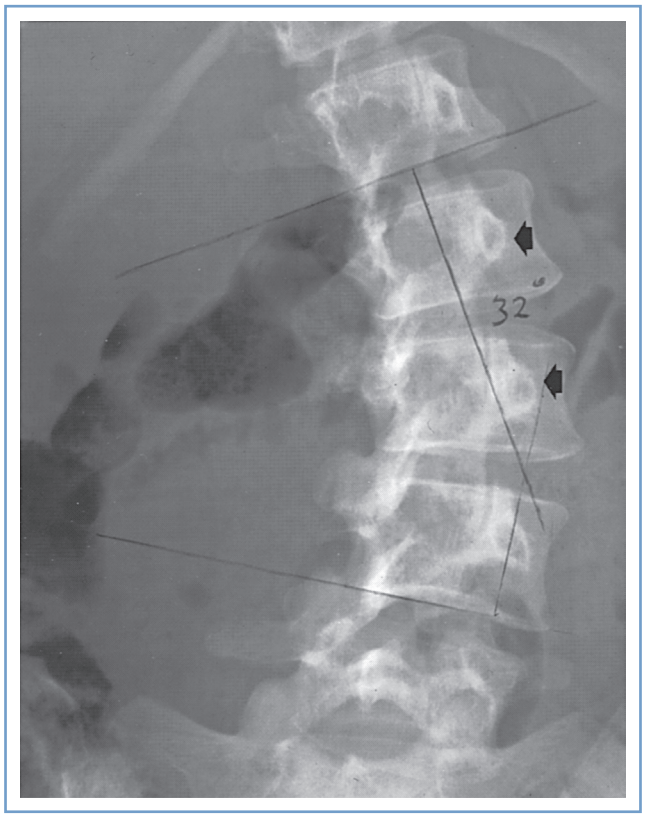

FIGURE 48-4 ■ Radiographic study of the lumbar spine in a 26-year-old woman with idiopathic scoliosis. The spinous processes and pedicles (*arrows*) are rotated away from the convexity and into the concavity of the curve. (The epidural space was entered easily with direction of the needle approximately 15 degrees off the perpendicular at the skin level toward the convexity of the curve.)

The natural history of severe, progressive scoliosis includes early death from cardiopulmonary failure.[33]

Permanent changes of the pulmonary vasculature are common in patients with a curve greater than 65 degrees. Pulmonary hypertension (a resting mean pulmonary artery pressure exceeding 25 mm Hg) occurs in many patients with severe deformity long before the onset of

right-sided heart failure and is largely attributable to increases in vascular resistance resulting from chronic alveolar hypoxia, hypoxic pulmonary vasoconstriction, and anatomic changes in the vascular bed. Fixed pulmonary hypertension carries a grave prognosis in pregnancy and may prompt a recommendation to avoid or terminate pregnancy.[34]

Scoliosis Associated with Neuromuscular Disease

When scoliosis develops secondary to a neurologic or myopathic disorder, abnormal respiratory function results not only from the skeletal deformity but also from abnormalities in the central control of respiration and the supraspinal innervation of the respiratory muscles, as well as from the loss of muscle function caused by the underlying disorder. Respiratory function may be further compromised by (1) impairment of the defense mechanisms of the airways due to loss of control of the pharynx and the larynx, (2) an ineffective cough mechanism, and (3) infrequent or reduced large breaths. Recurrent aspiration pneumonitis may result from compromised protective airway reflexes. In general, the prognosis of scoliosis due to neuromuscular disease is worse than that of idiopathic scoliosis and is determined predominantly by progression of the primary disorder. Affected patients typically develop irreversible respiratory failure at a younger age, and pulmonary hypertension is common; pregnancy is uncommon in this population.

Interaction with Pregnancy

Pregnancy may exacerbate both the severity of the spinal curvature and cardiopulmonary abnormalities in women with uncorrected scoliosis. Progression of a curve, defined as an increase in the Cobb angle of 5 degrees or more over subsequent assessments, most likely occurs during periods of rapid growth and in patients with larger curves at the time of diagnosis. Curves that are less than 25 degrees or curves that have been stable before pregnancy typically do not progress during pregnancy.[35,36] In contrast, more severe curves and those that have not stabilized may worsen. Some investigators have described a correlation between the severity of the curve and maternal morbidity and mortality. However, it is likely that the severity of functional cardiopulmonary impairment before pregnancy is a better predictor of maternal outcome than the severity of the curve.[37] Patients with a severe curve (i.e., Cobb angle > 60 degrees) but good cardiopulmonary function tolerate pregnancy well, whereas in those with significant cardiopulmonary compromise, and especially in those with pulmonary hypertension, maternal mortality is high.[38,39]

The physiologic changes of pregnancy include decreases in both functional residual and closing capacities and increases in minute ventilation and oxygen demand. The thoracic cage normally increases in circumference during pregnancy as a result of increases in both anteroposterior and transverse diameters. If the chest cage is relatively fixed by scoliosis, the diaphragm is responsible for all increments in minute ventilation. As the enlarging uterus causes elevation of the diaphragm, diaphragmatic activity is restricted and further decreases in residual and closing capacities may occur, which may result in both greater ventilation-perfusion mismatch and decreased arterial oxygen content. The antepartum onset of new symptoms of respiratory compromise or the exacerbation of preexisting symptomatology is associated with higher maternal morbidity and a greater likelihood that assisted ventilation will be required after cesarean delivery.[37]

Minute ventilation typically increases by 45% during pregnancy. In normal pregnancy, the increase is primarily a result of increased tidal volume. In the scoliotic patient with restrictive lung disease, a larger tidal volume may not be possible, and the increased minute ventilation is achieved by means of a higher respiratory rate and increased work of breathing. Peak increases in pulmonary activity are reached by the middle of the third trimester, but the uterus continues to grow until term, and it may further encroach on the noncompliant thorax, causing late gestational deterioration despite stabilization of respiratory demand.

Dyspnea on exertion is uncommon in patients with scoliosis who have curves less than 70 degrees, but it becomes more common as the deformity exceeds 100 degrees. In younger patients with a curve less than 70 degrees, exercise capacity is more likely to be impaired because of the lack of regular aerobic exercise and subsequent deconditioning rather than intrinsic ventilatory impairment.[40] Dyspnea is common in many pregnant women, typically begins in the first or second trimester, and is most prevalent at term. Two features help distinguish physiologic from pathologic dyspnea.[41] **Physiologic dyspnea** tends to occur earlier in pregnancy and often plateaus or even improves as term approaches. The **pathologic dyspnea** of cardiopulmonary decompensation more often begins in the second half of pregnancy and is progressive, often becoming most severe as gestation advances and the physiologic loading is maximal. Second, physiologic dyspnea is rarely extreme, and patients can maintain most daily activities. Dyspnea that is extreme or has a limiting effect on normal activity may signal maternal cardiorespiratory decompensation. Dyspnea at rest is also rare in the absence of cardiopulmonary dysfunction, as is dyspnea that is acute in onset or progressive and intractable.

Minute ventilation of the unmedicated parturient increases by a further 75% to 150% in the first stage of labor and by 150% to 300% in the second stage. Oxygen consumption increases above prelabor values by 40% in the first stage and 75% in the second stage. These levels may be unattainable by the scoliotic parturient with restrictive lung disease, and respiratory failure and hypoxemia may result during labor.

Pregnant women with pulmonary hypertension have a limited ability to increase cardiac output. During normal pregnancy, cardiac output increases 40% to 50% above nonpregnant measurements; during labor and delivery, even greater increases are observed. These increases are achieved with both larger stroke volume and a higher heart rate. These demands may put an excessive burden on the cardiovascular system in parturients who

had marginal cardiac reserve before pregnancy. If the right ventricle fails in the presence of pulmonary hypertension, left ventricular filling will decrease and low-output failure and sudden death may occur.[34]

Surgical Management

During spinal fusion and instrumentation, the spinal musculature is reflected off the vertebrae over the course of the curve and the spinous processes and interspinous ligaments are removed. The spine is subsequently extended, correcting the curve. The vertebrae are decorticated throughout the extent of the planned fusion, instrumentation is placed, and bone graft material from the ileum is placed over the decorticated vertebrae. A number of techniques for fusion have been described, but all involve both spinal instrumentation and extensive bone grafting in the axial spine (Figure 48-5).

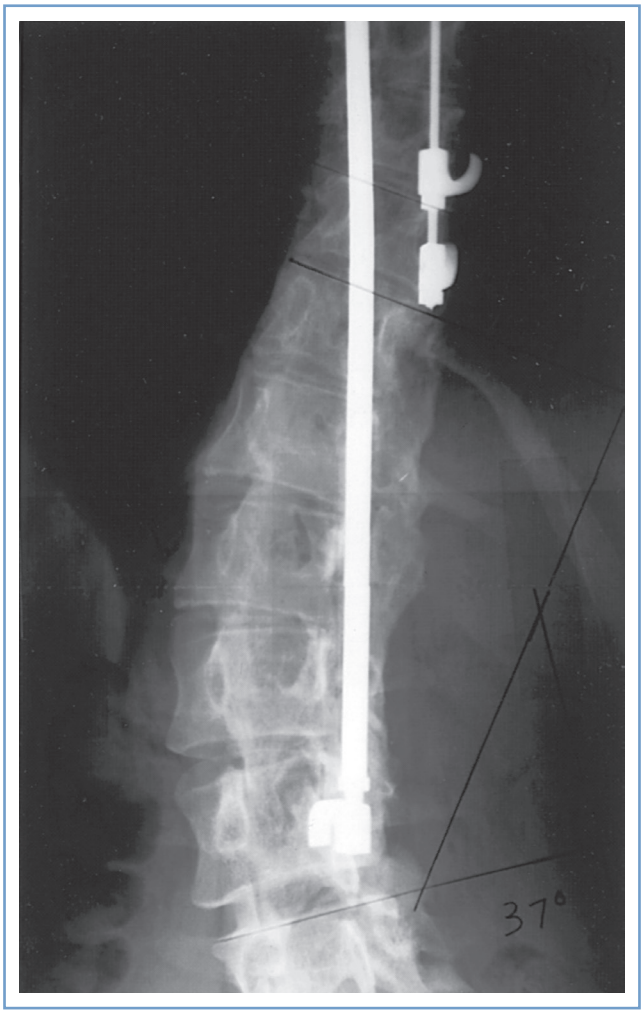

FIGURE 48-5 ■ Harrington rod instrumentation. Radiographic study of the lumbar spine in a 31-year-old woman with thoracolumbar scoliosis corrected with spinal instrumentation. There is rotation of the vertebrae into the curve (toward the rod), and extensive bone grafting is evident adjacent to the rod. Two lumbar interspaces (L4 to L5 and L5 to S1) are not involved in the fusion.

Obstetric Management

Pregnant women with corrected scoliosis tolerate pregnancy, labor, and delivery well. In the absence of major lumbosacral deformity, there is little alteration of the pelvic cavity and malpresentation is not more common than in women without scoliosis. Uterine function is normal, and labor is not prolonged. Spontaneous vaginal delivery is anticipated, and cesarean delivery should be reserved for obstetric indications.

One uncontrolled study suggested no difference in the requirement for cesarean delivery in patients with previous Harrington rod instrumentation for correction of idiopathic scoliosis[31]; a second and similar study reported a higher incidence of operative delivery.[42] The difference in outcomes may be influenced by the severity and etiology of the scoliosis in the populations reviewed and/or differences in the local practice patterns for managing atypical patients. Pelvic abnormalities are more common when scoliosis is associated with neuromuscular disorders and in patients with a severe, uncorrected curve.[43] In addition, abdominal and pelvic muscle weakness predisposes parturients to problems with expulsion of the infant during the second stage of labor and may necessitate instrumental vaginal delivery. The need for instrumental or cesarean delivery seems to be related to the severity of skeletal deformity, the resulting maternal compromise, and cephalopelvic disproportion.

In the second stage of labor, the diaphragm has a nonrespiratory function. With expulsive efforts, maximal isometric contractions may be sustained for 20 seconds or more, and diaphragmatic fatigue has been demonstrated even in normal, laboring women. In parturients whose diaphragmatic function is compromised by neuromuscular disease or severe scoliosis, the potential for fatigue and failure is greater; expulsive forces are decreased, the second stage may be prolonged, and a trial of labor may fail, necessitating instrumental or cesarean delivery. In addition, women with severe cardiopulmonary disease (especially those with gestational decompensation) may require urgent or emergency cesarean delivery because of maternal compromise or nonreassuring fetal status.

Anesthetic Management

Pregnant women who have thoracolumbar scoliosis with a Cobb angle greater than 30 degrees or who have undergone spinal instrumentation and fusion for scoliosis should be referred to an anesthesiologist for antepartum consultation. The anesthesiologist should (1) determine the etiology of the scoliosis, as well as the severity and stability of the curve; (2) obtain a history of maternal musculoskeletal and cardiopulmonary symptoms; and (3) review prior obstetric and anesthetic experiences. For patients with scoliosis secondary to neuromuscular disorders, the anesthesiologist should also become familiar with anesthetic considerations specific to those underlying disorders.

Women with suspected or evident pulmonary compromise should undergo evaluation by a pulmonologist, and pulmonary function studies and arterial blood gas measurements should be obtained. These patients must

be reevaluated periodically to ensure that they are tolerating the increasing physiologic demands of pregnancy. Echocardiography is useful to assess right-sided heart function in patients with one or more of the following: (1) a curve of 60 degrees or more, (2) hypoxemia on arterial blood gas measurement, (3) moderate or greater reductions in predicted lung volumes or flows, and/or (4) pulmonary hypertension. Radiographic studies performed before pregnancy and operative notes describing spinal surgical procedures should be reviewed before neuraxial anesthesia is given to any patient with significant scoliosis or previous spinal surgery. The anesthesiologist should also examine the spine and note the surface landmarks and interspaces that are least affected by the deformity. Modes of analgesia and anesthesia for labor and delivery can be discussed during antepartum consultation.

Invasive hemodynamic monitoring is rarely indicated during labor and delivery. Pulmonary function studies that suggest significant respiratory compromise or clinical evidence of impending respiratory failure warrant placement of an arterial catheter and serial assessment of blood gas measurements. Echocardiographic demonstration of significant right-sided heart dysfunction may warrant central venous pressure monitoring. The use of echocardiography may allow for detailed anatomic and physiologic assessment in severely ill mothers with advanced and decompensated cardiopulmonary disease.

The anesthesiologist may offer epidural analgesia for labor and delivery to patients with severe thoracolumbar scoliosis. Identification of the epidural space is more difficult in such patients, and the anesthesiologist should anticipate a greater incidence of complications. It is useful to remember the presence of the vertebral rotation during the performance of neuraxial anesthesia in a patient with a significant lumbar curve, which results in the spinous processes (which often may be structurally deformed) rotating into the concavity of the curve. Therefore, the midline of the epidural space is deviated toward the convexity of the curve relative to the spinous process palpable at the skin level (see Figures 48-3 and 48-4). The extent of lateral deviation is determined largely by the severity of the deformity.[44] One method of placing an epidural or spinal needle is to direct the needle from a palpated spinous process toward the convexity of the curve, often at a significant angle. The experienced anesthesiologist can track the resistance of both the interspinous ligament and the ligamentum flavum to maintain the correct course into the epidural space. The extent of the local anatomic distortion is the limiting factor, and the selection of spaces that are least involved with the curve is advised (Figure 48-6). More recently, Huang[45] suggested a modified paramedian approach based on Boon's[46] work in cadavers, in which the needle is placed lateral to the spinous process on the convex side of the curve (taking advantage of the wider interlaminar spaces on that side) and then aimed directly perpendicular to the skin. The intent is to find lamina with the needle tip and then "walk up or down" the lamina to enter the epidural space (Figure 48-7).

In patients with scoliosis resulting from myopathic or neurologic disease, distortion of spinal anatomy may be

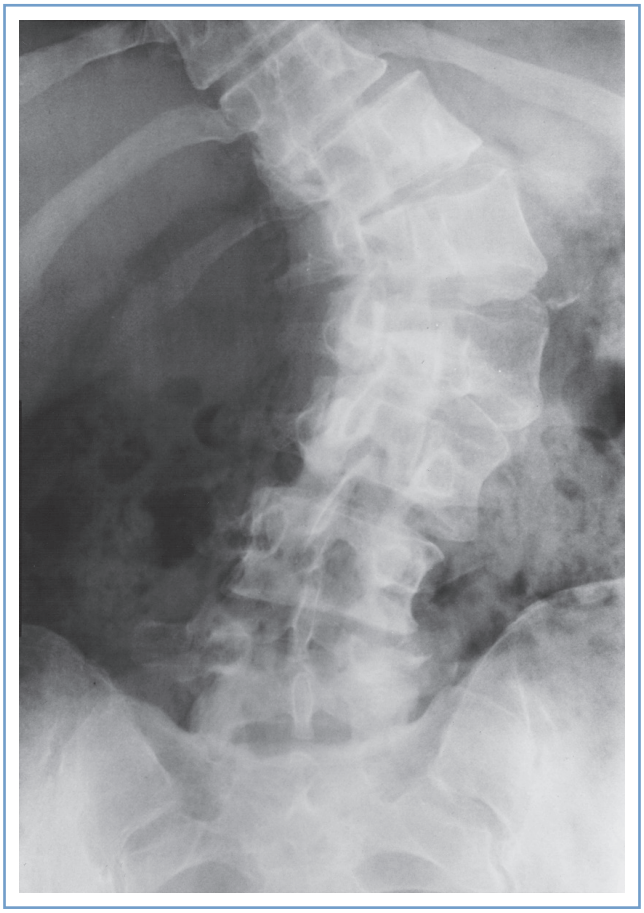

FIGURE 48-6 ■ Radiograph of the lower thoracolumbar spine in a young woman with scoliosis predominantly affecting the lumbar spine and markedly distorting her local anatomy. She received lumbar epidural analgesia for labor during her first pregnancy, after a catheter was placed with some difficulty. She received patient-controlled intravenous nalbuphine for labor analgesia during her second pregnancy after persistent, unsuccessful attempts to insert an epidural catheter. For her third pregnancy, this radiograph directed the practitioner toward the lower lumbar spaces, where anatomic distortion is less pronounced.

significant enough to prohibit the administration of neuraxial anesthesia. Ultrasonography is becoming a useful technique to facilitate administration of neuraxial anesthesia in parturients with challenging spinal anatomy, including those with scoliosis.[47,48] Asymmetry of the spine is not difficult to appreciate; learning how to use the information and determine the optimal space and needle direction requires more experience.[49] The paramedian view may provide the best information with respect to the widest interlaminar space in a woman with lumbar scoliosis.[46] There is limited published experience with use of *real-time* ultrasonography during neuraxial needle placement. One report described its use in two patients; one patient had scoliosis, for whom standard preprocedural ultrasonographic imaging did not provide adequate information.[50]

Local anesthetic dose requirements for epidural and spinal anesthesia in the patient with scoliosis are variable. Moreover, during administration of spinal anesthesia in a patient with a severe scoliotic curve, hyperbaric local

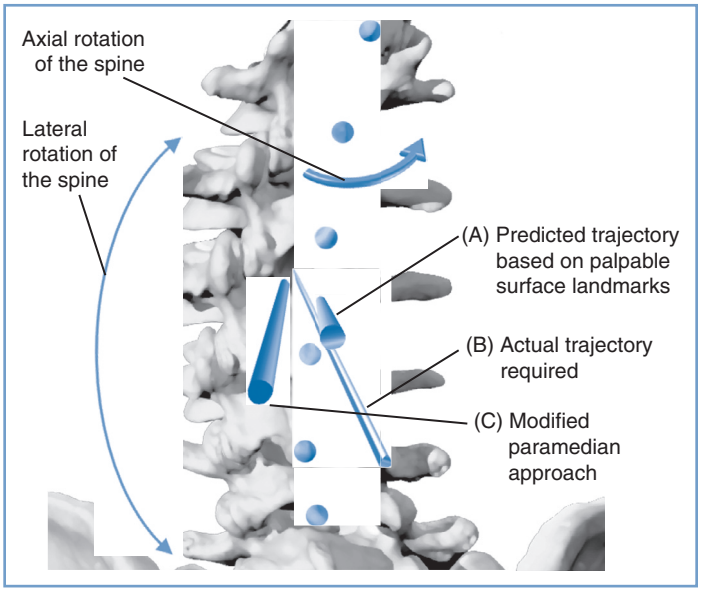

FIGURE 48-7 ■ Image of the lumbosacral vertebrae affected by a scoliotic curve to the left. Note the axial and lateral rotation of the vertebral bodies, and the rotation of the affected spinous processes (*blue dots*) into the concavity of the curve; these spinous processes are frequently anatomically abnormal. The apparent midline (*trajectory A*) suggested by palpated surface landmarks is to the right (toward the concavity of the curve) of the true midline. The figure demonstrates two approaches to enter the epidural/subarachnoid space: one where the needle is directed along the line of a spinous process toward the convexity of the curve (*trajectory B*), and the other a modified paramedian approach where needle entry starts on the convex side of the curve and is directed perpendicular to the skin (*trajectory C*). (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

anesthetic solution may pool in dependent portions of the spine, resulting in an inadequate block.[51] Thus, it may be preferable to use a continuous technique in those women with severe scoliosis so that the dose of local anesthetic agent can be titrated to the desired segmental level of anesthesia.

When offering neuraxial anesthesia to patients with a history of corrective surgery, the anesthesiologist must consider the following potential problems:

- Persistent back pain occurs in many patients with corrected scoliosis and correlates with both the extent of fusion and the time since surgery.[52,53]
- Degenerative changes occur in the spine below the area of fusion, and there is a higher incidence of both retrolisthesis and spondylolisthesis.[53]
- Twenty percent of patients undergo fusion to the lowest lumbar levels, limiting the potential for neuraxial anesthesia.[42,54]
- Insertion of an epidural needle in the fused area may not be possible because of the presence of instrumentation, scar tissue, and bone graft material.
- Intraoperative trauma to the ligamentum flavum may result in adhesions in or obliteration of the epidural space, and these changes may interfere with the spread of injected local anesthetic.[18]
- Obliteration of the epidural space may increase the incidence of unintentional dural puncture.
- These patients often manifest a high level of anxiety about their backs and may be reluctant to have neuraxial anesthesia.

A recent qualitative literature review by Ko and Leffert[55] on neuraxial anesthesia in the parturient with scoliosis provides insight into the challenges of neuraxial anesthesia administration in these women. There were 117 attempted neuraxial procedures, the majority (93) in surgically corrected patients. Overall, 71% had a successful neuraxial block; however, the corrected patients proved to be more challenging, with a 69% success rate versus 79% for the uncorrected group. The challenges in corrected patients included (1) inability to place the needle (22%), (2) multiple attempts (13%), (3) patchy analgesia (10%), (4) excessive local anesthetic dose requirements (9%), (5) unintentional dural puncture (4%), and (6) inadequate analgesia (4%). In the uncorrected group, the issues included (1) patchy, asymmetric, or unilateral blocks (8% of each) and (2) multiple attempts or failed placement (4% of each). There were also two cases of persistent low back pain of unknown etiology. Complications seem to occur more frequently in patients with fusion that extends to the lower lumbar and lumbosacral interspaces than in those with fusion that ends in the upper lumbar spine.

Both the anesthesiologist and the patient should anticipate the possibility that blind attempts to identify the epidural space may fail, and consideration should be given to the use of ultrasonography to guide the performance of a neuraxial block.[47] Although there is limited published experience to date with this specific population, Costello and Balki[56] reported the use of ultrasonography to facilitate the successful administration of neuraxial anesthesia in a patient with Harrington rod instrumentation. Alternative modes of intrapartum analgesia include administration of intraspinal opioids, caudal anesthesia, patient-controlled intravenous opioid analgesia, and inhalation analgesia.[55] Continuous spinal analgesia or anesthesia is a reasonable alternative to epidural analgesia or anesthesia for labor or cesarean delivery in parturients who have undergone major spinal surgery with instrumentation. Even making a dural puncture with a small-gauge spinal needle to confirm needle location and enhance spread of epidural local anesthetic is not unreasonable in this patient population.[55] It is possible to make an intentional dural puncture with a small-gauge needle either through or adjacent to a fusion mass in some patients in whom epidural space identification was previously unsuccessful and then consider performing repeat subarachnoid injections as needed for labor analgesia.

CHRONIC INFLAMMATORY ARTHRITIDES

This group of diseases includes rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and undifferentiated arthritis. Of these, rheumatoid arthritis is most affected by pregnancy and has been studied most extensively with respect to the immunologic relationship between mother and fetus. The most common arthritides seen in pregnancy are rheumatoid arthritis and ankylosing spondylitis and are discussed here in more detail.

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic systemic disorder characterized by synovial proliferation that leads to joint destruction and subsequent deformity. It is becoming increasingly a disease of older people. Since 1985, the overall prevalence in the United States has fallen from 1.07% to 0.6%; the greatest decline in prevalence has occurred among people younger than age 55 years.[57] The disease occurs approximately two times more frequently in women than in men.[57]

The lumbosacral spine is affected in only 5% of patients with rheumatoid arthritis. In contrast, the cervical spine is commonly involved, and atlantoaxial subluxation occurs in 30% to 45% of patients with rheumatoid arthritis.[58,59] Although atlantoaxial subluxation may occur early in the course of the disease, it most often occurs in patients with a history of 5 years or more of highly active and erosive disease.[60] Atlantoaxial subluxation occurs as a result of an attenuation or disruption of the transverse ligament, which allows anterior movement of C1 on C2 during neck flexion. Radiographically, atlantoaxial subluxation is marked by an increase in the atlas-dens interval, which is best demonstrated on the lateral cervical spine radiograph with the neck flexed (Figure 48-8).

Vertical subluxation of the odontoid process occurs primarily in older patients with severe and long-standing disease. A scoliotic deformity of the trachea and larynx has been reported in patients with vertical subluxation.[61] The deformity is complex, involving both rotation and deviation of the larynx from the midline, and it may make laryngoscopy and tracheal intubation difficult. However, vertical subluxations occur primarily in older patients with severe, long-standing disease and are unlikely to be seen in women of childbearing age. Other airway issues such as cricoarytenoiditis and temporomandibular joint (TMJ) dysfunction may occur earlier in the disease and complicate airway management of the parturient.[62]

Extra-articular features are common in patients with rheumatoid arthritis. Anesthesiologists have a special interest in abnormalities that affect the airway and the cardiovascular and respiratory systems (Box 48-2). Although these complications occur more typically in patients with long-standing disease, it is prudent to inquire about those with more significant anesthetic implications. Cardiovascular mortality is especially high in patients with rheumatoid arthritis, similar to that of patients with type 2 diabetes, and often presents atypically.[62]

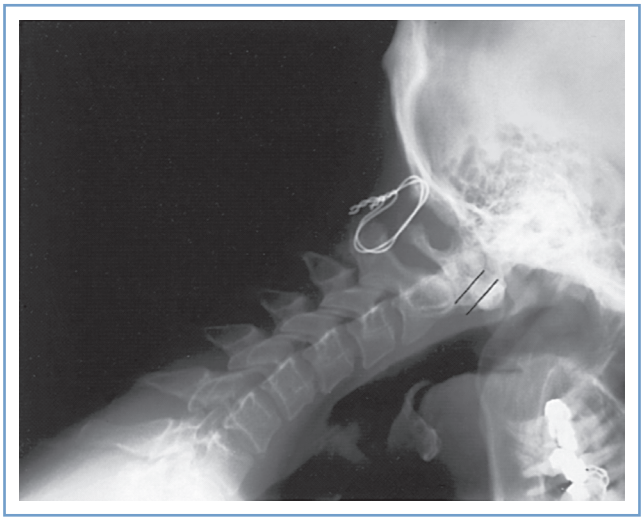

FIGURE 48-8 ■ Lateral radiographic study of the cervical spine (in flexion) in a 32-year-old woman with rheumatoid arthritis. There is isolated atlantoaxial subluxation (6 mm) in the absence of other radiologic changes of rheumatoid arthritis. She presented with neck pain, and a wire was placed between the occiput and the spinous process of C2 to limit the subluxation.

Interaction with Pregnancy

Rheumatoid arthritis is associated with a slightly higher incidence of preterm birth, small for gestational age infants, and elective cesarean delivery, as compared with a reference population of women as shown in large databases from Norway and the United States.[63,64] In the absence of vasculitis, fetal outcome is good, although as a group the chronic inflammatory arthritides are associated with a higher perinatal mortality rate.[63] Since the 1930s, evidence has consistently shown that pregnancy has a beneficial, ameliorating effect on the activity of rheumatoid arthritis.[65] Approximately 75% of women note improvement in symptoms during pregnancy, which is typically evident by the end of the first trimester, with a gradual resolution of pain, swelling, and stiffness. The clinical improvement usually continues throughout pregnancy and recurs in future pregnancies. This remission often occurs despite the discontinuation of effective but teratogenic disease-modifying antirheumatic drugs and a substantial reduction in the dosage of safe drugs (e.g., corticosteroids). Relapse occurs postpartum in approximately 60% to 90% of women,[66] beginning as early as the second week after delivery. It appears that most women return to a disease status comparable to their prepregnant state.

Medical Management

Drug therapy for rheumatoid arthritis is divided into (1) symptom-modifying drugs, (2) disease-modifying antirheumatic drugs, and (3) biologic drugs.

Symptom-modifying therapies include nonsteroidal anti-inflammatory drugs (NSAIDs), including cyclooxygenase-2 (COX-2) inhibitors, and corticosteroids. **NSAIDs** and **corticosteroids** have been the mainstay of therapy in rheumatoid arthritis during pregnancy for many years.[67] No evidence suggests that these drugs are teratogenic. However, there is limited experience with COX-2 inhibitors; hence, they are best avoided in pregnancy.[66] NSAIDs are classified as U.S. Food and Drug Administration (FDA) Category B medications in the first part of pregnancy, even though they are associated with an increased incidence of early pregnancy loss.[68] When used later in pregnancy, NSAIDs are associated with premature closure of the ductus arteriosus and increased risk for neonatal bleeding and are therefore classified as FDA Category C medications after 30 to 32 weeks' gestation. All NSAIDs except low-dose aspirin should be discontinued at 32 weeks' gestation.[67]

Corticosteroids are considered safe in doses up to 15 mg/day of prednisone equivalent. Larger doses increase risk for maternal infection and neonatal prematurity.[66]

Disease-modifying antirheumatic drugs reduce flares, prevent joint erosions, and have proven efficacy in decreasing morbidity and mortality from rheumatoid arthritis. This category of drugs for anti–rheumatoid arthritis treatment includes sulfasalazine, azathioprine, methotrexate, leflunomide, gold salts, and antimalarial agents. **Methotrexate** is considered a first-line treatment for rheumatoid arthritis and is typically started at diagnosis, but unfortunately it and **leflunomide** are highly teratogenic and must be stopped several months before conception.[66] **Sulfasalazine** inhibits folate synthesis, and therefore additional folate supplementation is required during pregnancy. **Azathioprine** is an FDA Category D drug, and although it may be used during pregnancy at doses less than 2 mg/kg/day, other options are preferable.

The **biologic drugs**, which are proving as effective as methotrexate in preventing erosions and reducing long-term disability, include the **anti–tumor necrosis factor-alpha (TNF-α) therapies** (e.g., etanercept), which are classified as FDA Category B in pregnancy and lactation. The other biologic drugs (e.g., abatacept, rituximab, tocilizumab) are Category C drugs, and there is very limited experience with their use in pregnancy; thus, the recommendation is to discontinue them 10 weeks before conception.[66]

An attempt is made to reduce the dose of all antirheumatic agents during pregnancy and resume antepartum therapy after delivery before disease activity flares.

Obstetric Management

Vaginal delivery is preferred for parturients with rheumatoid arthritis, and cesarean delivery should be reserved for obstetric indications. A major concern is maternal positioning during labor. Rheumatoid joints are unstable because of ligament loosening associated with chronic swelling and because of the destruction of ligaments and cartilage. It is important to determine the permissible range of motion and activity for affected joints. Special emphasis should be given to the hips, knees, and neck. Physicians and nurses should be aware of the potential risks of forcing motion beyond the disease-imposed limits.

Anesthetic Management

The preanesthetic evaluation should include a careful evaluation of the airway. Patients with rheumatoid arthritis may have a small mandible, TMJ dysfunction, cricoarytenoid arthritis, and laryngeal deviation, all of which may complicate direct laryngoscopy.[62] In particular, these findings may be present in parturients with juvenile rheumatoid arthritis. Cervical spine involvement is not common in young patients but may occur in patients with disease of long duration and in those with severe, deforming disease—typically, patients with juvenile rheumatoid arthritis. Although there is no guideline or consensus on the need to obtain cervical spine radiographs in patients with rheumatoid arthritis, it would be reasonable even in the pregnant woman if her rheumatoid arthritis includes severe erosive disease, neck symptoms, or a history of disease of 10 or more years' duration.[62] The cardiac and pulmonary features of rheumatoid arthritis are not common in young patients, but signs and symptoms of pleural and pericardial effusions and pulmonary parenchymal involvement should be sought.

No evidence contraindicates the administration of spinal or epidural anesthesia in patients with rheumatoid arthritis. However, recent evidence in the nonpregnant population has indicated that spinal blocks rise higher

than expected in patients with rheumatoid arthritis, independent of body mass index.[69,70] Care should be taken to avoid excessive manipulation of the neck during administration of general anesthesia. Finally, joints should be padded and protected appropriately during anesthesia.

Ankylosing Spondylitis

Ankylosing spondylitis is a chronic inflammatory arthropathy characterized by infiltration of granulation tissue into the bony insertions of ligaments and joint capsules, with subsequent fibrosis, ossification, and ankylosis. Ankylosing spondylitis is a major subtype of an interrelated group of rheumatic disease called the spondylarthritides, which are linked by the major histocompatibility complex (MHC) Class 1 tissue antigen HLA B27.[71] Ankylosing spondylitis primarily affects the sacroiliac, facet, and costovertebral joints; sacroiliitis is pathognomonic. There is progressive flexion and fusion of the spine and fixation of the rib cage; however, the clinical spectrum is wide, and only a small proportion of patients progress to total spinal ankylosis.

The prevalence of ankylosing spondylitis is 0.1% to 1.4%.[71] Onset is common during the second and third decades of life, a period of peak childbearing potential. The disease is milder in women than in men, but women are more likely to have peripheral arthritis and involvement of the cervical spine and symphysis pubis.[72] Although clinically significant lesions of the cervical spine may occur early in the course of the disease, they are far more common in patients with long-standing ankylosing spondylitis (Figure 48-9).[61,73] Ultimately, 21% of patients with ankylosing spondylitis develop clinically significant atlantoaxial subluxation. TMJ involvement causes limited mouth opening in 10% of patients early in the disease, increasing to 30% to 40%.[72] A slower development of radiologic changes of the dorsolumbar spine occurs in women, and spinal rigidity or deformity and extra-articular manifestations are rare in young patients (Box 48-3).[62,71,74]

The mainstays of therapy for ankylosing spondylitis are NSAIDs and exercise programs. Disease-modifying antirheumatic drugs have not been proven beneficial, but for those patients not controlled on NSAIDs, anti–TNF-α therapies have proven quite effective.[71]

Interaction with Pregnancy

In contrast to rheumatoid arthritis, pregnancy does not seem to reduce the symptoms or slow the progression of disease in patients with ankylosing spondylitis, and many patients experience an aggravation of morning stiffness and back pain.[75] However, a recent retrospective review of 35 case-control matched pregnancies revealed improvement in pain and stiffness in 51% of women in early pregnancy, although unfortunately there was some return of pain as pregnancy progressed.[76] Pregnancy may ameliorate the extra-articular features of this disease (e.g., psoriasis, inflammatory bowel disease, small joint arthritis), but it appears that women with ankylosing spondylitis are more likely than women with rheumatoid arthritis to enter pregnancy with active disease and, hence, to have higher levels of pain at the beginning of pregnancy.[75] Ankylosing spondylitis does not adversely affect pregnancy, labor, or delivery; in the absence of pelvic joint ankylosis and/or hip joint involvement, an uncomplicated vaginal delivery at term should be anticipated in most patients. As in rheumatoid arthritis, NSAID therapy should be withdrawn by 32 weeks' gestation.

FIGURE 48-9 ■ Lateral radiographic study of the cervical spine in a 31-year-old woman with ankylosing spondylitis. There is evidence of facet joint ankylosis (*arrowheads*), although the lordotic curve remains well preserved. The ligaments of the thoracic spine are undergoing calcification with the spine in flexion, and there is a compensatory increase in the lumbar lordosis to maintain erect posture. (Flexion of the lumbar spine proved difficult, and a paramedian approach was used to enter the epidural space.)

Anesthetic Management

An anesthesiologist should review the patient's history with respect to the duration of the disease, the presence of extra-articular features, and the recent use of analgesics. Temporomandibular joint disorders, cervical spine involvement, and cardiopulmonary complications are rare early in the disease course; however, difficult tracheal intubation has been reported in parturients.[77] Severity of back symptoms is often out of proportion to the radiographic appearance of the spine, and calcification of the spinal ligaments is typically not advanced in young patients. Neuraxial anesthesia is acceptable in parturients with ankylosing spondylitis; however, even in young patients it may be technically challenging. Calcification of the interspinous ligaments and osteophyte formation

may limit the parturient's ability to flex forward, making midline needle placement difficult.[72] A paramedian approach can be considered in this instance.[78] Additionally, the epidural space becomes narrowed in patients with ankylosing spondylitis, and there have been reports of unexpectedly high blocks,[79] as well as failed blocks despite confidence that the catheter was in the epidural space. After multiple failed attempts to provide epidural analgesia in a parturient with advanced ankylosing spondylitis, Hoffman et al.[80] suggested that a highly calcified posterior longitudinal ligament may limit rostral spread of local anesthetic in the epidural space. Preprocedural ultrasonography may be helpful, either to identify the best interlaminar space, or to indicate that administration of neuraxial anesthesia may be impossible.[81]

SPINA BIFIDA

Spina bifida results from the failure of the developing spine to completely enclose the neural elements in a bony canal. There is a wide spectrum with respect to the severity of the deformity and its implications. **Spina bifida occulta** is defined as failed fusion of the neural arch without herniation of the meninges or neural elements. A defect limited to a single vertebra, typically L5 or S1, is so common (occurring in 5% to 36% of the population) that it can be considered a normal variant.[82] Superficial signs of spina bifida occulta include a tuft of hair, cutaneous angioma, lipoma, or a skin dimple, but such signs are not common in patients with isolated vertebral arch anomalies and an underlying normal cord. Patients with spina bifida occulta rarely have symptoms related to this anomaly, although they may have a higher incidence of posterior disc herniation.[82]

Spina bifida cystica is defined as failed closure of the neural arch with herniation of the meninges (i.e., meningocele) or the meninges and neural elements (i.e., myelomeningocele) through the vertebral defect. These conditions are relatively uncommon, occurring in 1 to 3 per 1000 births.[83] Neurologic deficits involving the lower extremities and sphincters occur in almost all patients, and these deficits vary primarily in severity. Hydrocephalus is present in many patients, and shunting of the ventricular system is common, with revisions often required during childhood. By puberty as many as 50% of patients who have received shunts have little or no requirement for them.[84] Early and aggressive surgical treatment of spina bifida cystica has improved survival from 45% in the early 1970s to 70% to 90% by the mid-1980s. Obstetric and anesthesia providers can expect to encounter a growing number of pregnant women with spina bifida cystica.[85] Unfortunately, many surviving patients have significant residual neurologic impairment and ongoing orthopedic and genitourinary complications. Myelomeningocele is a progressive neurologic disease that eventually produces orthopedic, neurologic, and genitourinary complications. Kyphoscoliosis, which is common in patients with a thoracic lesion, occurs in 20% of patients with a lumbosacral defect.[86] Paralytic scoliosis is the most common type and results from an imbalance of paravertebral muscle tone.

Occult spinal dysraphism is an intermediate group of conditions in which the bony defect is associated with one or more anomalies of the spinal cord, including intraspinal lipomas (the most common), dermal sinus tracts, dermoid cysts, fibrous bands, and diastematomyelia (split cord). These lesions are differentiated from the more benign occulta lesions described previously.[87,88] Affected patients may have no neurologic symptoms or may have minor sensory, motor, and functional deficits of the lower limbs, bowel, and bladder[89]; they also may have orthopedic issues, such as scoliosis, limb pain, and lower extremity abnormalities.[90] Patients with cord abnormalities have cutaneous stigmata in 50% of cases, and 70% have a tethered spinal cord, which has implications for neuraxial anesthesia.[91]

Tethered Cord and Arnold-Chiari Malformation

Tethered cord syndrome (TCS) is characterized by neurologic deterioration secondary to traction on the conus medullaris, which typically, but not invariably, is low lying (L2 to L3).[87,91] Congenital abnormalities of the spinal cord such as lipoma, tight filum terminale, dermal sinus, meningocele manqué, and diastematomyelia are found in more than 50% of patients with adult-onset TCS.

A new classification of TCS in adults has been proposed to differentiate tethered cord occurring secondary to spina bifida cystica from the adult-onset neurologic

syndrome associated with spinal dysraphism.[92] Magnetic resonance imaging studies suggest that tethering is present in virtually all patients with spina bifida cystica and myelomeningocele, and it is also common in patients with occult spinal dysraphism.[88] Although many of the latter patients do not have obvious neurologic impairment secondary to the tethering, adults with TCS often have a long history of minor neurologic or orthopedic issues.[87,92] Others present with acute symptoms after a precipitating event that stretched the spinal cord, such as heavy lifting or placement in the lithotomy position.[93] Of note, more than 50% of adults with TCS present only with a history of low back and leg pain before a precipitating event that leads to the diagnosis.[87,88]

Low-lying spinal cords and the possibility of undiagnosed TCS have come to the attention of obstetric anesthesiologists with the publication of several case reports of neurologic injury after spinal or epidural anesthesia for delivery in women subsequently diagnosed with occult spinal dysraphism.[89,90] An important feature of adult TCS is that the low-lying cord is located more posteriorly than a normal cord, increasing the likelihood of direct needle trauma during administration of spinal or epidural anesthesia (Figure 48-10).[94] As noted previously, the isolated finding of a defective laminar arch (spina bifida occulta) is not associated with a low-lying or tethered cord.[87]

More severe forms of spina bifida may also be associated with **Arnold-Chiari malformation,** which is characterized by cerebellar herniation through the foramen magnum and descent of the pons and medulla. Tethered cord from a tight filum terminale has also been deemed causal in the development of syringomyelia and subsequent Arnold-Chiari syndrome.[95] Symptoms are more common if the cerebellar herniation exceeds 12 mm or if syringomyelia is present.[96,97]

FIGURE 48-10 ■ Magnetic resonance image of the spine in a 27-year-old woman with history of a lumbar myelomeningocele excised as a neonate, with residual bladder dysfunction. A tethered spinal cord is present with a typical posterior low-lying position. The *white arrow* indicates the termination of the conus medullaris at L4 to L5, and the *black arrow* indicates the filum terminale located at L5 to S1. (This patient had a vaginal delivery at term, requiring only nitrous oxide for analgesia.)

Obstetric Management

Pregnancy is not complicated by the presence of a spina bifida occulta lesion. However, women with known TCS should avoid both the squatting position and a prolonged lithotomy position for delivery. Recurrent urinary tract infection is the most common antenatal complication in patients with spina bifida cystica and is associated with preterm labor.[85] Intestinal and urinary tract obstruction, as well as problems related to ileal conduits and stomas, are common during pregnancy, as are pressure sores resulting from greater immobility.[85] Uterine enlargement may compromise pulmonary function, especially in patients with kyphoscoliosis. Vaginal delivery is more common in women who are independently mobile and is less common in wheelchair-dependent patients.[85] Pelvic and lower limb anomalies and contractures may obstruct the pelvic outlet and warrant cesarean delivery. The obstetrician should evaluate the adequacy of the pelvis to determine whether a trial of labor is appropriate. Cesarean delivery is reserved for obstetric indications, and its incidence is increased and proportionate to the severity of the underlying defect and its consequences. Cesarean delivery is complicated by the presence of stomas and conduits; postoperative complications and prolonged hospital stays are common.[85]

Anesthetic Management

The epidural space may be incomplete or discontinuous across the level of **spina bifida occulta** lesions because of absence of the lamina and variable formation of the ligamentum flavum at this site. An attempt to identify the epidural space at the site of this lesion will likely result in unintentional dural puncture, although successful epidural analgesia has been reported with the catheter placed within the zone of the lesion. Fortunately, for two reasons, spina bifida occulta rarely causes issues for administration of neuraxial anesthesia. First, the lesion typically occurs at the L5 to S1 segments, below the level at which most epidural and spinal anesthetics are administered. Second, the most common anomaly is a simple midline split in the lamina, and this defect rarely seems to interfere with either the performance or the development of spinal or epidural anesthesia.

Occult spinal dysraphism is of more concern because of the potential for a low-lying, posteriorly located, and tethered spinal cord. A neurologic history should be taken and a screening neurologic examination should be performed in all women with a known defective laminar arch, preferably antenatally, to determine whether magnetic resonance imaging for spinal dysraphism is necessary.[90,98] The presence of skin dimpling or hair tufts should raise suspicion that an underlying cord abnormality exists. In my judgment, in women with a known low-lying cord, epidural anesthesia performed by an experienced anesthesiologist is safer than spinal anesthesia. If spinal dysraphism is suspected but no imaging studies are available, it would be prudent to avoid neuraxial anesthesia. Women with TCS may prefer to avoid neuraxial anesthesia because of the greater potential for direct neural trauma.

In the patient with a **spina bifida cystica** lesion, the anesthesiologist should determine the level of the lesion and whether the patient has residual spinal cord function below it. Patients with a complete lesion at or above T11 are likely to experience painless labor. However, the risk for autonomic hyperreflexia should be evaluated in patients with thoracic lesions, and prophylaxis should be provided if the patient is deemed to be at risk; this issue is especially important if the lesion is between T5 and T8. If the patient has undergone ventricular shunt placement, the current status of the shunt should be determined. Neurosurgical consultation should be obtained if questions remain about the requirement for—or function of—the shunt. Pulmonary function should be assessed, especially in patients with scoliosis. Baseline renal function also should be determined.

There are published reports of the use of epidural and spinal anesthesia in patients with spina bifida cystica.[83,98-100] Unfortunately the experience is limited, and most published series of pregnant women with spina bifida cystica report neither the type of anesthesia provided nor the complications experienced. Tidmarsh and May[99] reported management of intrapartum analgesia in 16 patients with spina bifida, 8 of whom had spina bifida cystica (with meningomyelocele). Five of the eight patients with spina bifida cystica received epidural analgesia for labor and/or delivery. Three patients had a "normal" block, one patient had a somewhat high block (sensory block level of T3 after administration of 10 mL of 0.25% bupivacaine), and one patient had poor sacral analgesia. In the U.K. Registry of High-Risk Obstetric Anesthesia, the period from 1997 through 2002 included 23 cases of parturients with spina bifida among 102 cases of neurologic conditions.[101] Of those, the extent of spina bifida was defined further in only 10 cases, and 8 had spina bifida occulta. Neuraxial anesthesia was provided in 8 cases, although 17 patients had planned to receive neuraxial anesthesia if needed. Only epidural anesthesia was used owing to concern about a low-lying or tethered cord; only 5 patients had magnetic resonance imaging performed before delivery.

Limited data exist on the obstetric anesthesia experience in parturients with Arnold-Chiari malformations. The largest series is that of Chantigian et al.,[96] who described their experience with 12 parturients who delivered a total of 30 infants. Nine deliveries were accomplished with neuraxial anesthesia, including six vaginal deliveries with epidural analgesia, two cesarean deliveries performed with single-shot spinal anesthesia, and one cesarean delivery performed with a spinal catheter. No patient experienced postprocedural neurologic sequelae related to the use of neuraxial anesthesia.

Administration of epidural or spinal anesthesia may be considered in women with various forms of spina bifida and stable neurologic function. Patients should be informed that there is limited published information on the administration of neuraxial anesthesia (and the risk for neurologic injury) in patients with neural tube defects, and these patients should be actively involved in decision-making. In patients with either surgically corrected spina bifida cystica or occult spinal dysraphism, the anesthesiologist should be aware that the terminal portion of the spinal cord typically lies at a vertebral level lower than normal. Imaging studies provide valuable information on neural anatomy and facilitate anesthetic management. In women with spinal dysraphism, a neurologic examination, as well as a full discussion of the risks and benefits of neuraxial anesthesia, should be performed and documented before administration of neuraxial anesthesia. A recent report by Asakura demonstrated that ultrasonography can be used to detect spina bifida occulta[102]; however, ultrasonographic imaging of the terminal portion of the cord would be much more difficult, although it has been shown to be feasible in children.[103] Spinal anesthesia should be performed below the known level of the conus or avoided in favor of epidural anesthesia. In women with spina bifida or occult spinal dysraphism, the epidural space is often abnormal, which increases the likelihood of inadequate epidural anesthesia. In our judgment, spinal anesthesia is not contraindicated in women with negligible function of the lower extremities and sphincters, given that the concern for direct neural trauma to a low-lying spinal cord is not clinically relevant.

ACHONDROPLASIA

Achondroplasia, an inherited disorder of bone metabolism, is the most common cause of disproportionate dwarfism, with a prevalence of 1 in 26,000 live births. Although it is inherited in an autosomal dominant mode, most cases arise from spontaneous mutation.[104] The range of cervical motion may be decreased, lumbar lordosis and thoracic kyphosis are increased, and thoracic kyphoscoliosis occurs.[105] The vertebral pedicles are short, and reduced length of the neural arch leads to shortened anteroposterior and transverse diameters of the vertebral canal, resulting in foramen magnum and spinal stenosis.[106,107] Although it may occur earlier, symptomatic spinal stenosis often does not present until the fourth or fifth decade, when kyphosis, scoliosis, osteophytes, and herniated discs typically cause further narrowing of the spinal canal. There is considerable interindividual variation in the clinical and radiographic characteristics, and skeletal abnormalities often show more variation than consistency.[106,108]

Obstetric Management

The uterus is an abdominal organ in the achondroplastic patient.[109] With advancing pregnancy it may encroach on the small thoracic cage and lead to decreases in the functional residual and closing capacities; severe dyspnea may occur with advancing gestational age. Back discomfort is common during pregnancy, and the reported incidence of sciatica is greater than in normal pregnant women,[110] most likely owing to the underlying spinal abnormalities. Typically, an inadequate maternal pelvis combined with a normal-sized (nonachondroplastic) fetus results in cephalopelvic disproportion. Imaging techniques may be used to confirm this situation, and the obstetrician should anticipate the need to deliver most patients with achondroplasia by cesarean delivery.[105,106]

Anesthetic Management

The short, obese limbs of the patient with achondroplasia may make it difficult to obtain measurements of blood pressure with a noninvasive cuff, and an intra-arterial catheter may be necessary. Prominent paraspinal muscles and marked lumbar lordosis may complicate attempts to palpate landmarks during the administration of spinal or epidural anesthesia; the use of ultrasonography may help identify landmarks.[105] Scoliosis of the spine also may cause technical difficulties with neuraxial anesthesia attempts. The small stature and spinal stenosis reduce the dose of local anesthetic required for major neuraxial anesthesia.[105,108,109,111] It is difficult to estimate the appropriate dose of local anesthetic for single-shot spinal anesthesia. Continuous epidural anesthesia or CSE anesthesia is preferable because it allows the anesthesia provider to titrate the dose of local anesthetic to the desired level of anesthesia. Local anesthetic dose requirements are typically smaller than those in parturients of normal stature[112]; this is not always the case, however, supporting the use of a neuraxial anesthetic technique that may be titrated to the desired effect.[110,113,114]

Difficult tracheal intubation has been reported in achondroplastic patients and should be anticipated. A case report noted that use of a video laryngoscope did not allow visualization of the vocal cords, and flexible fiberoptic bronchoscopy was required to intubate the trachea in an achondroplastic dwarf undergoing cesarean delivery.[115]

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is an inherited condition that occurs with an incidence between 1 in 21,000 and 1 in 60,000.[116,117] The genetic defect is within the genome that encodes for type I collagen, the major collagen in tissues that require structural strength. The disease is a generalized connective tissue disorder, and expression ranges from mild osteoporosis to the classical clinical stigmata characterized by multiple bone fractures and skeletal deformities, blue sclera, and middle ear deafness (otosclerosis). Four types may be distinguished clinically, and a system of classification (types I through IV) has been proposed.[118] Type I is the prototype disease. It is inherited as an autosomal dominant trait and is the most common and mildest form of this disease. It typically manifests in childhood as multiple fractures after minor trauma.[118] Types II and III are inherited as autosomal recessive traits and are characterized by extreme bone fragility. Type II is uniformly lethal, and stillbirth or early neonatal death is common; death *in utero* is caused by skeletal collapse, and early neonatal death typically results from chest wall failure and respiratory insufficiency. Infants with type III disease may have fractures at birth and may have progressive skeletal deformities during the first two decades of life. Type IV, also autosomal dominant, is much less common and is variable in expressivity.

The majority of pregnant women with osteogenesis imperfecta have type I disease, although pregnancy has been reported in more severe forms of the disease.[117,119]

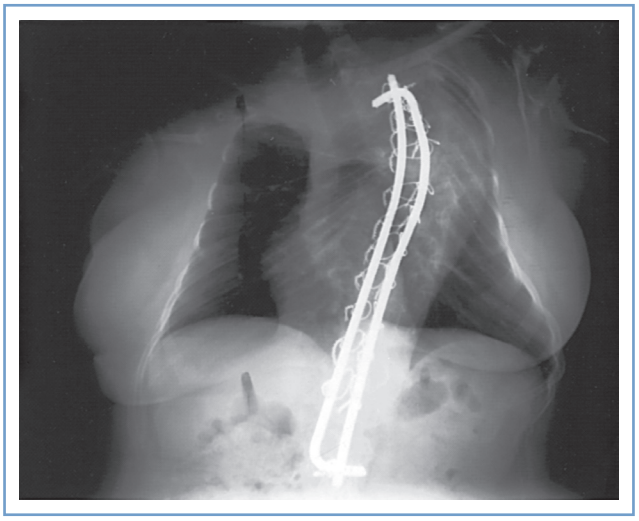

FIGURE 48-11 ■ A chest radiograph of a 30-year-old woman with osteogenesis imperfecta type I. Generalized osteoporosis, corrected thoracic kyphoscoliosis, a restricted thoracic cage, and multiple old fractures are demonstrated. (General anesthesia was provided for cesarean delivery and tubal ligation.)

There is considerable variability among affected patients as to the age at onset and frequency of fractures. Dwarfism is typical, and kyphoscoliosis is common, as are other chest wall abnormalities. These chest and spinal abnormalities result in restrictive lung disorders (Figure 48-11). Other abnormalities include a decrease in the range of motion of the shortened cervical spine, micrognathia, and malformed, brittle teeth.[119] Poor platelet adhesion may cause platelet dysfunction and a modest bleeding tendency. Hyperthyroidism occurs in 40% of patients with osteogenesis imperfecta; an elevated concentration of thyroxine leads to increases in both oxygen consumption and heat production.[118,119] Association with malignant hyperthermia is very weak; there is only one published case of a patient with osteogenesis imperfecta who developed malignant hyperthermia.[120] Intraoperative hyperthermia has often been reported; however, a recent retrospective cohort study of 49 patients with osteogenesis imperfecta undergoing noncardiac surgery revealed no difference in intraoperative temperature changes as compared with matched controls.[121] This recent information should allay ongoing concerns about risk for developing malignant hyperthermia.

Obstetric Management

Pregnancy results in transfer of calcium from the mother to the fetus, which in the patient with osteogenesis imperfecta can lead to increased fracture risk. In one published case, quantitative ultrasonometry of the phalanges was used to follow a woman with type I osteogenesis imperfecta who had increasing joint arthralgias to assess her fracture risk.[122] By 33 weeks' gestation, the ultrasonometry data and increased pain level guided the decision for early elective cesarean delivery. Platelet dysfunction in osteogenesis imperfecta may result in a higher incidence of intrapartum and postpartum hemorrhage,

although this finding is uncommon. Labor and vaginal delivery is associated with an increased risk for uterine rupture and pelvic fracture[123]; maternal pelvic fracture during pregnancy is an indication for cesarean delivery. These complications are also uncommon and most likely are influenced primarily by the severity of the underlying disease. Cephalopelvic disproportion typically mandates cesarean delivery in severely affected parturients.

Anesthetic Management

The anesthesiologist must be aware of the fragility of the bones, the potential for difficult tracheal intubation, and the presence and severity of restrictive lung disease. Transfers, positioning, and any invasive intervention must be accomplished with extreme care. Blood pressure cuffs and tourniquets to facilitate placement of intravenous catheters should be applied gently to prevent fractures. Difficult tracheal intubation may occur because of a short neck with limited range of motion and should be anticipated.[119] The anesthesiologist should take care not to hyperextend the neck, and laryngoscopy should be gentle to avoid fractures. Alternatives to direct laryngoscopy may be considered to reduce the applied forces necessary. If succinylcholine is used, a defasciculating dose of a nondepolarizing muscle relaxant should be employed in an attempt to prevent fasciculations.[124] An alternative to succinylcholine (e.g., rocuronium) may also be administered to prevent fasciculations.

Before administration of neuraxial anesthesia, the anesthesiologist should consider the technical difficulties inherent in performing neuraxial anesthesia in patients with spinal deformities. The anesthesiologist also should be aware of the platelet dysfunction in these patients. This risk is best evaluated by obtaining a thorough history before the administration of neuraxial anesthesia. In the setting of a reassuring history, neuraxial anesthesia need not be withheld. A hematology consult to better assess platelet function can be requested, if there is any doubt. Small stature and spinal abnormalities reduce the local anesthetic dose requirements and increase the risk for both misplaced injection and local anesthetic toxicity. It may be difficult to estimate the appropriate dose for single-shot spinal anesthesia in these patients. Thus, continuous epidural, continuous spinal, or CSE anesthesia is the neuraxial anesthetic technique of choice, barring other contraindications.[125] Yeo and Paech[126] reported the successful use of both epidural and subarachnoid blocks for cesarean delivery on five occasions over 9 years in a single patient with type I osteogenesis imperfecta. The use of ultrasonography may facilitate the administration of neuraxial anesthesia.

SPONDYLOLISTHESIS

Isthmic spondylolisthesis is a condition in which a defect in the pars interarticularis of a vertebra allows anterior slippage of the subjacent portion of the spine. As the body slips forward, it does not carry the neural arch with it; thus, there is little tendency toward spinal canal stenosis. Isthmic spondylolisthesis typically occurs at the lumbosacral junction, although it is not uncommon in the lumbar spine. Approximately 38% of cases occur in women.[127] The onset is common in the second and third decades, a period of peak childbearing potential.

Back pain is the presenting feature. Strenuous physical activity often precipitates the onset of pain. Pregnancy increases back symptoms in approximately half of patients with isthmic spondylolisthesis, but obstetric complications are unusual.[127,128] This disorder is not affected by pregnancy.[129]

Degenerative spondylolisthesis occurs when there is a forward slip of one vertebra on the subjacent level with no break in the neural arch.[130] It is four times more common in women than in men and occurs most frequently at the L4 to L5 level. It is not usually diagnosed before the onset of the fourth decade of life and seems to be twice as common in parous women. It is suggested that rotational and sheer stresses on the L4 to L5 joint during gestation may be responsible for the higher incidence of degenerative spondylolisthesis in women who have borne children.

There is no published case of neuraxial anesthesia during labor in a parturient with severe spondylolisthesis (e.g., lumbosacral subluxation). Ideally, an anesthesiologist will see the patient during pregnancy to assess her symptoms and lumbar spinal anatomy. In the absence of evidence of a neurologic deficit, it seems appropriate to administer either epidural or spinal anesthesia. There is one note of caution: Horduna and Legaye[131] have shown that the presence of spondylolisthesis affects the relative position of the palpated intercristine line. As a result, in patients with high-grade spondylolisthesis, the actual lumbar interspace is one to three segments higher than is normally expected when using the palpated intercristine line as a guide for neuraxial anesthesia needle placement. It would be reasonable to use preprocedural ultrasonography to identify the appropriate lumbar interspace before needle insertion in parturients with known spondylolisthesis.

KEY POINTS

- Lumbopelvic pain is the most common musculoskeletal complaint during pregnancy. It results from both hormonal and mechanical factors.
- Low back pain does not contraindicate the administration of spinal or epidural anesthesia.
- Corrected idiopathic thoracolumbar scoliosis is the most common major musculoskeletal disorder seen in pregnant women. Prepregnancy pulmonary function is a better predictor of maternal outcome than the severity of the curve.
- Neuraxial anesthesia is technically challenging in patients with scoliosis, and the anesthesiologist should anticipate a greater incidence of complications and inadequate anesthesia.

- Maternal rheumatoid arthritis is associated with prematurity and low birth weight, but ankylosing spondylitis does not adversely affect the outcome of pregnancy.
- Pregnancy often ameliorates the symptoms of rheumatoid arthritis.
- Spina bifida occulta is a common incidental finding and does not contraindicate the administration of spinal or epidural anesthesia.
- Spina bifida cystica and occult spinal dysraphism are associated with a high incidence of tethered cord, which may complicate the administration of subarachnoid (spinal) anesthesia.
- Cephalopelvic disproportion often mandates cesarean delivery in parturients with achondroplasia or osteogenesis imperfecta.
- Ultrasonography is rapidly becoming a useful tool to facilitate administration of neuraxial anesthesia in patients with challenging spinal anatomy.

CHAPTER 52

Renal Disease

Yaakov Beilin, MD

CHAPTER OUTLINE

"Children of women with renal disease used to be born dangerously or not at all—not at all if their doctors had their way."[1] This statement describes early experiences with maternal renal disease and pregnancy outcome. It remains true that renal disease, either preexisting or occurring during gestation, may impair maternal and fetal health. Experience and investigations during the past three decades have significantly improved the outcome for pregnant women with renal disease.[2]

PHYSIOLOGIC CHANGES IN PREGNANCY

A review of the renal physiologic changes that occur during normal pregnancy is helpful to understand and evaluate coexisting renal disorders (see Chapter 2). Early in gestation, increased intravascular volume leads to renal enlargement. Hormonal changes result in dilation of the renal pelvis and ureters; dilation often is accompanied by decreased ureteral peristalsis. Dilated uterine and ovarian veins, and the gravid uterus, may obstruct ureter drainage at the pelvic brim. Together, these changes predispose pregnant women to vesicoureteric reflux and ascending infection. Alterations in glomerular hemodynamics and tubular function also occur. Increased cardiac output and decreased intrarenal vascular resistance cause an 80% increase in renal blood flow and a 50% increase in glomerular filtration rate (GFR) during pregnancy. These changes are somewhat less pronounced near term. Because of the increased GFR, a serum creatinine concentration greater than 0.6 to 0.8 mg/dL and a blood urea nitrogen (BUN) concentration greater than 8 to 9 mg/dL (upper limit of normal for the pregnant patient) suggest renal insufficiency in the pregnant woman. Tubular sodium reabsorption and osmoregulation are reset, allowing a "physiologic hypervolemia" during gestation. Modest proteinuria, up to 300 mg in 24 hours, also occurs during pregnancy.[3]

Urinary tract infections (see Chapter 37) and renal dysfunction associated with hypertensive disorders of pregnancy (see Chapter 36) are discussed elsewhere in this text.

RENAL PARENCHYMAL DISEASE

Definition and Pathophysiology

Renal parenchymal disease consists of two general groups of disorders, **glomerulopathies** and **tubulointerstitial**

disease. Glomerulopathies are further subdivided into disorders that involve inflammatory or necrotizing lesions—the **nephritic syndromes**—and disorders that involve abnormal permeability to protein and other macromolecules—the **nephrotic syndromes**. More than 20 specific glomerulopathies exist. The nomenclature for these glomerulopathies is complex, and specific diseases are not discussed in detail here.

Tubulointerstitial diseases are disorders characterized by abnormal tubular function. They result in abnormal urine composition and concentration but are not characterized by decreased GFR until late in the disease course. The disorders in this category include interstitial nephritis, renal cystic disease, renal neoplasia, and functional tubular defects.

Patients with renal parenchymal disorders may remain asymptomatic for years, and they may exhibit only proteinuria and microscopic hematuria, with little if any evidence of reduced renal function. Spontaneous recovery or improvement with treatment occurs with many glomerulopathies. However, other patients exhibit progressive nephropathy, hypertension, and renal insufficiency. The incidence of kidney disease in pregnancy is approximately 0.12%.[4] In two thirds of these patients, the disorder results from glomerulopathy, and in one third, from tubulointerstitial disease.[5]

Diagnosis

Women with preexisting disease may choose to become pregnant without the counsel of their nephrologist. When such patients become pregnant, the obstetrician and nephrologist seek to define the extent of renal involvement. Serial blood pressure measurements are obtained to define the severity of hypertension and the efficacy of current antihypertensive therapy. Creatinine clearance and the level of proteinuria should be determined. Urinalysis yields information about the presence of renal casts and bacteriuria. The determination of serum creatinine and BUN concentrations defines the extent of renal insufficiency. A serum creatinine concentration greater than 0.8 mg/dL, which may be normal in the nonpregnant woman, may represent significant renal insufficiency during pregnancy. Alternatively, the obstetrician may first detect renal dysfunction through routine prenatal screening tests. If proteinuria, hematuria, or azotemia is detected, a complete biochemical evaluation should be performed.

Both preeclampsia and renal disease may manifest as hypertension, proteinuria, and edema. The distinction between the two disorders is often unclear, especially after 20 weeks' gestation. Fisher et al.[6] evaluated 176 renal biopsy specimens obtained from hypertensive women immediately postpartum, most of whom had a clinical diagnosis of preeclampsia. The clinicopathologic correlation was poor. Histologic evidence of preeclampsia (e.g., glomerular endotheliosis without hypercellularity) was present in only 65% of these hypertensive women. Primary renal disease was present in 20%, and hypertensive nephrosclerosis occurred in 11%. Nulliparous women (84%) were more likely to have a correct diagnosis of preeclampsia than parous women (38%).

Renal tissue biopsy is often used to establish a diagnosis in nonpregnant patients. Chen et al.[7] reported a series of 15 percutaneous renal biopsies performed in 15 pregnant women with onset of renal dysfunction of unknown cause during pregnancy. All patients underwent biopsy before 30 weeks' gestation. A biopsy-related complication occurred in only one patient who experienced gross hematuria. The authors judged that histologic results provided useful clinical guidance that facilitated successful fetal outcome in 14 of the pregnancies. More recently, Day et al.[8] performed renal biopsy in 20 pregnant women; the biopsy results led to altered management in 9 of 20. One patient had minor hematuria that resolved spontaneously. In contrast, Kuller et al.[9] reviewed 18 renal biopsies performed during pregnancy (n = 15) or in the immediate postpartum period (n = 3) in 15 women with elevated blood pressure. After the biopsy, renal hematoma was identified in 7 (39%) women, and 2 (11%) women required blood transfusion. Four intrauterine fetal deaths occurred, although none was a direct result of the biopsy. It is possible that women with elevated blood pressure are at a greater risk for postbiopsy complications. Because renal biopsy exposes the pregnant woman to potential complications, many perinatologists recommend biopsy only when sudden deterioration in renal function or symptomatic nephrotic syndrome occurs before 28 weeks' gestation, at which time definitive diagnosis may guide appropriate treatment. For problems beyond 28 weeks' gestation, the recommendation is to delay biopsy until the postpartum period.[8,9]

Effect of Pregnancy on Preexisting Kidney Disease

The extent to which pregnancy affects preexisting renal disease depends on the level of renal insufficiency before pregnancy. Among women with mild antenatal renal insufficiency, pregnancy does not substantially alter the natural course of renal disease.[10,11] Jungers et al.[10] evaluated the effect of pregnancy on renal function among 360 women with primary glomerulonephritis. During the study period, 171 (48%) women became pregnant. All study subjects had normal renal function at the time of entry into this study, and all of the patients who became pregnant had normal renal function at conception. In this case-controlled study, pregnancy was not identified as a risk factor for progression to end-stage renal failure. Limardo et al.[11] evaluated 223 women with biopsy-documented IgA nephropathy who had a serum creatinine level greater than 1.2 mg/dL, 136 of whom became pregnant. Women were observed for a minimum of 5 years (median, 10 years), and pregnancy did not seem to affect long-term outcome of kidney disease or the onset of proteinuria or hypertension.

In contrast, Jones and Hayslett[12] analyzed the outcome of 82 pregnancies in 67 women with preexisting moderate or severe renal insufficiency (i.e., serum creatinine level > 1.4 mg/dL before pregnancy or at the first antepartum visit). The mean ± SD serum creatinine concentration increased from 1.9 ± 0.8 mg/dL in early pregnancy to 2.5 ± 1.3 mg/dL in the third trimester. The prevalence of hypertension rose from 28% at baseline to 48%

during late pregnancy. Pregnancy-related deterioration of maternal renal function occurred in 43% of cases. Purdy et al.[13] also found that greater than 40% of women with moderate to severe kidney disease had deterioration in renal function due to pregnancy. Women with a serum creatinine concentration greater than 2.0 mg/dL who became pregnant had a one-in-three chance of developing dialysis-dependent end-stage renal disease during or shortly after pregnancy.[14]

The pathophysiology by which pregnancy exacerbates renal disease is unknown. One hypothesis is that increased glomerular perfusion, which normally accompanies pregnancy, paradoxically causes further injury to the kidneys in patients with preexisting impairment of function. However, this hypothesis is unsupported by published data, which demonstrate no evidence of hyperfiltration (i.e., an initial decline in serum creatinine concentration) during early pregnancy in patients with renal disease.[15] An alternative hypothesis is that preexisting renal disease may induce a cascade of platelet aggregation, microvascular fibrin thrombus formation, and endothelial dysfunction that leads to microvascular injury in the already tenuous kidneys.[14]

Effect on the Mother and Fetus

Pregnant women with chronic kidney disease are at an increased risk for maternal and fetal complications. Nevis et al.[16] systematically reviewed all published observational studies of women with chronic kidney disease that included a control group for comparison, excluding retrospective studies. They identified 13 studies that included at least five women between 1966 and 2010. Maternal complications included gestational hypertension, preeclampsia/eclampsia, and maternal mortality. Adverse fetal outcomes included preterm births, fetal growth restriction (also known as intrauterine growth restriction), small-for-gestational-age infants, neonatal mortality, stillbirths, and low birth weight. Adverse maternal outcomes were found in 12 studies, and the incidence was five times greater than in women without kidney disease. Adverse fetal outcomes were identified in nine studies, and the incidence was two times greater than in the normal healthy women.

The incidence of obstetric complications is proportional to the extent of preexisting maternal renal disease and preexisting hypertension.[17] Bar et al.[18] evaluated maternal and neonatal outcomes in 38 women (46 pregnancies) with primary renal disease. They observed an increase in complications compared with healthy women (Figure 52-1). In a logistic regression model, only preexisting hypertension and a high preconception serum uric acid level predicted worse outcome. Other factors (e.g., degree of preexisting renal impairment) were not significant predictors, but, of note, 90% of the cohort had mild disease. In a study of women with moderate to severe renal disease, Jones and Hayslett found the complication rate was much greater.[12] The incidence of preterm birth was 59%, the incidence of fetal growth restriction was 37%, and the cesarean delivery rate was 59%. Ramin et al.[19] reviewed the literature for studies of renal disease and maternal and fetal outcome. Overall, fetal survival ranged from 64% to 98% depending on the extent of renal insufficiency and the presence or absence of hypertension.

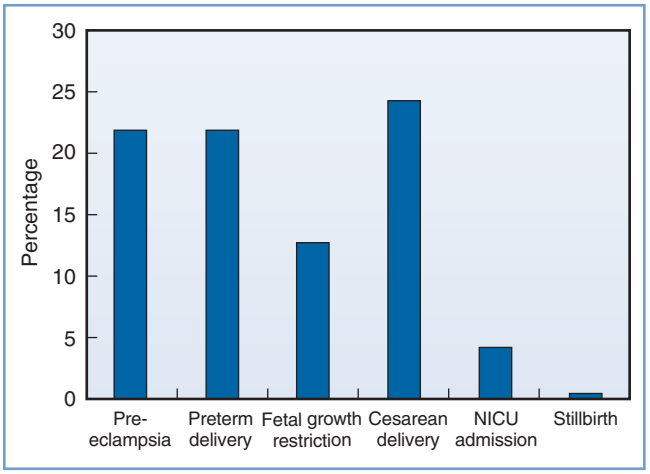

FIGURE 52-1 ■ Rate of short-term pregnancy outcome in women with primary renal disease. *NICU,* neonatal intensive care unit. (From Bar J, Orvieto R, Shalev Y, et al. Pregnancy outcome in women with primary renal disease. Isr Med Assoc J 2000; 2:178-81.)

Medical and Obstetric Management

During pregnancy, the nephrologist and the obstetrician monitor maternal renal function, blood pressure, and fetal development at frequent intervals. Monthly determination of serum creatinine concentration, creatinine clearance, and proteinuria allows the recognition of renal deterioration. An antepartum consultation with the anesthesiologist should also be considered.

Some glomerulopathies respond to corticosteroids, and corticosteroid therapy should be continued during pregnancy. Rapid deterioration of renal function that occurs before 28 weeks' gestation may require renal biopsy to exclude rapidly progressive glomerulopathies that require treatment. Antihypertensive therapy should be instituted as needed (see Chapter 36). Recombinant human erythropoietin improves maternal anemia during pregnancy.[20] Protein restriction places the fetus at risk for growth restriction and is not used. Deterioration of maternal renal function, the onset of preeclampsia, or evidence of fetal compromise may necessitate preterm delivery.

Hemodialysis and Long-Term Ambulatory Peritoneal Dialysis

When renal disease has progressed to end-stage renal failure (i.e., GFR < 5 mL/min), fertility is suppressed and conception and pregnancy are rare. Less than 10% of premenopausal patients undergoing dialysis have regular menses. Luteinizing hormone and follicle-stimulating hormone concentrations assume an anovulatory pattern, which causes 40% of affected women to be amenorrheic. Half of all female patients undergoing dialysis exhibit hyperprolactinemia because of reduced clearance and

hypothalamic disturbances.[21] Toma et al.[22] surveyed 2504 dialysis units in Japan and reported only 172 pregnancies among 38,889 women who were undergoing dialysis.

There are two modalities of dialysis: extracorporeal hemodialysis and intracorporeal peritoneal dialysis. **Hemodialysis** necessitates vascular access and the need for anticoagulation of the extracorporeal circuit and may be complicated by cardiovascular instability, large fluid and electrolyte shifts, and the risk for hepatitis. Hypotension may compromise uteroplacental perfusion and cause fetal compromise. Even when hypotension and major fluid shifts are avoided, Doppler ultrasonographic examination of uterine and umbilical artery flow during hemodialysis suggests the occurrence of a redistribution of arterial flow away from the uteroplacental vascular bed.[23] Fetal heart rate monitoring is recommended during dialysis.[24] Rapid removal of maternal solutes and reduced oncotic pressure with attendant free-water diffusion into the amniotic cavity may lead to polyhydramnios. Hemodynamic consequences are minimized by more frequent but shorter dialysis runs. Long-term ambulatory **peritoneal dialysis** allows less hemodynamic trespass, a more stable fetal environment, and the freedom to undergo dialysis at home. However, peritoneal dialysis may not be associated with greater fetal survival. Complications of this modality include peritonitis and catheter difficulties.[25]

Published reports have noted a wide range of successful pregnancies in dialysis-dependent pregnant women, regardless of the modality of dialysis. Toma et al.[22] reported that 90 (52%) of 172 pregnancies in women undergoing long-term hemodialysis were successful. More recently, because of improvement in maternal-fetal care, the success rate appears to be improving. Chou et al.[26] pooled data from 10 published case series and 12 case reports and found that 71% of women undergoing hemodialysis and 64% of women undergoing peritoneal dialysis had a successful delivery. Similarly, Piccoli et al.[27] pooled data from 10 studies that included 90 conceptions in 78 women and reported successful delivery can be achieved 75% of the time.

Maternal complications include malnutrition, anemia, and hypertension. Fetal complications include fetal growth restriction, fetal death, and preterm labor. BUN levels should be kept below 50 mg/dL before dialysis and below 30 mg/dL after dialysis.[25] At birth, azotemia in the newborn is similar to that in the mother, but this quickly corrects because the newborn has normal kidney function. The long-term effects of intrauterine azotemia on newborn cognitive development are unknown.[28]

Patients undergoing hemodialysis have a high prevalence of viral hepatitis, a greater frequency of active tuberculosis, and a higher rate of infection with vancomycin-resistant enterococci, human immunodeficiency virus (HIV), and methicillin-resistant *Staphylococcus aureus*. The risk for hepatitis C virus (HCV) infection is particularly of concern, with reported rates as high as 36%. However, with improvement in aseptic technique and more attention to hand washing, the decline in the reuse of dialysis equipment, and the use of dedicated isolated dialysis machines for HCV-seropositive patients, the rates of infection and seroconversion can be markedly reduced.[29,30]

Anesthetic Management

Anesthetic management is influenced by the extent of renal dysfunction and hypertension. The parturient with stable renal disease, mild to moderate renal insufficiency, well-controlled hypertension, and euvolemia requires minimal special consideration. In contrast, the dialysis patient with end-stage renal failure presents many anesthetic challenges because renal disease may affect almost every organ system (Box 52-1). Poorly controlled hypertension leads to left ventricular hypertrophy and dysfunction. Symptoms of cardiovascular compromise should prompt echocardiography to evaluate ventricular

BOX 52-1 Chronic Renal Failure: Abnormalities That May Affect Anesthetic Management

Cardiovascular
- Hypertension
- Fluid overload
- Ventricular hypertrophy
- Accelerated atherosclerosis
- Uremic pericarditis
- Uremic cardiomyopathy

Pulmonary
- Increased risk of difficult airway
- Recurrent pulmonary infections
- Pleural effusion

Metabolic and Endocrine
- Hyperkalemia
- Metabolic acidosis
- Hyponatremia
- Hypocalcemia
- Hypermagnesemia
- Decreased protein binding of drugs
- Hypoglycemia

Hematologic
- Anemia
- Platelet dysfunction
- Decreased coagulation factors
- Leukocyte dysfunction

Neurologic
- Autonomic neuropathy
- Mental status changes
- Peripheral neuropathy
- Restless legs syndrome
- Seizure disorder

Gastrointestinal
- Delayed gastric emptying
- Increased gastric acidity
- Hepatic venous congestion
- Hepatitis (viral or drug-induced)
- Malnutrition

Neurologic
- Autonomic neuropathy
- Peripheral neuropathy
- Cerebrovascular insufficiency

function. An intra-arterial catheter also may aid the management of the parturient with poorly controlled hypertension. Uremic pericarditis, cardiomyopathy, and accelerated atherosclerosis are rarely seen until advanced uremia has been present for several years.

Normochromic, normocytic anemia secondary to impaired erythropoietin production, chronic gastrointestinal bleeding, and vitamin deficiency are common findings. Typically, the anemia is well tolerated and does not require transfusion, unless excessive surgical bleeding occurs. Uremic toxins may cause functional platelet defects; these abnormalities are reversed by dialysis. Thrombocytopenia may also occur as a result of increased peripheral destruction of platelets. Generalized coagulopathy may result from the anticoagulation used during the dialysis process.[31] A full coagulation profile and careful bleeding history should be performed, especially before the initiation of neuraxial anesthesia. Hemodialysis fistulas should be padded carefully to prevent thrombosis. Blood pressure cuffs should not be placed on these extremities.

Neuraxial Anesthesia

Neuraxial anesthesia is the preferred technique for both labor analgesia and cesarean delivery, but there are some unique considerations in the parturient with renal disease. Uremic patients may be hypervolemic or hypovolemic, depending on the time elapsed since their last dialysis session. Hypovolemia and autonomic neuropathy may lead to profound hypotension during the initiation of sympathetic blockade. Intravascular volume should be assessed before induction of anesthesia. Assessment of clinical signs (e.g., skin turgor, mucous membranes, tachycardia) is generally sufficient. Central venous pressure monitoring or transthoracic echocardiography may be useful when the volume status remains unclear. Although there are no studies in the renal transplant patient, a role for intravenous prehydration to prevent hypotension is unlikely because this modality is not efficacious in the healthy parturient.[32] There is insufficient evidence to recommend spinal versus epidural techniques for the patient with renal disease. Frequent monitoring of blood pressure and immediate treatment of hypotension is suggested.[33] Preexisting peripheral neuropathy should be documented before the administration of neuraxial anesthesia.

Local anesthetic systemic toxicity (LAST) after bupivacaine brachial plexus blockade has been reported in patients with chronic renal failure.[34] Whether LAST is related to toxic levels of local anesthetic unique to the renal failure patient is unclear. Rice et al.[35] found no significant difference in the pharmacokinetic profile of bupivacaine after brachial plexus blockade in a group of uremic patients and in patients with normal renal function. There are no published data on the pharmacokinetics of epidurally administered local anesthetic agents in patients with chronic renal failure.

Orko et al.[36] administered spinal anesthesia with plain bupivacaine 22.5 mg to 20 nonpregnant patients with chronic renal failure and 20 control patients. Maximal segmental anesthesia occurred more rapidly in the patients with renal disease (21 versus 35 minutes), but the duration was reduced. Further, the extent of sensory blockade was two segments higher in the patients with renal disease. There were no untoward effects in any of the patients.

General Anesthesia

Patients with chronic uremia exhibit delayed gastric emptying and hyperacidity, which may increase the risk for aspiration pneumonitis. In addition to sodium citrate, when time allows, the anesthesia provider also should consider administering a histamine-2 (H_2)-receptor antagonist and metoclopramide. Recommended single doses for patients with renal failure are ranitidine 50 mg and metoclopramide 10 mg given intravenously. Weir and Chung[37] suggested that patients with chronic renal failure present greater difficulties with tracheal intubation than otherwise healthy patients; however, an objective analysis of airway difficulty has not been performed in this population.

All the standard induction agents are safe in patients with renal failure. Etomidate may have an advantage because it supports the circulation better than other induction agents. Propofol exhibits normal volume of distribution and elimination in patients with renal failure and is also commonly used. Protein binding of propofol is unaffected by renal failure.[38] Uremia increases blood-brain barrier permeability to many drugs.[39] These changes may warrant a small reduction in the dose of propofol or thiopental for induction. The serum potassium concentration should be determined before induction of anesthesia. If the potassium concentration is greater than 5.5 mEq/L, dialysis should be performed before an elective procedure. Succinylcholine will cause a 0.5 to 0.7 mEq/L increase in potassium concentration, which is similar to the increment that occurs in patients without renal disease.[40] If the patient is already hyperkalemic, this mild elevation may be sufficient to precipitate cardiac dysrhythmias. Plasma cholinesterase concentrations are normal, even after dialysis, and the duration of action of succinylcholine is not prolonged.[41]

Neuromuscular blockade should be maintained with an agent that does not rely on renal elimination. Cisatracurium undergoes Hofmann degradation, and therefore the duration of action is not prolonged in patients with renal failure. Hypermagnesemia, commonly found in patients with kidney disease, may potentiate neuromuscular blockade.[42] Although anticholinesterase agents undergo renal elimination and have a prolonged duration in patients with renal insufficiency, the volume of distribution remains the same and standard doses are used for the reversal of neuromuscular blockade.

Postoperative Analgesia

The principles of postoperative analgesia for the woman with renal disease are the same as for healthy woman, with some important considerations because drug clearance can be altered for opioids and their metabolites (see Chapters 27 and 28). Morphine is generally safe as a single dose, but with longer-term use its metabolite, morphine-6-glucuronide, may accumulate. Meperidine is

of particular concern because its active metabolite, normeperidine, is neurotoxic and is renally excreted. Hydromorphone and oxycodone, and their metabolites hydromorphone-3-glucuronide and α- and β-oxycodol, respectively, are also renally excreted and may accumulate with prolonged use. Methadone does not accumulate in patients with renal disease and may be a useful long-term analgesic. Fentanyl and sufentanil are only minimally excreted in the urine, and because they are short-acting drugs they may be particularly useful. Remifentanil is metabolized by blood and tissue esterases and is not dependent on the kidney for excretion, making it safe as well for use in patients with renal failure.[43] The safest approach may be to use neuraxial opioids because small doses are administered. Alternative techniques that avoid opioids such as transversus abdominis plane (TAP) block may also be considered, but the efficacy of TAP block for analgesia after cesarean delivery has been questioned (see Chapter 27).[44]

ACUTE RENAL FAILURE

Definition and Epidemiology

Acute renal failure (ARF) is an uncommon but serious complication of pregnancy. Rapid deterioration of renal function leads to an accumulation of fluid and nitrogenous waste products with impaired electrolyte regulation. In the mid-20th century, nearly a fourth of all cases of ARF were obstetric. Fortunately, during the past five decades, the incidence of ARF in developed countries has decreased significantly.[45,46] Stratta et al.[45] reported a steady decline in the incidence of ARF from 1 in 3000 to 1 in 18,000 pregnancies from 1958 to 1994. With respect to all ARF cases, the proportion related to pregnancy decreased from 43% to 0.5%. This progress has resulted from improved obstetric care and fewer septic abortions.

Pathophysiology and Diagnosis

ARF is suggested by a sharp increase in the plasma creatinine (> 0.8 mg/dL) and BUN (> 13 mg/dL) concentrations. In complete renal failure, the serum creatinine concentration increases at the rate of 0.5 to 1.0 mg/dL/day. Urine output typically decreases to less than 400 mL/day (oliguria), but some patients may be nonoliguric. ARF is subdivided according to underlying cause (i.e., prerenal, postrenal, and intrarenal) (Box 52-2). The inciting disorders vary throughout the world. In developing countries septic abortion is the leading cause of pregnancy-related ARF.[47,48] In developed countries, severe preeclampsia/eclampsia, acute pyelonephritis of pregnancy, and bilateral renal cortical necrosis are the most common underlying disorders.[45,46]

Prerenal Causes

The most common prerenal causes of ARF—hyperemesis gravidarum and obstetric hemorrhage—lead to hypovolemia and inadequate renal perfusion.[49,50] Urinary indices show urinary osmolality greater than 500 mOsm/kg water, urine sodium less than 20 mEq/L, fractional sodium excretion less than 1%, and a urinary-to-plasma creatinine ratio greater than 40.[51] Concealed uterine hemorrhage from placental abruption may remain unrecognized until hypotension and renal failure ensue.[52] Women with preeclampsia may be more likely to develop ARF after hemorrhage because of preexisting intravascular contraction and widespread maternal endothelial dysfunction.[53] Women who developed preeclampsia during pregnancy, with or without renal failure, are more likely to develop renal failure later in life.[54]

BOX 52-2 Causes of Acute Renal Failure during Pregnancy

PRERENAL
- Hyperemesis gravidarum
- Uterine hemorrhage
- Heart failure

INTRARENAL
- Acute tubular necrosis
- Septic abortion
- Amniotic fluid embolism
- Drug-induced acute interstitial nephritis
- Acute glomerulonephritis
- Bilateral renal cortical necrosis
- Acute pyelonephritis
- Preeclampsia/eclampsia
- Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome
- Acute fatty liver of pregnancy
- Idiopathic postpartum renal failure

POSTRENAL
- Urolithiasis
- Ureteral obstruction by the gravid uterus

Intrarenal Causes

An intrarenal cause is diagnosed once prerenal and postrenal causes of ARF have been excluded. In general, oliguric intrarenal ARF is not easily reversed and must run its course. Causes include acute tubular necrosis, interstitial nephritis, and acute glomerulonephritis as well as a few causes unique to pregnancy. These include renal cortical necrosis, acute pyelonephritis, severe preeclampsia/eclampsia, acute fatty liver of pregnancy, and idiopathic postpartum renal failure. A thorough history, review of medications, and urinalysis typically help determine the specific initiating factor.[55]

Acute tubular necrosis results from nephrotoxic drugs, amniotic fluid embolism, rhabdomyolysis, intrauterine fetal death, and prolonged renal ischemia secondary to hemorrhage or septic shock. Urinalysis demonstrates dirty brown epithelial cell casts and coarse granular casts. Urinary indices show urine osmolality less than 350 mOsm/kg water, urine sodium concentration greater than 40 mEq/L, fractional sodium excretion greater than 1%, and a urinary-to-plasma creatinine ratio less than 20.[55]

Acute interstitial nephritis is caused by nonsteroidal anti-inflammatory drugs (NSAIDs) and various

antibiotics. Patients typically have fever, rash, eosinophilia, and urine eosinophils.

Acute glomerulonephritis is rare during pregnancy. It is suggested by hematuria, red cell casts, and proteinuria. Urinary indices of acute glomerulonephritis are similar to those of prerenal ARF.

Bilateral renal cortical necrosis, which is rarely observed in the nonobstetric patient, is responsible for 10% to 38% of cases of obstetric ARF.[47,56-58] It may occur during early or late pregnancy. Hemorrhage is the most common precipitating event. The pathogenesis of this disorder is unclear but may involve renal hypoperfusion or endothelial damage by endotoxins imposed on the normal hypercoagulable state of pregnancy.[59] A single dose of endotoxin may precipitate bilateral renal cortical necrosis in pregnant animals and has led some investigators to view this disorder as a clinical analogue of the experimental Sanarelli-Shwartzman reaction.[60] Extensive microthrombi are found within the glomeruli and renal arterioles. Diagnosis is made by selective renal arteriography, which reveals absence or patchiness of blood flow in the cortex. Renal biopsy may also be performed in the absence of active coagulopathy.[9]

Acute pyelonephritis is one of the most common infectious complications of pregnancy (see Chapter 37). Although acute pyelonephritis rarely leads to ARF in the nongravid patient, it accounts for 5% of cases of ARF among pregnant women.[53] The reason for this greater susceptibility is unclear. Whalley et al.[61] noted that acute pyelonephritis causes a marked reduction of GFR in pregnant women. In contrast, pyelonephritis causes little reduction in GFR in nonpregnant patients. The kidney may be more sensitive to bacterial endotoxins during pregnancy.

Severe preeclampsia/eclampsia may be responsible for 20% of cases of obstetric ARF in developed countries[53] and as much as 35% of cases in developing countries.[62] Renal failure is generally associated with severe preeclampsia or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets); in these patients the incidence may be as high as 36%.[63] However, many cases of renal dysfunction and failure may only mimic preeclampsia and may actually result from other factors.[6] Other causes of ARF should be considered before preeclampsia is considered to be the basis of renal failure.

Sibai and Ramadan[64] reported 32 cases of ARF associated with HELLP syndrome. The majority of patients had derangement of multiple organ systems and other obstetric complications (e.g., placental abruption, intrauterine fetal death, disseminated intravascular coagulation, postpartum hemorrhage, sepsis). Renal histology in a woman with HELLP syndrome and renal failure demonstrated thrombotic microangiopathy and acute tubular necrosis, suggesting a possible pathogenesis of acute renal failure associated with HELLP syndrome.[65] In the Sibai and Ramadan[64] report, 4 (13%) parturients died, and 10 (31%) required dialysis. The perinatal mortality rate was 34%, with 72% of deliveries occurring preterm. Of interest, Flynn et al.[66] reported the successful use of cadaveric kidneys procured from a parturient who died after HELLP syndrome and ARF. Both recipients had acceptable graft function 2 years after transplantation.

Acute fatty liver of pregnancy, a rare but life-threatening disorder of pregnancy, is associated with a 60% to 100% incidence of ARF. Specific clinical features of acute fatty liver of pregnancy are discussed in Chapter 46.

The syndrome of **idiopathic postpartum renal failure** was initially described in 1968 by Robson et al.[67] Subsequently, approximately 200 cases have been reported. This syndrome is characterized by ARF, microangiopathic hemolytic anemia, and thrombocytopenia occurring 2 days to 10 weeks after an uncomplicated delivery. It appears closely related to the hemolytic-uremic syndrome. Idiopathic postpartum renal failure is typically preceded by a viral upper respiratory tract or gastrointestinal syndrome that rapidly progresses to ARF. The use of ethinyl estradiol as a contraceptive may also be causally related to this syndrome.[68] Spontaneous bleeding, congestive heart failure, hypertension, and seizures have been reported with this syndrome.[69] Some investigators believe that this syndrome represents a clinical analogue to the generalized Shwartzman reaction, a condition induced in laboratory animals by two successive injections of endotoxin, which results in factor XII activation, thrombin generation, and fibrin deposition.[60] Others consider the platelet deposition to be the primary event that leads to microvascular thrombi.[69]

Management involves plasma exchange transfusion, dialysis, and antiplatelet therapy. The role of heparin therapy in idiopathic postpartum renal failure is controversial. The morbidity and mortality among affected patients vary by study. Reports from 1979 and 1988 suggested a mortality rate of approximately 50%.[70,71] Although survival has improved with prompt diagnosis and aggressive treatment, morbidity is still high. Shrivastava et al.[72] reported three patients who had postpartum hemolytic-uremic syndrome and had initial recovery with immediate exchange transfusion; long-term follow-up was not reported. Dashe et al.[73] reported 10 patients with peripartum or postpartum hemolytic-uremic syndrome and followed their course for a mean of 9 years. Although all 10 initially survived, 1 subsequently died and all had major morbidity, including recurrence of renal failure, hypertension and seizures.

Postrenal Causes

The postrenal causes of ARF include nephrolithiasis and ureteral obstruction by the gravid uterus.[74] The latter complication is more likely in pregnant women with polyhydramnios or multiple gestation.[75] Preexisting ureteral dilation and impaired peristalsis increase the risk for obstructive uropathy during pregnancy. Flank pain and decreased urine output during late gestation should alert the clinician to this possibility. Courban et al.[76] reported an unusual case of obstructive uropathy leading to ARF in a pregnant woman with multiple uterine leiomyomas.

Effect on the Mother and Fetus

Maternal mortality from ARF has decreased significantly in the past 40 years. Stratta et al.[45] reviewed their

experience with ARF in pregnancy from 1958 to 1995. In the early period from 1956 to 1957 the maternal mortality rate was 31% but decreased to zero from 1988 to 1994. They hypothesized that this was probably due to improvement in medical and obstetric care, especially of women with preeclampsia. Although maternal prognosis has improved significantly in developed countries, mortality ranges between 20% and 30% in developing countries.[48,62] The prognosis for the fetus is worse than for the mother. Reported fetal mortality is as high as 40% to 50%,[77,78] although outcomes may be improving. Two groups reported much lower mortality rates (0% to 13%) with the use of aggressive hemodialysis (six times per week with the goal of maintaining the blood urea nitrogen level < 50 mg/dL).[79,80]

Medical and Obstetric Management

Management is directed toward rapid recognition of the underlying abnormality. Reversible disorders such as hypovolemia, concealed uterine hemorrhage, urinary tract infection, ureteral obstruction, and drug-induced ARF must be excluded. The urine-to-plasma osmolality ratio is a useful laboratory test to identify reversible prerenal causes. Intravascular volume should be optimized. Electrolyte and acid-base status should be monitored carefully. Hypertension and preeclampsia must be managed aggressively. Many obstetric causes of ARF also may cause disseminated intravascular coagulation; therefore, coagulation abnormalities should be excluded in pregnant women with ARF.[45]

Because urea and other metabolic products cross the placenta, hemodialysis or peritoneal dialysis should be directed toward maintaining the postdialysis BUN concentration at or below 30 mg/dL. Fluid shifts during hemodialysis should be minimized by short but frequent periods of dialysis. If the fetus is mature, delivery should be accomplished when the maternal condition is stabilized. The pediatrician must be alerted to the presence of high fetal BUN levels, which may lead to an osmotic diuresis and neonatal dehydration. Ertürk et al.[81] reported the first known delivery of a healthy infant during a hemodialysis session.

Anesthetic Management

A multidisciplinary approach involving anesthesiologists, obstetricians, and nephrologists should be employed to optimize the maternal condition before the induction of labor or performance of cesarean delivery in a woman with ARF. The level of azotemia, electrolyte balance, and hematologic status should be assessed. If the BUN level is greater than 80 mg/dL or the serum potassium concentration greater than 5.5 mEq/L, dialysis should be performed before elective vaginal or cesarean delivery. Neuraxial anesthesia may be administered in the absence of coagulopathy, thrombocytopenia, and severe hypovolemia. Volume status is difficult to assess. In the past, it was common to place a central line or pulmonary artery catheter to assess volume status, but this is now rarely done. Intravenous fluid without potassium (e.g., 0.9% saline) should be administered. Occult uterine hemorrhage should be excluded, and hypertension, if present, controlled. Both spinal and epidural analgesia/anesthesia are safe and preferred to general anesthesia. As the sympathetic blockade dissipates, the mother should be monitored for evidence of volume overload and pulmonary edema. General anesthesia may be required for urgent cesarean delivery or in patients with coagulopathy or hemorrhage.

RENAL TRANSPLANTATION

Although pregnancy is uncommon in women undergoing long-term dialysis,[22] fertility is improved within months of transplantation. The first recorded live birth to a woman with a kidney transplant was reported in 1958.[82] In a review of female renal transplant patients in the United States, a pregnancy rate of 20 per 1000 was estimated in transplanted patients in the year 2000 compared with 100 per 1000 in the general population.[83]

Although a successful obstetric outcome can be anticipated in more than 95% of kidney transplant recipients, they are at greater risk for both maternal and fetal complications than healthy women. In a systematic review of articles published between the years 2000 and 2010, Deshpande et al.[84] reported pregnancy-related outcome data in kidney transplant recipients. Fifty studies representing 4706 pregnancies in 3570 recipients met inclusion criteria. The incidences of preeclampsia (27%), gestational diabetes (8%), cesarean delivery (56.9%), and preterm delivery (45.6%) were greater than in the general population.

Effect of Pregnancy on the Renal Allograft

When a kidney is removed from a donor and transplanted into an anephric recipient, it undergoes a process of hyperfiltration. This is a maladaptive response that, in the short term, attempts to bring the GFR toward the rate of a bi-nephric system. In the long term, this hyperfiltration may lead to glomerular sclerosis and loss of renal function if it is associated with increased glomerular or capillary pressure.[85] In normal pregnancy, the GFR increases by 30% to 50% during the first and second trimesters and subsequently decreases somewhat during the third trimester. Theoretically, this additional hyperfiltration of pregnancy predisposes the patient to a loss of renal function.

Baylis et al.[86] allayed many of these concerns by demonstrating that gestational hyperfiltration is not associated with increased glomerular pressure because of matching afferent and efferent arteriolar vasodilation. They produced hyperfiltration in rodent kidneys by performing uninephrectomy, maintaining the animals on a high-protein diet, and subjecting them to five consecutive pregnancies. The investigators observed no functional impairment or renal histologic changes in this animal model. In addition, they demonstrated that glomerular pressure is lower in female rats than in male rats 10 months after uninephrectomy.[87] Similar sex advantage has been seen in humans after uninephrectomy.[88]

There have been a number of studies assessing graft function after pregnancy. Most studies suggest that there is no adverse effect provided renal function is normal before conception and there is no evidence of hypertension.[89-93] Levidiotis et al.[90] analyzed 40 years of outcome data from the Australian and New Zealand Dialysis and Transplant Registry and did not find any impact of pregnancy on 20-year graft or patient survival.

Rahamimov et al.[91] compared long-term graft survival, kidney function, and patient survival between women who became pregnant after renal transplantation (n = 39; 55 births) with those who did not (n = 117). Each pregnant woman was matched with three nonpregnant women for 12 factors that may affect graft survival. Graft (61.6%) and patient survival (84.8%) in the pregnant women did not differ from the matched nonpregnant group (68.7% graft and 78.8% patient survival) during the 15-year follow-up study.

Sturgiss and Davison[92] performed a case-control study of 36 renal transplant recipients, of whom 18 became pregnant and 18 did not. Groups were matched according to age, early rejection episodes, primary renal function, interval since transplantation, and extent of histocompatibility. The investigators noted no significant difference between the two groups in plasma creatinine concentration, GFR, mean arterial blood pressure, or the number who suffered graft loss or chronic rejection over a mean follow-up period of 12 years (Table 52-1).

Kashanizadeh et al.[93] also compared graft survival, allograft function, and patient survival between transplant recipients who conceived (n = 86) and those who did not (n = 125). They, too, did not find a difference in 5-year graft or patient survival between groups. Interestingly, they noted a smaller increase in creatinine levels in women who had conceived, suggesting that pregnancy might exert a protective effect, but this finding has not been confirmed by others.[94]

Effect on the Fetus

Although pregnancy seems to have minimal effect on maternal health or allograft survival in renal transplant recipients, fetal outcome is less favorable. The Toronto Renal Transplant Program reviewed 44 consecutive pregnancies in 26 women who had undergone renal transplantation.[95] Of these, 12 (27%) pregnancies ended with abortion (two elective, four spontaneous) or intrauterine death, and 32 (73%) pregnancies resulted in live-born infants. The mean birth weight in this group was 2540 g, versus 3590 g in a control group. In Singapore, Tan et al.[96] reported abortion or stillbirth among 13 (31%) of 42 pregnancies after renal transplantation. The remaining successful pregnancies were complicated by preterm delivery (45%) and fetal growth restriction (86%). Toma et al.[22] surveyed 194 pregnancies in renal transplant recipients. Spontaneous or elective abortion occurred in 28 (14%) of these gestations, and successful delivery of surviving infants occurred in 159 (82%). Deshpande et al.,[84] in their large systematic review, found a 73.5% live birth rate in renal transplant patients, which is similar to that found in the individual studies.[22,95,96]

Most post-transplantation protocols consist of a primary immunosuppressant (cyclosporine or tacrolimus) and one or two adjunctive agents (azathioprine, mycophenolate mofetil, sirolimus, and/or corticosteroids).[97] Despite transplacental exposure to immunosuppressant drugs, congenital anomalies and other adverse effects are not greater than in the general population, but none of the studies included patients who were receiving mycophenolate mofetil.[96,98] There have been reports of congenital defects with mycophenolate mofetil, including cleft lip and palate, microtia, absence of auditory canals, brachydactyly of the fifth finger, and hypoplastic toenails; therefore, its use has to be weighed against the risk for allograft rejection.[99]

Intrauterine exposure to cyclosporine impairs development and function of T, B, and NK lymphocytes in neonates. This effect, as well as depressed levels of serum immunoglobulin, persists during the first year of life.[100] These factors place the infant at risk for a suboptimal immunologic response after administration of classic vaccines and for adverse effects after administration of live, attenuated vaccines.

Transplant recipients may become infected with cytomegalovirus (CMV) at the time of transplantation, or they may experience reactivation secondary to immunosuppression. Active CMV infection during pregnancy is associated with congenital anomalies (e.g., cerebral cysts, microcephaly, mental retardation). In addition, active neonatal CMV infection may lead to serious illness or death.

After renal transplantation, residual impairment of renal function may lead to false-positive results of biochemical screening for trisomy 21. Karidas et al.[101] demonstrated a significant correlation between free β-subunit human chorionic gonadotropin and serum urea and creatinine concentrations. Similar alterations in alpha-fetoprotein levels were not observed. In this setting, the double-marker biochemical test may be interpreted inaccurately. In patients with altered serum urea and creatinine concentrations, first-trimester nuchal translucency measurement—in combination with second-trimester ultrasonography—may be a more useful screening regimen (see Chapter 6).

TABLE 52-1 Effect of Pregnancy on Long-Term Function of Renal Allografts*

Parameter	Pregnant Group (n = 18)	Nonpregnant Control Group (n = 18)
Plasma creatinine (mg/dL)	1.26 ± 0.83 (19% increase)	1.44 ± 0.59 (8% increase)
Glomerular filtration rate (mL/min)	58 ± 29 (18% decrease)	56 ± 32 (7% decrease)
Mean arterial pressure (mm Hg)	96 ± 12 (1% decrease)	101 ± 9 (5% increase)
Graft loss or chronic rejection	2 (11%)	2 (11%)

*Percentage increase or decrease represents change from initial assessment to end of follow-up. No statistically significant differences were noted.

From Sturgiss SN, Davison JM. Effect of pregnancy on long-term function of renal allografts. Am J Kidney Dis 1992; 19:167-72.

Medical and Obstetric Management

Discontinuation of immunosuppressant therapy, even years after transplantation, may lead to acute rejection. Thus, the renal transplant recipient's immunosuppressant regimen must be continued during pregnancy unless toxicity results, although some practitioners discontinue mycophenolate mofetil. Cyclosporine requirements increase during pregnancy, most likely because of enhanced metabolism.[102] The pregnant patient must be intensively monitored for any evidence of acute or chronic allograft rejection, infection, ureteral and renal artery obstruction, impaired renal function, hypertension, fluid volume disturbances, anemia, or any combination of these symptoms. Recombinant human erythropoietin (darbepoetin) has been successfully used to treat anemia during pregnancy.[103]

Initial laboratory studies in pregnant renal transplant patients include (1) complete blood cell count, (2) renal function tests, (3) serum electrolyte and glucose concentrations, and (4) viral serologic testing for CMV, hepatitis B virus, HCV, and HIV. Serial ultrasonographic assessments allow the recognition of fetal anomalies and the evaluation of fetal growth.

Cultures of the lower genital tract should be obtained in women with lesions suggestive of herpes simplex virus infection. A patient who presents in labor and with evidence of active genital herpes simplex virus infection should undergo cesarean delivery (see Chapter 37).

Vaginal examinations are minimized and always performed in a strict aseptic manner. The renal allograft is typically implanted in the extraperitoneal iliac fossa and does not impair vaginal delivery. Prophylactic antibiotics and stress-dose corticosteroids are indicated in patients who undergo cesarean delivery.

Anesthetic Management

In the absence of renal dysfunction and hypertension, anesthetic management of the parturient with a renal transplant is similar to that of the healthy parturient. Strict aseptic technique is maintained during the placement of intravascular catheters and the performance of neuraxial anesthetic techniques. Sowter et al.[104] reported an epidural abscess that occurred 23 days after epidural anesthesia in a nonpregnant patient receiving corticosteroid therapy for rheumatoid arthritis. Fortunately, this complication is exceedingly rare. In the absence of systemic infection, immunosuppression itself should not be considered a contraindication to administration of epidural or spinal anesthesia.

UROLITHIASIS

Definition and Epidemiology

Urolithiasis is characterized by the abnormal formation of calculi within the renal calyces or pelvis. Calculi may lodge within the ureters or bladder. Most stones are calcium oxalate (70%) or calcium phosphate (10%). The disorder affects 1% to 5% of the general U.S. population, but it is more common in the southeastern "stone belt" and mountainous regions. Symptomatic urolithiasis occurs during 1 in 240 to 1 in 3300 pregnancies and is more common among whites than African-Americans.[105] This incidence approximates that observed among nonpregnant young women, suggesting that pregnancy does not affect the rate of urolithiasis.

Pathophysiology

The presence of urolithiasis presumes an underlying physiologic abnormality that leads to persistent supersaturation of the particular minerals involved. During pregnancy, an elevated plasma 1,25-dihydroxyvitamin D level causes greater intestinal absorption of calcium, net mobilization of calcium from bone, and a state of absorptive hypercalciuria.[106] Ultimately, these changes provide calcium for the fetal skeleton. Because pregnant women do not develop urolithiasis at a rate greater than that in the general population, it would appear that the occurrence of other physiologic changes during pregnancy offsets this stone-forming factor. Calcium stone inhibitors such as citrate, magnesium, and glycoprotein are excreted in the urine to a greater extent during pregnancy.[107]

Diagnosis

Urolithiasis most commonly manifests during the second or third trimester. Only 20% of affected pregnant women recount a prior history of renal calculi. More than 80% of cases of gestational urolithiasis are diagnosed in parous women, possibly reflecting the higher incidence of this disease with advanced age.[108] Similar to that seen in the nonpregnant woman, stones occur with equal frequency on the right and left sides.[109] The signs and symptoms of urolithiasis during pregnancy must be differentiated from that of ectopic pregnancy, preterm labor, appendicitis, pyelonephritis, and benign hematuria of pregnancy. A history of previous urolithiasis, recurrent urinary tract infections, or urologic surgery is suggestive. Symptoms include flank and abdominal pain, urgency, dysuria, nausea, and fever. Examination reveals costovertebral tenderness, abdominal tenderness, pyuria, and hematuria. Urolithiasis must be considered in patients with pyelonephritis who remain febrile or have continued bacteriuria despite 48 hours of parenteral antibiotics.

The initial imaging modality for the evaluation of urolithiasis during pregnancy is transabdominal ultrasonography. Transabdominal ultrasonography is diagnostic in about 60% of cases and does not expose the mother or fetus to radiation.[110] Color Doppler ultrasonography allows the identification of ureteral jets; the asymmetry or absence of these jets indicates the presence of urinary calculi. Transvaginal ultrasonography may augment suboptimal transabdominal ultrasonographic images.[111] Combining ultrasound evaluation with assessment of the intrarenal artery resistive index increases the accuracy of ultrasonography to greater than 70%.[112]

If urinary calculi are not successfully visualized with ultrasonography and clinical suspicion for urolithiasis remains high, magnetic resonance (MR) urography

should be considered because it does not use ionizing radiation or iodinated contrast media (see Chapter 17).[113] If the diagnosis is still unclear and the patient has persistent flank pain after both these tests, some experts recommend low-dose computed tomography[114] whereas others recommend intravenous pyelography.[108]

Effect of Pregnancy on Urolithiasis

In an effort to determine any effect of pregnancy on the natural history of urolithiasis, Coe et al.[115] reviewed the records of 58 pregnancies in women with the preexisting diagnosis of urolithiasis. The stone recurrence rate in this group was 0.49 stone per patient-year, which was not significantly different from the rate of 0.44 stone per patient-year in the general population. The authors concluded that pregnancy does not alter the activity or severity of stone disease.

Effect on the Mother and Fetus

In a retrospective cohort study, Swartz et al.[116] compared pregnant women with nephrolithiasis (n = 2339) with randomly selected women without nephrolithiasis (n = 6729). The investigators found that women with nephrolithiasis had an almost twofold higher rate of preterm delivery. However, these women were not at increased risk for other adverse pregnancy outcomes, including premature rupture of the membranes, low birth weight, and infant death. The etiology of preterm labor and perhaps delivery is unclear but may be related to urinary tract infections that occur with a greater frequency in those with urolithiasis.[117] Honoré[118] suggested that there is a higher incidence of renal stones among women who have a spontaneous abortion. He hypothesized that abnormalities of calcium hemostasis may lead to myometrial hyperirritability or abnormal hormonal secretion by the corpus luteum, the placenta, or both. Rare cases of ureteral rupture[119] and obstructed labor caused by a bladder calculus[120] have been reported.

Urologic and Obstetric Management

Women with a history of urolithiasis should increase their intake of fluids. Calcium supplementation through prenatal vitamins should be avoided in women with recurrent urolithiasis. During pregnancy, 70% of calculi pass spontaneously with conservative management (e.g., hydration, antibiotics if the patient is febrile, bed rest, analgesia). More aggressive therapy will be required if conservative management is not successful. The decision to move beyond conservative therapy should be taken on a case-by-case basis. Infected hydronephrosis, especially with impaired renal function or urosepsis, is an indication for more aggressive therapy.[121]

Medical management, commonly used for treatment of urolithiasis,[122] is limited during pregnancy by fetal concerns. Medical expulsive therapy with alpha-adrenergic receptor blocking agents has been used successfully to increase the rate of stone passage and decrease pain associated with expulsion by relaxing ureteral smooth muscle.[123] However, there are no published reports of its use during pregnancy. Other medical treatments that are used to treat urolithiasis, including thiazide diuretics, xanthine oxidase inhibitors, and D-penicillamine, are contraindicated during pregnancy owing to possible effects on the fetus.[124,125]

Urologic intervention is indicated in the patient with persistent pyelonephritis, deterioration of renal function, massive hydronephrosis, persistent pain, or sepsis. Ureteral stent placement with ureteroscopy and ultrasonographic guidance, or percutaneous nephrostomy, should be considered because either can be performed without the need for anesthesia or radiation exposure.[105] Holmium:yttrium-aluminum-garnet (YAG) laser lithotripsy, using state-of-the-art ureteroscopes, is an emerging technique for stone management in pregnancy.[126] Extracorporeal lithotripsy should be avoided during pregnancy because the shockwaves may be harmful to the fetus.[127]

The following conditions may raise suspicion of the presence of **primary hyperparathyroidism** in a pregnant woman: (1) urolithiasis with or without pancreatitis, (2) hyperemesis beyond the first trimester, (3) a history of recurrent spontaneous abortion or intrauterine fetal death, (4) neonatal hypocalcemia or tetany, and (5) a total serum calcium concentration greater than 10.1 mg/dL during the second trimester or greater than 8.8 mg/dL during the third trimester.[128]

Anesthetic Management

Anesthesiologists are occasionally asked to provide analgesia for patients with renal or ureteral stones. The ureters receive sensory innervation through the renal, ovarian, and hypogastric plexuses (T11 to L1 spinal segments). During conservative management of urolithiasis, epidural analgesia provides the patient with significant pain relief and facilitates the passage of the calculus, possibly through decreased ureteral spasm.[129,130] Ready and Johnson[129] reported the use of epidural analgesia in a patient with severe renal colic at 23 weeks' gestation. Analgesia that was maintained for 16 hours allowed the passage of the stone. Neuraxial analgesia avoids the use of systemic opioids, which impair normal peristalsis in ureteric smooth muscle. Improved maternal pain control may also decrease endogenous catecholamine release and improve uteroplacental blood flow.

KEY POINTS

- Pregnant women with moderate or severe renal insufficiency are at increased risk for deterioration of renal function, exacerbation of hypertension, and other obstetric complications, including fetal growth restriction and preterm delivery.
- Patients requiring renal dialysis have decreased fertility, and pregnancy is rare.
- Pregnancy does not affect the long-term survival of a renal allograft.

- Both preeclampsia and renal disease may manifest as hypertension, proteinuria, and edema; the distinction between the two disorders is often unclear, especially after 20 weeks' gestation.
- Renal disease affects almost every organ system, so a thorough history before initiation of anesthesia, with emphasis on the cardiac and respiratory system, is critical.
- Anesthetic management is influenced by the extent of renal dysfunction and hypertension.
- Neuraxial anesthetic techniques are safe and are the preferred methods for labor analgesia and cesarean delivery anesthesia.
- Immunosuppressive therapy must be continued during pregnancy in renal transplant patients. The anesthesia provider should maintain strict aseptic technique during the placement of intravascular catheters and the performance of neuraxial anesthetic techniques.
- Epidural analgesia may facilitate the spontaneous passage of renal calculi.

CHAPTER 53

Respiratory Disease

Karen S. Lindeman, MD

CHAPTER OUTLINE

ASTHMA

Definition

Asthma is defined by the presence of the following three characteristic findings: (1) reversible airway obstruction, (2) airway inflammation, and (3) airway hyperresponsiveness. **Airway obstruction** produces the clinical manifestations of wheezing, cough, and dyspnea. **Airway inflammation** modulates the course of asthma by independently producing airway obstruction and enhancing airway hyperresponsiveness. **Airway hyperresponsiveness** is marked by exaggerated responses to a wide variety of bronchoconstrictor stimuli, including histamine, methacholine, prostaglandin $F_{2\alpha}$, hypo-osmotic solutions, and cold air.

Epidemiology

Asthma is an increasingly common problem among young, otherwise healthy women of childbearing age. Morbidity and mortality rates from this disease increased during the 1980s and 1990s. From 2001 to 2010, the prevalence of asthma in the United States increased from 7.3% to 8.4%.[1]

The prevalence of asthma in women of childbearing age also continues to rise. The rate was approximately 3% in the 1990s and has increased to approximately 8.8% in the early 2000s.[2]

Pathophysiology

Asthma is believed to occur under a variety of environmental influences in the presence of genetic susceptibility.[3] The underlying defect that produces the clinical syndrome of asthma is unknown. The most important potential mechanisms are (1) an enhancement of contractility or an impairment of relaxation of airway smooth muscle, (2) a neural imbalance, (3) airway inflammation, and (4) changes in the function of the airway epithelium.

Airway Smooth Muscle

Contraction of airway smooth muscle is believed to be the most important factor in producing acute airway obstruction. For many years, an enhancement of airway smooth muscle responsiveness to contractile agonists was assumed to be a major mechanism of asthma. To test this hypothesis, investigators attempted to correlate

airway responsiveness *in vivo* and *in vitro* in humans[4-8] and in the basenji-greyhound dog model of asthma.[9] These studies did not demonstrate a significant correlation between the airway response to histamine or cholinergic agonists *in vivo* and airway smooth muscle contraction *in vitro*. Some studies actually demonstrated a negative correlation between the *in vivo* and *in vitro* responses,[8,9] suggesting that diminished responsiveness may represent a chronic adaptive response of airway smooth muscle.

Instead of an enhancement in responsiveness to contractile stimuli, a reduction in responsiveness to relaxant stimuli may contribute to airway obstruction. One study demonstrated impaired relaxant responses to isoproterenol in airway smooth muscle from human asthmatic subjects in comparison with the responsiveness of airway smooth muscle from controls.[10] Other evidence substantiates the presence of impaired airway relaxation in asthmatic subjects *in vivo*.[11] Although the mechanism for this effect is poorly understood, a reduction in airway sensitivity to beta-adrenergic agonists could contribute to airway hyperresponsiveness by altering the balance between constricting and dilating influences.

Neural Components

A balance between constricting and dilating influences also exists with respect to the autonomic nervous system. A shift in this balance, with an increase in constricting influences, may be a mechanism of asthma.

The parasympathetic nervous system provides the dominant constrictor input to the airways (Figure 53-1). Efferent cholinergic fibers travel in the vagus nerve to synapse in ganglia within the airway wall.[12] Postganglionic fibers release acetylcholine to activate muscarinic receptors and stimulate airway smooth muscle contraction. A negative feedback system limits release of acetylcholine from nerve terminals. Muscarinic autoreceptors, or receptors on the nerve ending,[13] also are activated by acetylcholine and inhibit further release of acetylcholine from the nerve terminal.

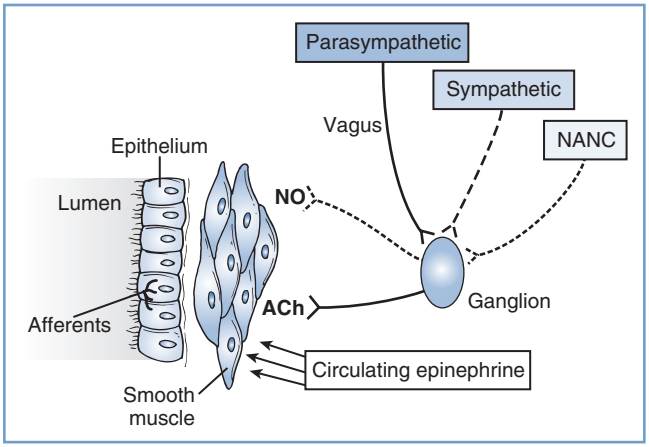

FIGURE 53-1 ■ Neural control of the airway. Parasympathetic, sympathetic, and nonadrenergic noncholinergic (NANC) efferents innervate ganglia within the airway wall. Postganglionic cholinergic efferents release acetylcholine (ACh) to constrict airway smooth muscle. Postganglionic NANC efferents release nitric oxide (NO) to relax airway smooth muscle. Circulating epinephrine relaxes the airway. Afferents from the airway originate in the epithelium and are activated by airway irritation, as occurs with tracheal intubation.

The importance of exaggerated cholinergic efferent activity in the pathogenesis of airway hyperreactivity has been debated extensively. The relatively limited efficacy of anticholinergic agents in relieving clinical bronchospasm, as well as growing evidence supporting other mechanisms, suggests that this pathway has a limited role in the pathophysiology of asthma. However, this mechanism appears to be very important in the perioperative management of asthmatic subjects. Reflex stimulation of airway smooth muscle by placement of a tracheal tube represents one of the most important causes of bronchospasm in the perioperative period.

An alternative mechanism by which the parasympathetic nervous system may contribute to airway hyperresponsiveness is through dysfunction of the muscarinic autoreceptors. Dysfunction of these receptors allows increased postganglionic release of acetylcholine after reflex stimulation.[14] This mechanism is well established in a guinea pig model of viral infection[15] and may explain the airway hyperresponsiveness that occurs for several weeks after an upper respiratory tract infection, although additional autoreceptor-independent mechanisms may also be present.[16] The role of this mechanism in the pathophysiology of clinical asthma is unclear.

The sympathetic nervous system primarily acts to decrease airway tone. In contrast to the parasympathetic nervous system, sympathetic innervation of airway smooth muscle in human subjects is either sparse or absent.[17] Circulating catecholamines activate beta-adrenergic receptors in airway smooth muscle and provide the primary sympathetic efferent input to human airways. Because airways of normal human subjects do not become hyperresponsive after beta-adrenergic blockade,[18] it is unlikely that impaired catecholamine secretion contributes significantly to the pathogenesis of asthma.

The alpha-adrenergic system is thought to play a relatively minor role in determining the state of airway responsiveness. Although alpha-adrenergic receptors are present in human airways,[19] the protective effects of alpha-adrenergic antagonists have been disappointing and can be attributed to other properties, such as antihistamine activity.

In addition to cholinergic and adrenergic input, a third neural system, the nonadrenergic noncholinergic (NANC) system, provides efferent nerves to the airways. Both constricting and dilating pathways have been identified.[20] Nitric oxide serves as the inhibitory NANC neurotransmitter in human airways.[21] Potentially, a relative increase in constricting influences or a decrease in dilating influences in the NANC system could contribute to asthma. However, asthmatic subjects demonstrated no deficit in NANC inhibitory pathways,[22] and inhibition of NANC excitatory neurotransmission did not improve airway hyperresponsiveness.[23] Thus, current evidence does not support imbalance of the NANC system as a major mechanism of asthma.

Airway Inflammation

Airway inflammation appears to serve primarily as a modulating influence in asthma. Inflammation is certainly present in some but not all asthmatic subjects.[24] The process of inflammation involves the occurrence of airway wall edema and infiltration of the mucosa by a variety of inflammatory cells, including neutrophils, mast cells, helper T lymphocytes, macrophages, and eosinophils.[25] These cells produce and release mediators of inflammation, such as histamine, leukotrienes, platelet-activating factor, prostaglandins, thromboxanes, cytokines, serotonin, and nitric oxide.[25] Mediators can modulate airway responsiveness by stimulating airway smooth muscle contraction,[26] directing migration of inflammatory cells,[27] modifying neural control of the airways,[28] increasing mucosal permeability,[29] or disrupting airway epithelium.[30] In addition, airway inflammation can reduce airway diameter. Airway hyperresponsiveness is correlated with increased baseline airway tone.[31] The overall importance of inflammation in asthma has been debated. Although inflammation appears to modulate the course of asthma, other factors certainly contribute to the pathogenesis.

Airway Epithelium

The epithelium provides a barrier to protect the subepithelial layers against stimuli that could provoke bronchospasm. Airways of asthmatic subjects demonstrate areas of epithelial destruction,[32] and the clinical significance of this finding has been demonstrated.[33]

The epithelium not only serves as a barrier but also plays an active role in the maintenance of airway tone. The epithelium produces constricting and dilating factors.[34,35] An alteration in the balance between these factors could alter airway responsiveness. The relative importance of alterations in epithelial function in the pathogenesis of asthma is unknown.

Diagnosis

Medical History

The classic symptoms of asthma include wheezing, cough, dyspnea, and chest tightness. A patient's medical history also should include information about the pattern and severity of the symptoms, precipitating and aggravating factors, and the duration and course of these symptoms.

Physical Examination

Physical examination is directed to the respiratory tract. Auscultation of the chest may reveal wheezing and a prolonged phase of expiration.

Laboratory Studies

Laboratory studies that aid in the diagnosis of asthma depend on findings from the medical history and physical examination. In general, pulmonary function tests are useful to document the severity and establish the reversibility of obstruction (Box 53-1). In the absence of additional findings, other tests are not as useful in establishing the diagnosis of asthma. Bronchoprovocation tests (with agents such as methacholine or histamine) are used when the history and physical examination strongly suggest the presence of asthma but spirometry does not show airway obstruction.

BOX 53-1 Pulmonary Function Tests in Patients with Asthma

Forced Vital Capacity (FVC)

- The volume of gas exhaled after maximal inspiration
- May be reduced in asthma

Forced Expiratory Volume in 1 Second (FEV_1)

- The volume exhaled in the first second after maximal inspiration
- May be reduced in asthma

$FEV_1/FVC < 0.75$ in Asthma

Interaction with Pregnancy

Effects of Pregnancy on Asthma

The overall course of asthma has been reported to improve, worsen, or remain the same during pregnancy.[36] Earlier evidence suggested that patients with more severe asthma are more likely to experience deterioration during pregnancy,[36] but a recent study demonstrated that asthma severity during pregnancy is similar to severity during the year before pregnancy, provided that patients continue to use their prescribed medication during pregnancy. The investigators concluded that even mild asthma is likely to become significantly more severe if women discontinue their prescribed medication during pregnancy.[37] A likely reason for the variation in the results of published studies is the difference in methods of assessing the severity of asthma. Most studies have used either clinical symptoms or requirements for pharmacologic therapy as indicators of the course of the disease. These measures do not correlate with objective measures of airway obstruction.[38] Juniper et al.[39] measured methacholine sensitivity before, during, and after pregnancy. Measurements of sensitivity to methacholine made during the second and third trimesters were lower than preconception or postpartum measurements (Figure 53-2). Although these findings suggest a reduction in airway hyperresponsiveness during pregnancy, the limited study population (16 subjects) makes extrapolation of the data to the general population unclear. Exacerbations of asthma during labor and delivery occur in as many as 20% of subjects[37] and occur more frequently after cesarean delivery than after vaginal delivery (41% and 4%, respectively).[40]

A number of mechanisms may be responsible for the changes in the clinical course of asthma during pregnancy (Box 53-2). An increase in the progesterone level is thought to be one mechanism that improves asthma during pregnancy. Progesterone relaxes uterine and gastrointestinal smooth muscle and may or may not have

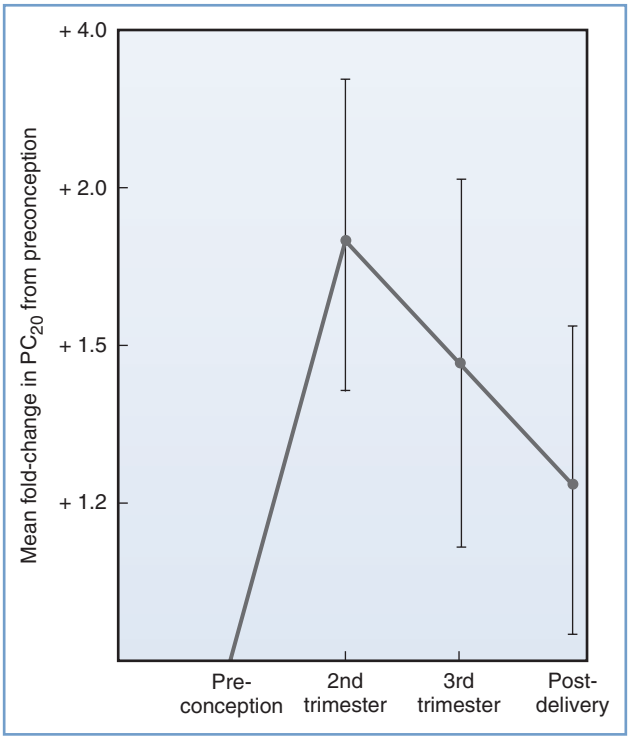

FIGURE 53-2 ■ Airway responsiveness before, during, and after pregnancy expressed as fold change in PC_{20}—dose of methacholine needed to reduce FEV_1 (forced expiratory volume in 1 second) by 20%—compared with values before conception (n = 16; $P = .033$ for the effect of pregnancy on airway responsiveness). (From Juniper EF, Daniel EE, Roberts RS, et al. Improvement in airway responsiveness and asthma severity during pregnancy. Am Rev Respir Dis 1989; 140:924-31.)

BOX 53-2 Factors That May Improve or Worsen Asthma during Pregnancy

Factors That May Improve Asthma

- Progesterone-induced relaxation of airway smooth muscle
- Increased production of bronchodilating prostaglandins
- Higher circulating cortisol level

Factors That May Worsen Asthma

- Decreased sensitivity to beta-adrenergic agonists
- Increased production of bronchoconstricting prostaglandins
- Reduced sensitivity to circulating cortisol because of binding of steroid hormones (e.g., progesterone) to cortisol receptors

similar effects on airway smooth muscle. However, Juniper et al.[39] did not demonstrate a strong association between methacholine responsiveness and progesterone levels during pregnancy, suggesting that progesterone does not play a central role in attenuating airway hyperresponsiveness. In contrast, progesterone may actually worsen asthma by enhancing inflammation.[41] Thus, effects of pregnancy on asthma appear to involve a number of factors other than direct effects of hormones on airway smooth muscle.

Effects of Asthma on the Parturient and Fetus

Many investigators have questioned whether maternal asthma adversely affects perinatal outcome. Differences in study design (e.g., retrospective, prospective) and differences in severity and treatment of asthma may account for different study results. Some studies have reported an increased incidence of preeclampsia,[42,43] cesarean delivery,[44-46] low-birth-weight (LBW) infants,[47] preterm labor,[45,48] antepartum and postpartum hemorrhage,[49] and perinatal mortality.[50] Diabetes mellitus appears to be more common among asthmatic patients treated with corticosteroids.[51] Severe or poorly controlled asthma is a predictor of adverse outcome.[40] Although asthma in pregnancy is associated with an increased risk for adverse perinatal outcomes, a meta-analysis of cohort studies suggested that active asthma management, which is intended to reduce the exacerbation rate, may reduce the risk for perinatal complications, particularly preterm delivery.[52] No controlled studies have documented better perinatal outcome with aggressive asthma treatment. Potential mechanisms of increased perinatal morbidity and mortality in patients with uncontrolled asthma include hypoxemia and hypocapnia, inflammation, and altered placental function from asthma-associated mediator release.[53] Siddiqui et al.[54] have documented an association between preeclampsia and airway hyperresponsiveness and have proposed that the mechanism involves an interaction between mast cells and smooth muscle. A large prospective study is needed to confirm this association.

Medical Management

Pharmacologic therapy for asthma during pregnancy is directed toward avoiding acute exacerbations and episodes of status asthmaticus. Ideally, management should begin before conception. Although general principles typically dictate that unnecessary medication should be avoided during pregnancy, studies investigating the effects of asthma on perinatal outcome suggest that the risks for uncontrolled asthma are significantly higher than medication-associated risks.[55] Medications that are currently used to treat asthma fall into two general categories: bronchodilators and anti-inflammatory agents. These agents generally are safe for the fetus. The prophylactic use of antibiotics is unnecessary.

Bronchodilators

Beta-adrenergic agonists exert beneficial effects in asthmatic patients by activation of β_2-adrenergic receptors, which mediate a number of processes (Box 53-3). Short-acting beta-adrenergic agonists represent the most effective therapy for acute exacerbations of asthma.[56] Daily use of long-acting beta-adrenergic agonists is controversial. Long-acting beta-adrenergic agonist therapy is associated with a significant increase in the risk for death,[57] but controlled studies have not confirmed a cause-and-effect relationship.[58] Certain genetic polymorphisms affect responses to short-acting but not long-acting beta-adrenergic agonists,[59] leading to hopes that a

BOX 53-3 Mechanisms of Beneficial Effects of Beta-Adrenergic Agonists in Asthma

- Direct airway smooth muscle relaxation
- Enhanced mucociliary transport
- Decreased airway edema
- Inhibition of cholinergic neurotransmission

personalized approach to therapy would improve clinical efficacy. Although regular use of beta-adrenergic agonists in asthma may be beneficial in conjunction with other forms of therapy, these agents do not appear to provide optimal control when used alone. Conversely, no compelling evidence requires that beta-adrenergic agonists be discontinued after conception or that their use be reserved for treatment of an acute exacerbation.

These agents may be administered as aerosols, orally, or parenterally. The aerosol route is generally preferred during pregnancy because high concentrations of the medication can be delivered directly to the site of activity in the airways, with relatively less drug delivered to the uteroplacental circulation.

The limited number of human studies investigating the fetal safety of long-term administration of a beta-adrenergic agonist have not shown significant adverse neonatal outcomes.[60,61] In addition, the long history of use of these agents without reports of teratogenicity suggests that their use should not be restricted because of fetal concerns. Optimal control of maternal symptoms of asthma appears to be more important for the fetus than potential detrimental effects of beta-adrenergic agonists.

On the basis of the potential risks of long-term single-agent therapy with a beta-adrenergic agonist, a paradoxical approach to the treatment of asthma may involve long-term administration of a beta-adrenergic antagonist.[62] This approach is analogous to the paradigm based in the cardiovascular system, in which long-term administration of a beta-adrenergic antagonist is beneficial in patients with congestive heart failure. Studies in asthmatic patients are ongoing.

Methylxanthines (e.g., **theophylline**, **aminophylline**) were used for many years in the long-term treatment of asthma. Although their mechanism of action is controversial, relaxation of airway smooth muscle is the most prominent effect. The ability of the agents to inhibit intracellular phosphodiesterase and increase concentrations of cyclic adenosine monophosphate (cAMP) is not the mechanism of bronchodilation, because these effects do not occur at clinically relevant concentrations *in vivo*.[63] Furthermore, in the patient taking anti-inflammatory agents and beta-adrenergic agonists, methylxanthines add little to optimal asthmatic control.[64] Although their use is now limited to patients whose asthma responds poorly to other forms of therapy, methylxanthines do not appear to cause significant adverse fetal outcomes.[61] Serum concentrations of theophylline should be monitored carefully, especially in the third trimester, when theophylline clearance decreases.[65]

Bronchodilation with **anticholinergic agents** occurs through the blockade of muscarinic receptors on airway smooth muscle. Overall, anticholinergic agents alone are not as effective as beta-adrenergic agonists, but some patients show better response to anticholinergic agents.[66] The effects of adding anticholinergic agents to beta-adrenergic agonists for acute[67] and chronic[68] asthma were evaluated in meta-analyses of randomized trials. Anticholinergic agents improved lung function in acute asthma[67] but had little benefit in chronic asthma.[68] The **quaternary anticholinergic agent ipratropium bromide** can be delivered as an aerosol, allowing higher concentrations in the lung with reduced systemic absorption and potential effects on the fetus. Human data on the safety of anticholinergic agents and on potential teratogenicity are lacking, but ipratropium bromide is not associated with teratogenicity in animal studies.[69]

Magnesium sulfate relaxes airway smooth muscle, most likely via its antagonism of calcium entry into airway smooth muscle cells.[70] Its use is limited primarily to acute bronchospasm.[71]

Anti-Inflammatory Agents

Proposed mechanisms of action for corticosteroids are (1) decreases in cellular infiltration and mediator release, (2) reductions in airway permeability, and (3) up-regulation of the beta-adrenergic system.[72] Unlike bronchodilators, corticosteroids not only reduce airway sensitivity to a constrictor stimulus[73] but also decrease the maximal extent of airway narrowing, a feature that may predict severity of an acute asthmatic episode.[74]

The use of **inhaled corticosteroids** has gained popularity. This route of administration is effective and may limit fetal side effects. Studies have assessed the effects of systemic and inhaled corticosteroids on the fetus. Neither systemic nor inhaled corticosteroids have been proven to increase the risk for congenital malformations in humans. Inhaled corticosteroids do not affect glucocorticoid-regulated pathways in the fetus and therefore are unlikely to cause adverse effects on fetal growth and development.[75] Although oral corticosteroid use is associated with an increased incidence of LBW infants,[76] inhaled corticosteroids do not appear to increase perinatal risk.[77] Further, a meta-analysis did not show an association between inhaled corticosteroid use and any adverse perinatal outcome.[78] Of interest, use of inhaled corticosteroids during pregnancy can be guided by measurements of exhaled nitric oxide, which, in a randomized trial, were shown to significantly reduce exacerbations when compared with use of a clinical algorithm based on symptoms alone.[79]

Corticosteroids may increase perinatal morbidity by exacerbating maternal glucose intolerance, especially in women who also receive treatment with a beta-adrenergic agonist. Thus, careful monitoring of maternal glucose concentration is indicated in asthmatic women who require treatment with a corticosteroid during pregnancy. However, because of the efficacy of corticosteroids in controlling severe asthma during pregnancy, these agents should not be withheld from the medical regimen.

Some authorities have recommended that corticosteroid-dependent asthmatic women receive large doses of parenteral corticosteroids during labor to prevent complications related to adrenal suppression.[55,80,81] The scientific basis for this recommendation is questionable. Although physiologic glucocorticoid replacement reduced hemodynamic instability and mortality in adrenalectomized primates that underwent surgery, supraphysiologic doses provided no additional benefit.[82] Furthermore, inhaled corticosteroids in moderate doses do not produce adrenocortical suppression.[83] There is little information about the benefit of corticosteroid replacement therapy during labor. The potential for adrenal insufficiency in infants of asthmatic mothers taking inhaled or oral corticosteroids appears to be very low,[81] most likely owing to the widespread use of either prednisone or prednisolone. In the mother, prednisone is converted rapidly to prednisolone, which crosses the placental barrier to a very limited extent.

Cromolyn sodium and **nedocromil sodium** belong to a class of drugs that are thought to reduce inflammation and mediator release primarily by stabilizing mast cells and perhaps other inflammatory cells. Nedocromil also inhibits cellular chloride ion flux, a feature that may explain its ability to affect a range of airway cells, including nerve cells.[84]

Cromolyn and nedocromil are administered as aerosols. Limited studies suggest that cromolyn is safe during pregnancy,[85] and clinical experience is greater with cromolyn than with nedocromil. Thus, use of cromolyn is preferred.

On the basis of the observation that leukotrienes are released into the airways by immune cells and contribute to the inflammatory process, other forms of anti-inflammatory therapy are **leukotriene receptor antagonists** and **leukotriene synthesis inhibitors**. Safety data for the use of these agents in pregnancy are scarce. Bracken et al.[47] did not observe adverse neonatal outcomes in nine women exposed to these agents. A later prospective study of 96 women showed that use of leukotriene receptor antagonists was not associated with a specific pattern of congenital abnormalities, but the investigators cautioned that extrapolation of the data to a large population would require additional studies because of the limited sample size of the study.[85]

Obstetric Management

The following aspects of obstetric management of the asthmatic parturient may differ from that of the nonasthmatic patient: (1) induction of labor, (2) management of postpartum hemorrhage, and (3) treatment of hypertension.

For induction of labor, prostaglandins should be administered cautiously in women with asthma. Prostaglandin $F_{2\alpha}$ constricts airways *in vivo*[86] and *in vitro*.[87] Airways of asthmatic subjects demonstrate greater sensitivity to prostaglandin $F_{2\alpha}$, and its use to induce labor is associated with bronchospasm.[88] Prostaglandin E_2 can have either dilating or constricting effects on the airways, perhaps because of its ability to activate a variety of different types of prostaglandin receptors.[89] Because of the known risk for bronchospasm after exposure to prostaglandin $F_{2\alpha}$ and the possible risk after exposure to prostaglandin E_2, alternative methods of induction of labor are preferred in asthmatic women.

Likewise, asthma represents a relative contraindication to the administration of 15-methyl prostaglandin $F_{2\alpha}$ (carboprost, Hemabate) for the treatment of postpartum hemorrhage. The use of ergot alkaloids to treat postpartum hemorrhage in asthmatic women has also been questioned. Although controlled studies have not been performed, ergot alkaloids have been associated with episodes of acute bronchospasm,[90,91] on the basis of either their tryptaminergic actions or their ability to activate α_1-adrenergic receptors on airway smooth muscle cells. Oxytocin, which does not significantly affect airway tone, is the preferred ecbolic agent in asthmatic patients.

Beta-adrenergic receptor antagonists are used to treat hypertension in some pregnant women. In asthmatic women, these agents may provoke bronchospasm when used acutely.[92] Other antihypertensive agents, such as hydralazine and sodium nitroprusside, do not seem to enhance airway responsiveness.

Anesthetic Management

Preoperative Assessment

During the preoperative evaluation, the anesthesia provider should assess the severity of the disease and whether an acute asthmatic episode is present. The medical history should include information about symptoms of wheezing, dyspnea, and cough. Further information should be sought about the frequency and severity of symptoms, the course of these symptoms during pregnancy, and the date of the most recent exacerbation. Patients who have frequent, severe attacks are at increased risk for morbidity in the peripartum period.

Physical examination should focus on the pulmonary system. Chest auscultation may demonstrate wheezing with or without a prolonged expiratory phase. However, wheezing may not be audible if air movement is markedly reduced. Additional signs of an acute exacerbation of asthma include tachypnea, an exaggerated (> 20 mm Hg) pulsus paradoxus, and the use of accessory respiratory muscles.

In a pregnant woman with stable asthma, laboratory tests add little to anesthetic management. However, if an acute exacerbation is suspected, chest radiographic examination, arterial blood gas measurements, and pulmonary function tests may assist with diagnosis and therapy. **Chest radiographic examination** helps diagnose precipitating or complicating conditions such as pneumonia, pneumothorax, and heart failure. During an episode of acute asthma, **arterial blood gas measurements** often show hypoxemia and respiratory alkalosis. After a prolonged, severe episode, arterial carbon dioxide tension increases as a result of fatigue. **Spirometry** measures the volume of gas exhaled over time (see Box 53-1). The most convenient indirect measurement for assessing airway obstruction during labor is the **peak expiratory flow rate,** which can be measured at the bedside with a Wright peak flowmeter.[93]

Management during Labor and Vaginal Delivery

The goals of analgesia for labor and delivery in asthmatic women include (1) provision of pain relief, (2) reduction in the stimulus to hyperpnea, and (3) prevention or relief of maternal stress. The goal of adequate pain relief does not differ for asthmatic women. It is important to prevent hyperpnea and stress in women who describe asthmatic episodes triggered by exercise or stress. These goals should be accomplished with minimal sedation, minimal paralysis of the muscles of respiration, and minimal depression of the fetus. Possible analgesic regimens include systemic opioids, paracervical block, pudendal nerve block, lumbar sympathetic block, and epidural or spinal analgesia using local anesthetic agents, opioids, or both.

Systemic opioids may provide reasonable pain relief and reduce the stimulus to hyperpnea, especially during the early part of the first stage of labor. In theory, opioids reduce the risk for bronchospasm in asthmatic subjects. Opiate receptors are believed to be present in the respiratory tract[94] and to inhibit release of excitatory neuropeptides. The clinical relevance of these findings is unknown, because moderate doses of inhaled morphine do not significantly alter airway tone.[95] Conversely, high doses of some opioids (e.g., morphine) may increase the risk for bronchospasm by releasing histamine. The risk of using moderate doses of morphine does not seem excessive, because airway tone does not change in subjects with moderate to severe asthma after inhalation of morphine.[95] An opioid that does not release histamine (e.g., fentanyl, remifentanil) may be a better choice for the asthmatic parturient. High doses of opioids are not desirable in subjects with active wheezing because of the risks for maternal and neonatal respiratory depression (see Chapter 22).

Paracervical block and **pudendal nerve block** performed by an obstetrician are acceptable choices for analgesia during the first and second stages of labor, respectively. These techniques provide analgesia without sedation or paralysis of the respiratory muscles. The problems with these techniques in asthmatic women are similar to those in nonasthmatic parturients (see Chapter 24).

Lumbar sympathetic block also provides pain relief without sedation or motor block during the first stage of labor. This technique has the same limitations as for women without asthma (see Chapter 24).

Intrathecal and **epidural opioid** techniques are useful during the first stage of labor and do not produce motor block (see Chapter 23). The advantage of the absence of motor block should be weighed against the risk for respiratory depression in asthmatic subjects.

Advantages of the use of local anesthetic agents for **lumbar epidural analgesia** in asthmatic patients include continuous pain relief and a reduction in the stimulus to hyperventilation. These goals typically are achieved without maternal sedation or neonatal depression. Unlike other analgesic techniques, continuous lumbar epidural analgesia adds a margin of safety by providing the opportunity to extend the sensory block for cesarean delivery. The possibility of extension allows the anesthesia provider to avoid some of the risks of general anesthesia. The most significant disadvantage of epidural local anesthetics in an asthmatic subject is the risk for a high thoracic motor block and respiratory insufficiency. Use of an appropriate epidural catheter test dose and maintenance of a sensory level at the 10th thoracic dermatome minimize this risk. In addition, the use of a dilute concentration of local anesthetic combined with a modest dose of an opioid produces satisfactory analgesia with less motor block than local anesthetic alone.[96]

Management during Cesarean Delivery

The choice between neuraxial anesthesia and general anesthesia for cesarean delivery depends on obstetric considerations and the respiratory status of the parturient. In general, avoidance of airway instrumentation is desirable, because tracheal intubation markedly increases airway tone in asthmatic subjects.[97]

The most significant advantage of neuraxial anesthesia in the asthmatic patient is that this technique obviates the necessity for tracheal intubation. Neuraxial anesthesia is associated with a lower incidence of bronchospasm than general anesthesia in asthmatic subjects.[98] Stable asthmatic patients can undergo either spinal anesthesia or epidural anesthesia. In unstable asthmatic patients who require the use of accessory muscles of respiration, neuraxial anesthesia may be hazardous because of impaired ventilatory capacity in the presence of a high thoracic motor block. Intrathecal administration of either ropivacaine or levobupivacaine, which may produce less motor block than bupivacaine, does not confer any advantage with respect to pulmonary function in women receiving spinal anesthesia for cesarean delivery.[99]

The adrenal medulla receives innervation from preganglionic sympathetic fibers arising from the sixth thoracic to the second lumbar spinal segment.[100] Some authors have postulated that neuraxial anesthesia and the ensuing sympathectomy could precipitate or potentiate bronchospasm during cesarean delivery in asthmatic subjects by reducing adrenal output of epinephrine. This possibility seems remote. First, although epinephrine infusion can reduce airway reactivity in asthmatic subjects,[101] epinephrine concentrations do not decrease during nonobstetric surgery performed with neuraxial anesthesia that achieves high thoracic sensory levels.[102,103] Second, the idea that neuraxial anesthesia may prevent increases in circulating epinephrine that are required to compensate for stress-induced bronchospasm does not appear to be valid. Bronchoconstriction does not stimulate epinephrine secretion in human asthmatic subjects.[104] Thus, neuraxial anesthesia is appropriate for cesarean delivery in stable asthmatic subjects.

General anesthesia for asthmatic women undergoing cesarean delivery requires a balance between the competing considerations of pulmonary aspiration and intraoperative bronchospasm. Although airway instrumentation provides a great stimulus for bronchospasm, the high risk for aspiration mandates tracheal intubation during administration of general anesthesia in parturients.

Most commonly, options for tracheal intubation include awake intubation and rapid-sequence induction,

although mask induction of general anesthesia with sevoflurane has been described in a parturient with status asthmaticus.[105] Indications for awake intubation in asthmatic subjects are similar to those for nonasthmatic patients, and pretreatment with a local anesthetic and a beta-adrenergic agonist can attenuate reflex-induced bronchoconstriction after awake intubation.[97] The benefits of topical local anesthetics and airway nerve blocks for awake intubation should be weighed against a possible increase in the risk for aspiration from the loss of protective airway reflexes. Rapid-sequence induction for cesarean delivery in asthmatic patients is most often accomplished using either **propofol** or **ketamine**. A sympathomimetic agent, ketamine has long been considered the intravenous induction agent of choice for asthmatic subjects. Ketamine relaxes airway smooth muscle and inhibits neural reflexes.[106] Propofol provides better protection than thiopental against bronchospasm associated with tracheal intubation in asthmatic patients,[107] but it has not been compared directly with ketamine in humans. Beneficial airway effects of propofol, like those of ketamine, also appear to occur via inhibition of airway reflexes.[106] Intravenous **lidocaine,** which also inhibits airway reflexes, attenuates irritant-induced bronchoconstriction,[108] including tracheal intubation, and produces an additional protective effect above that of beta-adrenergic agonist pretreatment alone.[109]

In patients *without* asthma, maintenance of general anesthesia typically includes administration of a low concentration of a volatile halogenated anesthetic agent, with or without nitrous oxide, before delivery of the infant. After delivery, maintenance of anesthesia typically consists of nitrous oxide and an intravenous opioid, with or without a low concentration of a volatile halogenated agent. In *asthmatic* parturients, the **volatile halogenated anesthetic agents** are considered the agents of choice for the maintenance of anesthesia. These agents attenuate airway responsiveness through direct effects on airway smooth muscle,[110-112] inhibition of airway reflexes,[113] and effects on the epithelium.[114]

A high concentration of a volatile halogenated anesthetic agent has salutary effects on the airways but also increases the risk for hemorrhage during cesarean delivery by causing dose-dependent uterine relaxation.[115] Alternatively, nitrous oxide, an intravenous opioid, and a low concentration of a volatile halogenated agent may be given. Although halothane and isoflurane are approximately equipotent bronchodilators at high concentrations, halothane produces greater bronchodilation at lower concentrations[116] and therefore may be preferable for anesthesia for cesarean delivery. Sevoflurane acts as a bronchodilator in large and small airways[117] and reverses airway constriction associated with tracheal intubation.[118] Effects of desflurane are controversial. Desflurane protects against a direct stimulus to the airways[119] but may be less effective against reflex stimuli, such as tracheal intubation.[120]

A bronchodilator can be added if bronchospasm occurs. The potential disadvantage of this technique is that the most effective bronchodilators (i.e., the beta-adrenergic agonists) also relax uterine smooth muscle. The administration of a beta-adrenergic agonist by aerosol delivers a relatively greater dose of drug to the airways and minimizes uterine relaxation.

Emergence from general anesthesia, as with induction, requires a balance between reducing the risk for aspiration and lowering the risk for bronchospasm. Extubation of the trachea when the patient is awake minimizes the risk for aspiration, but the tracheal tube may stimulate reflexes and precipitate bronchospasm as the depth of anesthesia is reduced. If bronchospasm occurs during emergence, bronchodilators can be administered. For refractory bronchospasm, continued mechanical ventilation in an intensive care unit may be required.

CIGARETTE SMOKING

Epidemiology

Cigarette smoking is a significant, preventable cause of maternal morbidity and perinatal morbidity and mortality.[121] The prevalence of smoking among pregnant women in the United States declined from 18.1% in 1991 to 16% in 2010.[122] Approximately 46% of women who smoke quit smoking during pregnancy.[123]

Pathophysiology

Cigarette smoke contains a large number of separate components that have a variety of biologic effects. Nonrespiratory effects of cigarette smoking are described in Chapter 54.

The primary respiratory effects of cigarette smoking include alterations in small airway function, increased mucus secretion, and impairment of ciliary transport.[124] The precise mechanisms for these effects are unknown. Smoking also is associated with an increase in nonspecific airway reactivity, possibly through epithelial damage, altered airway geometry due to increased mucus secretion, or up-regulation of endothelin receptors.[125] These changes lead to a marked increase in the incidence of postoperative pulmonary complications.[124]

Interaction with Pregnancy

Few studies have documented the respiratory effects of cigarette smoking during pregnancy. In one study, reductions in forced expiratory flow rates suggested that pregnant women who smoke cigarettes have greater small airway resistance than those who do not smoke.[126] These and other abnormalities were similar to the changes in airway function observed in nonpregnant smokers. Although further studies are warranted, other respiratory effects of cigarette smoking in pregnant women are likely to be similar to those effects in nonpregnant women.

Cigarette smoking adversely affects pregnancy in a number of ways. The association between smoking and LBW has a genetic influence, such that the specific variation of the nicotinic acetylcholine receptor gene cluster is associated with lower newborn birth weight in smokers but not in nonsmokers.[127] Although observational, this study suggests a causal relationship between smoking during pregnancy and lower offspring birth weight.

Further details regarding adverse maternal and fetal effects of smoking are described in Chapter 54.

Medical Management

Cessation of smoking is the preferred form of medical management. Smoking cessation programs are effective in pregnant women.[128] Nonpharmacologic methods are preferred to pharmacologic methods (e.g., nicotine patches) because of insufficient safety information for the latter.[123] Das et al.[129] demonstrated that smoking cessation before or early in pregnancy results in prompt improvement in maternal airway function. Smoking cessation reduces perioperative complications in the nonpregnant patient undergoing surgery,[130] but no controlled studies have evaluated effects of smoking cessation on peripartum outcome.

Anesthetic Management

Tracheal intubation is associated with bronchospasm in smokers.[131] For vaginal delivery, any of the analgesic techniques described earlier for asthmatic parturients are acceptable. For cesarean delivery, neuraxial anesthesia achieves the goal of avoiding airway instrumentation and is therefore preferable to general anesthesia, although no controlled studies have documented differences in peripartum morbidity. If general anesthesia is required, the methods for reducing the risk for intraoperative bronchospasm described previously may be considered. During induction of general anesthesia in smokers, the formulation of propofol containing sulfite results in greater respiratory resistance after tracheal intubation than the formulation containing ethylenediaminetetraacetic acid (EDTA).[132] The clinical significance of this finding is unknown. One study noted that respiratory resistance did not decrease after tracheal intubation in smokers anesthetized with desflurane,[120] suggesting that other volatile halogenated anesthetic agents might be preferable.

CYSTIC FIBROSIS

Epidemiology

Cystic fibrosis, a lethal genetic disorder that is transmitted as an autosomal recessive trait, affects approximately 1 in 3200 white neonates in the United States.[133] Because of improvements in diagnosis and therapy, a growing number of women with cystic fibrosis survive to reproductive age. The number of pregnancies reported to a national cystic fibrosis registry increased from fewer than 100 in the 1980s[134] to approximately 240 in 2010.[135]

Pathophysiology

Clinical features of cystic fibrosis result from abnormalities of epithelial tissues, especially in the respiratory, digestive, and reproductive tracts. The underlying mechanism is a defect in cAMP-mediated activation of chloride (Cl^-) conductance in the epithelium.[136,137] Normal epithelial cells secrete Cl^- in response to an increase in intracellular cAMP. In cystic fibrosis, a genetic mutation makes epithelial cells unable to alter Cl^- permeability in response to changes in cAMP. The gene responsible for cystic fibrosis is located on chromosome 7 and encodes a protein known as the *cystic fibrosis transmembrane regulator* (CFTR).[138,139] The CFTR acts as a Cl^- channel but also has a number of other actions.[140] Cystic fibrosis is characterized by obstruction of exocrine glands with mucus, but the precise molecular mechanism is not well understood. In sweat glands, however, patients with cystic fibrosis show abnormalities that can be readily explained by impairment of the CFTR, which limits reabsorption of Cl^- and therefore of salt. In the airways, two opposing hypotheses, one in which the airway epithelium behaves similarly to the sweat duct epithelium and one in which the airway epithelium "behaves in a fashion essentially opposite to that of the sweat duct," have been proposed to explain alterations in fluid and electrolyte composition of airway secretions in patients with cystic fibrosis.[140]

In the lungs, abnormalities of electrolyte transport alter the composition of airway secretions. Inflammation, with infiltration of polymorphonuclear leukocytes, also contributes to changes in airway secretions.[141] Large numbers of disintegrating neutrophils release DNA in quantities sufficient to overwhelm the ability of deoxyribonuclease I (DNAse I), an endogenously released enzyme, to digest extracellular DNA. Undigested DNA increases the viscosity of airway secretions, which causes obstruction of small airways and reduced lung volumes. The ensuing ventilation-perfusion inequalities produce arterial hypoxemia. Some patients have hyperreactive airways. Spontaneous pneumothorax often occurs. Chronic airway obstruction and impaired mucus clearance increase the frequency of pulmonary infection. Most patients become colonized or infected with *Pseudomonas aeruginosa*. Eventually, tissue damage leads to bronchiectasis and pulmonary insufficiency. Chronic hypoxemia and lung destruction may produce pulmonary hypertension and cor pulmonale. Nonrespiratory manifestations of cystic fibrosis include pancreatic exocrine insufficiency, intestinal obstruction, and infertility.

Diagnosis

Clinical criteria for the diagnosis of cystic fibrosis include (1) the presence of chronic obstructive lung disease and colonization with *Pseudomonas aeruginosa* before age 20 years, (2) exocrine pancreatic insufficiency, and (3) a family history of cystic fibrosis. Laboratory findings include (1) sweat Cl^- concentrations greater than 60 mEq/L, (2) CFTR genotype with two known cystic fibrosis mutations, and (3) detection of CFTR dysfunction by nasal potential difference test.[142] Chest radiographic examination often demonstrates hyperinflation, and arterial blood gas measurements may show hypoxemia. Pulmonary function tests, which can reveal obstructive or restrictive lung patterns, are useful to assess the severity of the disease. With serial measurements, clinicians should look for evidence of an increased residual volume and a reduced FEV_1 (forced expiratory volume in 1 second).[143]

Interaction with Pregnancy

Effect of Pregnancy on Cystic Fibrosis

The following factors may contribute to the deterioration of pulmonary function during pregnancy: (1) increased airway responsiveness and obstruction (as can occur in patients with asthma), (2) increased work of breathing, and (3) cardiovascular changes such as congestive heart failure and pulmonary hypertension associated with the increased blood volume of pregnancy.

In spite of potential negative effects of pregnancy on the course of cystic fibrosis, long-term survival does not appear to be affected.[144] However, enthusiasm for these results should be tempered by the knowledge that pregnant women with cystic fibrosis require more intensive medical care than healthy pregnant women.[145,146]

Effect of Cystic Fibrosis on Pregnancy

Cystic fibrosis has been associated with an increased risk for LBW infants and preterm delivery,[146] but recent evidence suggests that improved care of these patients can mitigate these problems.[147] Potential mechanisms for these complications include chronic hypoxemia and poor maternal nutrition. Low prepregnancy FEV_1 and BMI are associated with an increased risk for adverse fetal outcome.[148]

Medical Management

Respiratory management of cystic fibrosis is primarily symptomatic. Patients with large volumes of mucus production undergo mechanical airway clearance. Some patients inhale recombinant human deoxyribonuclease I to reduce viscosity of lung secretions caused by accumulating DNA.[133] Hypertonic saline inhalation aids clearance of airway mucus.[149] Bronchodilators may help those patients who manifest a reversible component of airway obstruction. Continuous oxygen therapy may benefit patients with hypoxemia and cor pulmonale.

Long-term antibiotic therapy with inhaled tobramycin reduces both the incidence of recurrent pulmonary infection and the frequency of exacerbations in patients with cystic fibrosis.[150] Long-term administration of oral azithromycin also decreases exacerbations from cystic fibrosis[151] through either its antibiotic or its anti-inflammatory properties. Effects of long-term antibiotic therapy on the fetus are unknown.

Other forms of therapy include gene therapy and lung transplantation. Gene therapy uses viral (recombinant adeno-associated) or nonviral (liposome) vectors to transfer the normal CFTR to airway epithelium of patients with cystic fibrosis. A meta-analysis of randomized trials provided no evidence that topical CFTR gene replacement therapy improved clinical outcome, but further studies are needed owing to a limited number of study subjects.[152] Significant pulmonary deterioration sometimes leads to double-lung transplantation, although it is unclear whether transplantation alters survival.[153]

Obstetric Management

Because of the influence of pregravid maternal health on pregnancy outcome, the primary obstetric issue centers on the advisability of pregnancy in patients with cystic fibrosis. Criteria for the termination of pregnancy are not clearly defined. Genetic counseling regarding the risks of cystic fibrosis in the offspring is another important component of obstetric management.

Anesthetic Management

Considerations for anesthetic management focus primarily on the pulmonary system. Because of the high incidence of hypoxemia in patients with cystic fibrosis, continuous monitoring of oxygen saturation and appropriate oxygen therapy are advisable.

The goals of pain relief during labor are to provide adequate analgesia and to prevent maternal hyperventilation while avoiding high thoracic motor block and respiratory depression. High thoracic motor block may impair the parturient's ability to cough and eliminate thick secretions. Hyperventilation increases the work of breathing and may cause decompensation in patients with severe pulmonary dysfunction. For pain relief during labor, parenteral opioid analgesia may worsen pulmonary function by depressing respiratory drive and inhibiting cough. Intrathecal opioids have been used successfully,[154] but patients should be monitored carefully for respiratory depression. An ideal way to deliver a short-acting intrathecal opioid might be through a microcatheter, which would provide a margin of safety by allowing repeated administration of small doses of the opioid.[155] Alternatively, continuous lumbar epidural analgesia, with a sensory nerve block maintained at the level of the 10th thoracic dermatome, can provide excellent pain relief and reduce the stimulus for hyperventilation, with minimal motor block of the thorax. A dilute solution of bupivacaine, with or without an opioid, provides sensory analgesia with minimal motor block and is therefore nearly ideal in this setting.[156] In healthy parturients, this technique actually improves respiratory function slightly.[157]

Cesarean delivery necessitates the choice between general anesthesia and neuraxial anesthesia. Among patients with cystic fibrosis, no studies have documented differences in outcome between general anesthesia and neuraxial anesthesia. Neuraxial anesthesia offers the advantage of avoiding tracheal intubation, which may be associated with bronchospasm or obstruction of the tracheal tube with secretions. Neuraxial anesthesia also avoids positive-pressure ventilation, which may enlarge a preexisting pneumothorax. The primary consideration for neuraxial anesthesia during cesarean delivery is to avoid a high thoracic motor block, which may impair ventilation and the ability to cough. Effective spinal anesthesia for cesarean delivery slightly decreases vital capacity.[158] Methods for reducing the risk for excessively high motor block include the use of a continuous catheter technique, which allows titration of the local anesthetic agent to achieve the desired sensory level, and the use of the lowest concentration of local anesthetic (with or without an opioid) that provides surgical anesthesia. Both epidural

anesthesia[159] and combined spinal-epidural anesthesia[160,161] have been used in parturients with cystic fibrosis.

For general anesthesia, techniques to reduce the risk for bronchospasm, as described for patients with asthma (see earlier discussion), may be warranted. Additional considerations include (1) humidification of gases to prevent inspissation of mucus, (2) frequent suctioning to remove excess secretions, and (3) use of ventilator settings that allow an appropriately long expiratory phase to prevent air trapping and pneumothorax. It may also be prudent to avoid nitrous oxide in the parturient with cystic fibrosis, because of the risk for pneumothorax. Patients with cystic fibrosis should be allowed to awaken fully before extubation of the trachea. Chest physiotherapy may be required in the immediate postoperative period.

RESPIRATORY FAILURE

Epidemiology

The prevalence of respiratory failure during pregnancy is unknown. A significant subset of patients with respiratory failure suffers from **acute respiratory distress syndrome** (ARDS). The prevalence of ARDS in pregnancy has been estimated at approximately 1 in 6000 to 7000 deliveries.[162,163] Mortality from respiratory failure during pregnancy is high.[164]

BOX 53-4 Etiology of Respiratory Failure during Pregnancy

Adult Respiratory Distress Syndrome (ARDS)

- Infection
  - Bacterial or viral pneumonia
  - Endometritis
  - Pyelonephritis
  - Sepsis
  - Preeclampsia
- Hemorrhage
  - Multiple transfusions
  - Disseminated intravascular coagulation
- Aspiration of gastric contents
- Embolism
- Drugs
  - Salicylates
  - Opioids

Pulmonary Embolism

- Thromboembolism
- Amniotic fluid embolism
- Venous air embolism

Cystic Fibrosis

Pulmonary Edema

- Beta-adrenergic receptor agonists (e.g., ritodrine, terbutaline)
- Cardiogenic

Pathophysiology

The pathophysiology of respiratory failure depends on the underlying disorder. ARDS results from a group of predisposing conditions, but a common final pathway leads to similar manifestations.[165] Damage to the alveolar and capillary membranes initiates a cascade of events leading to fluid transudation that often is accompanied by pulmonary venoconstriction. Direct injury to the alveolar and capillary membranes can result from pulmonary aspiration of gastric contents and perhaps oxygen toxicity. Indirect toxicity can result from humoral and cellular mechanisms caused by triggers such as sepsis and amniotic fluid embolism. Transudation of fluid leads to atelectasis, airway obstruction, reduced lung compliance, and altered ventilation-perfusion relationships. Both physiologic dead space and shunt fractions are increased.

Diagnosis

A variety of disorders can cause acute respiratory failure during pregnancy (Box 53-4). Specific diagnostic criteria depend on the disorder.

The diagnosis of ARDS requires the exclusion of other disorders. Prominent characteristics of ARDS include arterial hypoxemia, radiographic evidence of pulmonary infiltrates, and reduced lung compliance in the setting of a recognized predisposing condition.[166]

Interaction with Pregnancy

Pregnancy is not known to alter the overall course of respiratory failure. However, differences in outcome between pregnant and nonpregnant patients have been observed in subsets of patients with respiratory failure. In a series of patients with **severe acute respiratory syndrome** (SARS), pregnant patients had greater morbidity.[167] Mortality rates are similar in pregnant and nonpregnant subjects.[164]

The most significant effect of respiratory failure on pregnancy is a reduction in oxygen delivery to the fetus. This reduction results most commonly from maternal arterial hypoxemia or maternal hypotension, which often accompanies respiratory failure. Hypotension may result from associated underlying conditions or from elevated mean airway pressures during mechanical ventilation. High rates of prenatal complications with or without preterm delivery have been reported.[162,163]

Medical Management

Therapeutic strategies for managing respiratory failure during pregnancy do not differ qualitatively from those in nonpregnant patients. The primary goals of medical management are to (1) eliminate predisposing conditions, (2) limit fluid transudation, and (3) maintain maternal oxygen delivery. Fluid restriction and diuretics help limit fluid transudation, although this therapy must be used cautiously when the underlying cause of respiratory failure is associated with intravascular fluid depletion. The goals for maintenance of oxygen delivery may differ quantitatively during pregnancy. Oxygen delivery to the fetus worsens significantly when Pao_2 decreases below 70 mm Hg or oxygen saturation (Sao_2) falls below

95%.[162,168] Standard methods of maintaining oxygen delivery include (1) administration of a higher inspired concentration of oxygen, (2) administration of bronchodilators in the presence of reversible airway obstruction, (3) administration of pharmacologic agents to support the circulation as needed, and (4) mechanical ventilation. A higher inspired oxygen concentration, delivered by face mask, is safe during pregnancy and may obviate the necessity of tracheal intubation and its risks for aspiration and difficult airway management. Bronchodilator therapy can also be used for respiratory failure, as described earlier for asthma. Pharmacologic agents for circulatory support include agents with both alpha- and beta-adrenergic receptor activity.

Indications for tracheal intubation and mechanical ventilation are similar for pregnant and nonpregnant patients with respiratory failure.[167,169] Maternal and fetal effects of current approaches to mechanical ventilation, including use of low tidal volumes and permissive hypercapnia, have not been studied in pregnant patients. Positive end-expiratory pressure may be used if cardiac output is maintained to allow sufficient blood flow to the uterus.

Some pregnant patients with respiratory failure do not show adequate response to conventional methods of treatment. For these patients, treatment options include extracorporeal membrane oxygenation (ECMO),[170] high-frequency oscillatory ventilation,[171] and inhaled **nitric oxide**.[172,173] Nitric oxide relaxes vascular smooth muscle. Rapid inactivation of nitric oxide by binding to hemoglobin in the circulation allows inhaled nitric oxide to produce pulmonary vasodilation without systemic vascular effect. Selective pulmonary vasodilation in well-ventilated areas of the lung presumably would improve oxygen delivery. The safety of these alternative forms of treatment in pregnancy is unknown because reports of their use are anecdotal.

Obstetric Management

Because the beneficial effects of delivery on the course of respiratory failure have not been proved, indications for induction of labor or cesarean delivery in this setting are not well defined. Small observational studies have not clearly shown an association between delivery and improved respiratory status in pregnant women with respiratory failure.[163,174,175] Further, data to support decisions regarding mode of delivery are limited. Vaginal delivery is possible during mechanical ventilation[176,177] and may avoid complications of major intra-abdominal surgery in a critically ill woman.

Anesthetic Management

The anesthetic management of patients with respiratory failure requires appropriate medical management. During labor, analgesia for mechanically ventilated patients can be achieved with intravenous opioids, which are often used for sedation during mechanical ventilation. Lumbar epidural analgesia provides pain relief without the neonatal respiratory depression associated with high doses of opioids. Labor epidural analgesia also reduces oxygen consumption,[178] which may be beneficial in hypoxemic patients. The use of labor epidural analgesia in patients with respiratory failure depends on underlying conditions and ongoing therapy. Close attention should be paid to intravascular volume, adequacy of coagulation, and presence or absence of infection.

In mechanically ventilated patients, general endotracheal anesthesia is often the most convenient choice for cesarean delivery. Aside from the issues of medical management (as discussed earlier), the techniques and pharmacologic agents do not differ substantially from those used in patients without respiratory failure.

KEY POINTS

- Patients with asthma, infection, respiratory failure, or cystic fibrosis and patients who smoke cigarettes may have reversible airway obstruction.
- In patients with airway hyperresponsiveness, tracheal intubation provides one of the most significant stimuli for bronchospasm during the perioperative period.
- Inhaled β_2-adrenergic agonists are the most effective therapy for perioperative bronchospasm.
- Most bronchodilators also produce uterine relaxation. However, their administration by aerosol should minimize their effects on uterine tone.
- Neuraxial anesthesia is often the anesthetic technique of choice in patients with respiratory disease because it does not require tracheal intubation.
- Techniques of neuraxial anesthesia should be modified to reduce the likelihood of a high thoracic motor block in patients with significant respiratory disease.

CHAPTER 54

Substance Abuse

Lisa R. Leffert, MD

CHAPTER OUTLINE

Abuse of licit and illicit substances by pregnant women can pose a significant risk to maternal and fetal health. Estimates of the prevalence of substance abuse in pregnant women vary depending on the particular licit or illicit substance, the maternal age group, and the data source.[1-3] The rate of illicit drug use during pregnancy as reported in the National Survey on Drug Use and Health from 2009 to 2010 was 16.2% among pregnant women aged 15 to 17 years, 7.4% among pregnant women aged 18 to 25 years, and 1.9% among pregnant women aged 26 to 44 years. During the same time period, among pregnant women aged 15 to 44 years, 4.4% were current illicit drug users. This 4.4% rate was lower than the rate among nonpregnant women (10.9%).[1]

Depending on the particular substance ingested, pregnant women may experience little to no acute and chronic adverse effects, or alternatively, manifest one or more of the following: (1) cardiovascular, pulmonary, and neurologic complications; (2) obstetric complications (e.g., decreased intrauterine fetal growth, preterm labor, placental abruption, fetal death); and (3) heightened sensitivity to pain.[4-12] Anesthesia providers often care for these patients during the provision of analgesia for labor and anesthesia for cesarean delivery as well as during other obstetric procedures before and after delivery. Patients with substance abuse may have altered pain sensitivity, and anesthesia providers are often consulted for help with management of acute postoperative pain.

DRUG DETECTION

Optimal care requires developing a therapeutic bond with these patients and identifying what substances have been ingested.[13] The anesthesia provider should ask questions in a respectful and nonjudgmental manner. It is vital to respect patient confidentiality, and it may be necessary to speak to the patient without family or friends present. Self-reporting typically underrepresents the true incidence of substance abuse.[14-16] Therefore, health care providers should be familiar with the characteristic signs and symptoms associated with acute and chronic intoxication. The myriad of methods available to test pregnant patients and their infants for the presence of illicit drugs include analysis of urine, blood, saliva, hair, meconium, and umbilical cord tissue. Amniotic fluid and neonatal gastric aspirate have also been analyzed (Tables 54-1 and 54-2).[14-19] It is vital to understand which compounds a particular drug test identifies before interpreting the results. Caregivers should be aware that the immunoassays most commonly used in drug testing can have false-positive or false-negative results in the presence of structurally related drugs or additives. Gas chromatography with mass spectrometry ideally should be used to provide confirmation of positive results.[16]

LICIT DRUGS

Alcohol

Epidemiology

Alcohol (ethanol) abuse represents a significant problem for pregnant women and their developing fetus. Since 1981, official advisories have warned against the use of alcohol by pregnant women or women considering pregnancy.[20] Yet the 2010 National Survey on Drug Use and Health noted that 10.8% of pregnant women 15 to 44 years old reported current alcohol use, 3.7% reported binge drinking, and 1.0% reported heavy drinking. These rates are significantly lower than those of nonpregnant women in the same age brackets (54.7%, 24.6%, and 5.4%, respectively). Survey data indicate that among heavy drinkers, approximately 1.8% also use illicit drugs.[1]

TABLE 54-1 Drug Detection: Overview

Specimen	Advantages	Limitations
Urine	Detection of diverse group of illicit substances (except volatile alcohols) Specimen and test readily available Short turnaround time (30 minutes at point of care; 2 hours for laboratory specimens) More sensitive test (compared with meconium and hair) for cannabis	Underrepresents most illicit drug use Significant false-positive rate for phencyclidine (PCP) Narrow detection window compared with that for meconium and hair Specimen can more easily be adulterated
Blood	Most commonly used for volatile alcohols (can detect other illicit substances) Specimen and test readily available	Invasive Narrow detection window compared with that for urine, meconium, and hair
Meconium	Highly sensitive (compared with urine testing) for cocaine and opioids Wide detection window No false-positive results for cocaine	Report may be delayed (days) Low sensitivity and specificity for detecting cannabinoids and amphetamines via immunoassay
Hair	Highly sensitive test for detecting cocaine (three times that of urine) and opioids Wide detection window (reflects chronic cumulative use) Samples can be stored at room temperature Samples can be analyzed remote from collection	Multiple hairs required; harvested close to scalp Environmental contamination may cause false-positive result Low sensitivity for detecting tetrahydrocannabinol
Umbilical cord blood	Comparable to meconium with more rapid results May reflect a wide window of detection	Specimen not available before delivery
Oral fluid	Highly sensitive for methamphetamine and other basic drugs Easy, noninvasive Primarily detects parent compound	If mouth is dry, salivary stimulation may be associated with a decreased drug concentration in oral fluid

Data from references 3, 14, 15, 17, and 165.

TABLE 54-2 Drug Detection Window in Urine*

Drug†	Analyte	Detection Window
Tobacco	Cotinine Nicotine	19 h (urine $T_{1/2}$) 2 h (urine $T_{1/2}$)
Cocaine	Cocaine Benzoylecgonine	3-6 h IV use: 1-2 days Intranasal use: 2-3 days
Amphetamines	Amphetamine Methamphetamine	1-3 days Smoked: 60 h
Methylenedioxymethamphetamine (MDMA, ecstasy)	MDMA	1-3 days
Marijuana (cannabis)	Tetrahydrocannabinol (THC) THCCOOH	Smoked: 10 h Up to 25 days
Lysergic acid diethylamide (LSD)	LSD 2-Oxo-3-OH-LSD	24 h 96 h
Heroin	6-Acetyl morphine Morphine	IV use: 2-4.5 h 19-54 h
Benzodiazepines	Flunitrazepam: 7-aminoflunitrazepam	< 72 h Chronic use: 4-6 wk
γ-Hydroxybutyric acid (GHB)	Rapidly metabolized to CO_2 and H_2O	< 12 h

IV, intravenously; $T_{1/2}$, half-life.
*Average values based on recent use; precise values may vary according to method of ingestion, assay employed, and duration of use.
†Detection of methadone, buprenorphine, oxycodone, and oxymorphone typically requires an additional screening test.
Data from references 5, 19, 74, 120, and 166.

Pharmacology

Alcohol, usually ingested orally, is absorbed through the gastrointestinal tract, primarily within the small intestine. Ingested alcohol is metabolized by alcohol and acetaldehyde dehydrogenases. This process leads to the production of acetaldehyde and the reduction of nicotinamide adenine dinucleotide (NAD) to its reduced form NADH. The excess reduced form relative to NAD results in metabolic derangements. A small residual amount (2% to 8%) of alcohol is excreted via the lungs, urine, and sweat.[21-23]

Systemic Effects

According to legal statutes, the definition of "intoxication" requires a blood alcohol level of at least 80 to 100 mg/dL, although behavioral, cognitive, and psychomotor changes can occur at levels of 20 to 30 mg/dL (e.g., after one to two drinks) (Table 54-3).[21-23]

Alcohol has complex effects on the central nervous system (CNS); it acts as both a depressant and a stimulant through a variety of neurotransmitter pathways.[23] When alcohol is consumed in conjunction with barbiturates or benzodiazepines, these effects can be compounded. Endogenous opioids interact with alcohol to "reinforce" further alcohol use; this effect is blunted by opioid antagonists.[23]

Alcohol and its metabolites (e.g., acetaldehyde) can be directly toxic to brain tissue.[21,22] Chronic alcoholism is associated with brain atrophy that results in impairment of memory, abstract problem-solving, verbal learning, and visual-spatial processing.[21,22] Additional adverse neurologic effects result from vitamin (e.g., thiamine, vitamin B_{12}) deficiencies.[21,22]

Heavy alcohol consumption also damages other organs. Over time, hepatic cirrhosis can develop, which, in turn, can lead to encephalopathy, coagulopathy, and esophageal varices (Table 54-4). Gastrointestinal mucosa injury, pancreatitis, and cardiomyopathy may also occur.[9,10,22,24]

Women who abuse alcohol are at increased risk for depression, suicide, and accidents.[7] Symptoms of acute alcohol withdrawal (e.g., nausea, vomiting, tachycardia, hypertension, arrhythmias, tremor, hallucinations, agitation, seizures) usually occur within 6 to 48 hours after cessation of alcohol consumption (Table 54-5).[9,10,25] Pharmacologic therapy to minimize the signs and symptoms of alcohol withdrawal includes the use of benzodiazepines and α_2-adrenergic agonists (e.g., clonidine).[9] The most severe form of withdrawal symptoms, **delirium tremens**, manifests as agitation, disorientation, hallucinations, and fever combined with autonomic instability. Delirium tremens occurs rarely in pregnant women, but it can lead to maternal and fetal death if untreated.[6, 26]

Effects on Pregnancy and the Fetus

Intrauterine alcohol exposure is the leading cause of preventable birth defects in the United States.[27,28] No safe level of alcohol consumption by pregnant women has been identified.[26,27] In contrast to other investigations of high-risk populations, a 2010 population-based cohort study found no association between low or moderate prenatal alcohol exposure before or during pregnancy and the occurrence of birth defects.[29] However, the authors recognized that the incidence of birth defects is low and the sample size may not be sufficient to draw definitive conclusions. **Fetal alcohol syndrome** is defined as the presence of particular neonatal facial features (e.g., small palpebral fissures, flat midface with a short upturned nose, thin upper lip) and significant impairment in neurodevelopment and physical growth.[9,10,27,30] **Fetal alcohol spectrum disorders** refer to the wide range of possible adverse effects of fetal exposure to alcohol.[27] The extent to which an individual fetus is affected is related to the characteristics of the exposure, genetic variables, and the intrauterine environment.[31]

Alcohol exposure is also associated with pregnancy loss. Harlap and Shiono[32] reported an increased risk for second-trimester fetal loss in pregnant women who consumed alcohol early in pregnancy (relative risk, 1.98 for those consuming one to two drinks daily and 3.53 for those consuming more than three drinks daily, compared with nondrinkers). Identification of mothers at risk can facilitate treatment and perhaps improve pregnancy outcomes.[27]

Anesthetic Management

Alcohol-intoxicated parturients are at increased risk for behavioral problems, electrolyte abnormalities, greater gastric acid secretion, and co-intoxication with other substances.[9,10,26] Determining whether the patient can protect her airway is of paramount importance because acute intoxication increases the risk for pulmonary aspiration of gastric contents. In addition, these patients may have intravascular volume depletion secondary to vomiting, inadequate oral intake, diuresis, and hypoalbuminemia. Significant alcohol ingestion in the setting of poor oral intake may also manifest as severe hypoglycemia.[22,24,33]

Neuraxial analgesia or anesthesia can be safely administered for labor or cesarean delivery provided that (1) the patient is cooperative, (2) there is no evidence of coagulopathy (as a result of liver disease), (3) the patient is volume replete, and (4) baseline neurologic deficits (e.g., peripheral neuropathy, cognitive deficits) are assessed and documented.[9]

If emergency delivery is required and the patient is either uncooperative or too sedated to protect her airway, general anesthesia will be necessary. The patient should receive pharmacologic aspiration prophylaxis (e.g., nonparticulate antacid, histamine-2 (H_2)-receptor antagonist, metoclopramide) and should undergo a rapid-sequence induction of general anesthesia.[34]

Evidence from published reports is inconclusive about predictable differences in anesthetic requirements in patients with acute and chronic alcohol use.[35] Acute alcohol intoxication is believed to decrease a patient's anesthetic requirements, in part because of the additive effect of alcohol and other CNS depressants. The notion that chronic alcoholics require more anesthesia than their non–alcohol-using counterparts is based primarily on data from an abstract published by Han in 1969,[36] who demonstrated that the mean minimum alveolar concentration (MAC) for halothane in six chronic alcoholic patients who had been heavy drinkers for more than 10 years was significantly greater than that for six healthy adults. Subsequently, Swerdlow et al.[37] assessed the response to thiopental in 11 nonpregnant, chronic alcohol users. After eliminating potential confounders such as acute intoxication, withdrawal, polysubstance abuse, and end-organ dysfunction, they found that chronic alcohol intake did not alter thiopental dose requirements, pharmacokinetics, or pharmacodynamics. No large population studies have assessed dose requirements for volatile anesthetic agents or hypnotic agents in patients who chronically abuse alcohol.

TABLE 54-3 **Acute Intoxication and Organ Dysfunction**

Substance	Neurologic	Cardiovascular	Pulmonary	Gastrointestinal	Hematologic	Other
Alcohol	↓ Cognition	—	↑ risk for aspiration	—	—	↑ Cortisol ↓ Glucose
Tobacco	—	↑HR, BP, myocardial work	↓ Tissue oxygenation secondary to ↑ carboxyhemoglobin ↓ Mucociliary clearance ↑ Airway irritability	—	—	Impaired wound healing
Caffeine	—	Mild ↑ BP in low doses	—	—	—	Diuresis
Marijuana (cannabis)	↓ Cognitive and motor performance	Biphasic autonomic effect ST-segment and T-wave changes on ECG	↑ HR **If smoked:** effects similar to those of tobacco	Appetite stimulation	—	Conjunctival vasodilation and reddening
Cocaine	Subarachnoid or intracranial hemorrhage Cerebral infarct Seizures	Hemodynamic instability, arrhythmias Acute myocardial infarction Aortic dissection	**If free based:** pulmonary edema and pulmonary hemorrhage **If smoked:** see "Tobacco" **If snorted:** nasal septal injury and epistaxis	↑ AST and ALT	↓ Platelets (?)	Infection ↑ Temperature ↑ Cortisol ↑ Glucose
Amphetamines	Seizures Stroke Paranoia Hallucinations	Similar to effects associated with cocaine	—	—	—	Proteinuria ↑ Temperature
Hallucinogens	Hallucinations Paranoia Intracerebral hemorrhage (rare) Seizures (rare)	Supraventricular tachycardia (rare) Acute myocardial infarction (rare)	—	—	—	—
Opioids	—	↓ HR ↓ BP	Respiratory depression	—	—	—
Solvents	Encephalopathy Seizures	Arrhythmias Acute myocardial infarction	Hypoxemia Bronchospasm Acute respiratory distress syndrome	Mucosal injury		Ethylene glycol ingestion: Metabolic acidosis Renal failure

ALT, alanine aminotransferase; *AST,* aspartate aminotransferase; *BP,* blood pressure; *ECG,* electrocardiogram; *HR,* heart rate; ↑, increase in; ↓, decrease in; ?, questionable.

TABLE 54-4 **Effects of Chronic Substance Abuse**

Substance	Neurologic	Cardiac	Pulmonary	Gastrointestinal	Hematologic	Other
Alcohol	Peripheral neuropathy Brain atrophy Encephalopathy	Cardiomyopathy	—	Hepatitis Cirrhosis Gastric mucosal injury Pancreatitis	Anemia (± leukopenia, thrombocytopenia) Coagulopathy	↑ Cortisol
Tobacco	—	Atherosclerosis	Diffusion capacity abnormalities ↓ Pulmonary immune function ↑ Incidence of bronchitis, COPD ↑ Airway irritability ↑ Risk for lung cancer	—	—	—
Caffeine	Cessation may produce withdrawal headache	Does *not* negatively affect cardiac health at moderate dose	—	—	—	↑ Risk for bladder dysfunction with high dose
Marijuana (cannabis)	↓ Attention, memory ↓ Ability to process complex information	—	**If smoked:** effects similar to those associated with tobacco	↑ Rare forms of oropharyngeal cancer	—	—
Cocaine	Brain atrophy	Cardiomyopathy Myocarditis Blood vessel occlusion	**If smoked:** effects similar to those associated with tobacco **If snorted:** mucosal and nasal septal injury	Gastrointestinal ischemia/ulceration ↑ AST and ALT	↓ Platelets (?)	Renal failure
Amphetamines	Paranoid psychosis Impaired memory	—	—	—	—	↑ Tooth decay ("meth mouth")
Hallucinogens (episodic use)	Delayed hallucinations	—	—	—	—	—
Opioids	Abnormal pain sensitivity	Infective endocarditis	—	—	—	Hepatitis or HIV infection with exposure to contaminated needles
Solvents	Visual loss Cranial neuropathy Peripheral neuropathy Autonomic dysfunction Ataxia Brain atrophy Encephalopathy	Cardiomyopathy Acute myocardial infarction	—	Nonviral hepatitis Hepatocellular carcinoma	Aplastic anemia	"Glue-sniffer's" rash Renal failure

ALT, alanine aminotransferase; *AST,* aspartate aminotransferase; *COPD,* chronic obstructive pulmonary disease; *HIV,* human immunodeficiency virus; ↑, increase in; ↓, decrease in; ?, questionable.

TABLE 54-5 Symptoms of and Treatment for Substance Abuse Withdrawal

Substance	Symptoms	Therapy
Alcohol (ethanol)	Nausea Vomiting Tachycardia Hypertension Tremor Hallucinations Agitation	Benzodiazepines and α_2-adrenergic agonist (e.g., clonidine)
	Delirium tremens: • Autonomic instability/arrhythmias • Seizures • Severe tremors • Disorientation • Fever	Benzodiazepines and α_2-adrenergic agonist (e.g., clonidine) Antiarrhythmics Anticonvulsants (e.g., phenytoin)
Tobacco	Cravings Irritability Headache Cough Insomnia	Nicotine replacement therapies, including patch, gum, and inhalers
Caffeine	Headache Anxiety Depressed mood Fatigue	Supportive care Caffeine ingestion
Cannabis	Mild abstinence syndrome Headache Restlessness Tremor Anxiety Autonomic effects	Supportive care
Cocaine	Prolonged sleep phase Hunger Anxiety Weakness Headaches Tremors and seizures	Supportive care Reintroduction of drug, if necessary, with slow taper
Amphetamines	Fatigue Depression Hunger Intense cravings	Tricyclic antidepressants, dopaminergic agents (e.g., bromocriptine), and amino acid therapy (no therapy has proved to be successful)
Hallucinogens (e.g., phencyclidine [PCP], lysergic acid diethylamide [LSD])	No clearly associated withdrawal symptoms, although psychological dependence can occur	Not applicable
Opioids (e.g., heroin)	Flulike symptoms, such as fatigue, weakness, restlessness, rhinorrhea, perspiration, fever, diarrhea	Supportive therapy α_2-Adrenergic agonist (e.g., clonidine) Doxepin Reintroduction of drug, if necessary, with slow taper
Solvents (e.g., ethylene glycol, toluene, glue)	Not applicable	Not applicable

Short-term consumption of alcohol inhibits the metabolism of drugs by the liver (through competition for cytochrome P450), which results in higher plasma concentrations of drugs metabolized by the liver. *Long-term* consumption of alcohol increases the levels of cytochrome P450, resulting in decreased levels of medications such as diazepam and labetalol, and increased levels of toxic metabolites that occur from hepatic degradation of illicit drugs such as cocaine.[22] Both pregnancy and liver disease can lead to decreased plasma concentrations of pseudocholinesterase; however, this decrease does not seem to have a clinically significant effect on the degradation of succinylcholine and ester local anesthetics.[35]

Parturients who regularly consume large amounts of alcohol and undergo general anesthesia for cesarean delivery may be at high risk for awareness under anesthesia.[38] The high doses of volatile anesthetics often recommended in nonpregnant, chronic alcohol-using patients can lead to significant uterine atony and potential increased blood loss. Therefore, a balanced anesthetic technique that combines induction with generous doses of the hypnotic agent with succinylcholine (if not otherwise contraindicated), followed by maintenance with a volatile anesthetic agent (limited to 0.5 to 0.8 MAC after delivery to prevent uterine atony), nitrous oxide (up to 67%), and an opioid and a benzodiazepine (for analgesia and amnesia), should be employed. Withholding

additional muscle relaxation after induction and adding a brain function monitor if time and circumstance permits[39] may help to identify patients who could benefit from additional anesthesia.

Tobacco

Epidemiology

Cigarette smoking is the most common form of substance abuse during pregnancy. As public awareness has grown regarding the hazards of smoking during pregnancy, the prevalence of cigarette smoking during pregnancy has declined over the past 40 years. An estimated 18% of pregnant women reported smoking (in the past month) in 2003,[40] compared with 16% in 2010.[1] Although the overall smoking rate in pregnant women is lower than in nonpregnant women, the rate among pregnant teens aged 15 to 17 years is actually higher than that among nonpregnant teens (22.7% versus 13.4%).[1] Among the approximately 40% of patients who stop smoking when they discover that they are pregnant, 60% to 80% return to smoking by 6 months postpartum.[41]

Pharmacology

More than 4000 chemicals are found in tobacco, including nicotine, carbon monoxide, and cyanides.[23,42] Tobacco is most often smoked, but it can also be chewed or sniffed. Nicotine, the principal drug of abuse in tobacco, acts at peripheral and central nicotinic (acetylcholine) receptors throughout the body to affect the release of catecholamines. Nicotine's effects begin immediately on exposure; it is then rapidly metabolized in the liver and the lungs and excreted by the kidneys. The half-life is typically a few hours. The duration of the acute effects of nicotine is shorter in heavy smokers than in light smokers.[23]

Carbon monoxide, another constituent of cigarette smoke, interferes with oxygen delivery to the cells by competitively binding to hemoglobin, thereby decreasing the oxygen-binding capacity and shifting the oxyhemoglobin dissociation curve to the left.[43] Depending on the extent of smoke inhalation, carbon monoxide may occupy 3% to 15% (or more) of the oxygen-carrying capacity of the blood.[44]

Systemic Effects

Smoking alters maternal physiology through both the acute pharmacologic actions of tobacco's chemical constituents and their contribution to comorbid disease. Peripherally, nicotine increases sympathetic tone, thereby increasing maternal heart rate, blood pressure, and cardiac work (see Table 54-3).[45] Nicotine affects neurotransmitter release in different areas of the brain, producing feelings of alertness, euphoria, and, ultimately, dependence.[23,45]

Increased production of carboxyhemoglobin is thought to be a major factor in the impaired wound healing observed in smokers.[43] Smoking also promotes atherosclerosis. The effects of tobacco smoking on the lungs include changes in the volume and composition of mucus, impaired mucociliary clearance, and an increased incidence of bronchitis and chronic obstructive pulmonary disease (see Table 54-4).[45]

Tobacco is addictive, and cessation of its use produces withdrawal symptoms, including cravings, irritability, headache, cough, and insomnia (see Table 54-5). Smoking cessation interventions include counseling and therapy, hypnosis, acupuncture, and pharmacologic therapy. The use of nicotine replacement therapy (e.g., nicotine gum, patch, inhaler) has not undergone sufficient evaluation of safety during pregnancy; thus, the American College of Obstetricians and Gynecologists (ACOG) has recommended that nicotine replacement therapy be used only when nonpharmacologic interventions have failed.[40] The physiologic benefits of smoking cessation are progressive. Even brief smoke-free intervals can result in a reduction in the carboxyhemoglobin concentration, improved ciliary function, and decreased small airway obstruction.[46]

Effects on Pregnancy and the Fetus

Nicotine has a low molecular weight and readily crosses the placenta.[4] Smoking may result in decreased fetal oxygenation as a result of increased concentrations of carboxyhemoglobin and reduced uteroplacental perfusion. It also leads to decreased uptake of nourishing amino acids by the placenta.[42] Smoking is associated with a higher incidence of ectopic pregnancy, spontaneous fetal loss, placental abruption, and sudden infant death syndrome (SIDS).[32,40,47] Smoking may protect against the occurrence of preeclampsia (see Chapter 36).[48]

Smoking adversely affects fetal growth.[42,49,50] Low birth weight (LBW) is associated with increased neonatal and infant mortality.[42,50] Salihu et al.[50] documented that infant mortality was 40% higher in the offspring of women who smoked than in the offspring of nonsmoking women; this risk increased in a dose-dependent fashion for the infants who were small for gestational age (SGA). Smoking cessation before the third trimester ameliorates the smoking-associated reduction in birth weight.[40]

Intrauterine exposure to smoking (tobacco and/or marijuana) may also have long-term effects. Fried et al.[51] examined the cognitive performance in 145 adolescents (13 to 16 years of age) from a low-risk, middle-class population. After controlling data for socioeconomic status and polysubstance abuse, they found that measures of overall intelligence and auditory memory were negatively related to prenatal maternal smoking in a dose-related fashion.

Anesthetic Management

Smoking is a risk factor for several perioperative complications, including respiratory sequelae and impaired wound healing.[43,45] Smoking results in increased airway secretions, decreased ciliary motility, and impaired gas exchange.[45] Smoking is also associated with an increase in nonspecific airway reactivity, and tracheal intubation may provoke bronchospasm. Wilkes et al.[52] observed that coughing after exposure to desflurane was more pronounced in smokers. By contrast, Kim and Bishop[53]

observed that although most patients coughed as they awakened from general anesthesia maintained with isoflurane, smokers were not more likely to cough than nonsmokers.

Six months of abstinence may be required before the function of alveolar macrophages and pulmonary cytokines during and after general anesthesia in former smokers is similar to that of nonsmokers.[46] Administration of neuraxial anesthesia avoids airway manipulation and is typically preferred in parturients who smoke.

Caffeine

Epidemiology

On a daily basis, 80% to 98% of women drink caffeine-containing beverages.[9,54] The prevalence of consumption of caffeine-containing beverages during pregnancy is unknown.

Pharmacology

Caffeine (1,3,7-trimethylxanthine) is a naturally occurring alkaloid found in coffee, tea, cocoa, and some soft drinks and medicines.[9,54,55] The primary sources of caffeine in the adult diet are coffee (56 to 100 mg/100 mL if brewed) and tea (20 to 73 mg/100 mL). Caffeine is readily absorbed through the gastrointestinal tract, and maximum blood concentrations of caffeine are attained 1 to 1.5 hours after ingestion. Caffeine undergoes hepatic metabolism and is then excreted in the urine.[54,55] The elimination half-life of caffeine is 3 to 7 hours. In pregnancy, the half-life increases from 4 hours in the first trimester to 18 hours by the third trimester. Caffeine crosses the placenta and can also be found in breast milk.[54,56] Habitual use of caffeine at levels greater than 500 to 600 mg/day is defined as abuse.[54,56]

The half-life of caffeine in the neonate is prolonged in comparison with that in children and nonpregnant women.[54]

Systemic Effects

Caffeine acts as an antagonist at the adenosine receptor. In the absence of the inhibitory effects of adenosine, the neurotransmitters norepinephrine, dopamine, and serotonin are released in increased concentrations.[54,56] Systemic effects of caffeine include CNS stimulation, changes in blood pressure and metabolic rate, and diuresis (see Table 54-3).[55] The side effects commonly attributed to caffeine vary among individuals, in part related to the doses ingested and the degree of chronic use. Studies of the effects of caffeine on alertness, vigilance, mood, and memory have produced inconsistent results.[54]

Moderate caffeine intake (≤ 400 mg/day or ≤ 4 cups of coffee/day) does not seem to negatively affect cardiovascular health in most people. Although some people who ingest caffeine report tachycardia and palpitations, doses lower than 450 mg/day do not appear to increase significant cardiac arrhythmias in either healthy patients or in those with ischemia or ventricular ectopy. Caffeine doses as low as 250 mg have been reported to have a hypertensive effect after acute ingestion (an increase in systolic blood pressure of 5 to 15 mm Hg and an increase in diastolic blood pressure of 5 to 10 mm Hg), particularly in caffeine-naive individuals; however, epidemiologic studies have produced inconsistent results. In general, people who ingest caffeine on a long-term and frequent basis are less likely than occasional users to have difficulty sleeping.[54]

Caffeine appears to affect bladder function in women. Moderate caffeine intake may exacerbate preexisting bladder symptoms, and excessive intake (> 400 mg/day) increases the risk for bladder dysfunction.[54]

Evidence suggests that caffeine is not a human carcinogen.[55] The lethal dose of caffeine in humans has been estimated to be 10 g; however, only a few such cases have been reported.[54]

Caffeine withdrawal is associated with headache, anxiety, depressed mood, and fatigue (see Table 54-5). Typically, symptoms begin 12 to 24 hours after cessation of use, peak at 20 to 48 hours, and last up to 7 days. The severity and likelihood of symptoms are not predictable.[54]

Effects on Pregnancy and the Fetus

Caffeine readily crosses the placenta. Whereas animal studies have shown that very high doses can have a teratogenic effect, moderate doses do not appear to result in teratogenesis in humans.[54,57,58] There is some evidence that caffeine at doses greater than 300 mg/day may result in fetal growth restriction (also known as intrauterine growth restriction) and decreased birth weight, particularly in women who also smoke or drink significant amounts of alcohol.[54] Although previous studies[56] have not shown an association between low or moderate caffeine intake (< 300 mg/day) and greater risk for spontaneous abortion or preterm delivery, Weng et al.[59] found that caffeine consumption greater than 200 mg/day was associated with an increased risk for miscarriage, particularly among pregnant women who did not have a previous history of miscarriage. Moderate intake of caffeine in lactating women does not adversely affect postnatal development.[54,55]

Two studies have suggested that moderate caffeine intake during pregnancy may actually have beneficial effects on the mother and the fetus. Adeney et al.[60] found that women who consumed caffeinated coffee before conception had a significantly lower risk for development of gestational diabetes mellitus than women who did not consume coffee. No reduction in risk was associated with ingestion of tea or soda. Back et al.[61] showed that neonatal mice exposed to caffeine and subsequently subjected to hypoxia seemed to have less neurologic injury (i.e., less ventriculomegaly, less disruption in myelination) than non–caffeine-exposed mice.

Anesthetic Management

Caffeine may enhance the side effects of beta-adrenergic receptor agonists such as epinephrine and albuterol. Caffeine may also increase the risk for a hypertensive crisis in patients taking monoamine oxidase (MAO) inhibitors. Caffeine slows the elimination of theophylline and

acetaminophen, resulting in higher drug concentrations in the blood. In contrast, serum concentrations of lithium may be decreased secondary to caffeine-enhanced elimination.[55]

Perhaps of greatest significance to the anesthesia provider is the potential for **caffeine withdrawal headache** in parturients who abruptly decrease their usual caffeine intake during labor and delivery. Caffeine withdrawal should be considered in a postpartum patient who has a nonspecific, nonpositional headache without associated lateralizing neurologic findings (see Chapter 31). Evidence for the efficacy of caffeine in the treatment of post–dural puncture headache is scant (see Chapter 31).[62] Resumption of caffeine ingestion should be considered for treatment of caffeine withdrawal headache.

ILLICIT DRUGS

Marijuana (Cannabis)

Use of marijuana for medical and recreational purposes can be traced back thousands of years.[63] In 2010, approximately 2.4 million people in the United States used marijuana for the first time.[1] Marijuana was the illicit drug with the largest number of new users aged 12 or older. Estimates of marijuana use in the pregnant population vary from 6% to 7%.[17,64]

Pharmacology

Marijuana contains more than 400 compounds, including 60 cannabinoids. Most of the psychotropic effects are caused by 9-tetrahydrocannabinol (THC).[63,65] Noncannabinoid constituents of marijuana are similar to those in tobacco without the nicotine. Inhaled THC is absorbed through the lungs and reaches the brain within minutes. Oral ingestion of marijuana results in blood THC concentrations that are 25% to 30% of those obtained by smoking, but with a delayed onset of up to 2 hours. Cannabinoids are highly lipid-soluble compounds that are sequestered in fatty tissues and are gradually released into other tissues. Thus, a single ingestion can have an elimination half-life of up to 7 days; complete elimination of the inactive metabolite 11-nor-9-carboxy-delta-9-tetrahydrocannabinol (THCCOOH) takes as long as 25 to 30 days. Metabolism occurs in the liver, with excretion in the urine. Measured concentrations of THC and other cannabinoid metabolites in the blood and urine correlate poorly with the degree of intoxication.[65]

Systemic Effects

Cannabis interacts with specific cannabinoid receptors in the brain and peripheral nerves. Psychoactive effects include anxiolysis, analgesia, appetite stimulation, euphoria, and, sometimes, dysphoria (see Table 54-3).[65] Marijuana intoxication impairs cognitive and psychomotor function. Impairment of memory, attention, and the ability to process complex information can occur with long-time heavy use (see Table 54-4). It is unclear whether these effects are reversible.[66]

Acute intoxication with marijuana appears to have a biphasic effect on the autonomic nervous system; low doses cause tachycardia and higher cardiac output due to increased sympathetic and decreased parasympathetic tone. In contrast, high doses produce sympathetic inhibition and parasympathetic stimulation, resulting in bradycardia and hypotension.[5,63] Although ventricular ectopy can occur, life-threatening arrhythmias in patients without preexisting cardiac disease are rare and autonomic disturbances are generally well tolerated. Reversible ST-segment and T-wave abnormalities may occur, perhaps as a result of the higher heart rate associated with marijuana use.[5]

As with tobacco, the respiratory consequences of smoking marijuana include mucociliary dysfunction, increased susceptibility to bronchitis, and chronic obstructive pulmonary disease (see Table 54-4). Acute intoxication may cause conjunctival vasodilation and visible reddening of the eyes. Although high doses of marijuana can cause hallucinations and psychosis, fatal overdose has not been documented.[6,65]

Withdrawal from long-time marijuana use may produce a mild abstinence syndrome that includes headache, restlessness, tremor, anxiety, and autonomic effects, similar to those of withdrawal from benzodiazepines and hypnotic drugs (see Table 54-5).[5,66]

Effects on Pregnancy and the Fetus

It is difficult to ascertain specific effects of marijuana on pregnancy, because women who use marijuana often engage in polysubstance abuse. In a prospective study of more than 3800 pregnancies, Hatch and Bracken[66] showed that regular marijuana use by white women was associated with an increased risk for delivering an LBW and/or SGA infant, but occasional use was not. The risk for these adverse outcomes in nonwhite marijuana-using women was not elevated above their baseline level of increased risk. In a prospective multicenter study of more than 7000 multiethnic pregnant women, marijuana use was not associated with increased risk for LBW, preterm delivery, or placental abruption.[67]

Intrauterine exposure to marijuana has not been proven to be teratogenic, but some research suggests that it is associated with subtle postnatal neurologic derangements. Fried et al.[51] did not find an association between maternal marijuana use and overall intelligence quotient (IQ) and verbal memory in exposed offspring; however, certain aspects of cognition, such as memory at 4 years of age, attention at 6 years, attention and visually related cognition at 9 to 12 years, and stability of attention at 13 to 16 years, were negatively associated with prenatal marijuana exposure.

Anesthetic Management

Neuraxial analgesia is typically preferred during labor and delivery and can be safely performed in patients who use marijuana, in the absence of other contraindications. Drug-related changes in heart rate and blood pressure are usually well tolerated in otherwise healthy patients who are acutely intoxicated. However, the administration

of atropine, pancuronium, and ketamine can exacerbate existing tachycardia.[63]

Long-time marijuana smokers are at risk for many of the same respiratory complications during and after general anesthesia as are tobacco cigarette smokers; these patients may have increased airway secretions, impaired mucociliary clearance, and potentially increased airway reactivity.[45,65] Persistent postextubation laryngospasm in a patient with a history of heavy marijuana smoking has been reported.[68]

Acute intoxication with marijuana can have additive effects with those of sedative agents and volatile anesthetic agents, including myocardial depression[24,63]; careful titration to clinical effect is recommended.

The effect of marijuana on pain perception has been explored. Wallace et al.[69] presented a model of human experimental pain in which smoked marijuana had a differential effect on pain scores; a low dose had no effect, a medium dose reduced pain, and a high dose significantly increased pain. The clinical implications of these findings are unclear.

Cocaine

The use of cocaine, extracted from the leaf of the South American *Erythroxylum coca* bush, can be dated as far back as 600 AD.[70] Cocaine was introduced into clinical practice as a local anesthetic in the 1880s. During this period, Sigmund Freud also experimented with cocaine's ability to combat hunger and fatigue and opiate addiction.[70,71] Cocaine has both vasoconstrictive and local anesthetic properties as a result of its ability to block sodium channels during depolarization.

Epidemiology

The prevalence of cocaine use during pregnancy is difficult to estimate. Studies using a variety of detection techniques have reported rates that range from 1.8% to greater than 10% depending on the method and the population studied.[70] Survey data demonstrate that cocaine abuse in pregnancy is distributed broadly across ethnic and socioeconomic groups. In addition, an estimated 60% to 90% of pregnant cocaine users engage in polysubstance abuse, including the use of tobacco.[72,73] As with other illicit substances, the self-reporting of cocaine use results in identification of fewer drug users than urine testing and use of other biologic markers.[3] There is an association between cocaine use and an increased risk for sexually transmitted diseases, preterm labor, and failure to obtain prenatal care.[3]

Pharmacology

Cocaine (benzoylmethylecgonine) is an ester of benzoic acid and the base ecgonine, which is the parent compound of atropine and scopolamine.[71,74] Cocaine is consumed in a variety of forms. When dissolved in hydrochloric acid to form a water-soluble powder (cocaine hydrochloride), it can be chewed, administered intravenously ("mainlined"), or taken intranasally ("snorted"). Intrarectal and intravaginal use has also been reported.[75] When cocaine is processed with either sodium bicarbonate ("crack") or ammonia and ether ("free base"), the resulting cocaine alkaloid can be smoked.[71,74,76] The amount (dose) and duration of exposure are more important determinants of the effects of cocaine than is the chemical formulation. Smoked cocaine ("crack" or "free base") is rapidly absorbed through the lungs and reaches the brain in 6 to 8 seconds, intravenous cocaine reaches the brain in 12 to 16 seconds, and snorted cocaine reaches the brain in 3 to 5 minutes.[77] The typical half-life of cocaine is 30 to 90 minutes, although its effects can last as long as 6 hours.[71]

Cocaine is metabolized to ecgonine esters and benzoylecgonine (biologically inactive) by plasma and hepatic cholinesterases and to norcocaine (biologically active) by nonenzymatic hydrolysis. Only small amounts of cocaine are excreted unchanged in the urine. In the presence of alcohol, cocaine is transesterified to cocaethylene, which has a longer half-life and greater physiologic effects than cocaine.[76,77]

Systemic Effects

Cocaine has complex actions on the central and peripheral nervous systems and on nerve conduction. The powerful sympathomimetic effects of cocaine are due to the drug's inhibition of the reuptake of norepinephrine, dopamine, and serotonin, which allows these neurotransmitters to accumulate at the synaptic clefts and produce sustained stimulation.[70,76-78] This process can result in as much as a fivefold increase in circulating concentrations of catecholamines,[5] which, in turn, may lead to feelings of euphoria, increased energy, and decreased fear.[70,77] Repetitive use of cocaine eventually leads to depletion of neurotransmitter stores, up-regulation of receptors, and a higher dose requirement to achieve the desired euphoric effects.[71]

The peripheral nervous system effects of cocaine and its derivatives result from binding to tissue receptors involved in monoamine reuptake, which results in hypertension and/or labile blood pressure and tachycardia. Cocaine produces widespread small and large vessel occlusion through vasospasm, thrombosis, and endothelial injury, which may result in significant end-organ damage.[71]

Cocaine has profound effects on the **cardiovascular** system, and pregnancy appears to enhance them. Acute administration of cocaine increases peripheral vascular resistance, cardiac contractility, and myocardial oxygen demand (see Table 54-3).[71,79] Coronary vasoconstriction also occurs; a greater effect occurs in diseased vessel segments than in nondiseased segments.[76] Studies *in vitro* have indicated that cocaine can have a procoagulant effect in small and large vessels.[5] This may lead to thrombus formation and coronary plaque rupture in the setting of cocaine-induced hypertension.[71,80]

Cocaine-induced chest pain is a common complaint among young people presenting to the emergency department.[81] Mittleman et al.[80] found that cocaine use was associated with a significant, abrupt, and transient increase in the risk for acute myocardial infarction in patients who were otherwise at low risk.[82] The occurrence of cocaine-induced electrocardiographic changes is fairly common

and is not necessarily associated with true ischemia.[76,83] If true ischemia is suspected, treatment with supplemental oxygen, aspirin, vasodilators, with or without reperfusion therapy,[81] as well as measurement of troponin I levels,[82] is indicated. Although cocaine abusers who suffer a myocardial infarction have fewer postinfarction sequelae than the general population, the incidence of major cardiovascular complications is not trivial; 5% to 7% have congestive heart failure, 4% to 17% have ventricular arrhythmias, and up to 2% die.[76]

Prompt recognition of acute cocaine-induced cardiovascular toxicity facilitates management. However, not all cocaine-induced hypertension in pregnant women requires intervention. If pharmacotherapy is used, it is important to understand the potential undesired consequences. Beta-adrenergic receptor blockade may result in unopposed alpha-adrenergic receptor–mediated vasoconstriction that can lead to coronary artery vasoconstriction and myocardial failure. Labetalol, which is both an alpha- and a beta-adrenergic receptor antagonist, may be preferred, although it does not ameliorate cocaine-induced coronary artery vasoconstriction. Direct vasodilators (e.g., nitrates, hydralazine) can be used but may cause further tachycardia.[5,76] Hydralazine treated the hypertension in cocaine-intoxicated pregnant ewes but did not restore uterine blood flow.[84] Calcium entry–blocking agents can potentiate the toxic effects of cocaine.[5] Sedatives (e.g., benzodiazepines) or magnesium sulfate may ameliorate cocaine's cardiovascular effects.[5,76]

Other acute cardiovascular effects of cocaine include QT prolongation, bradycardia, and arrhythmias, including supraventricular or ventricular tachycardia and ventricular fibrillation.[71] Severe bradycardia can be treated with atropine or electrical pacing. If supraventricular tachycardia (SVT) occurs and is well tolerated, close observation, vagal maneuvers, and/or the use of adenosine are warranted. In the unstable patient with SVT, direct current (DC) cardioversion may be required.[85,86]

The use of lidocaine as an antiarrhythmic agent appears to be acceptable in patients who have used cocaine. In a retrospective multicenter study, Shih et al.[87] found that the use of lidocaine in nonpregnant patients with cocaine-induced myocardial infarction was not associated with significant cardiovascular or CNS toxicity. Although amiodarone therapy for maternal and fetal arrhythmias has been described as having only minor adverse effects in some patients, there are also reports of associated fetal hypothyroidism and fetal growth restriction.[85,88,89] Thus, the use of amiodarone in pregnant women is reserved for malignant arrhythmias that are refractory to other therapies.

Long-time cocaine abuse can cause left ventricular hypertrophy and dilated cardiomyopathy with accompanying systolic dysfunction (see Table 54-4).[71,76] Aortic dissection has also been reported.[76] Intravenous use of cocaine and other injectable drugs increases the risk for development of infective endocarditis. Noncardiogenic pulmonary edema, pulmonary hypertension, and right-sided heart failure can also occur in the setting of cocaine abuse.[5,71]

The **neurologic** complications of cocaine may be transient or permanent. Morbidity and mortality may result from subarachnoid hemorrhage, intracerebral hemorrhage, cerebral vasculitis, and/or transient ischemic attacks.[8,90,91] Many cocaine-abusing patients in whom cerebral infarct(s) and hemorrhage developed had additional risk factors for stroke, including hypertension, alcohol abuse, and smoking. Cocaine-induced seizures, if self-limited, are typically treated with supportive care and benzodiazepines.[90]

Respiratory complications occur in 25% of cocaine users. As with tobacco, smoking cocaine can have profound respiratory effects, which include bronchospasm, chronic cough, and diffusion capacity abnormalities.[75,77] Cocaine-abusing parturients are at increased risk for peripartum wheezing.[8] Inhaled cocaine vapor can produce thermal airway burns. "Snorting" cocaine can lead to epistaxis, oral ulcers, and nasal septal injury. The intense pulmonary and bronchial arterial vasoconstriction produced by cocaine can cause interstitial and alveolar hemorrhage. Pneumothorax, pneumomediastinum, and pneumopericardium have also been reported.[71]

Cocaine ingestion can result in serious **gastrointestinal** complications, such as ischemia, ulceration, and perforation.[77] In addition, cocaine's anticholinergic effects include delayed gastric emptying and an increased risk for aspiration.[71] Although some cocaine users have abnormal liver enzyme levels, cocaine is not clearly hepatotoxic.[77]

Hematologic consequences of cocaine exposure during pregnancy may include thrombocytopenia.[63,92,93] Cocaine-induced thrombocytopenia has a clinical course similar to that of idiopathic thrombocytopenic purpura, with platelet counts normalizing after termination of drug exposure, therapy with corticosteroids, and, in one published case, splenectomy.[93] Kain et al.[92] examined the prevalence of cocaine-associated thrombocytopenia in an inner-city obstetric hospital; the rate of thrombocytopenia was higher in the cocaine group than in the drug-free group (6.7% versus 1.5%, respectively), even when human immunodeficiency virus (HIV)–positive patients were excluded. However, Gershon et al.[94] compared platelet counts in a group of more than 7000 pregnant patients, 671 of whom tested positive for cocaine; only 2.5% of the cocaine-positive women had a platelet count lower than 140,000/mm^3, compared with 4.7% in the cocaine-negative group.

Renal failure can result from cocaine abuse on the basis of rhabdomyolysis, renal infarction, and impaired immunologic functions.[71] Cocaine-abusing patients have a higher prevalence of syphilis, HIV infection, and other **infectious diseases** compared with non–cocaine-using patients, even after controlling for intravenous drug abuse.[77,95] Studies of the **endocrine system** in gravid ewes have shown that cocaine exposure results in increases in maternal adrenocorticotropic hormone and cortisol as well as maternal and fetal plasma glucose and lactate.[96,97]

Cocaine also impairs cutaneous vasodilation and sweating. The lethal effects of cocaine are related, in part, to the drug's tendency to produce **hyperthermia**, particularly in hot weather.[98]

Cocaine use has been associated with **sudden death** from a variety of the above mentioned factors, including cardiac arrhythmias, respiratory arrest, status epilepticus, and impaired thermoregulation.

Cocaine withdrawal can be difficult to recognize because its signs and symptoms are nonspecific; they consist of a prolonged sleep phase followed by hunger, anxiety, weakness, headaches, tremors, and seizures (see Table 54-5). Recommended therapy involves supportive care and reintroduction of the drug, if necessary, followed by a slow taper of the dose over days to weeks.[24]

Effects on Pregnancy and the Fetus

Pregnant women metabolize cocaine to norcocaine to a greater extent than their nonpregnant counterparts, exposing both mother and fetus to this more potent metabolite.[70,74] Cocaine has a low molecular weight and high lipophilicity, and it is mostly un-ionized at physiologic pH; thus, it readily crosses the placenta.[8,70]

Woods et al.[99] demonstrated that cocaine increases both heart rate and myocardial oxygen consumption and decreases cardiac output to a greater extent in gravid ewes than in nonpregnant ewes. Cocaine also increases maternal blood pressure and decreases uterine blood flow in gravid ewes.[100]

In a 2011 meta-analysis, Gouin et al.[101] found that cocaine use during pregnancy was associated with significantly higher risk of preterm birth (odds ratio [OR], 3.38), SGA infants (OR, 3.23), and LBW infants (OR, 3.66). Obstetric complications associated with maternal cocaine use include a higher incidence of placental abruption and preterm labor; the latter occurs in 17% to 29% of women who use cocaine.[102] Acute cocaine toxicity can mimic preeclampsia or eclampsia when pregnant women present with hypertension, headache, blurred vision, and/or seizures. In one case series, cocaine-induced changes were distinguished through a positive urine test result for cocaine, the presence of normal laboratory measurements, and rapid resolution of symptoms without delivery.[103]

The impact of maternal use of cocaine (particularly "crack") on the fetus has been the subject of intense legal, political, and scientific debate since the 1980s.[104] Initial animal data and retrospective human studies have suggested an increased risk for major congenital anomalies such as genitourinary and abdominal wall defects in fetuses exposed to cocaine. However, these reports are confounded by concurrent use of other drugs and low statistical power.[105] Subsequent studies found no significant difference in type or number of congenital anomalies between infants who had and those who had not been exposed to cocaine *in utero*, after accounting for confounding variables.[106,107]

Frank et al.[108] reviewed studies published between 1984 and 2000 to assess the possible relationships between maternal cocaine use during pregnancy and childhood outcome. After controlling for possible confounding factors, they found no consistent negative association between intrauterine cocaine exposure and physical growth, developmental test scores within the first 6 years of life, or the presence of expressive or receptive language skills. They observed less optimal motor performance up to 7 months of age, but after this age, these effects did not appear to persist. They also indicated that there were insufficient data to comment on cocaine's effects on developmental scores in infants born preterm.

Subsequently, Mayes et al.[109] examined the trajectories of motor and mental development between the ages of 3 and 36 months in an impoverished high-risk population. These investigators found (1) a general decline (compared with age-adjusted equivalents) in motor performance for these high-risk children and a trend toward a greater decrease in performance in cocaine-exposed children; (2) a decline in performance on mental tasks until 24 months, with a similar trajectory of decline for the cocaine-exposed and non–cocaine-exposed cohorts; and (3) evidence of lower mental performance in cocaine-exposed children compared with non–cocaine-exposed children at all assessment ages.

Bauer et al.[106] found that infectious complications, such as hepatitis, syphilis, and, to a lesser extent, HIV infection, were more common in infants of cocaine-abusing mothers. Bae and Zhang[110] used a rat model to test prenatal cocaine exposure. Their results showed abnormal apoptosis and myocyte hypertrophy in the postnatal heart, which they speculated might result in greater susceptibility to myocardial ischemia and reperfusion injury.

Anesthetic Management

Cocaine-abusing patients are at risk for acute and chronic multiorgan system dysfunction[95] and the need for urgent cesarean delivery. During labor, early administration of neuraxial anesthesia should be encouraged provided that the patient is cooperative and has a platelet count above the threshold of concern for the anesthesia provider.[73] The use of neuraxial anesthesia can reduce levels of circulating catecholamines and thereby may mitigate the systemic effects of cocaine.[8] Existing epidural analgesia facilitates the extension to anesthesia for emergency cesarean delivery.

In one study, cocaine users had a greater incidence of hypotension during administration of epidural anesthesia for cesarean delivery; however, there was no difference between cocaine users and nonusers in the incidence of hypotension during spinal anesthesia.[8] When it occurs, treatment of hypotension should include volume resuscitation, and, if needed, careful titration of vasopressors. Depending on the level of circulating catecholamines, cocaine-intoxicated patients can be either more or less responsive to ephedrine; thus, phenylephrine may be a better choice for treatment of hypotension.[11,63,73]

When an ester local anesthetic or succinylcholine is administered to a patient who has ingested cocaine, the medication might compete with cocaine for available plasma cholinesterase.[8,74] Kain et al.[8] described a prolonged response to succinylcholine in a parturient who had abused cocaine chronically and had a normal dibucaine number but a low level of pseudocholinesterase.

Changes in μ- and κ-opioid receptors and altered baseline endorphin levels may result in an increased perception of pain in cocaine-abusing patients despite the presence of an apparently satisfactory level of neuraxial anesthesia.[63] Ross et al.[111] observed a reduction in duration of intrathecal sufentanil analgesia during labor in cocaine-abusing women, although the quality of analgesia was not diminished.

Cocaine-abusing patients who receive general anesthesia are at greater risk for hypertension and tachycardia during and after laryngoscopy and tracheal intubation.[8,9] If general anesthesia is required, premedication with a benzodiazepine or an opioid may help attenuate the acute physiologic effects of cocaine.

The anticholinergic effects of cocaine can delay gastric emptying and may also increase the risk for aspiration; pharmacologic prophylaxis and a rapid-sequence induction of general anesthesia are indicated. Ketamine and etomidate should be avoided because ketamine may stimulate the CNS and etomidate may precipitate myoclonus or hyperreflexia.[63] Induction of general anesthesia with propofol is commonly used in clinical practice. Dexmedetomidine, an α_2-adrenoreceptor agonist, has been shown in animal studies to delay the onset of cocaine-induced seizures and may be useful in selected patients.[112] Despite the theoretical risk for altered metabolism of succinylcholine, a standard intubating dose should be administered.[73] Early studies in dogs demonstrated that acute cocaine intoxication was associated with a dose-dependent increase in halothane dose requirements.[113] Whether this extends to other volatile agents has not been studied.

Cocaine can cause hyperthermia in both laboratory animals and humans[71,98]; core temperature should be monitored in cocaine-abusing patients. However, given the propensity for nasal septal defects in such patients, temperature probes (and other tubes and monitors) should *not* be inserted intranasally. Measures that provide active warming should be used only if needed.

Amphetamines and "Club" Drugs

Because of their high potential for abuse, amphetamines have been categorized by the U.S. Drug Enforcement Agency (DEA) as Schedule II stimulants since 1971.[64] Amphetamines have historically been prescribed as components of nasal decongestants, bronchodilators, weight loss drugs, and therapies for narcolepsy and attention deficit hyperactivity disorder.[114]

Methamphetamine ("ice") has become the most common illicit substance requiring medical treatment during pregnancy.[115] The availability of this compound is facilitated by its production in low-cost, home laboratories within and outside the United States.[114] It and MDMA (3,4-methylenedioxymethamphetamine) ("ecstasy") are thought to be the most widely abused amphetamines.[64]

Epidemiology

The number of new users of methamphetamine among persons aged 12 years or older was 105,000 in 2010, similar to the 2009 estimate (154,000) but lower than the 2002 to 2007 estimates (ranging from 157,000 to 318,000).[1] In a 2010 sample population between 12 and 49 years of age, the average age of new methamphetamine users was 18.8 years, which was not significantly different from corresponding 2002 to 2009 estimates.[1]

Arria et al.[64] observed that 5.2% of high-risk pregnant women had used methamphetamine at some time during pregnancy. Polydrug use in women who use methamphetamine and MDMA appears to be common.[64,116] According to analysis of national administrative data, the hospitalization ratio for amphetamine abuse has doubled, whereas that for cocaine abuse has decreased 44%.[117]

Pharmacology

Amphetamines (and related compounds) are amines that exist as either salts of various acids or free bases. Used illicitly, they can be ingested orally, inhaled, or, less commonly, injected, resulting in significant CNS penetration.[23] The plasma half-life ranges from 5 to 30 hours. Metabolism is variable; up to 30% of the parent compound can be found in the urine. Detection of these compounds and their metabolites in the urine is possible up to several days after ingestion.[5]

Methamphetamine ("speed" or "crystal meth") is a congener of amphetamine that contains a methyl radical.[64] This white, odorless, bitter-tasting powder can be smoked, snorted, ingested orally, or administered rectally.[116] Methamphetamine is more potent than amphetamine and has a longer half-life; 50% of the drug is cleared in 12 hours. When it is smoked or injected intravenously, the "flash" from this drug is intense and of short duration. Snorting produces euphoria within 5 minutes, and oral ingestion does so within 20 minutes.[114]

The amphetamine analogue, MDMA, or ecstasy, has been steadily growing in popularity, particularly in young women.[118] The methylenedioxy group that is attached to the aromatic ring of the amphetamine molecule confers some of the pharmacologic hallucinogenic effects.[119] The effects of MDMA typically begin approximately 20 minutes after ingestion and last approximately 6 hours; large doses have effects for up to 2 days. MDMA is metabolized by the liver and excreted by the kidneys.[5]

The "club" drug, **γ-hydroxybutyric acid** (GHB), derived from gamma-aminobutyric acid (GABA), readily enters the brain when ingested, producing anxiolytic, euphoric, and sedative effects.[120] Severe cardiorespiratory depression, coma, and seizures can occur at high doses. Overdose is common, owing in part to the variable individual responses to the drug.[120,121] Chronic use may be associated with a down-regulation of GABA receptors, and withdrawal manifests as insomnia, tachycardia, hypertension, and nausea/vomiting.[120]

The newest designer drug of the phenethylamine class is 3,4-methylenedioxypyrovalerone (MDPV), also known as "bath salts." Typically sold in crystal or powder form that can be snorted, smoked, or injected, these substances act as norepinephrine and dopamine reuptake inhibitors.[122] Until recently, "bath salts" could be purchased legally over the Internet, at some convenience stores, or in "head shops," but its active ingredients were banned by the DEA after several deaths were reported.[123]

Systemic Effects

Acute amphetamine ingestion leads to indirect sympathetic activation through the release of norepinephrine, dopamine, and serotonin from adrenergic nerve terminals (see Table 54-3).[5,124] The physiologic effects of amphetamines are similar to those of cocaine and other stimulants, with two important differences:

(1) amphetamines and their derivatives lack local anesthetic properties, and (2) amphetamine can inhibit monoamine oxidase activity, leading to decreased degradation of catecholamines.[5] Amphetamine-induced seizures can masquerade as eclampsia in parturients who have ingested the drug in the peripartum period.[125]

Long-term use of high doses of amphetamines can have a number of adverse maternal effects, including damage to the cardiovascular and neurologic systems, and behavioral changes such as hostility, violence, hallucinations, and paranoid psychosis (see Table 54-4).[116]

The **cardiovascular** effects of amphetamines and their derivatives are similar to those of cocaine.[5] Methamphetamine has a much longer duration of action than cocaine, because a smaller fraction of the former drug is metabolized.[114] Drug-induced effects include vasoconstriction, tachycardia, and labile blood pressure.[24] Patients are typically hypertensive, although catecholamine depletion over time can result in hypotension. Arrhythmias, myocardial ischemia, endothelial damage, and acceleration of atherosclerosis can also occur. Recommendations for the management of cardiovascular complications are similar to those for cocaine toxicity.[5]

The pleasurable effects of methamphetamine and the deleterious **neurologic** sequelae are believed to be the result of high levels of dopamine in the brain. In addition to positive feelings, patients who have taken methamphetamine may experience anxiety, mood disturbances, paranoia, and hallucinations. Severe intracranial hypertension[6] and hemorrhagic stroke[91] has been reported in the setting of acute use. Long-time use has been associated with impairment of motor function and verbal learning as well as with significant changes in the areas of the brain associated with memory and emotion (see Table 54-4).[114] Volkow et al.[126] observed that prolonged abstinence (12 to 17 months) resulted in significant recovery of brain dopamine transporters, although performance on neuropsychological tests did not improve to the same extent. In addition, psychotic features of long-time amphetamine use may be precipitated by stress in former users after months or even years of abstinence.[114] Ecstasy users are prone to drink excessive amounts of water, predisposing them to hyponatremia and the resulting CNS effects.[63]

Psychostimulant withdrawal causes fatigue, depression, hunger, and intense cravings (see Table 54-5). Pharmacologic therapy for stimulant withdrawal (e.g., tricyclic antidepressants, dopaminergic agents [e.g., bromocriptine], amino acid replacement therapy) has not been particularly successful.[127] In the setting of methamphetamine overdose, the ensuing seizures, severe hypertension, and hyperthermia can be fatal. Treatment goals include provision of a calm environment (with or without a benzodiazepine) and airway protection. Active cooling, antihypertensives, and anticonvulsants should be used as needed.[119,127]

Effects on Pregnancy and the Fetus

Ingestion of amphetamines results in high levels of circulating catecholamines, which may lead to vasoconstriction and decreased uteroplacental blood flow. Animal studies have suggested that intrauterine exposure to methamphetamine is associated with an increased incidence of retinal defects, cleft palate, and rib malformations and a decreased overall rate of growth and motor development.[116,128] Results from a meta-analysis revealed that exposure to amphetamines in pregnancy had a negative impact on birth outcomes, specifically, increasing the risk for preterm birth, LBW, and SGA infants.[129] Cernerud et al.[130] conducted long-term follow-up of 65 Swedish children with intrauterine exposure to amphetamines and found that a higher percentage of these children were in a grade lower than their chronologic age and that their performance in mathematics, language, and sports was significantly below that of their peers.

Specific pregnancy and fetal effects of ecstasy and bath salts are not known.

Anesthetic Management

Amphetamines cause (indirect) sympathetic activation. Intoxicated patients are at risk for dangerous cardiovascular events, including hemodynamic instability and cardiac arrest. Recommendations for anesthetic management are similar to those for patients with cocaine toxicity (as discussed earlier).[5]

A cooperative patient may be a candidate for neuraxial analgesia/anesthesia, although refractory hypotension has been reported in a case of a long-time amphetamine user undergoing neuraxial anesthesia with intravenous propofol sedation.[131] The authors attributed the response to down-regulation of beta-adrenergic receptors and catecholamine depletion. As with cocaine, phenylephrine may be a better choice than ephedrine for the treatment of hypotension in amphetamine-intoxicated patients.

Parturients who are amphetamine abusers may be at increased risk for urgent cesarean delivery requiring general anesthesia. Evidence from animal studies suggests that acute ingestion of amphetamines increases the MAC for volatile halogenated anesthetic agents, whereas chronic ingestion of amphetamines decreases the MAC of volatile agents.[132,133] There is a well-recognized association between methamphetamine abuse and severe tooth decay (i.e., "meth mouth") which can present a significant hazard during laryngoscopy. The airway assessment should include attention to the presence of fragile or loose teeth that might be dislodged during laryngoscopy as well as to the possible presence of burns throughout the airway. High doses of MDMA can cause rhabdomyolysis, and dantrolene has been used successfully in these cases.[119]

Hallucinogens

LSD (lysergic acid diethylamide), PCP (phencyclidine), psilocybin, and mescaline are drugs of abuse that are hallucinogens.[127] 3,4-Methylenedioxymethamphetamine (MDMA) also has hallucinogenic effects.

Epidemiology

Hallucinogen use is usually episodic.[9,134] In 2006, 1.1 million Americans 12 years or older used hallucinogens

for the first time; more than 75% of these encounters involved the hallucinogen MDMA.[135] The prevalence of hallucinogen use during pregnancy is unknown.

Pharmacology

The hallucinogens are a diverse group of drugs notable for their complex mechanism of actions, which include agonist, partial agonist, and antagonist effects at serotonergic, dopaminergic, and adrenergic receptors. Overall, the adrenergic effects of these drugs are mild compared with those of cocaine and amphetamine.[5]

Both **psilocybin**, the hallucinogen in some wild mushrooms, and **LSD**, manufactured synthetically,[127] are indole derivatives that chemically resemble serotonin.[5] When ingested, they evoke auditory, visual, and tactile hallucinations. Clinical effects usually develop over 15 to 60 minutes and last for 6 to 12 hours.[9,127] LSD is 100 times more potent than psilocybin and can be detected in urine or plasma for up to 3 days. LSD is metabolized by the liver and has a plasma half-life of 100 minutes.[5] The potency of individual samples of psilocybin varies, and the physiologic effects typically occur at doses of 20 to 60 mg. Animal studies indicate that 65% of psilocybin is excreted in urine and 15% to 20% is excreted in bile or feces. Most of the drug is excreted in the first 8 hours, although small amounts are excreted for up to a week.[127]

Phencyclidine, initially developed as a general anesthetic agent, was removed from the legal market in 1978. **Ketamine**, a related compound, is a clinically used anesthetic agent that is also a drug of abuse. In powder form these drugs can be ingested orally, intranasally, intravenously, or rectally and can be smoked. The psychological effects of PCP typically last 12 to 48 hours. Ketamine has a shorter duration of action.[127]

The phenethylamines include MDMA, GHB (see earlier discussion), and mescaline. **Mescaline**, the active ingredient in peyote cactus buttons, is typically eaten or drunk as a tea. The effects of mescaline, which last approximately 12 hours, include visual hallucinations, nausea, and vomiting.[127]

Systemic Effects

Ingestion of hallucinogens causes activation of the **sympathetic nervous system**, which results in hypertension, tachycardia, dilated pupils, and increased core body temperature (see Table 54-3).[9] The cardiovascular effects of these drugs are rarely serious, although some instances of supraventricular tachycardia and acute myocardial infarction have been reported. Myocardial infarction may result from vasospasm and increased platelet aggregation.[5]

Carotid artery occlusion has been reported after the use of LSD. PCP use has been associated with seizures, delayed hypertensive crisis, and intracerebral hemorrhage.[6] Overdose with PCP can be associated with confusion and combativeness, which may progress to seizures and catatonia.

Some users of LSD experience a "bad trip," which is likely to be a manifestation of an acute anxiety reaction. Other users report "flashbacks" or systemic effects of these drugs that occur months or even years after ingestion. Some of these episodes are likely due to delayed release of small amounts of drug from fatty tissues. The use of LSD may unmask an underlying psychiatric disorder in vulnerable patients.[127]

The psychological effects of psilocybin ("magic mushrooms") include giddiness, visual hallucinations, and gastrointestinal dysfunction. Morbidity is associated primarily with inadvertent ingestion of toxic species of mushrooms.[127] Although psychological dependence on these drugs has been observed, no clearly associated withdrawal symptoms occur with abstinence (see Table 54-5).[9]

A direct causal relationship between abuse of these drugs and death has not been documented; however, hallucinogens can cause feelings of paranoia and panic that can lead to accidents or fatalities.[6,9]

Effects on Pregnancy and the Fetus

There is conflicting evidence as to whether intrauterine PCP exposure has deleterious fetal effects. Mvula et al.[136] found that PCP-positive women had smaller and more preterm infants compared with non–PCP-positive women. The PCP-positive women were also more likely to have syphilis and diabetes and to use tobacco, alcohol, and marijuana. Early reports of chromosomal damage secondary to LSD were not confirmed by later studies.[6]

Anesthetic Management

Management of a hallucinogen-intoxicated patient is primarily supportive and noninterventional.[5] Stressful situations can provoke panic attacks, which in turn can intensify the physiologic effects of these drugs. Specific recommendations include provision of a quiet, supportive environment and administration of a benzodiazepine if needed. Neuroleptic medications are relatively contraindicated in such a patient, because they can intensify toxic reactions.[5, 9]

Hemodynamic perturbations are usually relatively mild and well tolerated.[63] Occasionally, patients experience supraventricular tachycardia, hypertension, and myocardial ischemia.[5] The acutely intoxicated patient may have an exaggerated response to ephedrine[9]; phenylephrine may be preferable and should be titrated to effect. LSD may have some intrinsic anticholinesterase activity, but the clinical significance is unclear. Hallucinogens may also prolong opioid-induced analgesia and respiratory depression.[63]

Either neuraxial or general anesthesia can be administered for vaginal or cesarean delivery as the clinical situation warrants.

Opioids

Opioids refer to the class of naturally occurring and synthetic drugs that are structurally and functionally related to morphine. The term *opiate* specifically describes any of the narcotic alkaloids found in the juice of poppy plants, including morphine and codeine.[23]

Epidemiology

The estimated prevalence of opioid use during pregnancy varies from 1.6% to 7.2%, depending on the methodology of the survey and the studied population.[137] The National Survey on Drug Use and Health estimated that more than 359,000 Americans 12 years of age and older used heroin in 2010, including approximately 140,000 who used it for the first time that year.[1] Among youths and young adults, nonmedical use of prescription drugs, particularly pain relievers, was the second most common form of drug abuse.[1]

Pharmacology

The naturally occurring opioids are metabolized first to morphine, which has a plasma half-life of 2 to 3 hours. Morphine then undergoes rapid metabolism in the liver and is excreted in the urine, where both active and inactive metabolites can be detected for up to 2 days in occasional users, and longer in chronic users.[5,23]

Heroin (diacetylmorphine or diamorphine) is a commonly abused and highly addictive semisynthetic analogue of morphine. It can be smoked, snorted, or injected intravenously or intramuscularly. Most fatal overdoses occur in users of intravenous heroin. The speed of onset varies from less than 1 minute to 15 minutes, depending on the delivery method; the elimination half-life is typically 1 to 2 hours. Heroin is metabolized by the liver and excreted in the urine.[5,23,24,138] The formulation of street heroin has become increasingly pure. In 1990, a typical 100-mg bag of powder had up to 8 mg of heroin mixed with inert, often toxic additives; subsequently the drug has become available with a purity as high as 45% to 90%. Heroin is more lipid soluble than other opioids; thus, it rapidly crosses the blood-brain barrier and has significant and toxic CNS effects.[138]

Rapidly acting semisynthetic opioids such as **oxycodone** and **hydrocodone** are prescribed legitimately and distributed illicitly. The oral bioavailability of oxycodone is higher than that of morphine, and its potency with oral ingestion is greater.[23]

Methadone is a synthetic compound that is structurally unrelated to the other opioids but has similar effects.[23,139] It is formulated as a racemic mixture of two enantiomers: R-methadone, which is a potent μ- and δ-opioid receptor agonist, and S-methadone, which is a noncompetitive *N*-methyl-D-aspartate (NMDA) antagonist that prevents the reuptake of 5-hydroxytryptamine and norepinephrine.[140] Typically available in powder form, methadone can be reconstituted for oral, rectal, or intravenous use.[141] Oral bioavailability of methadone is typically three times that of morphine.[140,141] There is significant inter-individual variability in its clinical effect and duration of action. The peak effect occurs approximately 3 hours after oral ingestion, and its half-life varies from 15 to 40 hours.[23,24,140-142] Life-threatening complications may result from the cumulative effects of successive doses.[140]

Unlike morphine, methadone undergoes biotransformation (rather than conjugation) in the liver and is excreted primarily by the fecal route. Methadone has been used since the 1960s for stabilization and maintenance therapy for patients suffering from opioid-addictive disorders and since the 1970s for the same reason in pregnant patients. It is also used for analgesia in patients with chronic pain.[140,142] Pregnancy is associated with greater methadone metabolism and reduced methadone bioavailability because of greater maternal blood volume and changes in hepatic enzymatic activity and glomerular filtration rate.[23,142,143]

Buprenorphine is a semisynthetic opioid that acts as a partial μ-receptor agonist (with low intrinsic opioid activity) and *k*-receptor antagonist and therefore can also be used as part of maintenance therapy for patients suffering from opioid-addictive disorders.[61,144,145] The two sublingual formulations of this drug (**Subutex** and **Suboxone)** contain naloxone, which becomes active only if the user attempts to snort, inject, or cook the drug.[144] Buprenorphine binds up to 1000 times more tightly to the μ- and *k*-receptors than morphine, and it has a slow dissociation half-life of approximately 166 minutes.[144] Primary metabolism of buprenorphine occurs in the liver with excretion in the bile.[146] Buprenorphine has a ceiling effect at 24 to 32 mg, which makes respiratory depression less likely and contributes to the opioid tolerance of treated patients.[144,147]

Two additional formulations for intravenous and transdermal administration of buprenorphine are used for analgesia and are *not* approved for opiate addiction therapy.[147]

When used as part of a maintenance therapy for patients with addiction to opioids, methadone must be prescribed and dispensed on a daily basis by a registered substance abuse treatment program; buprenorphine, however, can only be prescribed by physicians who have been specially trained and credentialed for distribution in an office-based setting.[148] All dose adjustments needed in the course of pregnancy or the postpartum period must be done in close consultation with the addiction treatment program (for methadone) or the providers responsible for prescribing and managing the patient's buprenorphine therapy.[148]

Systemic Effects

Opioids mimic the activity of endogenous peptides and exert their effects through binding to μ-, δ-, and κ-opioid receptors. Morphine and heroin exert their euphoric, analgesic, and reinforcing effects primarily through stimulation of the μ-opioid receptors. Long-time opioid use causes neuroadaptations in the brain that may explain the manifestations of withdrawal.[23,138]

Opioids act in the CNS to reduce sympathetic activity and increase parasympathetic activity; they also promote histamine release from mast cells. The resulting cardiovascular effects include bradycardia, hypotension, and, in some cases, potentially lethal tachyarrhythmias and bradyarrhythmias (see Table 54-3). Noncardiogenic pulmonary edema has been observed in some cases of overdose and is believed to be caused by hypoxia, intense pulmonary vasoconstriction, and, perhaps, the use of reversal agents (e.g., naloxone).[5]

Opioid-induced respiratory depression occurs through a direct effect on the brainstem that reduces the

ventilatory response to hypercarbia.[138] Opioid overdose can progress from miosis and respiratory depression to obtundation and death.[6,10] Treatment of overdose includes maintenance of a patent airway, provision of hemodynamic support, and, if necessary, administration of an opioid antagonist (e.g., naloxone).[5]

Women who abuse opioids or other drugs intravenously are at risk for infective endocarditis (usually affecting right-sided valves), HIV infection, viral hepatitis, septic emboli, and pulmonary abscess formation.[5,24] In addition, hilar adenopathy may develop as a result of ingestion of additives such as quinine and starch. Opioid-dependent patients may have additional end-organ damage and may exhibit opioid tolerance, physical dependence, and withdrawal.[139]

Animal studies have found an association between opioid administration and abnormal pain sensitivity, including hyperalgesia and allodynia (see Table 54-4).[149] Opioid tolerance develops with chronic use and is related to amount and duration of drug exposure; tolerance results from changes in drug distribution and metabolism (pharmacokinetics) and in receptor density and activity (pharmacodynamics).[139] Patients receiving methadone maintenance therapy often have diminished pain tolerance.[150]

Acute opioid withdrawal results from sympathetic hyperactivity, resulting in flulike signs and symptoms such as fatigue, weakness, restlessness, rhinorrhea, perspiration, fever, and diarrhea (see Table 54-5).[6,24] These can persist for several days if not treated. The onset and duration of withdrawal symptoms vary according to the opioid ingested; morphine or heroin withdrawal symptoms typically begin within 6 to 18 hours after the last dose, reach their peak intensity by 3 days, and last for 7 to 10 days. Methadone withdrawal symptoms are delayed—with an onset within 24 to 48 hours, a peak intensity within 3 to 21 days, and a duration of up to 6 to 7 weeks.[139] Clonidine, an α_2-adrenergic agonist, can modulate these effects, although postural hypotension may result.[24] Doxepin, a tricyclic antidepressant that inhibits the reuptake of serotonin and norepinephrine, has also been administered in this setting. Acute withdrawal can also be treated by administration of a short-acting opioid and initiation of a gradual dose taper.[9]

Substitution pharmacology (e.g., **methadone maintenance** or **buprenorphine therapy**) has been recommended for the treatment of opioid dependency if abstinence is not attainable and withdrawal is not feasible. Typically, long-acting μ-agonists (e.g., methadone) or partial agonists (e.g., buprenorphine) are substituted for the opioid of abuse in combination with behavioral modification therapy. Drug maintenance therapy decreases withdrawal symptoms and attenuates both craving and the positive rewards associated with subsequent opioid use (see later discussion on effects on the neonate).[142]

The U.S. Food and Drug Administration (FDA) guidelines for methadone administration in pregnancy were developed in 1970.[4,142] Several studies have shown that methadone maintenance therapy in heroin-addicted pregnant women is beneficial for both the mother and the infant. Specific benefits include better medical and prenatal care,[151] a lower incidence of unplanned pregnancy,[152] decreased neonatal abstinence symptoms and days of hospitalization, and less maternal illicit drug use at delivery.[141,143]

Effects on Pregnancy and the Fetus

In general, published reports have not shown an increased risk for birth defects after prenatal exposure to oxycodone, meperidine or propoxyphene, but they have shown an association between congenital heart defects and early use of codeine.[148] A retrospective population-based study (data from 1997 to 2005) identified an association between maternal therapeutic use of opioid medications early in pregnancy and atrial and ventricular septal cardiac defects, hypoplastic left heart syndrome, spina bifida, and gastroschisis.[153] Data were obtained retrospectively via maternal interviews and did not control for dose, therapeutic indication (including if the drug was administered within the context of a surgical procedure), duration, or frequency of opioid exposure.

Heroin use during pregnancy is associated with first-trimester spontaneous abortion, preterm delivery, and fetal growth restriction, in part as a result of poor maternal nutrition.[4,141,151,154] Maternal and neonatal infection and neonatal abstinence syndrome have also been described. **Neonatal abstinence syndrome (NAS)**, which occurs in neonates repeatedly exposed to opioids *in utero*, is characterized by irritability, poor feeding, abnormal sleep patterns, diarrhea, fever, and seizures. Affected neonates may also have autonomic symptoms such as yawning and mottling. If prolonged and untreated, NAS can result in death.[4,154] Children born to women using heroin have been found to have normal development at the time of entry into school.[4] However, *in utero* heroin exposure appears to be associated with a high rate of attention deficit hyperactivity disorder.[155]

In 2010, Jones et al.[145] performed a multicenter, randomized controlled trial comparing the neonatal effects of methadone and buprenorphine therapy on NAS when used as part of an opioid dependence program during pregnancy. They found the length of hospitalization and amount of morphine therapy needed for NAS was significantly less in the infants of buprenorphine-treated mothers, although the percentage of neonates requiring treatment for NAS did not differ between groups.

When obstetric complications were compared in methadone- and buprenorphine-treated pregnant women, maternal weight gain, cesarean delivery rates, birth weights, and Apgar scores were similar.[147] However, medical complications and overdoses were less frequent in buprenorphine-treated women.[147] Based on these data the ACOG issued a 2012 committee statement suggesting that buprenorphine be considered "a potential first-line medication for pregnant opioid-dependent women who are new to treatment."[148]

Anesthetic Management

Preanesthesia Assessment and Communication. Establishing trust and effective communication is critical in the care of opioid-tolerant, methadone- or buprenorphine-maintained or opioid-addicted patients

and may improve the ability to elicit a more complete drug history. Ideally, before the patient presents for delivery, a thorough anesthesia consultation and development of a mutually agreeable strategy for pain management with appropriate goals for pain intensity scores should be conducted.

Providers, family, and patients may express concern that exposing a previously addicted patient to opioids or other sedatives will prompt cravings or a frank relapse. However, withholding appropriate analgesic and anxiolytic medications from such a patient cannot be justified. Patient monitoring (e.g., drug screens, pill counts) may be necessary.[139]

Opioid Maintenance Requirements. Opioids used on a regular basis for chronic pain or methadone or buprenorphine maintenance therapy should be continued during the hospitalization,[108,139-141] with additional therapies added for acute pain management. The precise dose of methadone must be confirmed with the dispenser, because improper dosing can result in inadequate analgesia, withdrawal phenomena, or life-threatening overdose.[140] Any methadone or buprenorphine dose adjustments needed in the course of pregnancy or the postpartum period must be done in close consultation with the prescribing physicians and addiction treatment program.[148] Although some providers advocate trying to substitute a pure opioid agonist for buprenorphine in advance of elective induction of labor or elective cesarean delivery to maximize the effect of peripartum opioid analgesics, there are several potential pitfalls to this approach. First, most admissions for delivery are unplanned. Second, it can be extremely challenging to effectively manage predelivery transition from buprenorphine to opioid-agonist therapy in the outpatient setting. Third, reintroduction of buprenorphine therapy in the postpartum period may induce acute withdrawal symptoms.[156]

An alternative approach to switching to pure opioid agonist therapy is to continue the buprenorphine through the peripartum period. Kronfeld and Manfredi[156] described five nonpregnant patients who continued their buprenorphine through the operative period; postoperative pain was successfully controlled using full doses of agonist opioids. A third approach is to continue the buprenorphine through the operative period but to divide the usual dose into three or four partial doses that maximize the analgesic properties of the medication.[144,148] Importantly, the patient must receive the correct total methadone or buprenorphine dose; therefore, dividing the dose should only be attempted if administration of the correct total dose can be ensured.

Alterations of Drug Levels. Sedative medications can increase the depressant effects of chronically ingested opioids. Methadone has a long half-life and is metabolized by cytochrome P450; thus, women receiving methadone are particularly vulnerable to changes in metabolism that result from administration of other medications. Anticonvulsants (e.g., phenobarbital, phenytoin) increase methadone clearance, and selective serotonin reuptake inhibitors decrease it. Methadone dose requirements are typically established by titrating to effect; thus, the discontinuation of these other medications can have unintended consequences.[139]

Anesthetic Technique and Dose Requirements. Neuraxial analgesia or anesthesia is the technique of choice for chronic opioid-abusing parturients or those receiving methadone or buprenorphine maintenance therapy undergoing vaginal or cesarean delivery, assuming that the patient is cooperative and has no evidence of coagulopathy or other contraindication to a neuraxial technique.[148]

Providers should not assume that the cause of inadequate neuraxial labor analgesia is solely a result of the patient's addiction. Opioid-addicted patients can have objectively inadequate (failed) neuraxial analgesia and anesthesia just like their nonaddicted counterparts.

In a review of publications on opioid-dependent parturients, Cassidy and Cyna[157] catalogued the needs of these patients across a broad range of anesthetic techniques and modes of delivery. The proportion of opioid-dependent women who required general anesthesia for cesarean delivery, or the number who requested epidural labor analgesia, did not differ compared with the proportions in non–opioid-dependent women. However, a significant incidence of pain management challenges were observed, particularly after cesarean delivery; 26% of the patients required consultation for inpatient pain management in addition to usual labor analgesia, and 74% of the patients had difficulties with postcesarean analgesia. These patients also had significant vascular access problems and generated more emergency calls for fainting and collapse. Meyer et al.[152] noted that pregnant women on methadone maintenance therapy had similar pain scores and analgesia requirements during labor compared with matched control women, but the methadone-maintained patients required 70% more opioid analgesia after cesarean delivery.[152]

Although mixed opioid agonists/antagonists (e.g., nalbuphine) are commonly employed for labor analgesia or treatment of neuraxial opioid-induced pruritus in parturients, these agents should be *avoided* in patients with a history of opioid abuse because they can precipitate withdrawal.

If neuraxial techniques are contraindicated for labor, intravenous patient-controlled analgesia can be used. Patients who use either physician-prescribed or illicit opioids over the long term demonstrate a relative insensitivity to opioids. Their opioid dose requirements for intraoperative and postoperative analgesia may be 30% to 100% higher than those of opioid-naive patients.[139,158]

During administration of general anesthesia for cesarean delivery, the anesthesia provider should consider the potential for decreased MAC in a patient with acute opioid intoxication as well as the potential for cross-tolerance with CNS depressants in a patient with a history of long-time opioid use.[9]

Postpartum Analgesia. Postoperative pain management can be challenging in patients with a history of chronic opioid use. In one study, methadone-maintained women had higher pain scores but did not receive greater

doses of opioids after vaginal delivery. However, methadone-maintained women had higher pain scores and received greater doses of opioids after cesarean delivery.[152] Multimodal therapy, including nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, should be used after vaginal delivery.[139] For cesarean delivery, multimodal analgesia with neuraxial morphine and systemic NSAID therapy is recommended. Epidural analgesia, transversus abdominis plane (TAP) block, and intravenous patient-controlled opioid analgesia can also be considered, similar to that in women who are not chronic opioid users (see Chapters 27 and 28).

Solvents

Solvents are a chemically diverse group of readily available substances (e.g., toluene, ethylene glycol) that can be sniffed, aerosolized, or ingested to produce feelings of euphoria, excitement, and invulnerability.[5,159,160]

Epidemiology

In 2010, more than 700,000 individuals in the United States used an inhalant for the first time.[1] Of the 3 million persons aged 12 years or older who used illicit drugs for the first time within that year, 9% reported that their first drugs were inhalants. The prevalence of solvent abuse in pregnant patients is not known.

Pharmacology

Inhalants are quickly absorbed through the lungs and typically are rapidly metabolized in the liver. The precise mechanism of action of inhalants is variable and is not completely understood.

Detection, although difficult, can be suspected by the presence of the "glue sniffer's" facial rash[24] or the odor of the abused inhalant.[160] Laboratory assays can detect many solvents in the blood within 10 hours of exposure. Urine assays are available only for certain volatile substances (e.g., toluene, chlorinated solvents) but may provide a longer window of detection.[5]

Ethylene glycol, a bittersweet-tasting component of antifreeze, brake fluids, and industrial solvents, is sometimes ingested by substance-abusing adults as an inexpensive substitute for alcohol. Readily absorbed via the gastrointestinal tract with ingestion, this solvent reaches maximal blood concentrations within 1 to 4 hours. It is metabolized by the hepatic enzyme alcohol dehydrogenase to four toxic organic acids. The primary screening test findings for ethylene glycol intoxication include serum anion-gap metabolic acidosis, high urine osmolality with an osmol gap, and the presence of calcium oxalate crystals in the urine.[161,162]

Toluene, a primary component of household paint and cleaning agents, is also sniffed or ingested orally for its transient euphoric effects.[63]

Systemic Effects

Typically, the user of inhalants feels an initial sense of euphoria followed by a brief period of disinhibition and impulsivity. Intoxication can be prolonged through repeated inhalation of the solvent. As the dose increases, dizziness, diplopia, and disorientation manifest, followed by headache, nausea, vomiting, drowsiness, and sleep.[160]

Mucous membrane irritation can result in rhinorrhea, epistaxis, excessive salivation, and conjunctival redness. Nausea, vomiting, and diarrhea can also occur.[160] Ingestion of volatile substances can lead to potentially lethal tachyarrhythmias, likely secondary to sympathetic stimulation, or bradyarrhythmias from decreased sinoatrial node automaticity or direct vagal stimulation and myocardial depression (see Table 54-3).[5] Hypoxemia may occur as a result of formation of carboxyhemoglobinemia, methemoglobinemia, or suffocation.[5,160,163]

Chronic inhalant abuse can cause multiorgan system disease, with **cardiac** (e.g., cardiomyopathy, arrhythmias, myocardial infarction), **pulmonary** (e.g., wheezing, acute respiratory distress syndrome, pulmonary hypertension), **central and peripheral nervous system** (e.g., cognitive impairment, ataxia, muscle weakness, peripheral neuropathy), and **autonomic dysfunction** (see Table 54-4).[5,6] Renal toxicity, aplastic anemia, and hepatocellular carcinoma have also been reported.[127,160] Imaging studies have demonstrated loss of brain mass, white matter degeneration, and subcortical abnormalities in long-term users. Significant methemoglobinemia with attendant cyanosis can also occur from exposure to some compounds.[5,160,163]

Cessation of chronic use can lead to reversal of many of the pathophysiologic changes, although the CNS effects may persist. Death from inhalant use typically occurs from suffocation, aspiration, or accidental injury. **Sudden sniffing death syndrome**, likely secondary to a fatal arrhythmia in the setting of a sensitized myocardium, electrolyte abnormalities, and hypoxemia, has been reported in both new and long-term users.[160]

Ingestion of ethylene glycol has inebriating effects similar to those of alcohol with more devastating consequences. Accumulation of the toxic metabolite glycolic acid occurs, resulting in CNS depression and seizure activity. Cardiopulmonary manifestations are often delayed (12 to 24 hours after ingestion) and may be fatal. If the patient survives, she will likely experience **renal failure** 24 to 72 hours after ingestion. The estimated lethal dose of undiluted ethylene glycol is 1.4 mL/kg. Treatment of ethylene glycol ingestion may require the induction of emesis with ipecac in the alert and awake patient or the use of gastric lavage. The conversion of ethylene glycol to its toxic metabolites can be prevented with the use of the antidote **fomepizole** or **ethanol.** Hemodialysis may be warranted.[162]

Ingestion of toluene can similarly cause cardiac arrhythmias, acute respiratory distress syndrome, hepatic failure, cerebral edema, and death.[63]

Effects on Pregnancy and the Fetus

Solvent abuse has been associated with fetal growth restriction, preterm delivery, and perinatal mortality.[9] Infants born of inhalant-abusing women exhibit NAS symptoms, including excessive and high-pitched crying, sleep disorders, CNS irritability, and poor feeding.

Phenobarbital can be somewhat effective in ameliorating these manifestations.[164]

Ethylene glycol intoxication has been misdiagnosed as eclampsia in a patient who presented at 26 weeks' gestation with hypertension and seizures followed by coma. Her postoperative course was complicated by hemodynamic instability, severe metabolic acidosis, and acute renal failure, which prompted suspicion of substance intoxication. Toxicology investigation confirmed ethylene glycol poisoning. Subsequently, the patient was successfully treated with hemodialysis and intravenous ethanol; her neonate was treated with diuresis and replacement transfusion.[161]

Anesthetic Management

Identification of solvent abuse in the parturient is critical to safe anesthetic care.[163] The parturient's skin and clothing should be decontaminated if inhalation abuse is suspected.[160] A careful physical examination, including documentation of preexisting sensory and motor deficits, should be undertaken, and electrolyte abnormalities should be identified and corrected.[9]

If the patient is cooperative and able to protect her airway, neuraxial labor analgesia can be administered. It may be prudent to avoid administration of an epinephrine-containing local anesthetic solution, given the significant risk for arrhythmias in these patients. The treatment of hypotension should include the use of intravenous fluids. Phenylephrine may be preferable to ephedrine because the latter may predispose to arrhythmias. Atropine should be readily available but used with caution. In a stable patient with sustained tachyarrhythmias, beta-adrenergic receptor antagonists should be the first line of therapy.[5]

In intoxicated or otherwise uncooperative patients, rapid-sequence induction of general anesthesia for cesarean delivery may be indicated.[9]

KEY POINTS

- Substance abuse by pregnant women results in significant risks for maternal and fetal morbidity and mortality.
- Anesthesia providers often care for substance-abusing patients during labor or cesarean delivery.
- Maternal self-reporting underestimates the true incidence of substance abuse. Drug testing (e.g., urine, blood, oral fluid, hair, meconium) should be employed if substance abuse is suspected.
- Optimal care of these patients requires developing a therapeutic bond and an explicit pain management plan. Anesthesia providers should ask patients questions about substance abuse in a respectful and nonjudgmental manner.
- Neuraxial anesthetic techniques are the preferred methods for labor analgesia and cesarean delivery anesthesia for most patients with a history of substance abuse, provided that the patient is cooperative, is able to protect her airway, and does not have a coagulopathy or a platelet count below the threshold of concern for the anesthesia provider.
- Although patients with substance abuse may have abnormal pain sensitivity, providers should not assume that the etiology of inadequate neuraxial labor analgesia is solely a result of the patient's addiction. Opioid-addicted patients can have inadequate (failed) neuraxial analgesia and anesthesia just like their nonaddicted counterparts.
- Intrauterine alcohol exposure is the leading cause of preventable birth defects in the United States.
- Smoking during pregnancy negatively affects fetal growth. Pregnant women who smoke are more likely to suffer respiratory complications and impaired wound healing.
- Moderate maternal caffeine intake (< 300 mg/day) does not appear to have adverse maternal or fetal effects.
- Marijuana is thought to be the most common illicit substance used by pregnant women. Smoking marijuana increases maternal respiratory comorbidities. The long-term effects on exposed offspring are unclear.
- Cocaine use has been associated with sudden death from a variety of factors, including cardiac arrhythmias, respiratory arrest, status epilepticus, and impaired thermoregulation. Maternal cocaine use increases the likelihood of placental abruption and urgent cesarean delivery.
- Acute cocaine intoxication can mimic preeclampsia, eclampsia, or malignant hyperthermia.
- Evidence is conflicting as to whether intrauterine hallucinogen exposure has deleterious effects on the fetus.
- Inhalant abuse can lead to severe maternal hypoxemia and potentially lethal arrhythmias.
- Ingestion of amphetamines results in high levels of circulating catecholamines, leading to hemodynamic instability and, in some cases, cardiac arrest.
- Care of the opioid-dependent patient should involve maintenance of long-term opioid requirements, multimodal management of acute pain, and avoidance of opioid antagonists and mixed-agonists/antagonists (unless the patient shows signs of overdose or is undergoing medically supervised detoxification).
- Buprenorphine is increasingly becoming the opioid maintenance treatment of choice in patients who are addicted to heroin or other opioids. Goals of care in these and methadone-maintained patients include continuing their methadone or buprenorphine treatment, adding multimodal acute pain therapy, and avoiding opioid antagonists and mixed agonists/antagonists.

CHAPTER 55

Trauma and Critical Care

Luis Pacheco, MD • Paul Howell, MBChB, FRCA • Edward R. Sherwood, MD, PhD

CHAPTER OUTLINE

The management of critically ill obstetric patients most commonly involves treatment of disease processes that occur as a direct consequence of pregnancy. Although sometimes life threatening, these conditions are usually reversible. Delivery of the infant often attenuates or ablates the disease process, and the mother typically recovers with supportive and resuscitative measures. Primary obstetric disorders account for 50% to 80% of intensive care unit (ICU) admissions for pregnant patients; approximately 80% of these admissions result from preeclampsia, sepsis, and/or hemorrhage (Box 55-1).[1,2] The estimated ICU admission rate for obstetric patients is 0.5% to 1% in the United States; the mortality rate in this population is 12% to 20%.[3]

Trauma accounts for 45% to 50% of all maternal deaths in the United States, and it is the most common nonobstetric cause of maternal death.[4] Other common nonobstetric causes of ICU admission are respiratory failure, endocrine disorders, preexisting autoimmune disease, and thromboembolic disorders.[5] Ethnic minorities and women with low socioeconomic status have the highest rates of morbidity and mortality. Modern medicine has allowed women with complex medical problems such as congenital heart disease and cystic fibrosis to survive into childbearing age, and these patients are at increased risk for complications during pregnancy and have a higher incidence of ICU admission. Among critically ill obstetric patients admitted to an ICU, the most common cause of death is acute respiratory distress syndrome (ARDS), which can complicate both obstetric and nonobstetric disease processes.[6]

Critical maternal illness places the fetus at significant risk for morbidity and mortality. Important fetal risk factors include maternal shock, transfusion of blood products, and early gestational age at the time of critical maternal illness.[7]

TRAUMA DURING PREGNANCY

Epidemiology

Trauma affects 5% to 7% of pregnancies in the United States and is the leading nonobstetric cause of maternal death; as many as 20% of affected women require emergency surgery.[8,9] Motor vehicle accidents are the most common cause of injury-related maternal death (49% to 70%), followed by domestic violence (11% to 25%) and falls (9% to 23%).[10-12] Not using a seat belt is a major risk factor for maternal and fetal injury in motor vehicle trauma.[13] Penetrating trauma and burns are far less common than blunt mechanisms of injury. The rate of maternal trauma admission to an ICU increases with each trimester: 8% occur in the first trimester, 40% in the second trimester, and 52% in the third trimester.[14] Most women are able to continue their pregnancy at home, but up to 38% are hospitalized until delivery.

Risk factors for maternal trauma include age younger than 25 years, low socioeconomic status, minority race, use of illicit drugs or alcohol, and domestic violence.[14,15] It is important to remember that any female patient

BOX 55-1 Causes of Critical Illness in Pregnancy

Obstetric Causes

- Acute fatty liver of pregnancy
- Amniotic fluid embolism
- Cardiomyopathy
- Chorioamnionitis
- HELLP syndrome
- Hemorrhage
- Pelvic septic thrombophlebitis
- Placental abruption
- Preeclampsia/eclampsia
- Puerperal sepsis

Nonobstetric Causes

- Acute renal failure
- Autoimmune disorders
- Chronic respiratory disease
- Diabetic ketoacidosis
- Drug abuse
- Pneumonia
- Pulmonary thromboembolism
- Trauma
- Urinary tract infection

HELLP, hemolysis, elevated liver enzymes, low platelet count.

of reproductive age who is a victim of trauma could be pregnant at the time of injury.

Complications and Outcomes

As in the general population, hemorrhagic shock and brain injury are the most common mechanisms of death in pregnant trauma victims.[16] Pelvic and acetabular fractures also pose a significant risk. Injuries and complications that are unique to pregnant trauma victims include uterine rupture, placental abruption, preterm labor, and direct fetal injury. Although rare (0.6% of injuries), uterine rupture is a major threat to the life of both the mother (10% mortality) and the fetus (near 100% mortality).[17] Placental abruption complicates 1% to 5% of minor injuries and 20% to 60% of major trauma and usually occurs from 16 weeks' gestation onward.[18] Placental abruption can cause major overt and occult hemorrhage and coagulopathy and should be considered as a possible source of bleeding in the unstable pregnant trauma patient. Preterm labor is a common (25%) complication of trauma and can be precipitated even in cases of apparently minor injury.[19]

Premature rupture of membranes (PROM) increases the risk for both preterm labor and infection. Amniotic fluid embolism is a rare complication of maternal trauma, but it should be considered as part of the differential diagnosis in patients who are refractory to resuscitation.

Fetal-maternal (transplacental) hemorrhage can occur after trauma and result in maternal isoimmunization with the D antigen of the fetal red blood cell Rhesus protein complex (Rh_0[D]) in the Rh-negative mother (see Chapter 6). The Kleihauer-Betke test is used to identify fetal blood in the maternal circulation after maternal injury. When fetal-maternal hemorrhage is present, treatment

BOX 55-2 Factors Associated with Fetal Demise after Trauma

- Ejection from vehicle
- Maternal pelvic fracture
- High maternal Injury Severity Score (> 15)
- Maternal death
- Maternal hypotension
- Uterine rupture
- Uterine tenderness
- Placental abruption
- Vaginal bleeding
- Abnormal fetal heart rate pattern
- Amniotic fluid on pelvic examination
- Maternal history of alcohol use
- Maternal smoking history

with Rh_0(D) immune globulin (RhoGAM) is generally indicated. In a study performed at the R. Adams Cowley Shock Trauma Center of the University of Maryland, more than 50% of evaluated pregnant trauma victims were positive for fetal-maternal hemorrhage as determined by a positive Kleihauer-Betke test.[20] Essentially all patients with a positive test had uterine contractions, whereas patients with a negative Kleihauer-Betke test did not have contractions. The investigators concluded that the Kleihauer-Betke test was a sensitive and specific predictor of preterm labor in pregnant trauma patients and should be performed in all victims regardless of blood Rh phenotype.

Fetal Trauma and Outcome

The fetal mortality rate after maternal blunt trauma has been reported to range from 3.4% to 38.0%; placental abruption, uterine rupture, maternal shock, and maternal death are the most frequent factors associated with fetal demise (Box 55-2).[15,21] The risk for direct fetal trauma increases with gestational age because the bony pelvis protects the uterus and fetus prior to 13 weeks' gestation. Pregnant women who sustain blunt trauma have a lower risk for bowel injury than nonpregnant patients because the uterus acts as a shield and pushes the abdominal contents into the upper abdomen.[22,23] Maternal pelvic fractures are associated with uteroplacental injury and fetal skull fractures. Skull fracture is the most common direct fetal injury and has a reported fetal mortality rate of 42%.[24]

The relationship between the Injury Severity Score (ISS) (see later discussion) and fetal outcome is controversial. Some studies have shown a direct relationship between the ISS and the incidence of fetal demise, whereas others have not. Analysis of outcomes from 1195 pregnant trauma victims showed that an ISS of greater than 15 was associated with increased risk for fetal demise.[25,26] Evidence suggests that decreased serum bicarbonate, an indicator of systemic hypoperfusion, is associated with fetal demise after maternal trauma. Altered maternal mental status and the presence of head trauma have also been linked to adverse fetal outcomes.

It is crucial to preserve maternal cardiac output, blood pressure, and oxygen delivery to optimize maternal recovery and protect fetal well-being. However, fetal loss

can occur even if the mother has not incurred serious injuries. Thus, all pregnant women should be evaluated in a medical setting after trauma, regardless of the apparent severity of injury. The fetus remains at risk for delayed complications after maternal discharge from the hospital. Delayed complications include a twofold increase in the risk for preterm delivery and a ninefold increase in the risk for fetal death.[27] Late complications of trauma, such as cerebral palsy, have also been reported in children born to mothers who experienced trauma during pregnancy.[28,29]

Initial Assessment and Resuscitation

The initial assessment and resuscitation should focus on the mother; it is axiomatic that maternal resuscitation typically facilitates fetal resuscitation. A systematic approach to initial resuscitation and stabilization should be used (Figure 55-1).[4] Immediate interventions are initiated to identify and treat life-threatening conditions based on the principles of Advanced Trauma Life Support (ATLS).[30] Initial focus should be placed on ensuring adequate airway protection, ventilation (breathing),

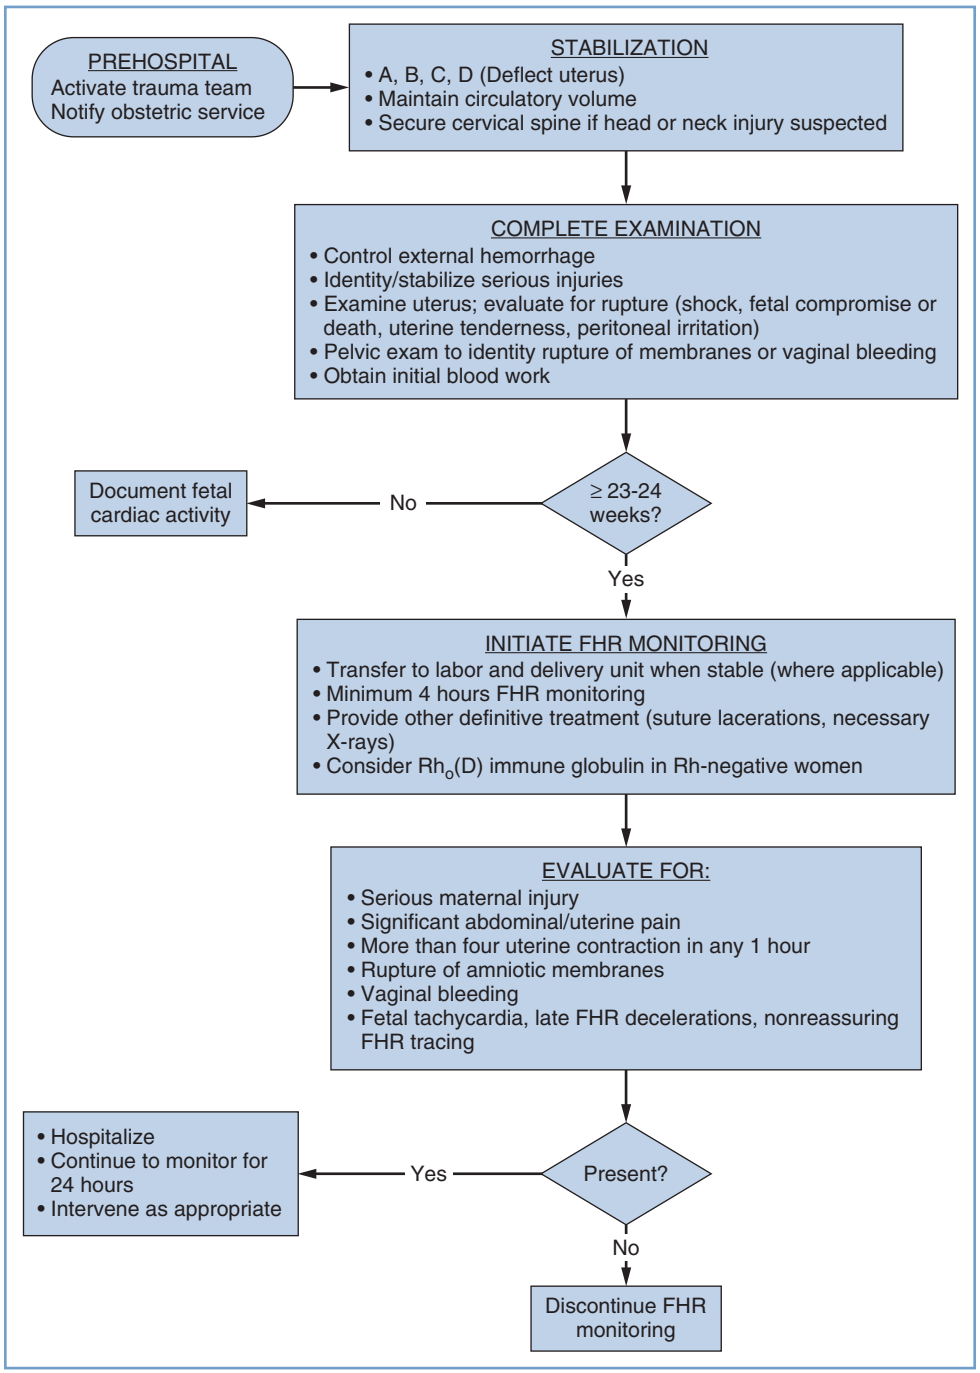

FIGURE 55-1 ■ Algorithm for management of the pregnant woman after trauma. *FHR,* fetal heart rate. (Modified from Chames MC, Pearlman MD. Trauma during pregnancy: outcomes and clinical management. Clin Obstet Gynecol 2008; 51:398-408.)

TABLE 55-1 Physiologic Changes of Pregnancy That May Affect Trauma Management

Parameter	Effect of Pregnancy	Implications
Airway		
Functional residual capacity	Decreased by 20%	More rapid oxyhemoglobin desaturation during periods of apnea
Oxygen consumption	Increased by 15%-20%	
Airway edema	May be present	Tracheal intubation more difficult
Lower esophageal sphincter tone	Decreased	Increased risk for aspiration
Gastric emptying	Decreased during labor	
Breathing		
Diaphragm	Displaced cephalad	Place chest tubes at higher intercostal space
Respiratory rate	No change	
Tidal volume	Increased 35%-45%	
pH	7.42-7.46, partially compensated respiratory alkalosis	
$PaCO_2$	28-32 mm Hg	Reflects normal hyperventilation
HCO_3^-	19-22 mEq/L	Reduced buffering capacity
Base deficit	2-3 mEq/L	
PaO_2	100-107 mm Hg	
Circulation		
Blood volume	Increased by 40%-50%	Significant blood loss may occur before onset of symptoms and hypotension
Cardiac output	Increased by 40%-50%	
Heart rate	Increased by 15%-25%	Early diagnosis of hypovolemia more difficult
Systolic blood pressure	Decreased by 5-15 mm Hg (more pronounced during mid pregnancy)	
Diastolic blood pressure	Decreased by 5-15 mm Hg (more pronounced during mid pregnancy)	
Hemoglobin	10-12 g/dL	Physiologic anemia
Gravid uterus	Aortocaval compression	Decreased cardiac output in the supine position; left uterine displacement required
Other		
Coagulation factors	Increased	Hypercoagulable state
BUN, creatinine	Decreased	Abnormal measurements often overlooked*
Symphysis pubis/sacroiliac joints	Widened	May alter radiographic interpretations

BUN, blood urea nitrogen.
*The reported measurements may fall within the normal range for the hospital laboratory, but the measurements may actually be abnormally high for a pregnant patient.

and circulation (the "ABCs" of resuscitation). Pregnant women experience significant changes in cardiopulmonary and metabolic function that must be considered during resuscitation (Table 55-1).

Airway

Airway patency, stabilization, and protection should be ensured as quickly as possible in all critically injured patients, including those who are pregnant. The status of the patient's airway can be quickly assessed by eliciting a verbal response. The inability to speak is an indication of severely impaired mental status or the inability to move adequate air to mediate phonation, either of which should prompt interventions to secure and protect the airway. Additional means of assessing airway patency include auscultation of the chest, assessment of chest movement, and assessment of air movement at the oral/nasal openings. Immediate interventions to establish airway patency include head tilt and jaw thrust maneuvers, as well as placement of an oral or nasopharyngeal airway to facilitate bag-mask ventilation and oxygenation.

It is essential to consider the possibility of cervical spine injury, facial fractures, and skull base injuries. Excessive head tilt maneuvers can worsen injury if a cervical spine fracture is present.[31] Patients who have sustained severe trauma should be suspected of having a cervical spine injury until proven otherwise. Cervical spine injury must be ruled out by radiographic and physical examination criteria.[32,33] The cervical spine should be stabilized with a hard collar and in-line stabilization until the severity of injury has been established. In cases of documented cervical spine injury, great care must be taken not to worsen spinal cord injury. A nasopharyngeal

airway should not be placed in patients with suspected facial or skull base fractures to avoid further trauma and worsening of preexisting conditions.

Most patients who require interventions to open or support the airway, as just described, will ultimately require tracheal intubation. Indications for tracheal intubation include impaired mental status, airway obstruction, inability to clear secretions or blood from the airway, inadequate spontaneous ventilation, and hypoxemia that is refractory to supplemental oxygen administration.[34] Tracheal intubation of pregnant patients is complicated by changes in respiratory system structure and function (see Table 55-1) (see Chapter 30).[18] Among the most prominent alterations are airway (including vocal cord) edema, decreased functional residual capacity, and increased oxygen consumption. Airway edema impairs vocal cord visualization, thus complicating laryngoscopy and tracheal intubation. Decreased functional residual capacity and increased oxygen consumption result in more rapid oxyhemoglobin desaturation during periods of apnea. These factors increase the risk for failed tracheal intubation and hypoxemia.

Gastric emptying is normal in pregnant women before the onset of labor. However, lower esophageal sphincter tone is commonly decreased in pregnant women (see Table 55-1). Thus, pregnant women are at increased risk for regurgitation and pulmonary aspiration of gastric contents, although all trauma victims are considered to have a full stomach on arrival in the emergency department or operating room. Therefore, in most cases, rapid-sequence induction of general anesthesia is performed to facilitate tracheal intubation. However, the specific tracheal intubation technique will depend on the practitioner's skills and resources, as well as on the location of the patient's injuries. Alternative approaches to rapid-sequence induction include awake tracheal intubation and tracheostomy.

Several factors can complicate tracheal intubation in the trauma patient. The patient may be combative, which complicates awake tracheal intubation strategies. Blood in the airway can also limit the use of a fiberoptic bronchoscope and impair visualization of the glottis when using a standard or video laryngoscope. The presence of facial fractures, direct airway injuries, trauma-induced airway edema, and tracheal deviation can limit access to the airway.

Finally, airway management, including tracheal intubation, is more challenging in the presence of cervical spine injury. If cervical spine injury is present or suspected, it is crucial to avoid flexion, extension, or lateral movement of the neck. The spine is protected using in-line stabilization and/or a hard cervical collar. Airway management devices such as a gum elastic bougie, a video laryngoscope, a lighted intubating stylette, and/or an intubating laryngeal mask airway (LMA), among others, should be available for use if standard laryngoscopy is difficult or impossible. A supraglottic airway device such as an LMA can be used to temporarily provide ventilation in cases in which mask ventilation and tracheal intubation have failed, but an LMA will not provide protection from aspiration and should be replaced by a secure airway device as soon as possible. In some cases, cricothyroidotomy or tracheostomy may be necessary to provide a secure airway.

Breathing

Adequate ventilation and oxygenation should be ensured for the benefit of both the mother and the fetus. Supplemental oxygen should be administered immediately, even if the patient is breathing spontaneously. Mechanical ventilation is often necessary after tracheal intubation in patients with respiratory failure and/or hypoxemia. Ventilation can be compromised by trauma-associated factors such as pneumothorax, hemothorax, lung contusion, mediastinal compression, and chest wall injuries. These problems must be identified during the primary survey and treated to optimize ventilation and oxygenation. In women with advanced pregnancy, it may be necessary to place chest tubes more cephalad than normal owing to the cephalad displacement of the diaphragm and intra-abdominal structures by the gravid uterus. Pregnant trauma patients should be ventilated to maintain $Paco_2$ at a level that is normal for pregnancy (28 to 32 mm Hg) (see Table 55-1). Positive end-expiratory pressure (PEEP) may be added to improve oxygenation, if indicated; however, PEEP should be titrated carefully in the hypovolemic patient because it may impair venous return and worsen cardiac output and organ perfusion.

Circulation

Once respiratory stabilization has been achieved, it is essential to assess cardiovascular function and to determine whether the patient is in shock. Two large-bore peripheral intravenous catheters should be placed in the upper extremities to facilitate resuscitation. Central venous access facilitates rapid resuscitation but may be difficult to obtain. Intraosseous cannulation should be considered if it is difficult or impossible to obtain peripheral or central venous access.

Fluid resuscitation should be initiated using crystalloid solution, but blood transfusion should be considered if significant blood loss is apparent or suspected. Left uterine displacement should be initiated immediately to prevent or minimize aortocaval compression by the gravid uterus. The adverse effects of aortocaval compression may be exacerbated during periods of trauma-associated hypovolemia. The use of the pneumatic antishock garment to stabilize fractures or control hemorrhage is relatively contraindicated in pregnant women owing to its adverse effects on venous return.

The hallmark clinical signs of shock are listed in Box 55-3. The presence of these signs indicates a need for timely and appropriate fluid resuscitation. A rapid assessment of sources of blood loss should be performed. In trauma victims, the most common locations of exsanguinating blood loss are the chest, abdomen, retroperitoneum, long bones, and external sites. In the pregnant trauma patient, placental abruption and uterine rupture are also potential sources of hemorrhage. A brief physical examination will identify fractures of the long bones and external sites of bleeding. Thoracic blood loss and pelvic fractures can be identified by chest and pelvic radiographs, respectively. Focused abdominal sonography in trauma (FAST) or diagnostic peritoneal lavage can be used to identify intra-abdominal bleeding. However,

BOX 55-3 Clinical Signs of Shock in the Trauma Patient

- Agitation
- Confusion
- Poor capillary refill
- Mottled appearance
- Cool extremities
- Diaphoresis
- Tachypnea
- Tachycardia
- Weak distal pulses
- Hypotension
- Decreased pulse pressure
- Decreased urine output
- Lactic acidosis

diagnostic peritoneal lavage may be difficult to perform safely in advanced pregnancy. FAST can be rapidly performed to assess the hepatorenal, splenorenal, and pelvic spaces, which are the most common sites of major hemorrhage in trauma patients. FAST can also be used to assess uteroplacental integrity and the presence of intrauterine bleeding. Finally, ultrasonography facilitates assessment of cardiac filling and recognition of cardiac tamponade in patients with thoracic trauma.

It is important to recognize that pregnant trauma patients may lose a significant amount of blood before the development of hypotension. Pregnant patients have a 40% to 50% increase in blood volume by the third trimester. Classic signs of hypovolemia such as tachycardia, hypotension, and poor capillary refill may not be evident until blood loss approaches 1.5 to 2 liters. Therefore, it is likely that a pregnant trauma victim will have lost significantly more blood volume and oxygen-carrying capacity than a comparable nonpregnant patient when signs of cardiovascular deterioration become evident. Resuscitation should be guided by apparent blood loss to maintain adequate maternal cardiac output and uteroplacental perfusion. Because of the physiologic anemia of pregnancy, oxygen-carrying capacity may be significantly impaired at the time that hypovolemia becomes evident. In addition, maternal perfusion of vital organs is often sustained at the expense of uteroplacental perfusion. Uterine blood flow may decrease by as much as 30% before the mother shows signs of hypovolemia. Therefore, a nonreassuring fetal heart rate (FHR) pattern may be the first sign of significant intravascular volume loss. Fluids should be warmed to minimize the risk for hypothermia, which can contribute to coagulopathy, arrhythmias, and altered drug responses.

Fluid Resuscitation. Current practice supports the use of **crystalloid solutions** to resuscitate the hypovolemic trauma victim. However, the crystalloid versus colloid debate remains to be fully resolved. The Saline versus Albumin Fluid Evaluation (SAFE)[35] did not show any difference in survival in nonpregnant trauma patients randomized to receive resuscitation with either colloid or crystalloid, with the exception of patients with head trauma, who had worse outcomes when resuscitated with albumin. However, colloid solutions are anecdotally preferred in some trauma centers. The current ATLS guidelines advocate the use of lactated Ringer's solution for initial fluid resuscitation.[30] Lactated Ringer's solution has significant buffering properties and is less likely to cause hyperchloremic metabolic acidosis during high-volume resuscitation than normal saline solution. Other buffered salt solutions such as Plasma-Lyte, Ringer's ethyl pyruvate, and Ringer's hydroxybutyrate also may have value. Currently, no evidence supports the use of one buffered isotonic crystalloid solution over another.

The use of **hypertonic crystalloid solutions** such as 3% sodium chloride is controversial; currently no evidence supports their use in pregnant trauma victims. Hypernatremia is a risk in patients resuscitated with hypertonic saline, and some studies have shown increased mortality in patients resuscitated with hypertonic crystalloid solutions.[36]

Some practitioners have advocated **hypovolemic resuscitation** in patients with major hemorrhage after trauma.[37] This technique employs **permissive hypotension** (systolic blood pressure of 80 to 90 mm Hg) until hemorrhage can be controlled in the operative setting. The underlying premise of hypovolemic (hypotensive) resuscitation is that over-resuscitation worsens ongoing blood loss as a result of higher perfusion pressure and dilution of clotting factors. Small boluses of fluids are administered to maintain perfusion in patients without evidence of closed head injury. The use of hypotensive resuscitation is likely to be detrimental in patients with closed head injury because it is crucial to maintain adequate cerebral perfusion pressure (CPP) in patients with elevated intracranial pressure (ICP).[38] (CPP is the difference between mean arterial pressure [MAP] and ICP.) No definitive published data support the use of hypotensive resuscitation in pregnant trauma patients. Current guidelines do not support this approach because it may compromise uteroplacental perfusion.

Damage Control Principles and Resuscitation. The traditional approach to treatment of traumatic life-threatening injuries has been definitive operative repair. However, some patients experience progressive physiologic decline during long surgical procedures and develop severe derangements such as hypothermia, metabolic acidosis, and coagulopathy, a combination that has become known as the *deadly triad*.[39] These pathologic alterations require rapid and effective treatment to prevent severe morbidity and death. More recently, some practitioners have advocated the use of a more targeted approach, termed *damage control*, which is initiated to control hemorrhage without providing early definitive repair of injuries.[40] Major surgical bleeding is controlled, and the thoracic and abdominal cavities are packed to provide hemostasis. Gastrointestinal diversion is performed, and body cavities are temporarily closed, often using vacuum-type closure systems. Active volume resuscitation is performed to achieve metabolic homeostasis. On achievement of stable hemodynamic and acid-base status, coagulation function, and temperature, the patient is taken back to the operating room for definitive repair of injuries.

Blood Products. All trauma centers should have rapid access to **type O**, **Rh-negative blood** for emergency use before type-specific or crossmatched blood is available. Recently, some trauma specialists have advocated damage-control resuscitation using packed red blood cells and fresh frozen plasma mixed in equal proportions (1 : 1) (see Chapter 38). Several investigators have reported the value of this approach in military practice, and they have specifically observed that this approach results in more effective resuscitation, less coagulopathy, and improved survival than more traditional approaches.[41] It remains unclear whether this approach will be advantageous in civilian practice, but many centers are investigating its use.

In the setting of uncontrolled hemorrhage, recombinant activated factor VII (rFVIIa) has been shown to be effective in treating severe coagulopathy in a small number of observational studies. Case reports and case series have described the efficacy of rFVIIa during massive hemorrhage in trauma and obstetric patients (see Chapter 38).[37] A multidisciplinary group in Israel reported that rFVIIa was effective in decreasing severe bleeding in 36 trauma patients.[42] European consensus guidelines also advocate the use of rFVIIa in trauma patients with massive uncontrolled hemorrhage that is refractory to conventional transfusion of blood products.[43] However, further research is needed before rFVIIa can be endorsed for treatment of massive hemorrhage, owing to its high cost and an incomplete risk-benefit analysis. A major concern is the potential increased risk for thromboembolism in patients treated with rFVIIa.

Secondary Survey

As in all trauma cases, it is crucial to evaluate the mother for significant abdominal, thoracic, orthopedic, and neurologic injuries. A head-to-toe examination should be performed to determine the presence of injuries and the need for intervention. A more detailed evaluation of neurologic function, as well as examination of the head and neck, should be performed. This survey includes examination of posterior structures that may be obscured by the supine position and the presence of a cervical collar. The torso should be examined to identify thoracic and abdominal injuries. The thoracic examination should include chest auscultation, inspection, and palpation. Palpation of the abdomen should be performed to evaluate abdominal tenderness, and a rectal examination should be performed to identify evidence of intraluminal bleeding. The extremities must be examined to identify deformities, and each joint should be manipulated. Distal perfusion of the extremities must be continuously monitored, especially in limbs that show signs of significant injury. This is accomplished by evaluation of distal pulses and capillary refill. In cases of penetrating injury, the sites of entry and exit should be identified. It is especially important to examine carefully the areas that are difficult to access such as the oral cavity, perineum, axilla, scalp, and back. Once the secondary survey has been performed, more targeted assessments of suspected injuries can be performed using radiologic imaging.

Fetal Survey. After initial stabilization of the mother, information about the pregnancy should be gathered through a focused history and physical examination. The history should include the date of the last menstrual period, expected date of delivery, and status of the pregnancy. In cases in which there is uncertainty regarding fetal age, an approximate determination can be made by measuring fundal height. The fetal age is estimated to be 1 week for each centimeter of fundal height above the symphysis pubis. In addition to the assessment of fundal height, the abdominal examination should include an assessment of uterine tenderness and consistency, the presence or absence of uterine contractions, and fetal position and movement.

A pelvic examination should be performed to evaluate cervical dilation and effacement, fetal station, and the presence of amniotic fluid and blood. The FHR is assessed by Doppler auscultation or ultrasonography. If maternal stability permits, ultrasonography facilitates estimation of fetal age and assessment of uteroplacental injury.

If no fetal cardiac activity is identified, fetal resuscitation should not be attempted (see Figure 55-1). In a series of 441 pregnant trauma patients, the absence of a detectable FHR was associated with fetal death in all cases.[9] When a FHR is detected, an assessment of fetal viability should be performed. An estimated gestational age of 24 to 25 weeks and an estimated fetal weight of 500 g are common thresholds for extrauterine fetal viability. The FHR should be monitored in cases in which the fetus is determined to be viable. In cases in which a nonviable fetus is present, the importance of FHR monitoring is unclear. However, alterations in FHR and FHR variability may signal maternal deterioration and serve as a good monitor of the effectiveness of maternal resuscitation.

FHR monitoring is generally performed with external Doppler auscultation, and a tocodynamometer is used to assess uterine contractions. Adverse fetal outcomes are unlikely in cases with a reassuring FHR tracing and no early warning signs of uteroplacental injury (bleeding, abdominal pain).[44] In contrast, an abnormal FHR tracing or evidence of uteroplacental injury (vaginal bleeding, uterine contractions, uterine tenderness, presence of amniotic fluid on vaginal examination) predicts poor fetal outcome in approximately 50% of cases.[45]

Fetal Monitoring

Continuous electronic FHR monitoring is the current standard of care for pregnant trauma victims with a viable fetus.[9,14] FHR monitoring should be initiated as soon as maternal stabilization is complete, because placental abruption can occur early during the course of resuscitation. Continuous electronic FHR monitoring is more sensitive for placental abruption than ultrasonography, physical examination, or Kleihauer-Betke testing. Occasional uterine contractions are common after trauma and are usually not associated with poor fetal outcome.[11,45,46] Random uterine contractions usually resolve within a few hours of the accident. However, regular and prolonged uterine contractions (eight contractions per hour for more than 4 hours) are associated with placental abruption, which has a high fetal mortality rate.[46]

The diagnosis of placental abruption should trigger immediate cesarean delivery; a large percentage of viable fetuses can be rescued if expedited delivery is performed. The presence of fetal bradycardia and frequent late FHR decelerations should also prompt delivery if the mother is stable and adequately resuscitated.

The ideal duration of FHR monitoring has not been determined. However, a common practice, based on a prospective study of 60 pregnant trauma patients at more than 20 weeks' gestation, is to monitor the FHR for 4 hours.[47] If maternal-fetal abnormalities are not detected within 4 hours, it is generally considered safe to discontinue FHR monitoring because a normal FHR tracing has a negative predictive value of 100% when combined with a normal maternal physical examination. However, the presence of abnormalities such as vaginal bleeding, spontaneous rupture of membranes, category II and III FHR patterns, persistent uterine contractions, uterine tenderness, abdominal pain, and/or need for maternal analgesia should prompt further FHR monitoring. The sensitivity of ultrasonography for placental abruption ranges from 50% to 80%, but ultrasonography is a safe and effective means of assessing fetal viability, FHR, placental location, gestational age, and amniotic fluid volume. It is particularly valuable in the presence of maternal tachycardia, when it can be difficult to differentiate maternal and fetal heart rates using Doppler auscultation.

Laboratory Studies

Laboratory evaluation in pregnant trauma patients does not differ from the evaluation for nonpregnant patients, with a few exceptions. As for all trauma patients, the laboratory evaluation will be driven by the type and severity of injury. For most patients with significant injury, standard analysis includes a complete blood cell count with a platelet count, coagulation studies, serum electrolyte measurements, blood glucose and lactate levels, liver function tests, arterial blood gas analysis, urinalysis, and toxicology screening, as well as sending a blood sample for typing and crossmatching for compatible blood products (Box 55-4).

The presence of disseminated intravascular coagulation (DIC) and low blood bicarbonate levels is associated with poor fetal outcome.[10,25] Both abnormalities reflect severe maternal injury and should prompt aggressive maternal resuscitation. Of special consideration in pregnant trauma patients is maternal-fetal hemorrhage. The Kleihauer-Betke acid elution assay is used to detect the entry of fetal blood into the maternal circulation.[20] It is typically performed in Rh_0(D) antigen–negative mothers to detect transplacental hemorrhage and the potential for developing Rh_0(D) sensitization, which can be prevented in 99% of cases by early treatment with Rh_0(D) immune globulin (RhoGAM). However, this test may help predict adverse fetal outcomes in all pregnant trauma patients (see earlier discussion).

BOX 55-4 Initial Laboratory Analysis for the Pregnant Trauma Patient

- Blood type and crossmatch
- Complete blood cell count with platelet count
- Prothrombin (INR) and partial thromboplastin times
- Fibrinogen
- Serum electrolytes, BUN, creatinine, glucose
- Liver function tests
- Serum amylase level
- Blood lactate
- Arterial blood gas measurement
- Toxicology screen
- Kleihauer-Betke assay
- Urinalysis

BUN, blood urea nitrogen; *INR*, international normalized ratio.

Imaging

The pregnant trauma patient often requires imaging to evaluate orthopedic, head, thoracic, and abdominal injuries. Although many patients and physicians are concerned about the fetal effects of ionizing radiation, the risks for teratogenesis, malignancy, and gene mutation are small with a radiation exposure less than 5 to 10 rads (see Chapter 17).[48] Less than 1% of trauma patients receive more than 3 rads of radiation exposure. When possible, the fetus should be shielded with lead. Intravenous pyelography subjects the fetus to as much as 1.4 rads of exposure, but the test can be invaluable in diagnosing injuries to the kidneys, ureters, and bladder. Computed tomography (CT) is associated with greater radiation exposure than plain radiography, but exposure levels are generally below that considered to be dangerous to the fetus. Modern multidetector (multislice) CT results in higher fetal radiation exposure, but it has significant advantages in speed and image resolution. Overall, the small risk for fetal radiation exposure is outweighed by the benefits to the injured mother and, by extension, the fetus.

Injury Scoring

Several injury scoring scales have been developed over the past 40 years. The scoring systems provide a framework for standardizing clinical management, benchmarking outcomes, and planning research. Presently, no reliable scoring tool exists for predicting maternal or fetal outcome after trauma. Currently used scoring systems include (1) anatomic injury scales that rely on physical examination and diagnostic procedures, (2) physiologic injury scales that rely on assessment of physiologic responses and function, and (3) combination injury scales.

One of the first anatomy-based injury scales was the **Abbreviated Injury Scale** (AIS) developed by the Association for the Advancement of Automotive Medicine.[49] Each of nine body regions is given an injury severity score that ranges from 1 (minor) to 6 (maximal [currently untreatable]). Although the AIS effectively describes the severity of injuries at specific locations, it provides a limited assessment of the overall pathophysiologic impact of all injuries. The **Injury Severity Score** (ISS), which was developed to address this issue, is obtained by summing the square of the three highest severity scores from the AIS. The ISS ranges from 1 to 75. Minor injuries are classified as an ISS of less than 9; moderate, from

9 to 15; serious, from 16 to 25; and severe, greater than 25. The ISS correlates with the risk for preterm delivery after trauma, but its value in predicting fetal death, placental abruption, and other adverse outcomes is controversial.[15] The American Association for the Surgery of Trauma developed the **Organ Injury Scale** (OIS)[50]; this is an organ-based severity scale designed to facilitate clinical investigation and outcomes research. The value of the OIS in predicting adverse maternal and fetal outcomes remains to be established.

Anatomic scoring systems have value in describing the extent and severity of injuries to specific organ systems. However, physiologic scoring systems may add prognostic value. The **Glasgow Coma Scale**, which is among the most widely used physiologic scoring systems, evaluates the neurologic status of the trauma patient. The Glasgow Coma Scale evaluates eye opening, verbal response, and motor activity; scores range from 3 to 15, with 3 indicating the absence of neurologic activity and 15 representing intact neurologic function. A Glasgow Coma Scale score of less than 9 reflects severe impairment, whereas as a score of 9 to 12 reflects moderate disability. However, concerns have been raised about inter-rater reliability and lack of prognostic utility for the Glasgow Coma Scale. Some researchers have proposed that a simplified motor score would be more reliable. Evidence suggests that the Glasgow Coma Scale has a poor correlation with fetal outcome.[15]

Traumatic Brain Injury

Brain injury is the most common severe injury in patients who suffer from motor vehicle accident, and it is a major cause of mortality among pregnant trauma victims.[51] It is important to perform a thorough neurologic examination with particular attention to level of consciousness. Altered mental status may be an indicator of evolving intracranial pathology, intoxication, hypoperfusion, and/or metabolic disturbances. Mental status should be reevaluated frequently because intracranial pathologic processes may not be apparent on initial evaluation and may evolve during the course of resuscitation.

Elevated ICP is a common finding in patients with traumatic brain injury and may be a significant threat to life. Head CT is the imaging study of choice for identifying the site and severity of intracranial pathologic processes in trauma patients, and it should be performed within 1 hour of arrival in the emergency department.

Crystalloid fluid resuscitation should be used for resuscitation in patients with traumatic brain injury; resuscitation with albumin is deleterious in patients with traumatic brain injury (see earlier discussion).[35] Hypotensive resuscitation is contraindicated in patients with traumatic brain injury and elevated ICP. It is crucial to maintain CPP to minimize the risk for brain ischemia and permanent brain injury. The extent of brain injury will worsen if CPP is not maintained. It is also important to maintain cerebral oxygen delivery by optimizing maternal cardiac output and blood oxygen-carrying capacity.

It may be necessary to intubate the trachea of patients with deteriorating mental status for airway protection and provision of ventilatory support. Hypoventilation should be avoided because it increases ICP. Hyperventilation to a $Paco_2$ between 25 and 30 mm Hg will provide a transient decrease in ICP and may be useful until definitive treatment can be initiated. However, hyperventilation can be disadvantageous for the fetus because it can decrease uteroplacental blood flow by decreasing maternal cardiac output and blood pressure, and perhaps by causing uteroplacental vasoconstriction. Therefore, it is prudent to maintain $Paco_2$ at levels that are normal in pregnant females (28 to 32 mm Hg). Additional maneuvers to decrease ICP include treatment with a diuretic such as mannitol or furosemide and elevation of the head 30 to 45 degrees.

Corticosteroids are no longer recommended for patients with traumatic brain injury because their administration in this setting is associated with increased mortality. Barbiturates decrease cerebral oxygen use and blood flow and may provide cerebral protection in patients with severe impairment. Both mannitol and furosemide cross the placenta and could cause alterations in fetal plasma osmolality and decrease fetal intravascular volume. However, concern regarding adverse fetal effects should be overridden by the needs of the mother in cases of traumatic brain injury.

Cardiopulmonary Resuscitation

The incidence of cardiac arrest in pregnancy is reported to be 1:20,000 to 1:30,000 patients in industrialized countries.[52] The most frequent causes are trauma, peripartum hemorrhage, embolic phenomena, stroke, preeclampsia/eclampsia, sepsis, status asthmaticus, and anesthesia-related complications.[53] Cardiopulmonary resuscitation should be initiated immediately (see Chapters 17 and 42). The 2010 American Heart Association (AHA) guidelines highlight the importance of initiating high-quality chest compressions to facilitate circulation.[52,54] The hands should be placed slightly above the center of the sternum because the diaphragm and abdominal contents are displaced cephalad during the third trimester of pregnancy (Box 55-5). In the hospital setting, the airway should be secured and the mother ventilated with 100% oxygen. Intravenous or intraosseous access should be secured to facilitate resuscitation. Advanced Cardiac Life Support (ACLS) guidelines should be followed to identify and treat causes of cardiopulmonary arrest.[52]

Cardiac arrest in the pregnant patient is complicated by the physiologic changes of pregnancy, particularly the effect of the gravid uterus on aortocaval blood flow. Well-performed chest compressions in the nonpregnant patient typically result in cardiac output that is approximately 30% of normal. In pregnant patients, aortocaval compression reduces the cardiac output that results from chest compressions. Although it is typically advised to tilt the patient 15 to 30 degrees to facilitate left uterine displacement and optimize venous return and cardiac output, such a maneuver may impede the effectiveness of chest compressions. Therefore, the AHA guidelines advocate manual left uterine displacement rather than the usual whole-body tilt (Figure 55-2).[52] If this technique is not successful, a firm wedge may be placed under a resuscitation board to tilt the patient approximately 30 degrees.

BOX 55-5 Modification of Cardiopulmonary Resuscitation during Pregnancy

- Chest compressions: place the hands slightly higher on the sternum.
- Perform manual left uterine displacement, or place a firm wedge under the resuscitation board to tilt patient approximately 30 degrees.
- Obtain intravenous access above the diaphragm.
- Anticipate difficult airway management.
- Discontinue magnesium sulfate (if applicable) and administer calcium chloride or calcium gluconate.
- Defibrillation: remove both internal and external fetal monitors.
- If spontaneous circulation does not return within 4 minutes of cardiac arrest, immediate hysterotomy or cesarean delivery should be performed if gestational age is 20 weeks or greater, aiming for delivery within 5 minutes of cardiac arrest.
- Continue all resuscitation efforts during and after cesarean delivery.
- Search for possible contributing factors (BEAU-CHOPS):
  - **B**leeding/disseminated intravascular coagulation
  - **E**mbolism: coronary/pulmonary/amniotic fluid embolism
  - **A**nesthetic complications
  - **U**terine atony
  - **C**ardiac disease (myocardial infarction/ischemia/cardiomyopathy)
  - **H**ypertension/preeclampsia/eclampsia
  - **O**ther: differential diagnosis included in standard ACLS algorithms
  - **P**lacenta abruption/previa
  - **S**epsis

Philadelphia, Mosby, 2009.)

In the field, the responder may use his or her knees to tilt the patient.

Chest impedance is unchanged during pregnancy. Therefore, the usual voltage levels for defibrillation should be used in pregnant patients.[52] Electric cardioversion during pregnancy appears to be safe for the fetus (see Chapter 42). If spontaneous circulation does not return within 4 minutes of cardiac arrest, immediate hysterotomy or cesarean delivery should be performed if gestational age is 20 weeks or greater, aiming for delivery within 5 minutes of cardiac arrest. Timely delivery facilitates successful resuscitation of both the mother and the infant.[52,54] Furthermore, early hysterotomy and uterine evacuation optimizes maternal resuscitation, even if the fetus has already died. Extrauterine fetal survival is unlikely before 24 to 25 weeks' gestation.

Management of the Brain-Dead Patient

Brain death in the pregnant patient is a rare occurrence. Esmaeilzadeh et al.[55] summarized 30 cases published between 1982 and 2010. Nontraumatic brain injury, primarily intracranial hemorrhage, was the cause of death in 26 of 30 cases. The mean gestational ages at times of injury and delivery were 22 and 29.5 weeks, respectively. Twelve viable infants survived beyond the neonatal period.

In cases of maternal brain death, care providers should focus on saving the life of the fetus; maternal organ preservation for harvest and donation is a secondary consideration. Maintenance of vital functions in mothers with catastrophic brain injury is justified to meet these two goals, but in many cases ethical and legal concerns must be addressed. Consideration must be given to gestational age and the chance for fetal survival. Before 24 weeks' gestation, the chance for extrauterine fetal survival is small. In general, management should follow current guidelines for organ preservation therapy.

The question of whether to preserve maternal circulation and organ function to facilitate fetal development is an ethical dilemma. A fundamental issue relates to the support of the brain-dead mother as an incubator for the unborn fetus. Some professionals argue such an approach is unethical, whereas others view prolonged somatic support as a case of organ donation with the fetus as the recipient. In many cases, the mother's wishes are not known. If the mother indicated a wish to donate organs, prolonged somatic maternal support may be appropriate. Currently, there is no generally accepted lower limit of gestational age for maintenance of maternal support. Each case must be addressed on an individual basis, with close communication among the family, a cohort of care providers, and the hospital ethics committee.

CRITICAL CARE DURING PREGNANCY

Stroke

Ischemic Stroke

Pregnant women are at increased risk for ischemic stroke compared with their nonpregnant counterparts.[56] Pregnancy is a hypercoagulable state characterized by decreased fibrinolysis, increased levels of clotting factors, and decreased levels of certain natural anticoagulants (e.g., protein S). Clinical manifestations of ischemic stroke are similar to those seen in the nonpregnant population and include focal neurologic symptoms, seizures, decreased level of consciousness, and abnormal cranial nerve function. Once the diagnosis is suspected, and initial evaluation and therapy—including airway protection—have been addressed, non–contrast-enhanced CT should follow immediately. The fetal radiation exposure from this test is less than 1 rad.[57] If CT shows no evidence of hemorrhagic stroke, the patient is assumed to have an ischemic stroke. Consideration of thrombolytic therapy should follow, including evaluation of contraindications for thrombolytic therapy (Box 55-6). Thrombolytic therapy with recombinant tissue plasminogen activator (r-tPA) has been reported during pregnancy and appears to be safe for the fetus; transplacental passage of r-tPA is minimal. However, retroplacental bleeding with pregnancy loss has been reported.[58-60] Consultation with an experienced neurologist is recommended.

The r-tPA is administered intravenously at a dose of 0.9 mg/kg (maximum, 90 mg) over 1 hour (10% of the dose is commonly administered as an initial bolus over the first minute). The therapeutic window (i.e., time from onset of symptoms to administration of the agent) is 4.5 hours.[61] Patients who are candidates for this therapy should be watched closely in an ICU environment that includes fetal surveillance by a maternal-fetal medicine specialist. Blood pressure should be maintained below

BOX 55-6 Major Contraindications for Thrombolysis in Ischemic Stroke Patients

- History of a previous intracranial hemorrhage
- Genitourinary or gastrointestinal bleeding in the previous 3 weeks
- Closed head trauma in the previous 3 months
- Major surgery in the previous 2 weeks
- Blood pressure above 185/110 mm Hg despite antihypertensive therapy
- Acute active bleeding
- Evidence that symptoms are clearing spontaneously
- Hemorrhagic transformation on initial imaging
- Massive ischemic stroke (hypodensity affecting more than one third of the cerebral hemisphere)
- Platelet count < 100,000/mm^3
- Concurrent heparin or warfarin therapy with a prolonged PT or aPTT
- Blood glucose < 50 mg/dL (symptoms may be due to hypoglycemia)
- Evidence of a seizure with postictal residual neurologic impairment

PT, prothrombin time; *aPTT*, activated partial thromboplastin time.
Modified from Adams HP Jr, del Zoppo G, Alberts MJ, et al. Guidelines for the early management of adults with ischemic stroke: a guideline from the American Heart Association/American Stroke Association Stroke Council, Clinical Cardiology Council, Cardiovascular Radiology and Intervention Council, and the Atherosclerotic Peripheral Vascular Disease and Quality of Care Outcomes in Research Interdisciplinary Working Groups: The American Academy of Neurology affirms the value of this guideline as an educational tool for neurologists. Circulation 2007; 115:e478-534.

180/105 mm Hg during r-tPA therapy. Neurologic deterioration during thrombolytic infusion should raise suspicion of **hemorrhagic transformation;** the infusion should be stopped immediately, and the head CT should be repeated. Transfusion of platelets (e.g., 10 units of pooled random donor platelet concentrate or 1 to 2 units of apheresis platelet concentrate) and 10 units of cryoprecipitate is recommended if hemorrhagic transformation of the stroke is documented.[62] Other potential therapies include fresh frozen plasma, activated rFVIIa, and antifibrinolytic therapy.[62]

Patients with ischemic stroke who are not candidates for r-tPA therapy should receive aspirin (162 to 325 mg/day) for 2 weeks; subsequently, the dose may be decreased to 100 mg/day.[61] Deep vein thrombosis prophylaxis with unfractionated heparin should also be started on admission unless contraindicated. Outcome data related to blood pressure management in patients with acute ischemic stroke are inconsistent; however, in 2007, the AHA and the American Stroke Association recommended that, in patients receiving thrombolytic therapy, emergency antihypertensive medication should be withheld unless the blood pressure is above 220/120 mm Hg.[63] If the patient has received thrombolytic therapy, aspirin and prophylactic doses of heparin should be withheld for 24 hours after completion of the infusion. Fever should be aggressively treated to achieve normothermia. Blood glucose measurements higher than 140 to 180 mg/dL should be treated with insulin. Seizure prophylaxis in ischemic stroke patients is not recommended.[63]

Cerebral sinus and vein thrombosis may occur during pregnancy and the puerperium, but most cases occur postpartum. The clinician should suspect cerebral sinus thrombosis in the presence of severe headache, focal neurologic symptoms, and/or papilledema. The diagnostic test of choice is magnetic resonance venography (MRV). Most cases involve the transverse sinuses. Initial imaging reveals concomitant areas of hemorrhage in as many as 40% of these cases. However, treatment involves immediate therapeutic anticoagulation with unfractionated heparin or low-molecular-weight heparin unless massive hemorrhage is present.[61,64]

Ischemic strokes that involve more than 50% of the territory of the middle cerebral artery are known as "malignant strokes." They occur more commonly in young people. In the vast majority of cases, these patients require early decompression hemicraniectomy because the stroke is usually associated with massive cerebral edema that frequently is not responsive to medical therapy.[65]

Hemorrhagic Stroke

Pregnancy typically is accompanied by a 40% to 50% increase in both cardiac output and effective blood volume. These changes, coupled with hormone-induced changes in the vessel wall structure, may render pregnant patients more susceptible to hemorrhagic strokes resulting from intracerebral and subarachnoid hemorrhage.[66]

Intracerebral Hemorrhage. Intracerebral hemorrhage is usually a secondary complication of hypertensive emergencies (e.g., preeclampsia, hypertensive encephalopathy). Clinical presentation is similar to that in nonpregnant individuals. The diagnosis is confirmed with non–contrast-enhanced CT.

As in any other stroke victim, initial management involves securing the airway and facilitating oxygenation and ventilation. Intracranial pressure monitoring should be considered in patients with a Glasgow Coma Scale score less than 8, clinical evidence of transtentorial herniation, and evidence of significant intraventricular hemorrhage or hydrocephalus.[67]

Blood pressure control in this setting is controversial. Current guidelines recommend antihypertensive therapy when the blood pressure exceeds 180/110 mm Hg or when MAP exceeds 130 mm Hg.[67,68] Some experts argue that hypertension leads to hematoma expansion and may worsen cerebral edema. Recent evidence suggests that it is safe to use antihypertensive agents to achieve a systolic blood pressure less than 140 mm Hg. Maintenance of systolic blood pressure below 140 mm Hg leads to decreased hematoma expansion, but the effect on outcomes is unknown.[68] In cases of intracerebral hemorrhage associated with preeclampsia, some practitioners recommend maintenance of systolic and diastolic blood pressures between 140 to 160 mm Hg and 90 to 110 mm Hg, respectively, to maintain uteroplacental perfusion pressure. Blood pressure should be monitored invasively and treated with a titratable intravenous agent such as labetalol or nicardipine.

In the setting of intracerebral hemorrhage secondary to the use of warfarin, rapid reversal of the anticoagulation effect is of paramount importance. Vitamin K (10 mg intravenously over a minimum of 20 minutes) should be administered.[69] Recent guidelines from the American College of Chest Physicians suggest that **prothrombin complex concentrate,** which contains the vitamin K–dependent clotting factors II, VII, IX, and X, should be first-line therapy.[69] Advantages of prothrombin complex concentrate over fresh frozen plasma include no requirement for blood typing and crossmatching, a lower risk for bloodborne infection, and little risk for volume overload. Prothrombin complex concentrate can be infused over 15 to 30 minutes.[69] The role of rFVIIa in this setting is limited, and its use cannot be recommended at this time.

The risk for seizures after intracerebral hemorrhage is higher in cases of lobar hemorrhage; the risk is small if hemorrhage is localized to the basal ganglia, and even less if limited to the posterior fossa. Unless clinical seizures are observed or nonconvulsive activity is noted on the electroencephalogram (EEG), routine seizure prophylaxis in patients with intracerebral hemorrhage is not recommended. Therapy may be associated with worse long-term functional outcome.[67] As with most brain injuries, glucose control is paramount in the management of intracerebral hemorrhage. Blood glucose should be maintained between 140 and 180 mg/dL in critically ill patients who require insulin therapy.[67,70] Once bleeding cessation is documented by repeat imaging, deep vein thrombosis prophylaxis with unfractionated heparin or low-molecular-weight heparin should be initiated (usually 1 to 4 days after the intracerebral hemorrhage).

Subarachnoid Hemorrhage. A subarachnoid hemorrhage may be traumatic or nontraumatic. This discussion is limited to nontraumatic forms of subarachnoid hemorrhage. The most common cause of nontraumatic subarachnoid hemorrhage is rupture of a berry **aneurysm.** The clinical presentation varies from the complaint of the "worst headache in my life" to profound coma. The diagnosis is made by CT followed by cerebral angiography to locate the source of the bleeding. Abdominal shielding is essential during all radiographic procedures to limit fetal radiation exposure. Once the aneurysm is located, two management options exist. Craniotomy with clipping of the aneurysm has been the traditional treatment. More recently, coiling of the aneurysm has emerged as a less invasive option. Controversy exists regarding which option results in the best outcome (see Chapter 49). The largest randomized study comparing both treatment modalities found that endovascular coiling resulted in a lower risk for death at 5 years[71]; however, the risk for rebleeding was higher in the endovascular coiling group. The 2009 AHA guidelines suggested that "endovascular coiling can be beneficial." [72] Endovascular coiling has not been specifically studied in the pregnant population, although several cases of successful endovascular treatment of ruptured intracranial aneurysms in pregnant women have been reported.

Regardless of the treatment modality, it is crucial to secure the aneurysm as early as possible. Before the aneurysm is secured, blood pressure control should target a systolic blood pressure below 160 mm Hg.[73]

Delayed vasospasm is one of the most serious complications of subarachnoid hemorrhage. The onset is usually 4 to 10 days after the hemorrhage and manifests as worsening of the neurologic examination (either new focal symptoms or decreased level of consciousness). If a change in the neurologic status is noted, immediate CT should be performed to rule out rebleeding or hydrocephalus; if absent, vasospasm is likely. Vasospasm is confirmed with cerebral angiography. All patients should be treated with nimodipine (60 mg orally every 4 hours for 21 days) as prophylaxis against delayed-onset ischemia secondary to cerebral vasospasm. Other potential treatments to prevent delayed vasospasm include magnesium sulfate and statins.[74] However, a 2012 meta-analysis does not lend support to the efficacy of magnesium sulfate,[74] and statins should be avoided during pregnancy because of the potential risk for teratogenicity.

Once surgical or endovascular treatment is completed, blood pressure control may be less rigorous because hypertension may be a compensatory mechanism to maintain cerebral perfusion pressure in the setting of vasospasm. During pregnancy, extremely high blood pressure may lead to placental abruption and should be avoided.

Historically, patients presenting with symptomatic delayed cerebral vasospasm have been treated with "triple H therapy." Triple H therapy consists of inducing *hypervolemia* (through administration of crystalloids or colloids), leading to *hemodilution*, accompanied by induced *hypertension* (by using vasopressors) in an attempt to increase cerebral perfusion. Evidence of the efficacy of triple H therapy is extremely limited.[74] The use of hypervolemia and subsequent hemodilution may even be detrimental as a result of a decrease in arterial oxygen content.[75] Instead, many practitioners recommend induced hypertension with intravenous infusion of norepinephrine, phenylephrine, or dopamine and titration of systolic blood pressure to measurements higher than 180 mm Hg (MAP > 120 mm Hg). However, during pregnancy, the use of high-dose vasopressors to induce hypertension may lead to uteroplacental vasoconstriction and hypoperfusion and subsequent fetal demise. Additionally, the hypertension may increase the risk for placental abruption. Pregnant patients requiring induced hypertension for delayed vasospasm present a significant clinical dilemma. If the fetus is sufficiently mature (e.g., more than 32 weeks' gestation), it may be advisable to deliver the fetus before initiation of induced hypertension. If delivery is not an option, balloon angioplasty of the constricted vessels by an interventional radiologist may be considered.

Subarachnoid hemorrhage may also lead to extracerebral manifestations, the most common of which are hyponatremia, cardiac dysfunction, and neurogenic pulmonary edema. Hyponatremia occurs secondary to increased secretion of atrial and ventricular natriuretic peptides (cerebral salt wasting syndrome).[73] Treatment should focus on isotonic sodium replacement (0.9% saline) and diuresis. The massive liberation of catecholamines that accompanies subarachnoid hemorrhage is believed to cause subendocardial ischemia, leading to "cardiac stunning" with concomitant arrhythmias and decreased cardiac output. Patients may require inotropic support and antiarrhythmic therapy. Neurogenic pulmonary edema has both a hydrostatic component (from cardiac stunning and pulmonary venous constriction as a result of increased catecholamine secretion) and a noncardiogenic component (from endothelial injury owing to activation of the inflammatory cascade). Treatment of neurogenic pulmonary edema is supportive and requires low tidal volume ventilation strategies and the use of PEEP to improve oxygenation.

Subarachnoid hemorrhage may also occur secondary to rupture of brain **arteriovenous malformations**.[76] General intensive care provided to these patients is similar to that used in aneurysmal subarachnoid hemorrhage, with a few exceptions. The risk for vasospasm after subarachnoid hemorrhage from arteriovenous malformations is lower and rarely warrants therapy. Once removed (surgically), adjacent brain tissue will be exposed to increased cerebral blood flow leading to cerebral edema. Localized cerebral edema may be prevented by avoidance of severe hypertension. The decision to surgically treat a ruptured arteriovenous malformation is controversial and depends on the location and type of venous drainage (superficial or deep).[76] The risk for rebleeding during pregnancy is increased, and treatment (e.g., surgical resection, embolization) is commonly recommended.[77]

As with intracerebral hemorrhage in general, pregnant patients with subarachnoid hemorrhage should be normothermic and the maximum blood glucose level should be maintained between 140 and 180 mg/dL. Seizure prophylaxis in the setting of subarachnoid hemorrhage is controversial. Prolonged use of phenytoin has been associated with poor neurologic outcomes and should be

avoided.[78] A systematic review suggested that 3 days of seizure prophylaxis therapy provides similar seizure prevention with better outcomes compared with longer-term treatment.[78]

Status Epilepticus

Status epilepticus is defined as a continuous, generalized convulsive seizure lasting more than 5 minutes or two or more seizures with no return to baseline consciousness between the seizures.[79] Status epilepticus may be caused by noncompliance with antiepileptic medications, stroke, brain tumor, central nervous system infection, head trauma, metabolic derangements (e.g., uremia, hepatic encephalopathy, electrolyte abnormalities), cerebral hypoxia, and hypoglycemia/hyperglycemia. Rarely, eclamptic seizures may progress to status epilepticus.

Initial management should include protecting the airway and arresting the epileptic convulsions. Intravenous access should be obtained and hypoglycemia ruled out promptly. If in doubt, a 50-mL bolus of intravenous 50% dextrose with 100 mg of thiamine should be administered. Adequate hydration is of paramount importance because seizure-induced muscle breakdown may lead to myoglobin-induced kidney injury.[79] Initial pharmacologic therapy includes an intravenous benzodiazepine (e.g., lorazepam 0.1 mg/kg) followed by a standard intravenous antiepileptic agent (e.g., phenytoin). If intravenous access is difficult, intramuscular drug administration is an option. A recent study showed that intramuscular midazolam (10 mg) was at least as effective as intravenous lorazepam in the prehospital management of status epilepticus.[80] If seizure control is not achieved, a continuous infusion of propofol, midazolam, or a barbiturate may be required.[81] There is no agreement on the recommended EEG titration goal (burst suppression versus seizure control).[81] Many practitioners recommend 24 to 48 hours of seizure control documented by EEG before slowly weaning the infusion.

Acute Respiratory Distress Syndrome and Acute Lung Injury

Acute respiratory distress syndrome (ARDS) is a severe form of noncardiogenic pulmonary edema; it is a common cause of mortality in the critically ill obstetric patient. Traditionally, it has been defined as (1) pulmonary edema manifested on chest radiograph as bilateral acute infiltrates, (2) normal left ventricular function (pulmonary artery occlusion pressure [PAOP] below 18 mm Hg or normal heart function as determined by transthoracic echocardiography), and (3) a Pao_2/Fio_2 ratio below 200.[82] If the same conditions are present but the Pao_2/Fio_2 ratio is between 200 and 300, then the term *acute lung injury* (ALI) is used. The mortality rate from ARDS is approximately 40%.[83]

ALI/ARDS may occur secondary to a pulmonary or extrapulmonary pathologic process. The common denominator is activation of the inflammatory cascade, leading to inflammation-induced endothelial/epithelial injury in the lung with subsequent leaking of protein-rich fluid into the alveoli. Direct (pulmonary) insults that may lead to ALI/ARDS include pneumonia, aspiration pneumonitis, pulmonary contusion, and smoke inhalation during burns. Indirect (extrapulmonary) causes include sepsis, pancreatitis, trauma, and massive transfusion. Similar to the nonobstetric population, the most common cause of ARDS/ALI in pregnant women is sepsis.[84] Certain obstetric conditions (e.g., placental abruption, amniotic fluid embolism, preeclampsia) may also cause ALI/ARDS because these conditions are associated with inflammation and subsequent diffuse endothelial injury. Also, patients with severe placental abruption or amniotic fluid embolism complicated by DIC are at increased risk for massive transfusion of blood products.

Initial treatment for the patient with acute hypoxemic respiratory failure of noncardiac origin falls into ventilatory and nonventilatory strategies (Box 55-7).

BOX 55-7 Management Strategies in Patients with Acute Lung Injury/Acute Respiratory Distress Syndrome during Pregnancy

Ventilatory Strategies

- Lung-protective mechanical ventilation
  - Limit tidal volume to 6 to 8 mL/kg (lean body weight*). If possible, maintain $Paco_2 < 60$ mm Hg. Limit plateau pressures to 30 to 35 cm H_2O.
- Oxygenation goals
  - Maintain $Pao_2 \geq 55$ mm Hg and $Spo_2 \geq 88\%$ as long as the electronic FHR tracing is reassuring. A higher Pao_2 may be required in patients with nonreassuring fetal status.
- Provide adequate PEEP
  - Titrate according to oxygen requirements.
- Rescue therapies
  - Prone ventilation, extracorporeal membrane oxygenation, high-frequency oscillatory ventilation. airway pressure release ventilation, recruitment maneuvers.

Nonventilatory Strategies

- Limit fluid administration
  - Avoid excessive fluids, especially after the initial phase of resuscitation.
- Neuromuscular blockade
  - May consider early use of cisatracurium for 48 hours. Avoid coadministration of corticosteroids and aminoglycosides.
- Corticosteroids
  - Methylprednisolone 1 mg/kg bolus over 30 minutes followed by a continuous infusion of 1 mg/kg/day for 14 days. The dose is then decreased by half for 1 week, then decreased by half again for 4 days, and finally decreased by half one last time for 3 days.
- Inhaled prostacyclin/nitric oxide
  - Despite improvements in oxygenation, data on survival benefit are lacking. Avoid intravenous vasodilators (e.g., epoprostenol) because these drugs may worsen oxygenation by increasing the shunt fraction.

PEEP, positive end-expiratory pressure.
*Lean body weight in kilograms (females) = 45.5 + 0.91 (height in centimeters − 152.4).

Of vital importance, the underlying cause of the ARDS must be addressed simultaneously with institution of supportive measures (e.g., broad-spectrum antibiotics and surgical drainage if indicated in cases of sepsis-related ARDS; immediate delivery in patients with chorioamnionitis).

Ventilatory Strategies

The only intervention that has convincingly decreased mortality in ARDS is **lung-protective mechanical ventilation**.[85] ALI/ARDS is a heterogeneous disease in which some areas of the lung are affected (consolidated with edema) and others are not. During tidal volume delivery, gas flow is predominantly distributed to unaffected portions of the lung. If large tidal volumes are used, these "normal" areas of the lung are exposed to excessive volumes and pressures that lead to **volutrauma** and **barotrauma**, respectively. Overdistention of the lung provokes a local inflammatory response that further injures the lung parenchyma; locally produced inflammatory mediators (i.e., cytokines) may translocate to the systemic circulation and provoke worsening multiorgan failure (**biotrauma**).[86] If large tidal volumes are used with low PEEP, the constant opening and closing of the recruited alveoli (**atelectrauma**) will also worsen lung inflammation. These four insults (volutrauma, barotrauma, biotrauma, and atelectrauma) constitute what is known as **ventilator-induced lung injury**.[87]

In a randomized clinical trial involving 861 patients with ALI/ARDS, those randomized to receive mechanical ventilation with a small tidal volume (6 mL/kg lean body weight) and a limitation of plateau pressure to less than 30 cm H_2O had a mortality of 31% compared with 40% in the group randomized to receive a larger tidal volume (12 mL/kg lean body weight).[85] Since the publication of this trial in 2000, most intensivists have adopted strategies that limit tidal volumes to decrease ventilator-induced lung injury and improve outcomes in patients with ARDS. By limiting tidal volumes, minute ventilation is invariably decreased, leading to hypercarbia and respiratory acidemia. To improve minute ventilation, the operator may increase the respiratory rate up to 35 breaths per minute to maintain, ideally, an arterial pH above 7.3.[87]

Significant maternal hypercarbia may result in decreased removal of carbon dioxide from the fetus, leading to fetal acidemia. Tidal volumes from 6 to 8 mL/kg (lean body weight) can be used to ventilate pregnant women with ARDS; attempts should be made to maintain maternal $Paco_2$ below 60 mm Hg. Because of decreased compliance of the chest wall during pregnancy, plateau pressures of up to 35 cm H_2O may be tolerated. Continuous electronic FHR monitoring is recommended because abnormal FHR patterns may occur during periods of fetal acidemia.

The use of low tidal volumes to limit ventilator-induced lung injury must be accompanied by the use of adequate levels of PEEP to recruit alveolar units. A discussion of optimization of PEEP is beyond the scope of this chapter, but the reader may access FIO_2-PEEP tables that titrate PEEP according to oxygen requirements.[88] The oxygenation goal is to achieve a Pao_2 of at least 55 mm Hg or higher with an Sao_2 (as measured by pulse oximetry) of at least 88% or higher.[88] The use of high PEEP (levels up to 15 cm H_2O or higher) has been associated with decreased mortality in the subset of patients with the most severe forms of ARDS.[89]

Other ventilatory strategies that may be used in ARDS, but have not been associated with reduced mortality, include the use of recruitment maneuvers, airway pressure release ventilation, high-frequency oscillatory ventilation, extracorporeal membrane oxygenation (ECMO), and prone ventilation.[88,90,91] When patients with ARDS are turned from the supine to the prone position, oxygenation often greatly improves, likely secondarily to anterior displacement of the heart with resultant recruitment of the posterior lung segments and improved ventilation-perfusion matching.[92] However, improved survival has not been documented.[93] A survival benefit may be gained in the subgroup of patients with the most severe forms of ARDS and if the periods of prone ventilation are extended to 12 to 20 hours per day.[94,95] Use of prone ventilation during the second half of pregnancy is obviously technically demanding (and may not be possible) because of the enlarged gravid uterus.

Nonventilatory Strategies

Nonventilatory strategies play an important role in the management of patients who suffer ALI/ARDS (see Box 55-7). The early use of neuromuscular blockade has recently been shown to improve survival in patients with ARDS.[96] A possible advantage of cisatracurium is its significant anti-inflammatory activity; the infusion should be limited to the first 48 hours of mechanical ventilation.[96] Pregnancy is not a contraindication to application of this treatment, if required.

Because ALI/ARDS occurs secondary to inflammation-mediated lung injury, interest has risen regarding the possible benefits of corticosteroid therapy. Theoretically, low-dose corticosteroids could be immunomodulatory (not immunosuppressive), leading to downregulation of excessive inflammation, and thus limiting acute lung injury.[97] Overall, published evidence indicates that low-dose corticosteroids reduce systemic inflammation, improve oxygenation, reduce multiorgan dysfunction, and decrease the duration of mechanical ventilation and ICU stay in patients with ALI/ARDS.[97] If used, low-dose corticosteroids (see Box 55-7) should be initiated before day 14 of the disease; after day 14, corticosteroid therapy is not recommended. The effect on survival is controversial, although some evidence suggests that corticosteroids decrease mortality in patients with ALI/ARDS.[98] Interestingly, the use of these low doses has not been associated with an increased risk for gastrointestinal hemorrhage, hyperglycemia, nosocomial infection, or myopathy.[97] If corticosteroids are used, the use of muscle relaxants should be avoided to prevent critical illness polyneuromyopathy. During pregnancy, the physician should consider the possible risk for fetal cleft lip (with and without cleft palate) associated with corticosteroid administration during the first trimester of pregnancy.[99]

Fluid Management. Management of fluid balance is fundamental in the care of patients with ALI/ARDS. A randomized trial found that conservative fluid management (mean fluid balance in the first 7 days, −136 mL) was associated with a shorter duration of mechanical ventilation and a shorter length of stay in the ICU than liberal fluid management (mean fluid balance, +6992 mL).[100] At the time of enrollment most patients had been fluid resuscitated and were hemodynamically stable. The incidence of adverse effects (e.g., shock, need for renal dialysis) did not differ between groups.

Fluid restriction in patients with ALI/ARDS is usually initiated on day 2 to 3 of the disease process; the first several days are commonly associated with hypotension and shock that invariably requires fluid resuscitation. Provided shock has resolved and vasopressors are not required to support blood pressure, fluids should be restricted to the amount required to maintain hemodynamic stability. Enteral feeding should be the main source of fluids in lieu of "maintenance fluids." If a diuretic is used to achieve a negative fluid balance, judicious use is recommended. Continuous electronic FHR monitoring is recommended to assess the adequacy of uteroplacental perfusion.

Right ventricular failure is a common occurrence in patients with ALI/ARDS. Alveolar "flooding" limits oxygenation with resultant hypoxic pulmonary vasoconstriction. The increase in pulmonary vascular resistances may lead to acute cor pulmonale and right ventricular failure, accompanied by a severe decrease in cardiac output (from both right-sided failure and left ventricular diastolic dysfunction). The administration of an inhaled pulmonary vasodilator such as nitric oxide or prostacyclin often leads to improved oxygenation and right ventricular function. However, there is no evidence that these interventions improve survival.[101] Pregnancy is not a contraindication for pulmonary vasodilator therapy. Pharmaconutritional therapy for ALI/ARDS (e.g., omega-3 fatty acids, linolenic acid, antioxidants) has not been shown to be beneficial and is not recommended.[102]

Nutrition and Glucose Control

Critically ill patients require nutrition to heal. Early aggressive enteral nutrition is of paramount importance and should be implemented within 24 to 48 hours of admission to the ICU.[103] Enteral nutrition (either through a nasogastric tube or a Dobhoff tube with the tip placed in the duodenum) helps maintain gut barrier integrity, thus preventing bacterial and cytokine translocation from the intestine. Enteral nutrition is generally preferred over parenteral nutrition because it is associated with less infectious morbidity and mortality. Enteral nutrition should be discontinued in patients requiring high doses of vasopressors because of a possible increase in the risk for bowel ischemia.[103]

The total amount of calories needed during critical illness is unknown.[104] More than 200 formulas exist to calculate daily energy requirements while in the ICU; many of these formulas coincide with a simple calculation of 25 Kcal/kg/day (ideal body weight).[103] An extra 300 Kcal/day should be added during pregnancy (500 Kcal/day in patients with multiple gestation). Overfeeding should be avoided because it may lead to fatty liver, volume overload, excessive carbon dioxide production, hyperglycemia, infection, and immunosuppression. Protein delivery should not be restricted, and critically ill patients should receive 1.2 to 2.0 g/kg/day of protein.[103] Most available enteral feeding formulas do not contain sufficient protein; it may be necessary to add additional protein to standard formulas.

Stress hyperglycemia refers to the elevation in blood glucose concentration associated with critical illness. Stress hyperglycemia is caused by multiple factors, including massive catecholamine release and systemic inflammation. Hyperglycemia is commonly worsened with initiation of nutritional support. Hyperglycemia worsens oxidative injury and potentiates inflammation and clotting. In 2001, a landmark paper suggested that tight glycemic control during critical illness (intravenous use of an insulin infusion to maintain blood glucose level between 80 and 110 mg/dL) was associated with (1) decreased mortality; (2) a lower incidence of sepsis, critical illness polyneuropathy, and liver injury; (3) reduced transfusion requirements; (4) fewer days of mechanical ventilation; and (5) a decreased need for renal replacement therapy.[105] These findings were not replicated in later studies; the largest available randomized controlled trial actually found that tight glucose control led to a 2.6% increase in mortality compared with less stringent glucose control. Maintaining blood glucose between 80 and 110 mg/dL commonly leads to episodes of iatrogenic hypoglycemia, which may worsen outcome. Current guidelines recommend a target blood glucose level between 140 and 180 mg/dL in ICU patients who are receiving insulin therapy.[70]

Transfusion Triggers

Most packed red blood cell (PRBC) transfusions in the ICU are used to treat anemia in hemodynamically stable patients who are not actively bleeding.[106] The efficacy of such an approach has not been demonstrated. Anemia in the critically ill patient commonly results from inflammation-induced inhibition of erythropoiesis and excessive phlebotomy.[106] Administration of PRBCs theoretically leads to an increase in arterial blood oxygen content, oxygen delivery, and, ultimately, oxygen consumption. Unfortunately, no clear evidence indicates that PRBC transfusions improve oxygen consumption.[107,108] During storage in the blood bank, red blood cells undergo a series of changes that include anomalies in the cytoskeleton, which hinders the red blood cells' capacity for deformability. As a result, transfusion of these rigid red blood cells may cause occlusion of the microvasculature and distal ischemia. These cells do not effectively release oxygen in the tissues because of a deficit in 2,3-diphosphoglycerate (2,3-DPG). Thus, oxygen-carrying capacity often is not improved by PRBC transfusion. In reality, significant risks are associated with transfusion of blood products in the ICU (Table 55-2).[109]

The largest published trial to date evaluating the role of PRBC transfusion in hemodynamically stable ICU patients found no difference in outcome between patients

TABLE 55-2 Potential Complications Associated with Transfusion of Blood Products

Transfusion-related acute lung injury (TRALI)	Noncardiogenic pulmonary edema that occurs within 6 hours of transfusion Risk higher after platelet and fresh frozen plasma transfusions Supportive treatment
Transfusion-related circulatory overload (TACO)	Hydrostatic pulmonary edema secondary to volume overload
Transfusion-related immunomodulation (TRIM)	After transfusion, decreased immunity with increased risk for nosocomial infections
Infectious complications	Viral (hepatitis B and C, HIV, cytomegalovirus, parvovirus B19, West Nile virus, human T-lymphotropic virus) or bacterial (*Staphylococcus* species, *E. coli, Pseudomonas* species, *Yersinia*) Bacterial infections more common
Febrile reactions	Secondary to leukocytes and cytokines accumulated during storage
Allergic nonhemolytic reactions	Urticaria and pruritus, secondary to soluble antigens in the donor plasma
Hemolytic reactions	Secondary to preexisting recipient alloantibodies against donor erythrocytes Sudden onset of fever and chills, pain, hypotension, dyspnea, renal injury, and DIC
Post-transfusion purpura	Purpura and bleeding manifestations after transfusion of blood products Usually seen in patients with antibodies that react against the human platelet antigen-1 from donor platelets Treat with intravenous immunoglobulin
Increased risk for multiorgan system failure	Likely secondary to cytokines contained in stored blood products
Graft-versus-host reaction	Lymphocytes transfused to patient not recognized as foreign but may react against host tissues, leading to pancytopenia, rashes, hepatitis, and diarrhea Mainly seen in patients with profound immunosuppression or in patients receiving blood products from close relatives who share human leukocyte antigens May be prevented with leukoreduction and gamma radiation of blood products.

DIC, disseminated intravascular coagulopathy; *HIV,* human immunodeficiency virus.
Modified from Gilliss BM, Looney MR, Gropper MA. Reducing noninfectious risks of blood transfusion. Anesthesiology 2011; 115:635-49.

randomized to a liberal transfusion strategy (transfuse to maintain hemoglobin above 10 g/dL) or a restrictive strategy (transfuse to maintain a hemoglobin > 7 g/dL).[110] A subgroup analysis revealed that mortality was *increased* with the liberal transfusion strategy in the subgroup of patients younger than 50 years old and with less severe disease (Acute Physiology and Chronic Health Evaluation II [APACHE II] score < 20). Based on these findings, most intensivists do not transfuse hemodynamically stable patients in the ICU until the hemoglobin level is less than 7 g/dL. (In patients with acute coronary syndrome, the threshold may be higher at 8 g/dL.[106]) Although each case should be individualized, it seems reasonable to apply these guidelines to critically ill pregnant patients. Fresh frozen plasma, cryoprecipitate, and platelets should not be transfused for the sole purpose of correcting laboratory measurements in patients who are not actively bleeding and are not undergoing an invasive procedure.

Sepsis

Sepsis occurs as the result of a maladaptive systemic inflammatory response to an infectious insult. It is the leading cause of mortality in ICUs in developed countries, and the incidence is increasing worldwide.[111] Sepsis is also one of the leading causes of maternal mortality.[112] The incidence of death from severe sepsis in obstetric patients is lower than that of nonobstetric patients. This likely reflects the fact that pregnant women are younger and have fewer coexisting medical pathologic processes.

Pregnancy affects both humoral and cell-mediated immunologic functions. The white blood cell count rises as pregnancy progresses, and some authors have described neutrophils in pregnant patients as "activated," thus favoring severe inflammatory reactions to infectious stimuli.[113] Cellular immunity is altered as a consequence of a decline in T-helper type 1 cell and natural killer cell function. The impaired cellular immunity may predispose pregnant women to infections from viruses and parasites. In contrast, antibody-mediated immunity is enhanced in pregnancy despite depressed levels of immunoglobulins (likely from hemodilution). Pregnancy is not a state of generalized immunosuppression; rather, it is a state of *immunomodulation* with compromised cellular and enhanced humoral immunity. Unfortunately, published information regarding the management of sepsis in pregnant women is limited; pregnant women typically have been excluded from large trials that have guided the evolution of the management of sepsis over the past several decades.

Definitions

Traditionally, *sepsis* has been defined as the presence of a **systemic inflammatory response syndrome** (SIRS) in

a patient with a defined or suspected infection. The concept of SIRS was introduced by the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) in 1992.[114] A patient is considered to have SIRS if two or more of the following criteria are present:

- Temperature greater than 38° C (100.4° F) or less than 36° C (96.8° F)
- Heart rate greater than 90 beats per minute
- Respiratory rate greater than 20 breaths per minute or a $Paco_2$ less than 32 mm Hg
- White blood cell count greater than 12,000/mm^3 or less than 4000/mm^3 or bandemia greater than 10%

Severe sepsis is defined as sepsis with signs of dysfunction of at least one organ (e.g., confusion, respiratory failure, acute kidney injury, thrombocytopenia, prolonged clotting times, elevated liver enzymes, hypotension). *Septic shock* is defined as severe sepsis with hypotension despite adequate fluid resuscitation, accompanied by a requirement for vasopressor therapy.

This definition of sepsis has been criticized for being too sensitive and nonspecific because most ICU patients will meet SIRS criteria.[115] Defining sepsis in pregnant patients is complicated by the fact that normal physiologic changes of pregnancy may include a heart rate above 90 beats per minute, a $Paco_2$ below 32 mm Hg, and a white blood cell count above 12,000/mm^3.

In 2001, extended criteria were developed to improve the diagnosis of sepsis by expanding the list of signs and symptoms of sepsis to reflect bedside clinical experience (Box 55-8).[115] These signs and symptoms serve as clinical guidelines; not every patient with sepsis will manifest these alterations, and some alterations may be present in nonseptic patients.

Pathophysiology

The pathophysiology of sepsis is complicated and not fully understood. After exposure to a microorganism (bacteria, virus, parasite, fungus), the inflammatory cascade is activated. Massive production and release of inflammatory (interleukin-1 beta [IL-1β], tumor necrosis factor-alpha [TNF-α], IL-6, IL-8) and anti-inflammatory (IL-4, IL-10) cytokines, endothelial factors (nitric oxide), and other mediators (prostaglandins, leukotrienes, complement) results in loss of vasomotor tone, profound vasodilation, and increased vascular permeability (secondary to cytokine-induced endothelial injury). Fluids subsequently move out of the vascular space, resulting in so-called third spacing.[111]

The profound decrease in systemic vascular resistance and accompanying tachycardia results in the so-called hyperdynamic state seen in septic patients. However, myocardial function is profoundly altered by the actions of nitric oxide, IL-1, oxygen-derived free radicals, and TNF-α. Up to 60% of patients with sepsis have an ejection fraction less than 45%. Both systolic and diastolic dysfunction may occur. Not infrequently, myocyte injury from proinflammatory cytokines may lead to leakage of troponins. Typically, patients with systolic dysfunction tend to present with biventricular dilation. This dilation appears to be an adaptive response that allows for increased intracavitary filling, leading to an increased stroke volume despite a decrease in ejection fraction (preload recruitment). These cardiac changes tend to resolve spontaneously among survivors of sepsis.

Almost all patients with severe sepsis have clotting abnormalities, ranging from asymptomatic changes to severe DIC.[116] Activation of the clotting cascade results from tissue factor production by macrocytes, neutrophils, and the endothelium as part of the inflammatory response. Tissue factor expressed in the surface of these cells binds factor VII, thus activating the clotting cascade. Excessive activation of the clotting cascade may lead to consumptive coagulopathy and the development of DIC. Development of DIC contributes to organ hypoperfusion (secondary to microvascular occlusion) and multiorgan system failure.

Natural anticoagulant proteins are often consumed in patients with severe sepsis[111]; alterations in protein C, antithrombin III, and plasminogen activator inhibitor have been described. Consumption of activated protein C has been associated with poor outcome in septic patients. Activated protein C is generated by thrombin-thrombomodulin–mediated protein C cleavage. Activated protein C, which inhibits clotting factors V and VIII, promotes fibrinolysis and has anti-inflammatory properties. Cytokines decrease the activity of thrombomodulin, leading to a lack of protein C activity during sepsis. Thus, the decline in activated protein C observed in severe sepsis results in amplified inflammation and a disruption in the normal balance between procoagulant and anticoagulant activity.

Mitochondrial dysfunction is also common in severe sepsis.[116] Even in the presence of adequate oxygen delivery, oxygen consumption cannot be guaranteed if the mitochondria are dysfunctional and cannot extract oxygen and use it in oxidative respiration. This pathologic process explains why patients with sepsis may have normal or above normal oxyhemoglobin saturation in the central or pulmonary circulation despite poor tissue oxygen utilization.

BOX 55-8 Signs and Symptoms Associated with Severe Sepsis

- Altered mental status
- Decreased capillary refill and skin mottling
- Fever or hypothermia
- Tachycardia
- Tachypnea
- Arterial hypotension
- Hypoxemia
- Significant edema or positive fluid balance
- Oliguria or elevated creatinine concentration
- Ileus and feeding intolerance
- Hyperglycemia
- Leukocytosis, leukopenia, or bandemia
- Elevated C-reactive protein or procalcitonin
- Thrombocytopenia and coagulation abnormalities
- Elevated liver enzyme levels
- Elevated blood lactate concentration

Management

Of pivotal importance in the management of sepsis is achieving early infection source control and instituting adequate antibiotic therapy and resuscitation. Infected fluid collections or tissues should be drained/excised if clinically indicated.[117] Broad-spectrum antibiotics should be initiated quickly (ideally after cultures have been obtained); narrow-spectrum antibiotic administration should follow once culture results are available.

Fluid Management. The cornerstone of resuscitation in sepsis is early **goal-directed fluid administration**. Classically, hemodynamic resuscitation in severe sepsis has been directed to achieve a MAP of 65 mm Hg. The placenta should be regarded as the maternal end organ that is most sensitive to hypoperfusion. For this reason, FHR decelerations are often the first sign of maternal hypoperfusion.

Early goal-directed fluid resuscitation improves tissue perfusion by increasing driving pressure and modulating early inflammation by decreasing concentrations of pro-inflammatory cytokines. The Surviving Sepsis Campaign guidelines recommend the use of either crystalloid or colloid for the early resuscitation of sepsis.[35,117] Crystalloids (normal saline, Ringer's lactate, Plasma-Lyte) have an intravascular half-life of 30 to 60 minutes compared with 16 hours for colloids such as albumin. Theoretically, the use of colloid leads to a more efficient resuscitation. The largest published trial comparing the use of crystalloids and colloids in critically ill patients found no difference in outcomes between groups.[35] However, a subgroup analysis suggested that patients with sepsis might benefit from albumin administration.[35] A 2011 systematic review and meta-analysis[118] found a small reduction in mortality in septic patients randomized to receive albumin rather than crystalloid for resuscitation (pooled estimate of the odds ratio, 0.82; 95% confidence interval, 0.62 to 1.0; $P = .047$). The authors suggested that additional study is required before a definitive conclusion can be made.[118]

Randomized trials (and a meta-analysis) that compared hydroxyethyl starch (e.g., 6% hetastarch solution) with crystalloid therapy in patients with severe sepsis found an increased incidence of 90-day mortality and an increased need for renal replacement therapy in the hydroxyethyl starch group.[119,120] Therefore, carbohydrate-based colloid solutions may not be the optimal choice for resuscitation of the septic patient.

One of the most challenging clinical decisions in daily critical care practice is the precise identification of adequate fluid resuscitation. Goal-directed fluid therapy (defined as "adjustments in cardiac preload, afterload, and contractility to balance oxygen delivery with oxygen demand"[121]) is fundamental in the initial management of sepsis, but one must consider the endpoints of resuscitation. Premature initiation of vasopressors may be harmful because it will worsen tissue ischemia. On the other hand, excessive fluid resuscitation and a positive fluid balance have consistently been associated with increased mortality in critically ill patients. It appears that early in sepsis (the first 6 hours), patients benefit from goal-directed fluid therapy.[121] Later, a conservative fluid strategy may be beneficial. In a randomized trial, Rivers et al.[121] compared early goal-directed fluid therapy with standard care in patients with severe sepsis or septic shock. Goal-directed therapy consisted of early aggressive fluid resuscitation (central venous pressure [CVP] goal of 8 to 12 mm Hg), coupled with the use of vasopressors, inotropes, and blood transfusions to achieve a central venous oxygen saturation of greater than 70%. The in-hospital mortality was 30.5% in the goal-directed therapy group compared with 46.5% in the standard therapy group.[121]

A subsequent trial in patients with ALI or ARDS showed that *after* the initial phase of resuscitation, patients who were randomized to receive a conservative fluid regimen had improved lung function and a shorter duration of mechanical ventilation and ICU stay compared with patients who received a liberal fluid regimen.[100] The study did not have sufficient power to identify a difference in 60-day mortality.

Traditionally, clinicians have titrated fluid therapy to *static* measurements such as CVP or the PAOP. The Surviving Sepsis Campaign still recommends fluid therapy that targets a CVP between 8 to 12 mm Hg (12 to 15 mm Hg in the setting of mechanical ventilation).[117] This recommendation also likely applies to pregnant patients because neither CVP nor PAOP change during gestation. Unfortunately, static measurements of preload are less than ideal for predicting response to fluid administration. Echocardiographic-derived measurements provide further data on the adequacy of fluid resuscitation but suffer from the same limitations.

Current evidence supports the titration of fluid resuscitation to *dynamic* rather that static measurements of preload.[122] For example, an increase in stroke volume as assessed by transthoracic echocardiography during passive leg raising is an accurate predictor of response to fluid administration.[122] The validity of dynamic measures of preload during pregnancy requires investigation.

Vasopressors and Inotropes. When fluid therapy alone is unable to achieve a MAP above 60 to 65 mm Hg, vasopressors are commonly used. The vasopressors of choice in septic shock are **dopamine** and **norepinephrine**.[123] Norepinephrine increases blood pressure primarily by increasing systemic vascular resistance; dopamine's main effect is to increase stroke volume. Although most studies have not found one vasopressor to be clearly superior to others, a 2008 meta-analysis of randomized controlled and observational trials found that dopamine was associated with greater mortality and a higher incidence of arrhythmic events than norepinephrine.[124] Currently, it appears appropriate for the clinician to use the agent with which he or she is most familiar.

Obstetricians have traditionally expressed concern regarding the potential adverse effects of vasopressors on uteroplacental perfusion. However, in the setting of septic shock, restoration of maternal organ perfusion pressure is essential for fetal survival. Multiple case reports have described improved fetal status with the use of vasopressors to increase MAP.

Vasopressin is a peptide hormone synthesized in the hypothalamus and stored in the pituitary gland. A relative deficiency of vasopressin has been described during

septic shock. Vasopressin causes direct vascular smooth muscle constriction via stimulation of V_1 receptors. It also increases the response to catecholamines, likely by increasing cortisol secretion through its action on V_3 receptors in the pituitary gland. Additionally, vasopressin achieves vasoconstriction by closing ATP-dependent potassium channels. Observational studies have shown that the addition of low-dose vasopressin (0.04 U/min) to traditional vasopressor therapy can raise blood pressure in vasopressor-refractory septic shock. A large randomized clinical trial reported no difference in mortality in patients with vasopressor-dependent septic shock who were randomized to receive either vasopressin or norepinephrine in addition to open-label vasopressor therapy.[124] However, the trial did not address the use of vasopressin as rescue therapy for septic shock that is resistant to conventional vasopressors.

No good data exist regarding the use of vasopressin during septic shock in pregnant women. Theoretically, it may activate uterine V1a receptors, leading to uterine contractions. Extreme caution is recommended if this agent is used during pregnancy.

Contrary to popular belief, myocardial contractility is compromised in septic shock because TNF-α, IL-1, and nitric oxide lead to myocardial depression. Patients may develop both systolic and diastolic dysfunction, commonly involving both ventricles. In the subgroup of patients with mainly systolic dysfunction, the ventricles dilate to accommodate increased preload. This adaptive mechanism allows a transient increase in stroke volume and has been associated with improved outcomes. Patients with predominantly diastolic dysfunction do not usually develop this compensatory chamber dilation.

Septic cardiomyopathy may be "unmasked" when vasopressors are used to increase systemic vascular resistance. Assessment of cardiac output (e.g., bedside transthoracic echocardiography) is beneficial when vasopressors (primarily norepinephrine and vasopressin) are used without concomitant inotropic support. If worsening cardiac output is noted after initiating vasoconstrictor therapy, inotropic support (dobutamine or dopamine) may be beneficial.

Anecdotal data suggest that catecholamines may not be effective in patients with severe acidemia. However, data do not support the use of sodium bicarbonate therapy during resuscitation. In septic patients, bicarbonate therapy is not indicated if the pH is above 7.15.[117] If the pH is less than 7.15, the use of sodium bicarbonate should be individualized. Particular care should be taken if the clinician chooses to use bicarbonate during pregnancy because bicarbonate does not cross the placenta, but the carbon dioxide generated from its administration crosses the placenta to the fetal compartment, leading to potential fetal acidemia.

Corticosteroids. Approximately 50% to 75% of patients with severe sepsis/septic shock have **critical illness–related corticosteroid insufficiency**. Cytokines lead to a dysfunctional hypothalamic-pituitary-adrenal axis with a consequent decrease in cortisol secretion. Cortisol plays a pivotal role in the up-regulation of catecholamine receptors at the vascular level (leading to an increased response to endogenous and exogenous catecholamines).

The use of corticosteroid therapy in patients with septic shock has long been controversial. In the past, large doses of corticosteroids were used; however, evidence suggested that the use of high-dose corticosteroids in patients with sepsis/septic shock may be harmful. Studies performed in the past decade suggest that low-dose corticosteroids (hydrocortisone ≤ 300 mg/day) may be beneficial.[125] Currently, physiologic doses of corticosteroids are recommended in patients who fail to respond to catecholamine therapy.[125] Patients who receive vasopressors and are unable to maintain a systolic blood pressure above 90 mm Hg are candidates for corticosteroid therapy.[125] The agent of choice is hydrocortisone (50 mg bolus intravenously every 6 hours or a continuous intravenous infusion at 10 mg/h). This low dose of glucocorticoid is believed to be immunomodulatory; the excessive immune response that leads to shock is down-regulated without causing immunosuppression. Once begun, treatment should be maintained for at least 4 to 7 days, and the dose should be tapered over 1 week to avoid rebound inflammation and shock. The adrenocorticotropic hormone (ACTH) stimulation test should not be used to identify patients with septic shock who should receive glucocorticoids. The same guidelines are applied during pregnancy to decide who might benefit from corticosteroid therapy. The clinician should be cognizant of the possible association between corticosteroid use during the first trimester of pregnancy and the development of fetal cleft lip and palate.[99]

Monitoring Resuscitation. Traditionally, the main goal of resuscitation efforts in sepsis has been to achieve "normal" vital signs (MAP greater than 65 mm Hg, urine output greater than 0.5 mL/kg/h, normal heart rate).[117] Unfortunately, clinical signs and symptoms lack sensitivity for detection of tissue hypoperfusion. Patients may have normal vital signs and still have organ hypoperfusion and anaerobic metabolism. Different strategies have been proposed to detect these patients with "occult shock." Resuscitation may be guided by blood lactate levels. Patients with persistent lactic acidosis, despite apparently normal vital signs, may require further resuscitation to increase tissue oxygen delivery.

Another option is to optimize hemodynamic support using central ($Sc\bar{v}O_2$) and mixed venous ($S\bar{v}O_2$) oxyhemoglobin saturation monitoring. $S\bar{v}O_2$ is the saturation of hemoglobin obtained from blood sampled from the pulmonary artery. It requires placement of a pulmonary artery catheter; a normal value is greater than 65%. Pregnancy *per se* does not alter the $S\bar{v}O_2$.[126]

$Sc\bar{v}O_2$ is the oxyhemoglobin saturation of a blood sample obtained from the junction of the superior vena cava and the right atrium. This measurement is readily achieved by obtaining a blood sample from a central venous catheter. The normal value is greater than 70%. To our knowledge, normal values for $Sc\bar{v}O_2$ during pregnancy have not been described. Patients with tissue hypoperfusion will extract more oxygen in an attempt to increase aerobic metabolism. The increased extraction will lead to a decrease in the oxygen saturation of

hemoglobin returning to the central circulation. Low values of either $S\bar{v}O_2$ or $Sc\bar{v}O_2$ may warrant an attempt to increase oxygen delivery by volume expansion, blood transfusion, or the use of an inotrope.

The Fetus during Critical Maternal Illness

In the vast majority of cases, therapeutic interventions in the critically ill pregnant patient should not be withheld because of fetal concerns. When the alternative is death or severe injury, very few drugs or diagnostic or therapeutic maneuvers are contraindicated. Most medications (sedatives, neuromuscular blocking agents, corticosteroids, vasopressors, inotropes, antibiotics) may be used safely (or with minimal risks that are commonly outweighed by the benefits) during pregnancy. Some of the common agents used in the ICU setting, and the associated fetal risks, are listed in Table 55-3.

Imaging studies should be performed as needed with the use of abdominal shielding to limit fetal radiation exposure. When possible, ultrasonography and magnetic resonance imaging (MRI) are preferred because no ionizing radiation is used. Radiation exposure from common studies, such as a chest or abdominal radiography or CT of the head or chest, are all below the upper limit of safety (5 rads) recommended by the American College of Obstetricians and Gynecologists (ACOG).[57] Similarly, the use of radiopaque (iodide containing) or paramagnetic contrast media during pregnancy is acceptable, provided the study is considered fundamental to the care of the patient.[57]

Critically ill pregnant patients should receive continuous electronic FHR monitoring after 24 weeks' gestation (lower age limit of viability) to continuously evaluate fetal well-being. The presence of fetal bradycardia, tachycardia, or persistent FHR decelerations may signal uterine hypoperfusion that requires improved resuscitation

TABLE 55-3 **Common Medications Used during Critical Illness**

Medication	FDA Pregnancy Category*	Comments
Norepinephrine	C	Uterine vessels are very sensitive to vasoconstriction because they are rich in alpha-adrenergic receptors. As with any vasopressor, this agent may be used after adequate volume resuscitation and with continuous electronic FHR monitoring. Recent evidence suggests that norepinephrine may be the vasopressor of choice during sepsis.
Dopamine	C	Many clinicians are more familiar with the use of dopamine as a vasopressor in sepsis during pregnancy. Dopamine is associated with more tachyarrhythmias than norepinephrine. As with norepinephrine, it should be used after adequate fluid resuscitation and with continuous electronic FHR monitoring.
Vasopressin	C	Low doses used for the treatment of diabetes insipidus have not been associated with fetal harm. No data exist on its use as a continuous infusion for septic shock in pregnancy. Potentially, vasopressin may lead to activation of V1a receptors and uterine contractions; thus, extreme caution is recommended if used during pregnancy. Continuous electronic FHR monitoring is highly desirable.
Dobutamine	B	
Milrinone	C	
Phenylephrine	C	
Epinephrine	C	
Hydrocortisone	C	Some data suggest an association between corticosteroid use during the first trimester and fetal cleft lip/palate. However, if required to improve maternal outcomes, use should not be deferred.
Midazolam	D	No clear correlation between the use of midazolam and fetal anomalies has been described. Use of any sedative close to the time of delivery is associated with neonatal depression.
Lorazepam	D	Limited data have associated prolonged use with fetal anomalies. It is unlikely that its use during a few days of critical illness outside the first trimester is teratogenic.
Propofol	B	
Dexmedetomidine	C	This agent crosses the placenta, but no published studies link dexmedetomidine to fetal malformations.
Cisatracurium	B	May have anti-inflammatory properties
Vecuronium	C	
Morphine	C	
Fentanyl	C	
Hydromorphone	C	
Haloperidol	C	

FHR, fetal heart rate.
*U.S. Food and Drug Administration (FDA) pregnancy category (see Box 14-1).

efforts. Each case should be evaluated individually with the aid of a maternal-fetal medicine specialist. Pregnant women beyond 20 weeks' gestation should be positioned either in the left or right decubitus position to avoid uterine compression of the inferior vena cava, which results in a decrease in cardiac preload.

KEY POINTS

- Trauma is the most common nonobstetric cause of maternal death.
- Head injury and hemorrhagic shock are the most common causes of death in the pregnant trauma victim.
- Even minor trauma increases the risk for placental abruption and preterm labor.
- Resuscitation of the critically ill or injured obstetric patient should be based on the premise that optimized maternal resuscitation will be most beneficial to the fetus.
- Care of the pregnant trauma patient should be based on Advanced Trauma Life Support principles. Additional attention should be given to complications that are specific to pregnancy, such as uterine rupture and placental abruption.
- In addition to standard Advanced Cardiac Life Support guidelines, considerations for resuscitation of the pregnant patient include maintenance of left uterine displacement and evacuation of the uterus. If spontaneous circulation does not return within 4 minutes of cardiac arrest, immediate hysterotomy or cesarean delivery should be performed if the gestational age is 20 weeks or greater, aiming for delivery within 5 minutes of cardiac arrest.
- Neurologic emergencies during pregnancy require prompt intensive care to avoid secondary brain injury due to hypoxia, hypercarbia, seizures, hyponatremia, hyperglycemia, and rebleeding episodes.
- Patients with acute lung injury should receive lung-protective mechanical ventilation. When possible, excessive fluid administration should be avoided.
- Early enteral nutrition and glucose control are basic tenants of contemporary critical care.
- Transfusion of blood products in critically ill patients should follow a restrictive strategy.
- Prompt diagnosis, infection source control, adequate antibiotic therapy, and goal-directed fluid resuscitation are fundamental principles of the early management of sepsis.
- Fetal heart rate monitoring is indicated in pregnant trauma victims and critically ill obstetric patients beginning at 24 weeks' gestation; altered fetal heart rate patterns can serve as a valuable indicator of inadequate resuscitation.

APPENDIX A

American Society of Anesthesiologists Guidelines for Neuraxial Anesthesia in Obstetrics*

COMMITTEE OF ORIGIN: OBSTETRICAL ANESTHESIA

These guidelines apply to the use of neuraxial anesthesia and labor anesthesia or analgesia in which local anesthetics are administered to the parturient during labor and delivery. They are intended to encourage quality patient care but cannot guarantee any specific patient outcome. Because the availability of anesthesia resources may vary, members are responsible for interpreting and establishing the guidelines for their own institutions and practices. These guidelines are subject to revision from time to time as warranted by the evolution of technology and practice.

GUIDELINE I
NEURAXIAL ANESTHESIA SHOULD BE INITIATED AND MAINTAINED ONLY IN LOCATIONS IN WHICH APPROPRIATE RESUSCITATION EQUIPMENT AND DRUGS ARE IMMEDIATELY AVAILABLE TO MANAGE PROCEDURALLY RELATED PROBLEMS.

Resuscitation equipment should include, but is not limited to: sources of oxygen and suction, equipment to maintain an airway and perform endotracheal intubation, a means to provide positive pressure ventilation, and drugs and equipment for cardiopulmonary resuscitation.

GUIDELINE II
NEURAXIAL ANESTHESIA SHOULD BE INITIATED BY A PHYSICIAN WITH APPROPRIATE PRIVILEGES AND MAINTAINED BY OR UNDER THE MEDICAL DIRECTION[1] OF SUCH AN INDIVIDUAL.

Physicians should be approved through the institutional credentialing process to initiate and direct the maintenance of obstetric anesthesia and to manage procedurally related complications.

GUIDELINE III
NEURAXIAL ANESTHESIA SHOULD NOT BE ADMINISTERED UNTIL: 1) THE PATIENT HAS BEEN EXAMINED BY A QUALIFIED INDIVIDUAL[2]; AND 2) A PHYSICIAN WITH OBSTETRICAL PRIVILEGES TO PERFORM OPERATIVE VAGINAL OR CESAREAN DELIVERY, WHO HAS KNOWLEDGE OF THE MATERNAL AND FETAL STATUS AND THE PROGRESS OF LABOR AND WHO APPROVED THE INITIATION OF LABOR ANESTHESIA, IS READILY AVAILABLE TO SUPERVISE THE LABOR AND MANAGE ANY OBSTETRIC COMPLICATIONS THAT MAY ARISE.

Under circumstanced defined by department protocol, qualified personnel may perform the initial pelvic examination. The physician responsible for the patient's obstetrical care should be informed of her status so that a decision can be made regarding present risk and further management.[2]

GUIDELINE IV
AN INTRAVENOUS INFUSION SHOULD BE ESTABLISHED BEFORE THE INITIATION OF NEURAXIAL ANESTHESIA AND MAINTAINED THROUGHOUT THE DURATION OF THE NEURAXIAL ANESTHETIC.

GUIDELINE V
NEURAXIAL ANESTHESIA FOR LABOR AND/OR VAGINAL DELIVERY REQUIRES THAT THE

*Approved by the ASA House of Delegates on October 12, 1988, and last amended on October 12, 2010.

[1]The Anesthesia Care Team (Approved by ASA House of Delegates 10/26/82 and last amended 10/18/2006).

[2]American Academy of Pediatrics and American College of Obstetricians and Gynecologists. Guidelines for Perinatal Care, 5th Edition. Elk Grove Village, IL: AAP; Washington, DC: ACOG, 2002.

PARTURIENT'S VITAL SIGNS AND THE FETAL HEART RATE BE MONITORED AND DOCUMENTED BY A QUALIFIED INDIVIDUAL. ADDITIONAL MONITORING APPROPRIATE TO THE CLINICAL CONDITION OF THE PARTURIENT AND THE FETUS SHOULD BE EMPLOYED WHEN INDICATED. WHEN EXTENSIVE NEURAXIAL BLOCKADE IS ADMINISTERED FOR COMPLICATED VAGINAL DELIVERY, THE STANDARDS FOR BASIC ANESTHETIC MONITORING[3] *SHOULD BE APPLIED.*

GUIDELINE VI

NEURAXIAL ANESTHESIA FOR CESAREAN DELIVERY REQUIRES THAT THE STANDARDS FOR BASIC ANESTHETIC MONITORING[3] *BE APPLIED AND THAT A PHYSICIAN WITH PRIVILEGES IN OBSTETRICS BE IMMEDIATELY AVAILABLE.*

GUIDELINE VII

QUALIFIED PERSONNEL, OTHER THAN THE ANESTHESIOLOGIST ATTENDING THE MOTHER, SHOULD BE IMMEDIATELY AVAILABLE TO ASSUME THE RESPONSIBILITY FOR RESUSCITATION OF THE NEWBORN.[3]

The primary responsibility of the anaesthesiologist is to provide care to the mother. If the anesthesiologist is also requested to provide brief assistance in the care of the newborn, the benefit to the child must be compared to the risk to the mother.

GUIDELINE VIII

A PHYSICIAN WITH APPROPRIATE PRIVILEGES SHOULD REMAIN READILY AVAILABLE DURING THE NEURACIAL ANESTHETIC TO MANAGE ANESTHETIC COMPLICATIONS UNTIL THE PATIENT'S POSTANESTHESIA CONDITION IS SATISFACTORY AND STABLE.

GUIDELINE IX

ALL PATIENTS RECOVERING FROM NEURAXIAL ANESTHESIA SHOULD RECEIVE APPROPRIATE POSTANESTHESIA CARE. FOLLOWING CESAREAN DELIVERY AND/OR EXTENSIVE NEURAXIAL BLOCKADE, THE STANDARDS FOR POST-ANESTHESIA CARE[4] *SHOULD BE APPLIED.*

GUIDELINE X

THERE SHOULD BE A POLICY TO ASSURE THE AVAILABILITY IN THE FACILITY OF A PHYSICIAN TO MANAGE COMPLICATIONS AND TO PROVIDE CARDIOPULMONARY RESUSCITATION FOR PATIENTS RECEIVING POSTANESTHESIA CARE.

[3]Standards for Basic Anesthetic Monitoring (Approved by ASA House of Delegates 10/21/86 and last amended 10/25/2005).

[4]Standards for Postanesthesia Care (Approved by ASA House of Delegates 10/12/88 and last amended 10/27/04).

Practice Guidelines for Obstetric Anesthesia: An Updated Report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia*

PRACTICE guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints and are not intended to replace local institutional policies. In addition, practice guidelines are not intended as standards or absolute requirements, and their use cannot guarantee any specific outcome. Practice guidelines are subject to revision as warranted by the evolution of medical knowledge, technology, and practice. They provide basic recommendations that are supported by a synthesis and analysis of the current literature, expert opinion, open forum commentary, and clinical feasibility data.

This update includes data published since the "Practice Guidelines for Obstetrical Anesthesia" were adopted by the American Society of Anesthesiologists in 1998; it also includes data and recommendations for a wider range of techniques than was previously addressed.

*Excerpted from Practice Guidelines for Obstetric Anesthesia: An Updated Report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia. Anesthesiology 2007; 106:843-63. A copy of the full text can be obtained from American Society of Anesthesiologists, 520 N. Northwest Highway, Park Ridge, IL 60068-2573.

Developed by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia: Joy L. Hawkins, MD (Chair), Denver, Colorado; James F. Arens, MD, Houston, Texas; Brenda A. Bucklin, MD, Denver, Colorado; Richard T. Connis, PhD, Woodinville, Washington; Patricia A. Dailey, MD, Hillsborough, California; David R. Gambling, MBBS, San Diego, California; David G. Nickinovich, PhD, Bellevue, Washington; Linda S. Polley, MD, Ann Arbor, Michigan; Lawrence C. Tsen, MD, Boston, Massachusetts; David J. Wlody, MD, Brooklyn, New York; and Kathryn J. Zuspan, MD, Stillwater, Minnesota.

Submitted for publication October 31, 2006. Accepted for publication October 31, 2006. Supported by the American Society of Anesthesiologists under the direction of James F. Arens, MD, Chair, Committee on Standards and Practice Parameters. Approved by the House of Delegates on October 18, 2006. A list of the references used to develop these Guidelines is available by writing to the American Society of Anesthesiologists.

Methodology

A. Definition of Perioperative Obstetric Anesthesia

For the purposes of these Guidelines, *obstetric anesthesia* refers to peripartum anesthetic and analgesic activities performed during labor and vaginal delivery, cesarean delivery, removal of retained placenta, and postpartum tubal ligation.

B. Purposes of the Guidelines

The purposes of these Guidelines are to enhance the quality of anesthetic care for obstetric patients, improve patient safety by reducing the incidence and severity of anesthesia-related complications, and increase patient satisfaction.

C. Focus

These Guidelines focus on the anesthetic management of pregnant patients during labor, nonoperative delivery, operative delivery, and selected aspects of postpartum care and analgesia (*i.e.*, neuraxial opioids for postpartum analgesia after neuraxial anesthesia for cesarean delivery). The intended patient population includes, but is not limited to, intrapartum and postpartum patients with uncomplicated pregnancies or with common obstetric problems. The Guidelines do not apply to patients undergoing surgery during pregnancy, gynecologic patients, or parturients with chronic medical disease (*e.g.*, severe cardiac, renal, or neurologic disease). In addition, these Guidelines do not address (1) postpartum analgesia for vaginal delivery, (2) analgesia after tubal ligation, or (3) postoperative analgesia after general anesthesia (GA) for cesarean delivery.

D. Application

These Guidelines are intended for use by anesthesiologists. They also may serve as a resource for other

anesthesia providers and healthcare professionals who advise or care for patients who will receive anesthetic care during labor, delivery, and the immediate postpartum period.

E. Task Force Members and Consultants

The American Society of Anesthesiologists (ASA) appointed a Task Force of 11 members to (1) review the published evidence, (2) obtain the opinion of a panel of consultants including anesthesiologists and nonanesthesiologist physicians concerned with obstetric anesthesia and analgesia, and (3) obtain opinions from practitioners likely to be affected by the Guidelines. The Task Force included anesthesiologists in both private and academic practices from various geographic areas of the United States and two consulting methodologists from the ASA Committee on Standards and Practice Parameters.

The Task Force developed the Guidelines by means of a seven-step process. First, they reached consensus on the criteria for evidence. Second, original published research studies from peer-reviewed journals relevant to obstetric anesthesia were reviewed. Third, the panel of expert consultants was asked to (1) participate in opinion surveys on the effectiveness of various peripartum management strategies and (2) review and comment on a draft of the Guidelines developed by the Task Force. Fourth, opinions about the Guideline recommendations were solicited from active members of the ASA who provide obstetric anesthesia. Fifth, the Task Force held open forums at two major national meetings[†] to solicit input on its draft recommendations. Sixth, the consultants were surveyed to assess their opinions on the feasibility of implementing the Guidelines. Seventh, all available information was used to build consensus within the Task Force to finalize the Guidelines (Appendix 1).

F. Availability and Strength of Evidence

Preparation of these Guidelines followed a rigorous methodologic process. To convey the findings in a concise and easy-to-understand fashion, these Guidelines use several descriptive terms. When sufficient numbers of studies are available for evaluation, the following terms describe the strength of the findings.

Support: Meta-analysis of a sufficient number of randomized controlled trials[‡] indicates a statistically significant relationship ($P < .01$) between a clinical intervention and a clinical outcome.

Suggest: Information from case reports and observational studies permits inference of a relationship between an intervention and an outcome. A meta-analytic assessment of this type of qualitative or descriptive information is not conducted.

Equivocal: Either a meta-analysis has not found significant differences among groups or conditions, or there is insufficient quantitative information to conduct a meta-analysis and information collected from case reports and observational studies does not permit inference of a relationship between an intervention and an outcome.

The *lack* of scientific evidence in the literature is described by the following terms.

Silent: No identified studies address the specified relationship between an intervention and outcome.

Insufficient: There are too few published studies to investigate a relationship between an intervention and outcome.

Inadequate: The available studies cannot be used to assess the relationship between an intervention and an outcome. These studies either do not meet the criteria for content as defined in the Focus section of these Guidelines, or do not permit a clear causal interpretation of findings due to methodologic concerns.

Formal survey information is collected from consultants and members of the ASA. The following terms describe survey responses for any specified issue. Responses are solicited on a five-point scale ranging from 1 (strongly disagree) to 5 (strongly agree), with a score of 3 being equivocal. Survey responses are summarized based on median values as follows:

Strongly Agree: Median score of 5 (at least 50% of the responses are 5).

Agree: Median score of 4 (at least 50% of the responses are 4 or 4 and 5).

Equivocal: Median score of 3 (at least 50% of the responses are 3, or no other response category or combination of similar categories contain at least 50% of the responses).

Disagree: Median score of 2 (at least 50% of the responses are 2 or 1 and 2).

Strongly Disagree: Median score of 1 (at least 50% of the responses are 1).

Guidelines

I. Perianesthetic Evaluation

History and Physical Examination. Although comparative studies are insufficient to evaluate the peripartum impact of conducting a focused history (*e.g.*, reviewing medical records) or a physical examination, the literature reports certain patient or clinical characteristics that may be associated with obstetric complications. These characteristics include, but are not limited to, preeclampsia, pregnancy-related hypertensive disorders, HELLP syndrome, obesity, and diabetes.

The consultants and ASA members both strongly agree that a directed history and physical examination, as well as communication between anesthetic and obstetric providers, reduces maternal, fetal, and neonatal complications.

Recommendations. The anesthesiologist should conduct a focused history and physical examination before

[†]International Anesthesia Research Society, 80th Clinical and Scientific Congress, San Francisco, California, March 25, 2006; and Society of Obstetric Anesthesia and Perinatology 38th Annual Meeting, Hollywood, Florida, April 29, 2006

[‡]A prospective nonrandomized controlled trial may be included in a metaanalysis under certain circumstances if specific statistical criteria are met.

providing anesthesia care. This should include, but is not limited to, a maternal health and anesthetic history, a relevant obstetric history, a baseline blood pressure measurement, and an airway, heart, and lung examination, consistent with the ASA "Practice Advisory for Preanesthesia Evaluation."[§] When a neuraxial anesthetic is planned or placed, the patient's back should be examined.

Recognition of significant anesthetic or obstetric risk factors should encourage consultation between the obstetrician and the anesthesiologist. A communication system should be in place to encourage early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team.

Intrapartum Platelet Count. The literature is insufficient to assess whether a routine platelet count can predict anesthesia-related complications in uncomplicated parturients. The literature suggests that a platelet count is clinically useful for parturients with suspected pregnancy-related hypertensive disorders, such as preeclampsia or HELLP syndrome, and for other disorders associated with coagulopathy.

The ASA members are equivocal, but the consultants agree that obtaining a routine intrapartum platelet count does *not* reduce maternal anesthetic complications. Both the consultants and ASA members agree that, for patients with suspected preeclampsia, a platelet count reduces maternal anesthetic complications. The consultants strongly agree and the ASA members agree that a platelet count reduces maternal anesthetic complications for patients with suspected coagulopathy.

Recommendations. A specific platelet count predictive of neuraxial anesthetic complications has not been determined. The anesthesiologist's decision to order or require a platelet count should be individualized and based on a patient's history, physical examination, and clinical signs. A routine platelet count is not necessary in the healthy parturient.

Blood Type and Screen. The literature is insufficient to determine whether obtaining a blood type and screen is associated with fewer maternal anesthetic complications. In addition, the literature is insufficient to determine whether a blood cross-match is necessary for healthy and uncomplicated parturients. The consultants and ASA members agree that an intrapartum blood sample should be sent to the blood bank for all parturients.

Recommendations. A routine blood cross-match is not necessary for healthy and uncomplicated parturients for vaginal or operative delivery. The decision whether to order or require a blood type and screen, or cross-match, should be based on maternal history, anticipated hemorrhagic complications (*e.g.*, placenta accreta in a patient with placenta previa and previous uterine surgery), and local institutional policies.

Perianesthetic Recording of the Fetal Heart Rate. The literature suggests that anesthetic and analgesic agents may influence the fetal heart rate pattern. There is insufficient literature to demonstrate that perianesthetic recording of the fetal heart rate prevents fetal or neonatal complications. Both the consultants and ASA members agree, however, that perianesthetic recording of the fetal heart rate reduces fetal and neonatal complications.

Recommendations. The fetal heart rate should be monitored by a qualified individual before and after administration of neuraxial analgesia for labor. The Task Force recognizes that *continuous* electronic recording of the fetal heart rate may not be necessary in every clinical setting and may not be possible during initiation of neuraxial anesthesia.

II. Aspiration Prevention

Clear Liquids. There is insufficient published evidence to draw conclusions about the relationship between fasting times for clear liquids and the risk of emesis/reflux or pulmonary aspiration during labor. The consultants and ASA members both agree that oral intake of clear liquids during labor improves maternal comfort and satisfaction. Although the ASA members are equivocal, the consultants agree that oral intake of clear liquids during labor *does not* increase maternal complications.

Recommendations. The oral intake of modest amounts of clear liquids may be allowed for uncomplicated laboring patients. The uncomplicated patient undergoing elective cesarean delivery may have modest amounts of clear liquids up to 2 h before induction of anesthesia. Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, black coffee, and sports drinks. The volume of liquid ingested is less important than the presence of particulate matter in the liquid ingested. However, patients with additional risk factors for aspiration (*e.g.*, morbid obesity, diabetes, difficult airway) or patients at increased risk for operative delivery (*e.g.*, nonreassuring fetal heart rate pattern) may have further restrictions of oral intake, determined on a case-by-case basis.

Solids. A specific fasting time for solids that is predictive of maternal anesthetic complications has not been determined. There is insufficient published evidence to address the safety of *any* particular fasting period for solids in obstetric patients. The consultants and ASA members both agree that the oral intake of solids during labor increases maternal complications. They both strongly agree that patients undergoing either elective cesarean delivery or postpartum tubal ligation should undergo a fasting period of 6-8 h depending on the type of food ingested (*e.g.*, fat content).[‖] The Task Force recognizes that in laboring patients the timing of delivery is uncertain; therefore, compliance with a predetermined fasting period before nonelective surgical procedures is not always possible.

[§]American Society of Anesthesiologists Task Force on Preanesthesia Evaluation: Practice advisory for preanesthesia evaluation. Anesthesiology 2002; 96:485–96.

[‖]American Society of Anesthesiologists Task Force on Preoperative Fasting: Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration. Anesthesiology 1999; 90:896–905.

Recommendations. Solid foods should be avoided in laboring patients. The patient undergoing elective surgery (*e.g.*, scheduled cesarean delivery or postpartum tubal ligation) should undergo a fasting period for solids of 6-8 h depending on the type of food ingested (*e.g.*, fat content).[ll]

Antacids, H_2 Receptor Antagonists, and Metoclopramide. The literature does not sufficiently examine the relationship between reduced gastric acidity and the frequency of emesis, pulmonary aspiration, morbidity, or mortality in obstetric patients who have aspirated gastric contents. Published evidence supports the efficacy of preoperative nonparticulate antacids (*e.g.*, sodium citrate, sodium bicarbonate) in decreasing gastric acidity during the peripartum period. However, the literature is insufficient to examine the impact of nonparticulate antacids on gastric volume. The literature suggests that H_2 receptor antagonists are effective in decreasing gastric acidity in obstetric patients and supports the efficacy of metoclopramide in reducing peripartum nausea and vomiting. The consultants and ASA members agree that the administration of a nonparticulate antacid before operative procedures reduces maternal complications.

Recommendations. Before surgical procedures (*i.e.*, cesarean delivery, postpartum tubal ligation), practitioners should consider the timely administration of nonparticulate antacids, H_2 receptor antagonists, and/or metoclopramide for aspiration prophylaxis.

III. Anesthetic Care for Labor and Vaginal Delivery

Overview. Not all women require anesthetic care during labor or delivery. For women who request pain relief for labor and/or delivery, there are many effective analgesic techniques available. Maternal request represents sufficient justification for pain relief. In addition, maternal medical and obstetric conditions may warrant the provision of neuraxial techniques to improve maternal and neonatal outcome.

The choice of analgesic technique depends on the medical status of the patient, progress of labor, and resources at the facility. When sufficient resources (*e.g.*, anesthesia and nursing staff) are available, neuraxial catheter techniques should be one of the analgesic options offered. The choice of a specific neuraxial block should be individualized and based on anesthetic risk factors, obstetric risk factors, patient preferences, progress of labor, and resources at the facility.

When neuraxial catheter techniques are used for analgesia during labor or vaginal delivery, the primary goal is to provide adequate maternal analgesia with minimal motor block (*e.g.*, achieved with the administration of local anesthetics at low concentrations with or without opioids).

When a neuraxial technique is chosen, appropriate resources for the treatment of complications (*e.g.*, hypotension, systemic toxicity, high spinal anesthesia) should be available. If an opioid is added, treatments for related complications (*e.g.*, pruritus, nausea, respiratory depression) should be available. An intravenous infusion should be established before the initiation of neuraxial analgesia or anesthesia and maintained throughout the duration of the neuraxial analgesic or anesthetic. However, administration of a fixed volume of intravenous fluid is not required before neuraxial analgesia is initiated.

Timing of Neuraxial Analgesia and Outcome of Labor. Meta-analysis of the literature determined that the timing of neuraxial analgesia does not affect the frequency of cesarean delivery. The literature also suggests that other delivery outcomes (*i.e.*, spontaneous or instrumented) are also unaffected. The consultants strongly agree and the ASA members agree that early initiation of epidural analgesia (*i.e.*, at cervical dilations of less than 5 cm vs. equal to or greater than 5 cm) improves analgesia. They both *disagree* that motor block or maternal, fetal, or neonatal side effects are increased by early administration.

Recommendations. Patients in early labor (*i.e.*, < 5 cm dilation) should be given the option of neuraxial analgesia when this service is available. Neuraxial analgesia should not be withheld on the basis of achieving an arbitrary cervical dilation, and should be offered on an individualized basis. Patients may be reassured that the use of neuraxial analgesia does not increase the incidence of cesarean delivery.

Neuraxial Analgesia and Trial of Labor after Previous Cesarean Delivery. Nonrandomized comparative studies suggest that epidural analgesia may be used in a trial of labor for previous cesarean delivery patients without adversely affecting the incidence of vaginal delivery. Randomized comparisons of epidural *versus* other anesthetic techniques were not found. The consultants and ASA members agree that neuraxial techniques improve the likelihood of vaginal delivery for patients attempting vaginal birth after cesarean delivery.

Recommendations. Neuraxial techniques should be offered to patients attempting vaginal birth after previous cesarean delivery. For these patients, it is also appropriate to consider early placement of a neuraxial catheter that can be used later for labor analgesia, or for anesthesia in the event of operative delivery.

Early Insertion of a Spinal or Epidural Catheter for Complicated Parturients. The literature is insufficient to assess whether, when caring for the complicated parturient, the early insertion of a spinal or epidural catheter, with later administration of analgesia, improves maternal or neonatal outcomes. The consultants and ASA members agree that early insertion of a spinal or epidural catheter for complicated parturients reduces maternal complications.

Recommendations. Early insertion of a spinal or epidural catheter for obstetric (*e.g.*, twin gestation or preeclampsia) or anesthetic indications (*e.g.*, anticipated difficult airway or obesity) should be considered to reduce the need for GA if an emergent procedure becomes necessary. In these cases, the insertion of a spinal or epidural catheter may precede the onset of labor or a patient's request for labor analgesia.

Continuous Infusion Epidural Analgesia

CIE Compared with Parenteral Opioids. The literature suggests that the use of continuous infusion epidural (CIE) local anesthetics with or without opioids provides greater quality of analgesia compared with parenteral (*i.e.*, intravenous or intramuscular) opioids. The consultants and ASA members strongly agree that CIE local anesthetics with or without opioids provide improved analgesia compared with parenteral opioids.

Meta-analysis of the literature indicates that there is a longer duration of labor, with an average duration of 24 min for the second stage, and a lower frequency of spontaneous vaginal delivery when continuous epidural local anesthetics are administered compared with *intravenous* opioids. Meta-analysis of the literature determined that there are no differences in the frequency of cesarean delivery. Neither the consultants nor ASA members agree that CIE local anesthetics compared with parenteral opioids significantly (1) increase the duration of labor, (2) decrease the chance of spontaneous delivery, (3) increase maternal side effects, or (4) increase fetal and neonatal side effects.

CIE Compared with Single-injection Spinal. There is insufficient literature to assess the analgesic efficacy of CIE local anesthetics with or without opioids compared to *single-injection spinal opioids* with or without local anesthetics. The consultants are equivocal, but the ASA members agree that CIE local anesthetics improve analgesia compared with single-injection spinal opioids; both the consultants and ASA members are equivocal regarding the frequency of motor block. The consultants are equivocal, but the ASA members disagree that the use of CIE compared with single-injection spinal opioids increases the duration of labor. They both *disagree* that CIE local anesthetics with or without opioids compared to single-injection spinal opioids with or without local anesthetics decreases the likelihood of spontaneous delivery or increases maternal, fetal, or neonatal side effects.

CIE with and without Opioids. The literature supports the *induction* of analgesia using epidural local anesthetics combined *with opioids* compared with equal concentrations of epidural local anesthetics *without opioids* for improved quality and longer duration of analgesia. The consultants strongly agree and the ASA members agree that the addition of opioids to epidural local anesthetics improves analgesia; they both disagree that fetal or neonatal side effects are increased. The consultants disagree, but the ASA members are equivocal regarding whether the addition of opioids increases maternal side effects.

The literature is insufficient to determine whether induction of analgesia using local anesthetics with opioids compared with *higher concentrations* of epidural local anesthetics without opioids provides improved quality or duration of analgesia. The consultants and ASA members are equivocal regarding improved analgesia, and they both disagree that maternal, fetal, or neonatal side effects are increased using lower concentrations of epidural local anesthetics with opioids.

For *maintenance of analgesia*, the literature suggests that there are no differences in the analgesic efficacy of *low concentrations* of epidural local anesthetics with opioids compared with *higher concentrations* of epidural local anesthetics without opioids. The Task Force notes that the addition of an opioid to a local anesthetic infusion allows an even lower concentration of local anesthetic for providing equally effective analgesia. However, the literature is insufficient to examine whether a bupivacaine infusion concentration of *less than or equal to 0.125%* with an opioid provides comparable or improved analgesia compared with a bupivacaine concentration *greater than 0.125%* without an opioid.[#] Meta-analysis of the literature determined that low concentrations of epidural local anesthetics with opioids compared with higher concentrations of epidural local anesthetics without opioids are associated with reduced motor block. No differences in the duration of labor, mode of delivery, or neonatal outcomes are found when epidural local anesthetics with opioids are compared with epidural local anesthetics without opioids. The literature is insufficient to determine the effects of epidural local anesthetics with opioids on other maternal outcomes (*e.g.*, hypotension, nausea, pruritus, respiratory depression, urinary retention).

The consultants and ASA members both agree that maintenance of epidural analgesia using *low* concentrations of local anesthetics with opioids provides improved analgesia compared with *higher* concentrations of local anesthetics without opioids. The consultants agree, but the ASA members are equivocal regarding the improved likelihood of spontaneous delivery when lower concentrations of local anesthetics with opioids are used. The consultants strongly agree and the ASA members agree that motor block is reduced. They agree that maternal side effects are reduced with this drug combination. They are both equivocal regarding a reduction in fetal and neonatal side effects.

Recommendations. The selected analgesic/anesthetic technique should reflect patient needs and preferences, practitioner preferences or skills, and available resources. The continuous epidural infusion technique may be used for effective analgesia for labor and delivery. When a continuous epidural infusion of local anesthetic is selected, an opioid may be added to reduce the concentration of local anesthetic, improve the quality of analgesia, and minimize motor block.

Adequate analgesia for uncomplicated labor and delivery should be administered with the secondary goal of producing as little motor block as possible by using dilute concentrations of local anesthetics with opioids. The lowest concentration of local anesthetic infusion that provides adequate maternal analgesia and satisfaction should be administered. For example, an infusion concentration greater than 0.125% bupivacaine is unnecessary for labor analgesia in most patients.

Single-injection Spinal Opioids with or without Local Anesthetics. The literature suggests that spinal opioids with or without local anesthetics provide effective

[#]References to bupivacaine are included for illustrative purposes only, and because bupivacaine is the most extensively studied local anesthetic for continuous infusion epidural analgesia. The Task Force recognizes that other local anesthetics are appropriate for continuous infusion epidural analgesia.

analgesia during labor without altering the incidence of neonatal complications. There is insufficient literature to compare spinal opioids with parenteral opioids. There is also insufficient literature to compare single-injection spinal opioids *with* local anesthetics *versus* single-injection spinal opioids *without* local anesthetics.

The consultants strongly agree and the ASA members agree that spinal opioids provide improved analgesia compared with parenteral opioids. They both disagree that, compared with parenteral opioids, spinal opioids increase the duration of labor, decrease the chance of spontaneous delivery, or increase fetal and neonatal side effects. The consultants are equivocal, but the ASA members disagree that maternal side effects are increased with spinal opioids.

Compared with spinal opioids *without* local anesthetics, the consultants and ASA members both agree that spinal opioids *with* local anesthetics provide improved analgesia. They both disagree that the chance of spontaneous delivery is decreased and that fetal and neonatal side effects are increased. They are both equivocal regarding an increase in maternal side effects. However, they both agree that motor block is increased when local anesthetics are added to spinal opioids. Finally, the consultants disagree, but the ASA members are equivocal regarding an increase in the duration of labor.

Recommendations. Single-injection spinal opioids with or without local anesthetics may be used to provide effective, although time-limited, analgesia for labor when spontaneous vaginal delivery is anticipated. If labor is expected to last longer than the analgesic effects of the spinal drugs chosen or if there is a good possibility of operative delivery, a catheter technique instead of a single injection technique should be considered. A local anesthetic may be added to a spinal opioid to increase duration and improve quality of analgesia. The Task Force notes that the rapid onset of analgesia provided by single-injection spinal techniques may be advantageous for selected patients (*e.g.*, those in advanced labor).

Pencil-point Spinal Needles. The literature supports the use of pencil-point spinal needles compared with cutting-bevel spinal needles to reduce the frequency of post–dural puncture headache. The consultants and ASA members both strongly agree that the use of pencil-point spinal needles reduces maternal complications.

Recommendations. Pencil-point spinal needles should be used instead of cutting-bevel spinal needles to minimize the risk of post–dural puncture headache.

Combined Spinal-Epidural Analgesia. The literature supports a faster onset time and equivalent analgesia with combined spinal-epidural (CSE) local anesthetics with opioids *versus* epidural local anesthetics with opioids. The literature is equivocal regarding the impact of CSE versus epidural local anesthetics with opioids on maternal satisfaction with analgesia, mode of delivery, hypotension, motor block, nausea, fetal heart rate changes, and Apgar scores. Meta-analysis of the literature indicates that the frequency of pruritus is increased with CSE.

The consultants and ASA members both agree that CSE local anesthetics with opioids provide improved early analgesia compared with epidural local anesthetics with opioids. They are equivocal regarding the impact of CSE with opioids on overall analgesic efficacy, duration of labor, and motor block. The consultants and ASA members both disagree that CSE increases the risk of fetal or neonatal side effects. The consultants disagree, but the ASA members are equivocal regarding whether CSE increases the incidence of maternal side effects.

Recommendations. Combined spinal-epidural techniques may be used to provide effective and rapid onset of analgesia for labor.

Patient-controlled Epidural Analgesia. The literature supports the efficacy of patient-controlled epidural analgesia (PCEA) *versus* CIE in providing equivalent analgesia with reduced drug consumption. Meta-analysis of the literature indicates that the duration of labor is longer with PCEA compared with CIE for the first stage (*e.g.*, an average of 36 min) but not the second stage of labor. Meta-analysis of the literature also determined that mode of delivery, frequency of motor block, and Apgar scores are equivalent when PCEA administration is compared with CIE. The literature supports greater analgesic efficacy for PCEA with a background infusion compared with PCEA without a background infusion; meta-analysis of the literature also indicates no differences in the mode of delivery or frequency of motor block. The consultants and ASA members agree that PCEA compared with CIE improves analgesia and reduces the need for anesthetic interventions; they also agree that PCEA improves maternal satisfaction. The consultants and ASA members are equivocal regarding a reduction in motor block, an increased likelihood of spontaneous delivery, or a decrease in maternal side effects with PCEA compared with CIE. They both agree that PCEA with a background infusion improves analgesia, improves maternal satisfaction, and reduces the need for anesthetic intervention. The ASA members are equivocal, but the consultants disagree that a background infusion decreases the chance of spontaneous delivery or increases maternal side effects. The consultants and ASA members are equivocal regarding the effect of a background infusion on the incidence of motor block.

Recommendations. Patient-controlled epidural analgesia may be used to provide an effective and flexible approach for the maintenance of labor analgesia. The Task Force notes that the use of PCEA may be preferable to fixed-rate CIE for providing fewer anesthetic interventions and reduced dosages of local anesthetics. PCEA may be used with or without a background infusion.

IV. Removal of Retained Placenta

Anesthetic Techniques. The literature is insufficient to assess whether a particular type of anesthetic is more effective than another for removal of retained placenta. The consultants strongly agree and the ASA members agree that, if a functioning epidural catheter is in place and the patient is hemodynamically stable, epidural anesthesia is the preferred technique for the removal of retained placenta. The consultants and ASA members both agree that, in cases involving major maternal hemorrhage, GA is preferred over neuraxial anesthesia.

Recommendations. The Task Force notes that, in general, there is no preferred anesthetic technique for removal of retained placenta. However, if an epidural catheter is in place and the patient is hemodynamically stable, epidural anesthesia is preferable. Hemodynamic status should be assessed before administering neuraxial anesthesia. Aspiration prophylaxis should be considered. Sedation/analgesia should be titrated carefully due to the potential risks of respiratory depression and pulmonary aspiration during the immediate postpartum period. In cases involving major maternal hemorrhage, GA with an endotracheal tube may be preferable to neuraxial anesthesia.

Uterine Relaxation. The literature suggests that nitroglycerin is effective for uterine relaxation during the removal of retained placenta. The consultants and ASA members both agree that the administration of nitroglycerin for uterine relaxation improves success in removing a retained placenta.

Recommendations. Nitroglycerin may be used as an alternative to terbutaline sulfate or general endotracheal anesthesia with halogenated agents for uterine relaxation during removal of retained placental tissue. Initiating treatment with incremental doses of intravenous or sublingual (*i.e*., metered dose spray) nitroglycerin may relax the uterus sufficiently while minimizing potential complications (*e.g*., hypotension).

V. Anesthetic Choices for Cesarean Delivery

Equipment, Facilities, and Support Personnel. The literature is insufficient to evaluate the benefit of providing equipment, facilities and support personnel in the labor and delivery operating suite comparable to that available in the main operating suite. The consultants and ASA members strongly agree that the available equipment, facilities, and support personnel should be comparable.

Recommendations. Equipment, facilities, and support personnel available in the labor and delivery operating suite should be comparable to those available in the main operating suite. Resources for the treatment of potential complications (*e.g*., failed intubation, inadequate analgesia, hypotension, respiratory depression, pruritus, vomiting) should also be available in the labor and delivery operating suite. Appropriate equipment and personnel should be available to care for obstetric patients recovering from major neuraxial anesthesia or GA.

General, Epidural, Spinal, or Combined Spinal-Epidural Anesthesia. The literature suggests that induction-to-delivery times for GA are lower compared with epidural or spinal anesthesia and that a higher frequency of maternal hypotension may be associated with epidural or spinal techniques. Meta-analysis of the literature found that Apgar scores at 1 and 5 min are lower for GA compared with epidural anesthesia and suggests that Apgar scores are lower for GA *versus* spinal anesthesia. The literature is equivocal regarding differences in umbilical artery pH values when GA is compared with epidural or spinal anesthesia.

The consultants and ASA members agree that GA reduces the time to skin incision when compared with either epidural or spinal anesthesia; they also agree that GA increases maternal complications. The consultants are equivocal and the ASA members agree that GA increases fetal and neonatal complications. The consultants and ASA members both agree that epidural anesthesia increases the time to skin incision and decreases the quality of anesthesia compared with spinal anesthesia. They both disagree that epidural anesthesia increases maternal complications.

When spinal anesthesia is compared with epidural anesthesia, meta-analysis of the literature found that induction-to-delivery times are shorter for spinal anesthesia. The literature is equivocal regarding hypotension, umbilical pH values, and Apgar scores. The consultants and ASA members agree that epidural anesthesia increases time to skin incision and reduces the quality of anesthesia when compared with spinal anesthesia. They both disagree that epidural anesthesia increases maternal complications.

When CSE is compared with epidural anesthesia, meta-analysis of the literature found no differences in the frequency of hypotension or in 1-min Apgar scores; the literature is insufficient to evaluate outcomes associated with the use of CSE compared with spinal anesthesia. The consultants and ASA members agree that CSE anesthesia improves anesthesia and reduces time to skin incision when compared with *epidural* anesthesia. The ASA members are equivocal, but the consultants disagree that maternal side effects are reduced. The consultants and ASA members both disagree that CSE improves anesthesia compared with *spinal* anesthesia. The ASA members are equivocal, but the consultants disagree that maternal side effects are reduced. The consultants strongly agree and the ASA members agree that CSE compared with spinal anesthesia increases flexibility of prolonged procedures, and they both agree that the time to skin incision is increased.

Recommendations. The decision to use a particular anesthetic technique for cesarean delivery should be individualized, based on several factors. These include anesthetic, obstetric, or fetal risk factors (*e.g*., elective vs. emergency), the preferences of the patient, and the judgment of the anesthesiologist. Neuraxial techniques are preferred to GA for most cesarean deliveries. An indwelling epidural catheter may provide equivalent onset of anesthesia compared with initiation of spinal anesthesia for urgent cesarean delivery. If spinal anesthesia is chosen, pencil-point spinal needles should be used instead of cutting-bevel spinal needles. However, GA may be the most appropriate choice in some circumstances (*e.g*., profound fetal bradycardia, ruptured uterus, severe hemorrhage, severe placental abruption). Uterine displacement (usually left displacement) should be maintained until delivery regardless of the anesthetic technique used.

Intravenous Fluid Preloading. The literature supports and the consultants and ASA members agree that intravenous fluid preloading for spinal anesthesia reduces the frequency of maternal hypotension when compared with no fluid preloading.

Recommendations. Intravenous fluid preloading may be used to reduce the frequency of maternal hypotension after spinal anesthesia for cesarean delivery. Although fluid preloading reduces the frequency of maternal hypotension, initiation of spinal anesthesia should not be delayed to administer a fixed volume of intravenous fluid.

Ephedrine or Phenylephrine. The literature supports the administration of ephedrine and suggests that phenylephrine is effective in reducing maternal hypotension during neuraxial anesthesia for cesarean delivery. The literature is equivocal regarding the relative frequency of patients with breakthrough hypotension when infusions of ephedrine are compared with phenylephrine; however, lower umbilical cord pH values are reported after ephedrine administration. The consultants agree and the ASA members strongly agree that ephedrine is acceptable for treating hypotension during neuraxial anesthesia. The consultants strongly agree and the ASA members agree that phenylephrine is an acceptable agent for the treatment of hypotension.

Recommendations. Intravenous ephedrine and phenylephrine are both acceptable drugs for treating hypotension during neuraxial anesthesia. In the absence of maternal bradycardia, phenylephrine may be preferable because of improved fetal acid-base status in uncomplicated pregnancies.

Neuraxial Opioids for Postoperative Analgesia. For improved postoperative analgesia after cesarean delivery during epidural anesthesia, the literature supports the use of epidural opioids compared with intermittent injections of intravenous or intramuscular opioids. However, a higher frequency of pruritus was found with epidural opioids. The literature is insufficient to evaluate the impact of epidural opioids compared with intravenous PCA. In addition, the literature is insufficient to evaluate spinal opioids compared with parenteral opioids. The consultants strongly agree and the ASA members agree that neuraxial opioids for postoperative analgesia improve analgesia and maternal satisfaction.

Recommendations. For postoperative analgesia after neuraxial anesthesia for cesarean delivery, neuraxial opioids are preferred over intermittent injections of parenteral opioids.

VI. Postpartum Tubal Ligation

There is insufficient literature to evaluate the benefits of neuraxial anesthesia compared with GA for postpartum tubal ligation. In addition, the literature is insufficient to evaluate the impact of the timing of a postpartum tubal ligation on maternal outcome. The consultants and ASA members both agree that neuraxial anesthesia for postpartum tubal ligation reduces complications compared with GA. The ASA members are equivocal but the consultants agree that a postpartum tubal ligation within 8 h of delivery *does not* increase maternal complications.

Recommendations. For postpartum tubal ligation, the patient should have no oral intake of solid foods within 6–8 h of the surgery, depending on the type of food ingested (*e.g.*, fat content). Aspiration prophylaxis should be considered. Both the timing of the procedure and the decision to use a particular anesthetic technique (*i.e.*, neuraxial vs. general) should be individualized, based on anesthetic risk factors, obstetric risk factors (*e.g.*, blood loss), and patient preferences. However, neuraxial techniques are preferred to GA for most postpartum tubal ligations. The anesthesiologist should be aware that gastric emptying will be delayed in patients who have received opioids during labor, and that an epidural catheter placed for labor may be more likely to fail with longer postdelivery time intervals. If a postpartum tubal ligation is to be performed before the patient is discharged from the hospital, the procedure should not be attempted at a time when it might compromise other aspects of patient care on the labor and delivery unit.

TABLE 1 Suggested Resources for Obstetric Hemorrhagic Emergencies

- Large-bore intravenous catheters
- Fluid warmer
- Forced-air body warmer
- Availability of blood bank resources
- Equipment for infusing intravenous fluids and blood products rapidly. Examples include, but are not limited to, hand-squeezed fluid chambers, hand-inflated pressure bags, and automatic infusion devices

The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and health-care facility.

VII. Management of Obstetric and Anesthetic Emergencies

Resources for Management of Hemorrhagic Emergencies. Observational studies and case reports suggest that the availability of resources for hemorrhagic emergencies may be associated with reduced maternal complications. The consultants and ASA members both strongly agree that the availability of resources for managing hemorrhagic emergencies reduces maternal complications.

Recommendations. Institutions providing obstetric care should have resources available to manage hemorrhagic emergencies (table 1). In an emergency, the use of type-specific or O negative blood is acceptable. In cases of intractable hemorrhage when banked blood is not available or the patient refuses banked blood, intraoperative cell-salvage should be considered if available.

Central Invasive Hemodynamic Monitoring. There is insufficient literature to examine whether pulmonary artery catheterization is associated with improved maternal, fetal, or neonatal outcomes in patients with pregnancy-related hypertensive disorders. The literature is silent regarding the management of obstetric patients with central venous catheterization alone. The consultants and ASA members agree that the routine use of central venous or pulmonary artery catheterization does not reduce maternal complications in severely preeclamptic patients.

TABLE 2 Suggested Resources for Airway Management during Initial Provision of Neuraxial Anesthesia

- Laryngoscope and assorted blades
- Endotracheal tubes, with stylets
- Oxygen source
- Suction source with tubing and catheters
- Self-inflating bag and mask for positive-pressure ventilation
- Medications for blood pressure support, muscle relaxation, and hypnosis
- Qualitative carbon dioxide detector
- Pulse oximeter

The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and health-care facility.

TABLE 3 Suggested Contents of a Portable Storage Unit for Difficult Airway Management for Cesarean Delivery Rooms

- Rigid laryngoscope blades of alternate design and size from those routinely used
- Laryngeal mask airway
- Endotracheal tubes of assorted size
- Endotracheal tube guides. Examples include, but are not limited to, semirigid stylets with or without a hollow core for jet ventilation, light wands, and forceps designed to manipulate the distal portion of the endotracheal tube.
- Retrograde intubation equipment
- At least one device suitable for emergency nonsurgical airway ventilation. Examples include, but are not limited to, a hollow jet ventilation stylet with a transtracheal jet ventilator, and a supraglottic airway device (*e.g.*, Combitube®, Intubating LMA [*Fastrach*™])
- Fiberoptic intubation equipment
- Equipment suitable for emergency surgical airway access (*e.g.*, cricothyrotomy)
- An exhaled carbon dioxide detector
- Topical anesthetics and vasoconstrictors

The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and health-care facility.

Adapted from Practice guidelines for management of the difficult airway: An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Anesthesiology 2003; 98:1269–77.

Recommendations. The decision to perform invasive hemodynamic monitoring should be individualized and based on clinical indications that include the patient's medical history and cardiovascular risk factors. The Task Force recognizes that not all practitioners have access to resources for use of central venous or pulmonary artery catheters in obstetric units.

Equipment for Management of Airway Emergencies. Case reports suggest that the availability of equipment for the management of airway emergencies may be associated with reduced maternal, fetal, and neonatal complications. The consultants and ASA members both strongly agree that the immediate availability of equipment for the management of airway emergencies reduces maternal, fetal, and neonatal complications.

Recommendations. Labor and delivery units should have personnel and equipment readily available to manage airway emergencies, to include a pulse oximeter and qualitative carbon dioxide detector, consistent with the ASA Practice Guidelines for Management of the Difficult Airway.** Basic airway management equipment should be immediately available during the provision of neuraxial analgesia (table 2). In addition, portable equipment for difficult airway management should be readily available in the operative area of labor and delivery units (table 3). The anesthesiologist should have a preformulated strategy for intubation of the difficult airway. When tracheal intubation has failed, ventilation with mask and cricoid pressure, or with a laryngeal mask airway or supraglottic airway device (*e.g.*, Combitube®, Intubating LMA [*Fastrach*™]) should be considered for maintaining an airway and ventilating the lungs. If it is not possible to ventilate or awaken the patient, an airway should be created surgically.

Cardiopulmonary Resuscitation. The literature is insufficient to evaluate the efficacy of cardiopulmonary resuscitation in the obstetric patient during labor and delivery. In cases of cardiac arrest, the American Heart Association has stated that 4–5 min is the maximum time rescuers will have to determine whether the arrest can be reversed by Basic Life Support and Advanced Cardiac Life Support interventions.†† Delivery of the fetus may improve cardiopulmonary resuscitation of the mother by relieving aortocaval compression. The American Heart Association further notes that "the best survival rate for infants > 24 to 25 weeks in gestation occurs when the delivery of the infant occurs no more than 5 min after the mother's heart stops beating. This typically requires that the provider begin the hysterotomy about 4 min after cardiac arrest."†† The consultants and ASA members both strongly agree that the immediate availability of basic and advanced life-support equipment in the labor and delivery suite reduces maternal, fetal, and neonatal complications.

Recommendations. Basic and advanced life-support equipment should be immediately available in the operative area of labor and delivery units. If cardiac arrest occurs during labor and delivery, standard resuscitative measures should be initiated. In addition, uterine displacement (usually left displacement) should be maintained. If maternal circulation is not restored within

**American Society of Anesthesiologists Task Force on Management of the Difficult Airway: Practice guidelines for management of the difficult airway: An updated report. Anesthesiology 2003; 98:1269–77.

††2005 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Circulation 2005; 112(suppl):IV1–203.

4 min, cesarean delivery should be performed by the obstetrics team.

Appendix 1: Summary of Recommendations

I. Perianesthetic Evaluation

- Conduct a focused history and physical examination before providing anesthesia care
  - Maternal health and anesthetic history
  - Relevant obstetric history
  - Airway and heart and lung examination
  - Baseline blood pressure measurement
  - Back examination when neuraxial anesthesia is planned or placed
- A communication system should be in place to encourage early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team
- Order or require a platelet count based on a patient's history, physical examination, and clinical signs; a routine intrapartum platelet count is not necessary in the healthy parturient
- Order or require an intrapartum blood type and screen or cross-match based on maternal history, anticipated hemorrhagic complications (*e.g.*, placenta accreta in a patient with placenta previa and previous uterine surgery), and local institutional policies; a routine blood cross-match is not necessary for *healthy and uncomplicated* parturients
- The fetal heart rate should be monitored by a qualified individual before and after administration of neuraxial analgesia for labor; *continuous* electronic recording of the fetal heart rate may not be necessary in every clinical setting and may not be possible during initiation of neuraxial anesthesia

II. Aspiration Prophylaxis

- Oral intake of modest amounts of clear liquids may be allowed for uncomplicated laboring patients
- The uncomplicated patient undergoing elective cesarean delivery may have modest amounts of clear liquids up to 2 h before induction of anesthesia
- The volume of liquid ingested is less important than the presence of particulate matter in the liquid ingested
- Patients with additional risk factors for aspiration (*e.g.*, morbid obesity, diabetes, difficult airway) or patients at increased risk for operative delivery (*e.g.*, nonreassuring fetal heart rate pattern) may have further restrictions of oral intake, determined on a case-by-case basis
- Solid foods should be avoided in laboring patients
- Patients undergoing elective surgery (*e.g.*, scheduled cesarean delivery or postpartum tubal ligation) should undergo a fasting period for solids of 6–8 h depending on the type of food ingested (*e.g.*, fat content)
- Before surgical procedures (*i.e.*, cesarean delivery, postpartum tubal ligation), practitioners should consider timely administration of non-particulate antacids, H_2 receptor antagonists, and/or metoclopramide for aspiration prophylaxis

III. Anesthetic Care for Labor and Delivery

Neuraxial Techniques: Availability of Resources.

- When neuraxial techniques that include local anesthetics are chosen, appropriate resources for the treatment of complications (*e.g.*, hypotension, systemic toxicity, high spinal anesthesia) should be available
- If an opioid is added, treatments for related complications (*e.g.*, pruritus, nausea, respiratory depression) should be available
- An intravenous infusion should be established before the initiation of neuraxial analgesia or anesthesia and maintained throughout the duration of the neuraxial analgesic or anesthetic
- Administration of a fixed volume of intravenous fluid is not required before neuraxial analgesia is initiated

Timing of Neuraxial Analgesia and Outcome of Labor.

- Neuraxial analgesia should not be withheld on the basis of achieving an arbitrary cervical dilation, and should be offered on an individualized basis when this service is available
- Patients may be reassured that the use of neuraxial analgesia does not increase the incidence of cesarean delivery

Neuraxial Analgesia and Trial of Labor after Previous Cesarean Delivery.

- Neuraxial techniques should be offered to patients attempting vaginal birth after previous cesarean delivery
- For these patients, it is also appropriate to consider early placement of a neuraxial catheter that can be used later for labor analgesia or for anesthesia in the event of operative delivery

Early Insertion of Spinal or Epidural Catheter for Complicated Parturients.

- Early insertion of a spinal or epidural catheter for obstetric (*e.g.*, twin gestation or preeclampsia) or anesthetic indications (*e.g.*, anticipated difficult airway or obesity) should be considered to reduce the need for general anesthesia if an emergent procedure becomes necessary
  - In these cases, the insertion of a spinal or epidural catheter may precede the onset of labor or a patient's request for labor analgesia

Continuous Infusion Epidural (CIE) Analgesia.

- The selected analgesic/anesthetic technique should reflect patient needs and preferences, practitioner preferences or skills, and available resources
- CIE may be used for effective analgesia for labor and delivery

- When a continuous epidural infusion of local anesthetic is selected, an opioid may be added to reduce the concentration of local anesthetic, improve the quality of analgesia, and minimize motor block
- Adequate analgesia for uncomplicated labor and delivery should be administered with the secondary goal of producing as little motor block as possible by using dilute concentrations of local anesthetics with opioids
- The lowest concentration of local anesthetic infusion that provides adequate maternal analgesia and satisfaction should be administered

Single-injection Spinal Opioids with or without Local Anesthetics.

- Single-injection spinal opioids with or without local anesthetics may be used to provide effective, although time-limited, analgesia for labor when spontaneous vaginal delivery is anticipated
- If labor is expected to last longer than the analgesic effects of the spinal drugs chosen or if there is a good possibility of operative delivery, a catheter technique instead of a single injection technique should be considered
- A local anesthetic may be added to a spinal opioid to increase duration and improve quality of analgesia

Pencil-point Spinal Needles.

- Pencil-point spinal needles should be used instead of cutting-bevel spinal needles to minimize the risk of post–dural puncture headache

Combined Spinal–Epidural (CSE) Anesthetics.

- CSE techniques may be used to provide effective and rapid analgesia for labor

Patient-controlled Epidural Analgesia (PCEA).

- PCEA may be used to provide an effective and flexible approach for the maintenance of labor analgesia
- PCEA may be preferable to CIE for providing fewer anesthetic interventions, reduced dosages of local anesthetics, and less motor blockade than fixed-rate continuous epidural infusions
- PCEA may be used with or without a background infusion

IV. Removal of Retained Placenta

- In general, there is no preferred anesthetic technique for removal of retained placenta
  - If an epidural catheter is in place and the patient is hemodynamically stable, epidural anesthesia is preferable
- Hemodynamic status should be assessed before administering neuraxial anesthesia
- Aspiration prophylaxis should be considered
- Sedation/analgesia should be titrated carefully due to the potential risks of respiratory depression and pulmonary aspiration during the immediate postpartum period
- In cases involving major maternal hemorrhage, general anesthesia with an endotracheal tube may be preferable to neuraxial anesthesia
- Nitroglycerin may be used as an alternative to terbutaline sulfate or general endotracheal anesthesia with halogenated agents for uterine relaxation during removal of retained placental tissue
  - Initiating treatment with incremental doses of intravenous or sublingual (*i.e.*, metered dose spray) nitroglycerin may relax the uterus sufficiently while minimizing potential complications (*e.g.*, hypotension)

V. Anesthetic Choices for Cesarean Delivery

- Equipment, facilities, and support personnel available in the labor and delivery operating suite should be comparable to those available in the main operating suite
  - Resources for the treatment of potential complications (*e.g.*, failed intubation, inadequate analgesia, hypotension, respiratory depression, pruritus, vomiting) should be available in the labor and delivery operating suite
  - Appropriate equipment and personnel should be available to care for obstetric patients recovering from major neuraxial or general anesthesia
- The decision to use a particular anesthetic technique should be individualized based on anesthetic, obstetric, or fetal risk factors (*e.g.*, elective vs. emergency), the preferences of the patient, and the judgment of the anesthesiologist
  - Neuraxial techniques are preferred to general anesthesia for most cesarean deliveries
- An indwelling epidural catheter may provide equivalent onset of anesthesia compared with initiation of spinal anesthesia for urgent cesarean delivery
- If spinal anesthesia is chosen, pencil-point spinal needles should be used instead of cutting-bevel spinal needles
- General anesthesia may be the most appropriate choice in some circumstances (*e.g.*, profound fetal bradycardia, ruptured uterus, severe hemorrhage, severe placental abruption)
- Uterine displacement (usually left displacement) should be maintained until delivery regardless of the anesthetic technique used
- Intravenous fluid preloading may be used to reduce the frequency of maternal hypotension after spinal anesthesia for cesarean delivery
- Initiation of spinal anesthesia should not be delayed to administer a fixed volume of intravenous fluid
- Intravenous ephedrine and phenylephrine are both acceptable drugs for treating hypotension during neuraxial anesthesia
  - In the absence of maternal bradycardia, phenylephrine may be preferable because of improved fetal acid-base status in uncomplicated pregnancies
- For postoperative analgesia after neuraxial anesthesia for cesarean delivery, neuraxial opioids

are preferred over intermittent injections of parenteral opioids

VI. Postpartum Tubal Ligation

- For postpartum tubal ligation, the patient should have no oral intake of solid foods within 6-8 h of the surgery, depending on the type of food ingested (*e.g.*, fat content)
- Aspiration prophylaxis should be considered
- Both the timing of the procedure and the decision to use a particular anesthetic technique (*i.e.*, neuraxial *vs.* general) should be individualized, based on anesthetic risk factors, obstetric risk factors (*e.g.*, blood loss), and patient preferences
- Neuraxial techniques are preferred to general anesthesia for most postpartum tubal ligations
  - Be aware that gastric emptying will be delayed in patients who have received opioids during labor and that an epidural catheter placed for labor may be more likely to fail with longer postdelivery time intervals
- If a postpartum tubal ligation is to be performed before the patient is discharged from the hospital, the procedure should not be attempted at a time when it might compromise other aspects of patient care on the labor and delivery unit

VII. Management of Obstetric and Anesthetic Emergencies

- Institutions providing obstetric care should have resources available to manage hemorrhagic emergencies
  - In an emergency, the use of type-specific or O negative blood is acceptable
  - In cases of intractable hemorrhage when banked blood is not available or the patient refuses banked blood, intraoperative cell-salvage should be considered if available
  - The decision to perform invasive hemodynamic monitoring should be individualized and based on clinical indications that include the patient's medical history and cardiovascular risk factors
- Labor and delivery units should have personnel and equipment readily available to manage airway emergencies, to include a pulse oximeter and qualitative carbon dioxide detector, consistent with the ASA Practice Guidelines for Management of the Difficult Airway
  - Basic airway management equipment should be immediately available during the provision of neuraxial analgesia
  - Portable equipment for difficult airway management should be readily available in the operative area of labor and delivery units
  - The anesthesiologist should have a preformulated strategy for intubation of the difficult airway
  - When tracheal intubation has failed, ventilation with mask and cricoid pressure, or with a laryngeal mask airway or supraglottic airway device (*e.g.*, Combitube®, Intubating LMA [*Fastrach*™]) should be considered for maintaining an airway and ventilating the lungs
  - If it is not possible to ventilate or awaken the patient, an airway should be created surgically
- Basic and advanced life-support equipment should be immediately available in the operative area of labor and delivery units
- If cardiac arrest occurs during labor and delivery, standard resuscitative measures should be initiated
  - Uterine displacement (usually left displacement) should be maintained
  - If maternal circulation is not restored within 4 min, cesarean delivery should be performed by the obstetrics team

APPENDIX C

Optimal Goals for Anesthesia Care in Obstetrics*

COMMITTEE OF ORIGIN: OBSTETRICAL ANESTHESIA

This joint statement from the American Society of Anesthesiologists (ASA) and the American College of Obstetricians and Gynecologists (ACOG) has been designed to address issues of concern to both specialties. Good obstetric care requires the availability of qualified personnel and equipment to administer general or neuraxial anesthesia both electively and emergently. The extent and degree to which anesthesia services are available varies widely among hospitals. However, for any hospital providing obstetric care, certain optimal anesthesia goals should be sought. These include:

1. Availability of a licensed practitioner who is credentialed to administer an appropriate anesthetic whenever necessary. For many women, neuraxial anesthesia (epidural, spinal, or combined spinal epidural) will be the most appropriate anesthetic.
2. Availability of a licensed practitioner who is credentialed to maintain support of vital functions in any obstetric emergency.
3. Availability of anesthesia and surgical personnel to permit the start of a cesarean delivery within 30 minutes of deciding to perform the procedure.
4. Because the risks associated with trial of labor after cesarean delivery (TOLAC) and uterine rupture may be unpredictable, the immediate availability of appropriate facilities and personnel (including obstetric anesthesia, nursing personnel, and a physician capable of monitoring labor and performing cesarean delivery, including an emergency cesarean delivery) is optimal. When resources for immediate cesarean delivery are not available, patients considering TOLAC should discuss the hospital's resources and availability of obstetric, anesthetic, pediatric and nursing staff with their obstetric provider[1]; patients should be clearly informed of the potential increase in risk and the management alternatives. The definition of immediately available personnel and facilities remains a local decision based on each institution's available resources and geographic location.
5. Appointment of qualified anesthesiologist to be responsible for all anesthetics administered. There are many obstetric units where obstetricians or obstetrician-supervised nurse anesthetists administer labor anesthetics. The administration of general or neuraxial anesthesia requires both medical judgment and technical skills. Thus, a physician with privileges in anesthesiology should be readily available.

Persons administering or supervising obstetric anesthesia should be qualified to manage the infrequent but occasionally life-threatening complications of neuraxial anesthesia such as respiratory and cardiovascular failure, toxic local anesthetic convulsions, or vomiting and aspiration. Mastering and retaining the skills and knowledge necessary to manage these complications require adequate training and frequent application.

To ensure the safest and most effective anesthesia for obstetric patients, the Director of Anesthesia Services, with the approval of the medical staff, should develop and enforce written policies regarding provision of obstetric anesthesia. These include:

1. A qualified physician with obstetric privileges to perform operative vaginal or cesarean delivery should be readily available during administration of anesthesia. Readily available should be defined by each institution within the context of its resources and geographic location. Neuraxial and/or general anesthesia should not be administered until the patient has been examined and the fetal status and progress of labor evaluated by a qualified individual. A physician with obstetric privileges who concurs with the patient's management and has knowledge of the maternal and fetal status and the progress of labor should be responsible for midwifery back up in hospital settings that utilize certified nurse midwives/ certified midwives as obstetric providers.
2. Availability of equipment, facilities, and support personnel equal to that provided in the surgical suite. This should include the availability of a properly equipped and staffed recovery room capable of receiving and caring for all patients recovering from neuraxial or general anesthesia. Birthing facilities, when used for labor services or surgical anesthesia, must be appropriately equipped to provide

*Approved by the ASA House of Delegates on October 17, 2007 and last amended on October 20, 2010.

safe anesthetic care during labor and delivery or postanesthesia recovery care.

3. Personnel, other than the surgical team, should be immediately available to assume responsibility for the depressed newborn. The surgeon and anesthesiologist are responsible for the mother and may not be able to leave her to care for the newborn, even when a neuraxial anesthetic functioning adequately. Individuals qualified to perform neonatal resuscitation should demonstrate:
   - 3.1 Proficiency in rapid and accurate evaluation of the newborn condition, including Apgar scoring.
   - 3.2 Knowledge of the pathogenesis of a depressed newborn (acidosis, drugs, hypovolemia, trauma, anomalies, and infection), as well as specific indications for resuscitation.
   - 3.3 Proficiency in newborn airway management, laryngoscopy, endotracheal intubations, suctioning of airways, artificial vertilation, cardiac massage, and maintenance of thermal stability.

In larger maternity units and those functioning as high-risk centers, 24-hour in-house anesthesia, obstetric and neonatal specialists are usually necessary. Preferably, the obstetric anesthesia services should be directed by an anesthesiologist with special training or experience in obstetric anesthesia. These units will also frequently require the availability of more sophisticated monitoring equipment and specially trained nursing personnel.

A survey jointly sponsored by ASA and ACOG found that many hospitals in the United States have not yet achieved the goals mentioned previously. Deficiencies were most evident in smaller delivery units. Some small delivery units are necessary because of geographic considerations. Currently, approximately 34% of hospitals providing obstetric care have fewer than 500 deliveries per year.[2] Providing comprehensive care for obstetric patients in these small units is extremely inefficient, not cost-effective and frequently impossible. Thus, the following recommendations are made:

1. Whenever possible, smaller units should consolidate.
2. When geographic factors require the existence of smaller units, these units should be part of a well-established regional perinatal system.

The availability of the appropriate personnel to assist in the management of a variety of obstetric problems is a necessary feature of good obstetric care. The presence of a pediatrician or other trained physician at a high-risk cesarean delivery to care for the newborn or the availability of an anesthesiologist during active labor and delivery when TOLAC is attempted and at a breech or multifetal delivery are examples. Frequently, these physicians spend a considerable amount of time standing by for the possibility that their services may be needed emergently, but may ultimately not be required to perform the tasks for which they are present. Reasonable compensation for these standby services is justifiable and necessary.

A variety of other mechanisms have been suggested to increase the availability and quality of anesthesia services in obstetrics. Improved hospital design, to place labor and delivery suites closer to the operating rooms, would allow for safer and more efficient anesthesia care, including supervision of nurse anesthetists. Anesthesia equipment in the labor and delivery area must be comparable to that in the operating room.

Finally, good interpersonal relations between obstetricians and anesthesiologists are important. Joint meetings between the two departments should be encouraged. Anesthesiologists should recognize the special needs and concerns of the obstetrician and obstetricians should recognize the anesthesiologist as a consultant in the management of pain and life-support measures. Both should recognize the need to provide high quality care for all patients.

APPENDIX D

Information Technology Resources for Obstetric Anesthesia Providers

William Camann, MD • Larry F. Chu, MD, MS (BCHM), MS (Epidemiology)

A variety of information technology–based resources exist for obstetric anesthesia providers. These websites offer information regarding clinical practice, ongoing research, and recent publications. This appendix should serve as a brief guide to some of these resources, which include websites, mobile computing applications, and social media resources such as Facebook and Twitter.

These sites were active at the time that this guide was prepared (October, 2013). The authors of this appendix, and the editors and publisher of this textbook, bear no responsibility for the accuracy (or lack thereof) of any information found in these sites. Publication of this list does not imply endorsement of these sites.

We have also included QR code technology that will allow users with mobile computing devices such as smartphones and tablets to scan the links of the printed page into their web browsers. Numerous QR code scanning applications are available for iOS and Android platforms. Finally, for long web addresses, we have used URL-shortening (Bit.ly) to facilitate web browser entry.

OBSTETRIC ANESTHESIOLOGY SOCIETIES

http://www.oaa-anaes.ac.uk

The Obstetric Anaesthetists Association (OAA). The OAA provides both education and training for anesthesia practitioners in the United Kingdom and other countries, and serves as a resource for women seeking information about analgesia for labor and anesthesia for cesarean delivery. Significant amounts of educational material are freely available for all users.

http://www.soap.org

The Society for Obstetric Anesthesia and Perinatology (SOAP). The SOAP is a subspecialty anesthesiology society based in the United States that promotes excellence in research, education and the clinical practice of obstetric anesthesiology and perinatology. Significant amounts of educational material are freely available for all users.

OTHER PROFESSIONAL SOCIETIES OF INTEREST

http://www.aap.org

The American Academy of Pediatrics (AAP). The AAP promotes the attainment of optimal physical, mental, and social health and well-being for all infants, children, adolescents, and young adults. Significant amounts of educational material are freely available.

http://www.acog.org

The American College of Obstetricians and Gynecologists (ACOG). The ACOG promotes health care for women through policy and guideline development, education, and advocacy. A password is required for access to much of the online information, including committee opinions and practice bulletins and guidelines.

http://www.asahq.org

ASA OB Anesthesia practice guidelines

The American Society of Anesthesiologists (ASA). The ASA encourages education, research, and scientific progress in anesthesiology. The ASA strives to be an advocate for all patients who require anesthesia or relief from pain. The majority of documents, policies, and guidelines are freely available; some sections require a password for access. The ASA practice guidelines for obstetric anesthesia can be found at https://ecommerce.asahq.org/p-119-practice-guidelines-for-obstetric-anesthesia.aspx (shortened URL: http://bit.ly/SnsTWu).

http://www.asra.com

The American Society of Regional Anesthesia and Pain Medicine (ASRA). The ASRA provides clinical and professional education for physicians and scientists, promotes excellence in patient care, and encourages research to advance the scientific basis of regional anesthesia and pain medicine. The ASRA consensus statement on regional (neuraxial) anesthesia in the anticoagulated patient can be found at http://www.asra.com/consensus-statements/2.html. The ASRA consensus statements regarding infectious complications of neuraxial blockade can be found at http://asra.com/consensus-statements/3.html.

http://www.apsf.org/

The Anesthesia Patient Safety Foundation (APSF). The APSF seeks to improve patient safety during anesthesia care by encouraging and conducting research and education, programs and campaigns, and national and international exchange of information and ideas. Significant amounts of educational material are freely available for all users. The APSF Newsletter can be found at http://www.apsf.org/resource_center/newsletters.mspx.

http://bit.ly/bTdBYs

The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN). The AWHONN seeks to improve the health of women and newborns and to strengthen the nursing profession through advocacy, research, education, and provision of other professional and clinical resources for nurses and other health care professionals. Some content is freely available for all users. The AWHONN position statement on the role of the registered nurse in the care of the pregnant woman receiving analgesia/anesthesia by neuraxial catheter techniques is available at http://bit.ly/XtA1P5.

http://www.cas.ca/

The Canadian Anesthesiologists' Society (CAS). The CAS promotes science, vigilance, and compassion in the practice of anesthesiology. Significant amounts of information (including practice guidelines) are freely available for all users. The CAS guidelines for regional (neuraxial) analgesia in obstetric patients can be found at http://www.cas.ca/members/sign_in/guidelines/practice_of_anesthesia/default.asp?load=obstetrical_regional_analgesia.

http://www.iars.org

The International Anesthesia Research Society (IARS). The IARS encourages the development and dissemination of current, state-of-the-art basic and clinical research data and the newest advances in all areas of clinical anesthesia care.

http://www.ifmss.org

The International Fetal Medicine and Surgery Society (IFMSS). The IFMSS promotes education and research related to the field of fetal diagnosis and therapy.

http://www.nasom.org

The North American Society of Obstetric Medicine (NASOM). The NASOM promotes and supports research collaboration, communication, and teaching concerning the medical care of pregnant women. General internists from the United States and Canada form the core membership of the society.

http://www.smfm.org

The Society for Maternal-Fetal Medicine (SMFM). The SMFM seeks to promote and expand education and research in maternal-fetal medicine and encourages the exchange of new ideas and research concerning the most recent approaches and treatments for obstetric problems.

http://www.somanz.org

The Society of Obstetric Medicine of Australia and New Zealand (SOMANZ). The SOMANZ seeks to advance clinical and scientific knowledge of hypertensive diseases and medical disorders in pregnancy and to foster collaboration with other regional and international societies interested in hypertension in pregnancy and obstetric medicine.

GOVERNMENTAL REGULATORY AND INFORMATIONAL WEBSITES

http://www.cdc.gov/

The Centers for Disease Control and Prevention (CDC). The CDC provides extensive information on most health-related subjects. For example, information is available on assisted reproductive technologies, birth rates, birth defects, breast-feeding, medication use during pregnancy, nutrition in pregnancy, preterm labor, maternal mortality, and various disease processes in pregnancy.

http://www.cemach.org.uk

The Confidential Enquiries into Maternal and Child Health (CEMACH). The CEMACH provides extensive information on maternal and perinatal mortality statistics, including anesthesia-related deaths, in the United Kingdom.

JOURNALS AND SCIENTIFIC LITERATURE

iTUNES PODCASTS

http://bit.ly/XW1MUj

Openanesthesia.org Podcast. Drs. Edward Nemergut and Robert Thiel from the Department of Anesthesiology at the University of Virginia host this podcast from Openanesthesia.org, an organization dedicated to promoting evidence-based medicine in anesthesiology, critical care, and pain management.

http://bit.ly/10lTg2p

The World of Anesthesia Podcast. Drs. Rajnish Gupta and Nahel Saied from the Department of Anesthesiology at Vanderbilt University host this podcast that discusses topics of general anesthesiology, critical care, and pain medicine.

http://bit.ly/ZQ1r5X

Medscape Anesthesia Podcasts. A collection of podcasts that cover various aspects of the specialty of anesthesiology, including clinical care, research, and politics.

http://bit.ly/11mNq06

The ASA Podcast Series. A series of podcasts from the American Society of Anesthesiologists that highlight the society's accomplishments and topics from its journal, *Anesthesiology*.

http://bit.ly/XW3sNt

The California Society of Anesthesiologists Podcasts. A collection of lectures from annual meetings of the California Society of Anesthesiologists.

SOCIAL MEDIA AND VIDEO PAGES

http://on.fb.me/XW4dWQ

The SOAP Facebook Page. The Society for Obstetric Anesthesia and Perinatology (SOAP) was founded in 1968 to provide a forum for discussion of problems unique to the peripartum period. Their Facebook page brings their community into the social media age with regular postings of SOAP-related information for their members and the public at large.

http://bit.ly/UR1wkI

The SOAP Video Page (Anesthesia Illustrated). This website has a large number of obstetric anesthesia videos including many of the major presentations from the Sol Shnider and SOAP annual meetings.

http://on.fb.me/XqaNRz

Obstetric Anesthesia Facebook Interest Page. This Facebook page is dedicated to the science, practice, and research of obstetric anesthesia and is hosted by Dr. Alex Butwick from the Department of Anesthesia, Stanford University School of Medicine.

http://on.fb.me/13mfzno

***The Obstetric Anesthesia Digest* Facebook Page.** *Obstetric Anesthesia Digest* posts frequent updates linking to original research studies from the peer-reviewed literature on topics related to the practice of obstetric anesthesia.

http://twitter.com/acognews

The American College of Obstetricians and Gynecologists (ACOG) Twitter Page. The ACOG uses Twitter to post updates related to ACOG's activities, as well as popular news items related to obstetric medicine.

http://on.fb.me/VPSrdL

The American College of Obstetricians and Gynecologists (ACOG) Facebook Page. On its Facebook page, the ACOG updates the public on ACOG activities, research findings, and public health initiatives related to obstetric and gynecologic medicine.

iOS AND ANDROID APPLICATIONS

http://bit.ly/WJjLGB

***Anesthesiology* iOS Application.** This application provides iPad access to journal subscribers of the journal *Anesthesiology*. Issues older than 6 months are available to non-subscribers free of charge.

http://bit.ly/13mgzrt

***Anesthesia & Analgesia* iOS Application.** This application provides iPad access to journal subscribers of *Anesthesia & Analgesia*. Issues older than 6 months are available to non-subscribers free of charge.

http://bit.ly/13nHfHt

Anesthesia 411 iOS Application. Anesthesia 411 provides information on 125 of the most common cases seen in the practice of anesthesiology. Topics include intravenous access, drug and drug administration, monitors, and specialized equipment.

http://bit.ly/XqcGgU

Crisis Code iOS Application. This application teaches the principles of crisis management for Advanced Cardiac Life Support.

http://bit.ly/UV2Fvu

CommunicatOR iOS Application. The application enhances communication between the anesthesia care providers and patients who do not speak the same language. Recordings of phrases commonly used during induction, emergence, and the provision of neuraxial anesthetic techniques are communicated to patients in their native language. This application also allows the patient to anticipate what is going to happen during a procedure.

http://bit.ly/WXbJuE

Pain Relief OAA: Android Application. This application gathers the Obstetric Anaesthetists' Association's information leaflets (translated into 35 languages) about pain relief and anesthesia for use by anesthesia providers, obstetricians, midwives, and mothers and their partners.

http://bit.ly/ZC37eC

Miniatlas Anesthesia Android Application. The application provides a library of detailed, high-quality images to support the daily clinical practice of anesthesiology by allowing patients to visualize procedures while the anesthesia provider is discussing them. These images can also be used for peer presentations or teaching and are supplemented with referenced texts.

http://bit.ly/Ubd6aw

Anesthesia Core Journals. This RSS-reader list provides summary headlines and/or abstracts of recent anesthesiology articles that have been indexed within journals under the category of Anesthesia and Emergency Medicine in the Abridged Index Medicus (AIM).
