CHESTNUT'S OBSTETRIC ANESTHESIA

CHESTNUT'S OBSTETRIC ANESTHESIA: PRINCIPLES AND PRACTICE

FIFTH EDITION

David H. Chestnut, MD
Professor of Anesthesiology
Chief, Division of Obstetric Anesthesiology
Vanderbilt University School of Medicine
Nashville, Tennessee

Formerly, Director of Medical Education
Gundersen Health System
Professor of Anesthesiology
Associate Dean for the Western Academic Campus
University of Wisconsin School of Medicine and Public Health
La Crosse, Wisconsin

Cynthia A. Wong, MD
Professor and Vice Chair of Anesthesiology
Northwestern University Feinberg School of Medicine
Section Chief for Obstetric Anesthesiology
Northwestern Memorial Hospital
Chicago, Illinois

Lawrence C. Tsen, MD
Associate Professor of Anaesthesia
Harvard Medical School
Vice Chair, Faculty Development and Education
Director of Anesthesia, Center for Reproductive Medicine
Department of Anesthesiology, Perioperative and Pain Medicine
Associate Director, Center for Professionalism and Peer Support
Brigham and Women's Hospital
Boston, Massachusetts

Warwick D. Ngan Kee, BHB, MBChB, MD, FANZCA, FHKCA, FHKAM
Professor
Department of Anaesthesia and Intensive Care
The Chinese University of Hong Kong
Shatin, Hong Kong, China

Yaakov Beilin, MD
Professor of Anesthesiology and Obstetrics Gynecology and Reproductive Sciences
Director of Obstetric Anesthesiology
Vice Chair for Quality
Department of Anesthesiology
Icahn School of Medicine at Mount Sinai
New York, New York

Jill M. Mhyre, MD
Associate Professor of Anesthesiology
The University of Arkansas for Medical Sciences
Little Rock, Arkansas

Naveen Nathan, MD*
Assistant Professor of Anesthesiology
Northwestern University Feinberg School of Medicine
Northwestern Memorial Hospital
Chicago, Illinois

*Graphics Editor

CHESTNUT'S OBSTETRIC ANESTHESIA: PRINCIPLES AND PRACTICE, FIFTH EDITION ISBN: 978-1-4557-4866-2

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Acknowledgment of Contributors to Previous Editions

The editors gratefully acknowledge the work of the following authors who contributed to chapters of previous editions of this book. Their expertise, wisdom, and scholarship have provided the foundation for the fifth edition.

Chapter 2: Physiologic Changes of Pregnancy
Kenneth A. Conklin, MD, PhD
Anita Backus Chang, MD

Chapter 3: Uteroplacental Blood Flow
James C. Eisenach, MD
Carl P. Weiner, MD

Chapter 4: The Placenta: Anatomy, Physiology, and Transfer of Drugs
Norman L. Herman, MD, PhD

Chapter 5: Fetal Physiology
Andrew P. Harris, MD, MHS
Kenneth E. Nelson, MD

Chapter 6: Antepartum Fetal Assessment and Therapy
Katharine D. Wenstrom, MD
Katherine Campbell, MD

Chapter 9: Neonatal Assessment and Resuscitation
Rhonda L. Zuckerman, MD
Marvin Cornblath, MD

Chapter 10: Fetal and Neonatal Neurologic Injury
Donald H. Penning, MD

Chapter 12: Spinal, Epidural, and Caudal Anesthesia: Anatomy, Physiology, and Technique
David L. Brown, MD
Vijaya Gottumkkala, MBBS, MD, FRCA

Chapter 13: Local Anesthetics and Opioids
Hilda Pedersen, MD
Mieczyslaw Finster, MD

Chapter 14: Pharmacology and Nonanesthetic Drugs during Pregnancy and Lactation
Jennifer R. Niebyl, MD

Chapter 15: *In Vitro* Fertilization and Other Assisted Reproductive Technology
Robert D. Vincent, Jr., MD

Chapter 16: Problems of Early Pregnancy
Robert C. Chantigian, MD
Paula D. M. Chantigian, MD

Chapter 17: Nonobstetric Surgery during Pregnancy
Sheila E. Cohen, MB, ChB, FRCA
Norah N. Naughton, MD

Chapter 18: Obstetric Management of Labor and Vaginal Delivery
Frank J. Zlatnik, MD

Chapter 20: The Pain of Childbirth and Its Effect on the Mother and the Fetus
Theodore G. Cheek, MD
Brett B. Gutsche, MD
Robert R. Gaiser, MD

Chapter 22: Systemic Analgesia: Parenteral and Inhalational Agents
Marsha L. Wakefield, MD
Tanya Jones, MB, ChB, MRCP, FRCA

Chapter 23: Epidural and Spinal Analgesia/Anesthesia for Labor and Vaginal Delivery
Beth Glosten, MD
Brian K. Ross, MD, PhD
David H. Chestnut, MD
Edward T. Riley, MD
Linda S. Polley, MD

Chapter 26: Anesthesia for Cesarean Delivery
Laurence S. Reisner, MD
Dennis Lin, MD
Krzysztof M. Kuczkowski, MD

Chapter 27: Postoperative and Chronic Pain: Systemic and Regional Analgesic Techniques
Robert K. Parker, DO
David Hepner, MD
Sunil Eappen, MD

Chapter 28: Postoperative Analgesia: Epidural and Spinal Techniques
Raymond S. Sinatra, MD, PhD
Chakib M. Ayoub, MD

Chapter 29: Aspiration: Risk, Prophylaxis, and Treatment
Thomas S. Guyton, MD
Charles P. Gibbs, MD

Chapter 30: The Difficult Airway: Risk, Assessment, Prophylaxis, and Management
Sheila D. Cooper, MD
Jonathan L. Benumof, MD
Laurence S. Reisner, MD
Krzysztof M. Kuczkowski, MD
John A. Thomas, MD
Carin A. Hagberg, MD

Chapter 31: Postpartum Headache

Preface

The first edition of this text was published exactly 20 years ago. In the preface to the first edition, I identified two goals: (1) to collate the most important information that anesthesia providers should know about obstetrics, and (2) to prepare a thorough and user-friendly review of anesthesia care for obstetric patients. I asked each contributor to write a thorough, scholarly discussion of the subject and also to provide clear, practical recommendations for clinical practice. Those goals remain intact in the fifth edition, and the result is a comprehensive resource for all anesthesia providers (and obstetricians) who provide care for pregnant women.

The fifth edition is an extensive revision with much new **content**. A new chapter discusses psychiatric disorders, 14 chapters have been rewritten from start to finish, and most other chapters have undergone substantial revision. The trauma chapter now includes a focused review of critical care medicine, and other chapters have been expanded to include discussions of obstetric pharmacology and chronic pain. The chapters on fetal physiology and fetal and neurologic injury have undergone extensive revision, as have the chapters on problems of early pregnancy, preterm labor, hemorrhage, embolic disorders, obesity, and airway management. The chapter on cardiovascular disease was rewritten by a cardiologist who is also an anesthesiologist. The chapter on hypertensive disorders not only underwent comprehensive revision, but also was moved so that it is now grouped with other obstetric complications. And the keystone chapters on neuraxial labor analgesia and cesarean delivery underwent extensive revision to include abundant new information that is highly relevant for clinical practice.

The fifth edition includes 26 new **contributors**. I am also happy to welcome three outstanding new editors: **Warwick D. Ngan Kee, BHB, MBChB, MD, FANZCA, FHKCA, FHKAM** (our first international editor), **Yaakov (Jake) Beilin, MD**, and **Jill M. Mhyre, MD**. Both **Cynthia A. Wong, MD**, and **Lawrence C. Tsen, MD**, have continued their work as editors, and Dr. Wong has assumed editorial responsibility equal to my own. Each chapter has been carefully reviewed by at least two editors, and we sought the input of all six editors for resolution of difficult issues. Altogether, the fifth edition reflects the collective wisdom of a diverse group of prominent anesthesiologists and obstetricians from 20 states and 7 countries.

The fifth edition **cover** again features a striking maternal-fetal image, which draws attention to the fact that the anesthesia provider and the obstetrician provide simultaneous care for two (or more) patients—both the mother and her unborn child(ren). The new cover image was created by an extraordinarily talented anesthesiologist and artist, **Naveen Nathan, MD**, who prepared abundant new illustrations (and revised existing illustrations) throughout the text. We are indebted to Dr. Nathan for his invaluable contributions as graphics editor for the fifth edition.

It remains gratifying to receive positive feedback on this text. At the risk of sounding self-congratulatory, I should like to summarize the three most common comments about the first four editions: The content is **comprehensive**, the material is both **current** and **relevant**, and the writing is **clear**. Indeed, the other editors and I place high value on clarity. I trust that you will conclude that the fifth edition meets and perhaps exceeds the standards set by the previous four editions.

The other editors and I would like to acknowledge the important roles of four groups of special people. First, we express our heartfelt thanks to the 79 distinguished and talented contributors to the fifth edition (including **Linda S. Polley, MD**, who helped edit the fourth edition), as well as the contributors to previous editions of this text. Second, we gratefully acknowledge the invaluable help provided by our competent and loyal assistants, including Jennifer Lee and Jodi Vogel. Third, we acknowledge the encouragement, expertise, and attention to detail provided by the professional production team at Elsevier. And finally, we should like to thank *you*, the readers, not only for your continued confidence in this text, but especially for your ongoing commitment to the provision of safe and compassionate care for pregnant women and their unborn children.

David H. Chestnut, MD

Micah 6:8

CHAPTER 1

The History of Obstetric Anesthesia

Donald Caton, MD

CHAPTER OUTLINE

For I heard a cry as of a woman in travail, anguish as of one bringing forth her first child, the cry of the daughter of Zion gasping for breath, stretching out her hands, "Woe is me!"

—JEREMIAH 4:31

"The position of woman in any civilization is an index of the advancement of that civilization; the position of woman is gauged best by the care given her at the birth of her child." So wrote Haggard[1] in 1929. If his thesis is true, Western civilization made a giant leap on January 19, 1847, when James Young Simpson used diethyl ether to anesthetize a woman with a deformed pelvis for delivery. This first use of a modern anesthetic for childbirth occurred a scant 3 months after Morton's historic demonstration of the anesthetic properties of ether at the Massachusetts General Hospital in Boston. Strangely enough, Simpson's innovation evoked strong criticism from contemporary obstetricians, who questioned its safety, and from many segments of the lay public, who questioned its wisdom. The debate over these issues lasted more than 5 years and influenced the future of obstetric anesthesia.[2]

JAMES YOUNG SIMPSON

Few people were better equipped than Simpson to deal with controversy. Just 36 years old, Simpson already had 7 years' tenure as Professor of Midwifery at the University of Edinburgh, one of the most prestigious medical schools of its day (Figure 1-1). By that time, he had established a reputation as one of the foremost obstetricians in Great Britain, if not the world. On the day he first used ether for childbirth, he also received a letter of appointment as Queen's Physician in Scotland. Etherization for childbirth was only one of Simpson's contributions. He also designed obstetric forceps (which still bear his name), discovered the anesthetic properties of chloroform, made important innovations in hospital architecture, and wrote a textbook on the practice of witchcraft in Scotland that was used by several generations of anthropologists.[3]

An imposing man, Simpson had a large head, a massive mane of hair, and the pudgy body of an adolescent. Contemporaries described his voice as "commanding," with a wide range of volume and intonation. Clearly Simpson had "presence" and "charisma." These attributes were indispensable to someone in his profession, because in the mid-nineteenth century, the role of science in the development of medical theory and practice was minimal; rhetoric resolved more issues than facts. The medical climate in Edinburgh was particularly contentious and vituperative. In this milieu, Simpson had trained, competed for advancement and recognition, and succeeded. The rigor of this preparation served him well. Initially, virtually every prominent obstetrician, including Montgomery of Dublin, Ramsbotham of London, Dubois of Paris, and Meigs of Philadelphia, opposed etherization for childbirth. Simpson called on all of his professional and personal finesse to sway opinion in the ensuing controversy.

MEDICAL OBJECTIONS TO THE USE OF ETHER FOR CHILDBIRTH

Shortly after Simpson administered the first obstetric anesthetic, he wrote, "It will be necessary to ascertain anesthesia's precise effect, both upon the action of the uterus and on the assistant abdominal muscles; its influence, if any, upon the child; whether it has a tendency to hemorrhage or other complications."[4] With this

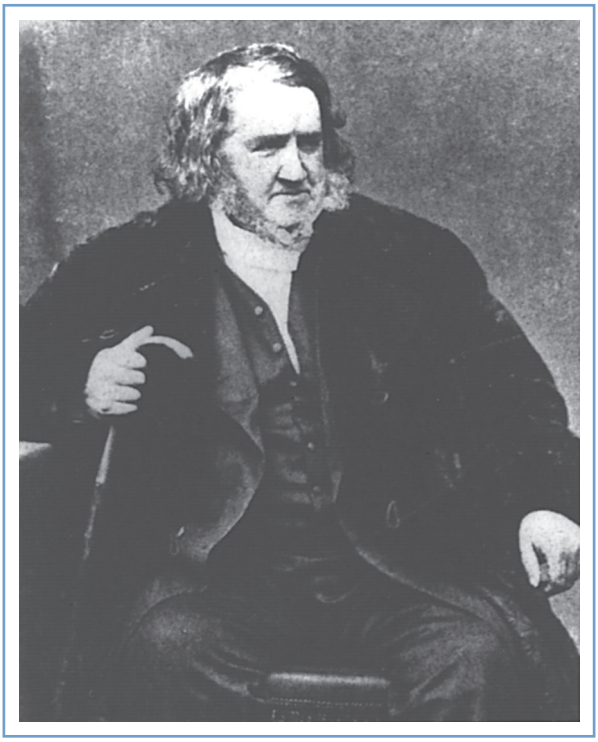

FIGURE 1-1 ■ James Young Simpson, the obstetrician who first administered a modern anesthetic for childbirth. He also discovered the anesthetic properties of chloroform. Many believe that he was the most prominent and influential physician of his day. (Courtesy Yale Medical History Library.)

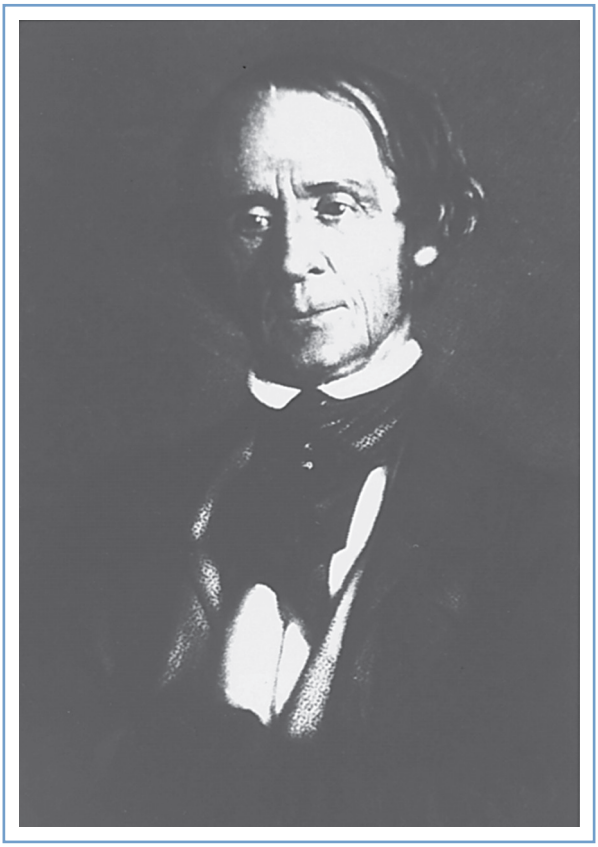

FIGURE 1-2 ■ Charles D. Meigs, the American obstetrician who opposed the use of anesthesia for obstetrics. He questioned the safety of anesthesia and said that there was no demonstrated need for it during a normal delivery. (Courtesy Wood-Library Museum.)

statement he identified the issues that would most concern obstetricians who succeeded him and thus shaped the subsequent development of the specialty.

Simpson's most articulate, persistent, and persuasive critic was Charles D. Meigs, Professor of Midwifery at Jefferson Medical College in Philadelphia (Figure 1-2). In character and stature, Meigs equaled Simpson. Born to a prominent New England family, Meigs' forebears included heroes of the American revolutionary war, the first governor of the state of Ohio, and the founder of the University of Georgia. His descendants included a prominent pediatrician, an obstetrician, and one son who served the Union Army as Quartermaster General during the Civil War.[5]

At the heart of the dispute between Meigs and Simpson was a difference in their interpretation of the nature of labor and the significance of labor pain. Simpson maintained that all pain, labor pain included, is without physiologic value. He said that pain only degrades and destroys those who experience it. In contrast, Meigs argued that labor pain has purpose, that uterine pain is inseparable from contractions, and that any drug that abolishes pain will alter contractions. Meigs also believed that pregnancy and labor are normal processes that usually end quite well. He said that physicians should therefore not intervene with powerful, potentially disruptive drugs (Figure 1-3). We must accept the statements of both men as expressions of natural philosophy, because neither had facts to buttress his position. Indeed, in 1847, physicians had little information of any sort about uterine function, pain, or the relationship between them. Studies of the anatomy and physiology of pain had just begun. It was only during the preceding 20 years that investigators had recognized that specific nerves and areas of the brain have different functions and that specialized peripheral receptors for painful stimuli exist.[2]

In 1850, more physicians expressed support for Meigs's views than for Simpson's. For example, Baron Paul Dubois[6] of the Faculty of Paris wondered whether ether, "after having exerted a stupefying action over the cerebrospinal nerves, could not induce paralysis of the muscular element of the uterus?" Similarly, Ramsbotham[7] of London Hospital said that he believed the "treatment of rendering a patient in labor completely insensible through the agency of anesthetic remedies … is fraught with extreme danger." These physicians' fears gained credence from the report by a special committee of the Royal Medical and Chirurgical Society documenting 123 deaths that "could be positively assigned to the inhalation of chloroform."[8] Although none involved obstetric patients, safety was on the minds of obstetricians.

The reaction to the delivery of Queen Victoria's eighth child in 1853 illustrated the aversion of the medical community to obstetric anesthesia. According to private records, John Snow anesthetized the Queen for the delivery of Prince Leopold at the request of her personal physicians. Although no one made a formal

announcement of this fact, rumors surfaced and provoked strong public criticism. Thomas Wakley, the irascible founding editor of *The Lancet*, was particularly incensed. He "could not imagine that anyone had incurred the awful responsibility of advising the administration of chloroform to her Majesty during a perfectly natural labour with a seventh child."[9] (It was her eighth child, but Wakley had apparently lost count—a forgivable error considering the propensity of the Queen to bear children.) Court physicians did not defend their decision to use ether. Perhaps not wanting a public confrontation, they simply denied that the Queen had received an anesthetic. In fact, they first acknowledged a royal anesthetic 4 years later when the Queen delivered her ninth and last child, Princess Beatrice. By that time, however, the issue was no longer controversial.[9]

PUBLIC REACTION TO ETHERIZATION FOR CHILDBIRTH

The controversy surrounding obstetric anesthesia was not resolved by the medical community. Physicians remained skeptical, but public opinion changed. Women lost their reservations, decided they wanted anesthesia, and virtually forced physicians to offer it to them. The change in the public's attitude in favor of obstetric anesthesia marked the culmination of a more general change in social attitudes that had been developing over several centuries.

Before the nineteenth century, pain meant something quite different from what it does today. Since antiquity, people had believed that all manner of calamities—disease, drought, poverty, and pain—signified divine retribution inflicted as punishment for sin. According to Scripture, childbirth pain originated when God punished Eve and her descendants for Eve's disobedience in the Garden of Eden. Many believed that it was wrong to avoid the pain of divine punishment. This belief was sufficiently prevalent and strong to retard acceptance of even the idea of anesthesia, especially for obstetric patients. Only when this tradition weakened did people seek ways to free themselves from disease and pain. In most Western countries, the transition occurred during the nineteenth century. Disease and pain lost their theologic connotations for many people and became biologic processes subject to study and control by new methods of science and technology. This evolution of thought facilitated the development of modern medicine and stimulated public acceptance of obstetric anesthesia.[10]

The reluctance that physicians felt about the administration of anesthesia for childbirth pain stands in stark contrast to the enthusiasm expressed by early obstetric patients. In 1847, Fanny Longfellow, wife of the American poet Henry Wadsworth Longfellow and the first woman in the United States anesthetized for childbirth, wrote:

> *I am very sorry you all thought me so rash and naughty in trying the ether. Henry's faith gave me courage, and I had heard such a thing had succeeded abroad, where the surgeons extend this great blessing more boldly and universally than our timid doctors.... This is certainly the greatest blessing of this age.*[11]

Queen Victoria, responding to news of the birth of her first grandchild in 1860 and perhaps remembering her own recent confinement, wrote, "What a blessing she [Victoria, her oldest daughter] had chloroform. Perhaps without it her strength would have suffered very much."[9] The new understanding of pain as a controllable biologic process left no room for Meigs's idea that pain might have physiologic value. The eminent nineteenth-century social philosopher John Stuart Mill stated that the "hurtful agencies of nature" promote good only by "inciting rational creatures to rise up and struggle against them."[12]

Simpson prophesied the role of public opinion in the acceptance of obstetric anesthesia, a fact not lost on his adversaries. Early in the controversy he predicted, "Medical men may oppose for a time the superinduction of anaesthesia in parturition but they will oppose it in vain; for certainly our patients themselves will force use of it upon the profession. The whole question is, even now, one merely of time."[13] By 1860, Simpson's prophecy came true; anesthesia for childbirth became part of medical practice by public acclaim, in large part in response to the demands of women.

OPIOIDS AND OBSTETRICS

The next major innovation in obstetric anesthesia came approximately 50 years later. *Dämmerschlaff*, which means "twilight sleep," was a technique developed by von Steinbüchel[14] of Graz and popularized by Gauss[15] of Freiberg. It combined opioids with scopolamine to make women amnestic and somewhat comfortable during labor (Figure 1-4). Until that time, opioids had been used sparingly for obstetrics. Although opium had been part of the medical armamentarium since the Roman Empire, it was not used extensively, in part because of the difficulty of obtaining consistent results with the crude extracts available at that time. Therapeutics made a substantial advance in 1809 when Sertürner, a German pharmacologist, isolated codeine and morphine from a crude extract of the poppy seed. Methods for administering the drugs remained unsophisticated. Physicians gave morphine orally or by a method resembling vaccination, in which they placed a drop of solution on the skin and then made multiple small puncture holes with a sharp instrument to facilitate absorption. In 1853, the year Queen Victoria delivered her eighth child, the syringe and hollow metal needle were developed. This technical advance simplified the administration of opioids and facilitated the development of twilight sleep approximately 50 years later.[16]

Although reports of labor pain relief with hypodermic morphine appeared as early as 1868, few physicians favored its use. For example, in an article published in *Transactions of the Obstetrical Society of London*, Sansom[17] listed the following four agents for relief of labor pain: (1) carbon tetrachloride, the use of which he favored; (2) bichloride of methylene, which was under evaluation; (3) nitrous oxide, which had been introduced recently by Klikgowich of Russia; and (4) chloroform. He did not mention opioids, but neither did he mention diethyl ether, which many physicians still favored. Similarly, Gusserow,[18] a prominent German obstetrician, described using salicylic acid but not morphine for labor pain. (Von Baeyer did not introduce acetylsalicylic acid to medical practice until 1899.) In retrospect, von Steinbüchel's and Gauss's descriptions of twilight sleep in the first decade of the century may have been important more for popularizing morphine than for suggesting that scopolamine be given with morphine.

Physicians reacted to twilight sleep as they had reacted to diethyl ether several years earlier. They resisted it, questioning whether the benefits justified the risks. Patients also reacted as they had before. Not aware of, or perhaps not concerned with, the technical considerations that confronted physicians, patients harbored few doubts and persuaded physicians to use it, sometimes against the physicians' better judgment. The confrontation between physicians and patients was particularly strident in the United States. Champions of twilight sleep lectured throughout the country and published articles in popular magazines. Public enthusiasm for the therapy subsided slightly after 1920, when a prominent advocate of the method died during childbirth. She was given twilight sleep, but her physicians said that her death was unrelated to any complication from its use. Whatever anxiety this incident may have created in the minds of patients, it did not seriously diminish their resolve. Confronted by such firm insistence, physicians acquiesced and used twilight sleep with increasing frequency.[19,20]

Although the reaction of physicians to twilight sleep resembled their reaction to etherization, the medical milieu in which the debate over twilight sleep developed was quite different from that in which etherization was deliberated. Between 1850 and 1900, medicine had changed, particularly in Europe. Physiology, chemistry, anatomy, and bacteriology became part of medical theory and practice. Bright students from America traveled to leading clinics in Germany, England, and France. They returned with new facts and methods that they used to examine problems and critique ideas. These developments became the basis for the revolution in American medical education and practice launched by the Flexner report published in 1914.[21]

Obstetrics also changed. During the years preceding World War I, it had earned a reputation as one of the most exciting and scientifically advanced specialties. Obstetricians experimented with new drugs and techniques. They recognized that change entails risk, and they examined each innovation more critically. In addition, they turned to science for information and methods to help them solve problems of medical management. Developments in obstetric anesthesia reflected this change in strategy. New methods introduced during this time stimulated physicians to reexamine two important but unresolved issues, the effects of drugs on the child, and the relationship between pain and labor.

THE EFFECTS OF ANESTHESIA ON THE NEWBORN

Many physicians, Simpson included, worried that anesthetic drugs might cross the placenta and harm the newborn. Available information justified their concern. The idea that gases cross the placenta appeared long before the discovery of oxygen and carbon dioxide. In the sixteenth century, English physiologist John Mayow[22]

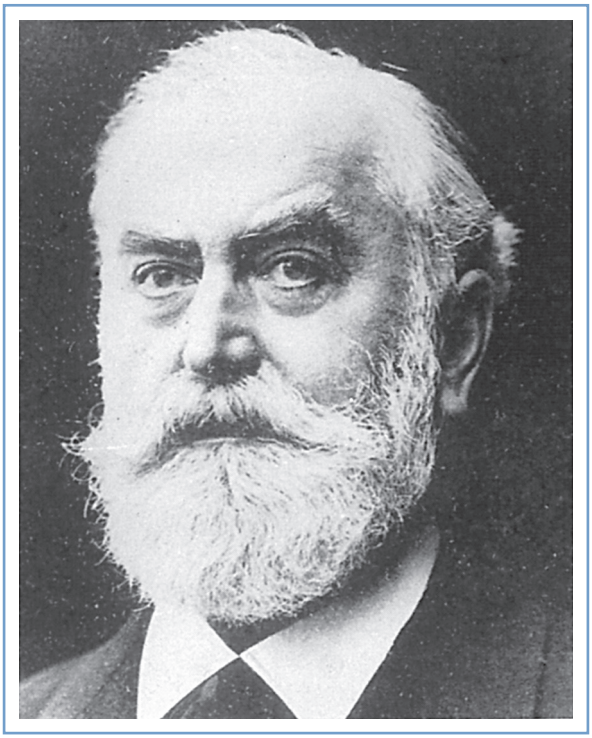

FIGURE 1-5 ■ Paul Zweifel, the Swiss-born obstetrician who performed the first experiments that chemically demonstrated the presence of chloroform in the umbilical blood and urine of infants delivered by women who had been anesthetized during labor. (Courtesy J.F. Bergmann-Verlag, München, Germany.)

suggested that "nitro aerial" particles from the mother nourish the fetus. By 1847, physiologists had corroborative evidence. Clinical experience gave more support. John Snow[23] observed depressed neonatal breathing and motor activity and smelled ether on the breath of neonates delivered from mothers who had been given ether. In an early paper, he surmised that anesthetic gases cross the placenta. Regardless, some advocates of obstetric anesthesia discounted the possibility. For example, Harvard professor Walter Channing denied that ether crossed the placenta because he could not detect its odor in the cut ends of the umbilical cord. Oddly enough, he did not attempt to smell ether on the child's exhalations as John Snow had done.[24]

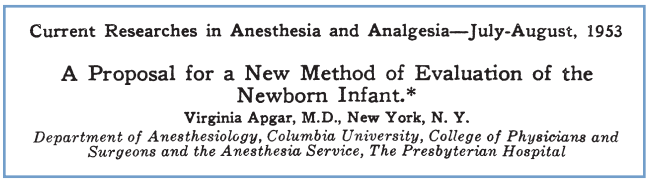
In 1874, Swiss obstetrician Paul Zweifel[25] published an account of work that finally resolved the debate about the placental transfer of drugs (Figure 1-5). He used a chemical reaction to demonstrate the presence of chloroform in the umbilical blood of neonates. In a separate paper, Zweifel[26] used a light-absorption technique to demonstrate a difference in oxygen content between umbilical arterial and venous blood, thereby establishing the placental transfer of oxygen. Although clinicians recognized the importance of these data, they accepted the implications slowly. Some clinicians pointed to several decades of clinical use "without problems." For example, Otto Spiegelberg,[27] Professor of Obstetrics at the University of Breslau, wrote in 1887, "As far as the fetus is concerned, no unimpeachable clinical observation has yet been published in which a fetus was injured by chloroform administered to its mother." Experience lulled them into complacency, which may explain their failure to appreciate the threat posed by twilight sleep.

Dangers from twilight sleep probably developed insidiously. The originators of the method, von Steinbüchel and Gauss, recommended conservative doses of drugs. They suggested that 0.3 mg of scopolamine be given every 2 to 3 hours to induce amnesia and that no more than 10 mg of morphine be administered subcutaneously for the whole labor. Gauss, who was especially meticulous, even advised physicians to administer a "memory test" to women in labor to evaluate the need for additional scopolamine. However, as other physicians used the technique, they changed it. Some gave larger doses of opioid—as much as 40 or 50 mg of morphine during labor. Others gave additional drugs (e.g., as much as 600 mg of pentobarbital during labor as well as inhalation agents for delivery). Despite administering these large doses to their patients, some physicians said they had seen no adverse effects on the infants.[28] They probably spoke the truth, but this probability says more about their powers of observation than the safety of the method.

Two situations eventually made physicians confront problems associated with placental transmission of anesthetic drugs. The first was the changing use of morphine.[29] In the latter part of the nineteenth century (before the enactment of laws governing the use of addictive drugs), morphine was a popular ingredient of patent medicines and a drug frequently prescribed by physicians. As addiction became more common, obstetricians saw many pregnant women who were taking large amounts of morphine daily. When they tried to decrease their patients' opioid use, several obstetricians noted unexpected problems (e.g., violent fetal movements, sudden fetal death), which they correctly identified as signs of withdrawal. Second, physiologists and anatomists began extensive studies of placental structure and function. By the turn of the century, they had identified many of the physical and chemical factors that affect rates of drug transfer. Thus, even before twilight sleep became popular, physicians had clinical and laboratory evidence to justify caution. As early as 1877, Gillette[30] described 15 instances of neonatal depression that he attributed to morphine given during labor. Similarly, in a review article published in 1914, Knipe[31] identified stillbirths and neonatal oligopnea and asphyxia as complications of twilight sleep and gave the incidence of each problem as reported by other writers.

When the studies of obstetric anesthesia published between 1880 and 1950 are considered, four characteristics stand out. First, few of them described effects of anesthesia on the newborn. Second, those that did report newborn apnea, oligopnea, or asphyxia seldom defined these words. Third, few used controls or compared one mode of treatment with another. Finally, few writers used their data to evaluate the safety of the practice that they described. In other words, by today's standards, even the best of these papers lacked substance. They did, however, demonstrate a growing concern among physicians about the effects of anesthetic drugs on neonates. Perhaps even more important, their work prepared clinicians for the work of Virginia Apgar (Figure 1-6).

FIGURE 1-6 ■ Virginia Apgar, whose scoring system revolutionized the practice of obstetrics and anesthesia. Her work made the well-being of the infant the major criterion for the evaluation of medical management of pregnant women. (Courtesy Wood-Library Museum.)



Current Researches in Anesthesia and Analgesia—July-August, 1953

A Proposal for a New Method of Evaluation of the Newborn Infant.*

Department of Anesthesiology, Columbia University, College of Physicians and Surgeons and the Anesthesia Service, The Presbyterian Hospital

FIGURE 1-7 ■ Title page from the paper in which Virginia Apgar described her new scoring system for evaluating the well-being of a newborn.

Apgar became an anesthesiologist when the chairman of the Department of Surgery at the Columbia University College of Physicians and Surgeons dissuaded her from becoming a surgeon. After training in anesthesia with Ralph Waters at the University of Wisconsin and with E. A. Rovenstine at Bellevue Hospital, she returned to Columbia Presbyterian Hospital as Director of the Division of Anesthesia. In 1949, she was appointed professor, the first woman to attain that rank at Columbia University.[32]

In 1953, Apgar[33] described a simple, reliable system for evaluating newborns and showed that it was sufficiently sensitive to detect differences among neonates whose mothers had been anesthetized for cesarean delivery by different techniques (Figure 1-7). Infants delivered of women with spinal anesthesia had higher scores than those delivered with general anesthesia. The Apgar score had three important effects. First, it replaced simple observation of neonates with a reproducible measurement—that is, it substituted a numerical score for the ambiguities of words such as oligopnea and asphyxia. Thus it established the possibility of the systematic comparison of different treatments. Second, it provided objective criteria for the initiation of neonatal resuscitation. Third, and most important, it helped change the focus of obstetric care. Until that time the primary criterion for success or failure had been the survival and well-being of the mother, a natural goal considering the maternal risks of childbirth until that time. After 1900, as maternal risks diminished, the well-being of the mother no longer served as a sensitive measure of outcome. The Apgar score called attention to the child and made its condition the new standard for evaluating obstetric management.

THE EFFECTS OF ANESTHESIA ON LABOR

The effects of anesthesia on labor also worried physicians. Again, their fears were well-founded. Diethyl ether and chloroform depress uterine contractions. If given in sufficient amounts, they also abolish reflex pushing with the abdominal muscles during the second stage of labor. These effects are not difficult to detect, even with moderate doses of either inhalation agent.

Simpson's method of obstetric anesthesia used significant amounts of drugs. He started the anesthetic early, and sometimes he rendered patients unconscious during the first stage of labor. In addition, he increased the depth of anesthesia for the delivery.[34] As many people copied his technique, they presumably had ample opportunity to observe uterine atony and postpartum hemorrhage.

Some physicians noticed the effects of anesthetics on uterine function. For example, Meigs[35] said unequivocally that etherization suppressed uterine function, and he described occasions in which he had had to suspend etherization to allow labor to resume. Other physicians waffled, however. For example, Walter Channing,[36] Professor of Midwifery and Medical Jurisprudence at Harvard (seemingly a strange combination of disciplines, but at that time neither of the two was thought sufficiently important to warrant a separate chair), published a book about the use of ether for obstetrics (Figure 1-8). He endorsed etherization and influenced many others to use it. However, his book contained blatant contradictions. On different pages Channing contended that ether had no effect, that it increased uterine contractility, and that it suspended contractions entirely. Then, in a pronouncement smacking more of panache than reason, Channing swept aside his inconsistencies and said that whatever effect ether may have on the uterus he "welcomes it." Noting similar contradictions among other writers, W. F. H. Montgomery,[37] Professor of Midwifery at the King and Queen's College of Physicians in Ireland, wrote, "By one writer we are told that, if uterine action is excessive, chloroform will abate it; by another that if feeble, it will strengthen it and add new vigor to each parturient effort."

FIGURE 1-8 ■ Frontispiece from Walter Channing's book on the use of etherization for childbirth. Channing favored the use of etherization, and he persuaded others to use it, although evidence ensuring its safety was scant.

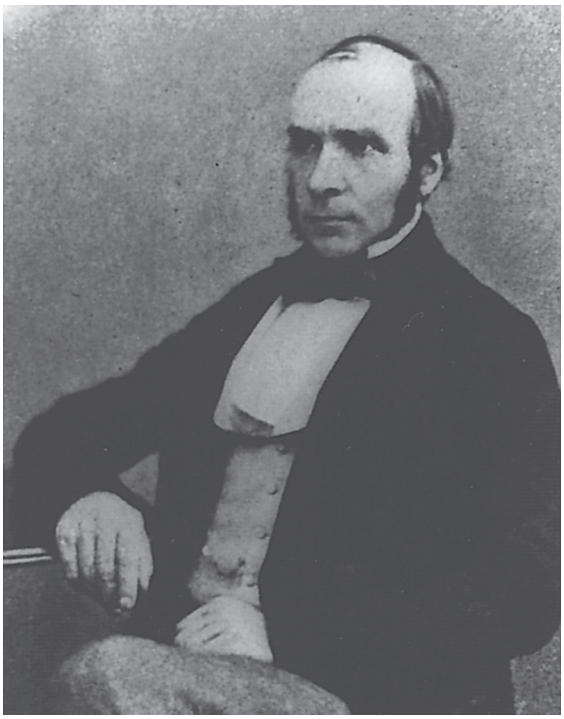

FIGURE 1-9 ■ John Snow, a London surgeon who gave up his surgical practice to become the first physician to devote all his time to anesthesia. He wrote many monographs and papers, some of which accurately describe the effects of anesthesia on infant and mother. (Courtesy Wood-Library Museum.)

John Snow[23] gave a more balanced review of the effects of anesthesia on labor. Originally a surgeon, Snow became the first physician to restrict his practice to anesthesia. He experimented with ether and chloroform and wrote many insightful papers and books describing his work (Figure 1-9). Snow's technique differed from Simpson's. Snow withheld anesthesia until the second stage of labor, limited administration to brief periods during contractions, and attempted to keep his patients comfortable but responsive. To achieve better control of the depth of anesthesia, he recommended using the vaporizing apparatus that he had developed for surgical cases. Snow[23] spoke disparagingly of Simpson's technique and the tendency of people to use it simply because of Simpson's reputation:

> *The high position of Dr. Simpson and his previous services in this department, more particularly in being the first to administer ether in labour, gave his recommendations very great influence; the consequence of which is that the practice of anesthesia is presently probably in a much less satisfactory state than it would have been if chloroform had never been introduced.*

Snow's method, which was the same one he had used to anesthetize Queen Victoria, eventually prevailed over Simpson's. Physicians became more cautious with anesthesia, reserving it for special problems such as cephalic version, the application of forceps, abnormal presentation, and eclampsia. They also became more conservative with dosage, often giving anesthesia only during the second stage of labor. Snow's methods were applied to each new inhalation agent—including nitrous oxide, ethylene, cyclopropane, trichloroethylene, and methoxyflurane—as it was introduced to obstetric anesthesia.

Early physicians modified their use of anesthesia from experience, not from study of normal labor or from learning more about the pharmacology of the drugs. Moreover, they had not yet defined the relationship between uterine pain and contractions. As physicians turned more to science during the latter part of the century, however, their strategies began to change. For example, in 1893 the English physiologist Henry Head[38] published his classic studies of the innervation of abdominal viscera. His work stimulated others to investigate the role of the nervous system in the control of labor. Subsequently, clinical and laboratory studies of pregnancy after spinal cord transection established the independence of labor from nervous control.[39] When regional anesthesia appeared during the first decades of the twentieth century, physicians therefore had a conceptual basis from which to explore its effects on labor.

Carl Koller[40] introduced regional anesthesia when he used cocaine for eye surgery in 1884. Recognizing the potential of Koller's innovation, surgeons developed techniques for other procedures. Obstetricians quickly adopted many of these techniques for their own use. The first papers describing obstetric applications of spinal, lumbar epidural, caudal, paravertebral, parasacral, and pudendal nerve blocks appeared between 1900 and 1930 (see Figure 1-4).[41-43] Recognition of the potential effects of regional anesthesia on labor developed more slowly, primarily because obstetricians seldom used it. They continued to rely on inhalation agents and opioids, partly because few drugs and materials were available for regional anesthesia at that time, but also because obstetricians did not appreciate the chief advantage of regional over general anesthesia—the relative absence of drug effects on the infant. Moreover, they rarely used regional anesthesia except for delivery, and then they often used elective forceps anyway. This set of circumstances limited their opportunity and motivation to study the effects of regional anesthesia on labor.

Among early papers dealing with regional anesthesia, one written by Cleland[44] stands out. He described his experience with paravertebral anesthesia, but he also wrote a thoughtful analysis of the nerve pathways mediating labor pain, an analysis he based on information he had gleaned from clinical and laboratory studies. Few investigators were as meticulous or insightful as Cleland. Most of those who studied the effects of anesthesia simply timed the length of the first and second stages of labor. Some timed the duration of individual contractions or estimated changes in the strength of contractions by palpation. None of the investigators measured the intrauterine pressures, even though a German physician had described such a method in 1898 and had used it to evaluate the effects of morphine and ether on the contractions of laboring women.[45]

More detailed and accurate studies of the effects of anesthesia started to appear after 1944. Part of the stimulus was a method for continuous caudal anesthesia introduced by Hingson and Edwards,[46] in which a malleable needle remained in the sacral canal throughout labor. Small, flexible plastic catheters eventually replaced malleable needles and made continuous epidural anesthesia even more popular. With the help of these innovations, obstetricians began using anesthesia earlier in labor. Ensuing problems, real and imagined, stimulated more studies. Although good studies were scarce, the strong interest in the problem represented a marked change from the early days of obstetric anesthesia.

Ironically, "natural childbirth" appeared just as regional anesthesia started to become popular and as clinicians began to understand how to use it without disrupting labor. Dick-Read,[47] the originator of the natural method, recognized "no physiological function in the body which gives rise to pain in the normal course of health." He attributed pain in an otherwise uncomplicated labor to an "activation of the sympathetic nervous system by the emotion of fear." He argued that fear made the uterus contract and become ischemic and therefore painful. He said that women could avoid the pain if they simply learned to abolish their fear of labor. Dick-Read never explained why uterine ischemia that results from fear causes pain, whereas ischemia that results from a normal contraction does not. In other words, Dick-Read, like Simpson a century earlier, claimed no necessary or physiologic relationship between labor pain and contractions. Dick-Read's book, written more for the public than for the medical profession, represented a regression of almost a century in medical thought and practice. It is important to note that contemporary methods of childbirth preparation do not maintain that fear alone causes labor pain. However, they do attempt to reduce fear by education and to help patients manage pain by teaching techniques of self-control. This represents a significant difference from and an important advance over Dick-Read's original theory.

SOME LESSONS

History is important in proportion to the lessons it teaches. With respect to obstetric anesthesia, four lessons stand out. First, every new drug and method entails risks. Physicians who first used obstetric anesthesia seemed reluctant to accept this fact, perhaps because of their inexperience with potent drugs (pharmacology was in its infancy) or because they acceded too quickly to patients, who wanted relief from pain and had little understanding of the technical issues confronting physicians. Whatever the reason, this period of denial lasted almost half a century, until 1900. Almost another half-century passed before obstetricians learned to modify their practice to limit the effects of anesthetics on the child and the labor process.

Second, new drugs or therapies often cause problems in completely unexpected ways. For example, in 1900, physicians noted a rising rate of puerperal fever.[48] The timing was odd. Several decades had passed since Robert Koch had suggested the germ theory of disease and since Semmelweis had recognized that physicians often transmit infection from one woman to the next with their unclean hands. With the adoption of aseptic methods, deaths from puerperal fever had diminished dramatically. During the waning years of the nineteenth century, however, they increased again. Some physicians attributed this resurgence of puerperal fever to anesthesia. In a presidential address to the Obstetrical Society of Edinburgh in 1900, Murray[49] stated the following:

> *I feel sure that an explanation of much of the increase of maternal mortality from 1847 onwards will be found in, first the misuse of anaesthesia and second in the ridiculous parody which, in many hands, stands for the use of antiseptics.…Before the days of anaesthesia, interference was limited and obstetric operations were at a minimum because interference of all kinds increased the conscious suffering of the patient.…When anaesthesia became possible, and interference became more frequent because it involved no additional suffering, operations were undertaken when really unnecessary … and so complications arose and the dangers of the labor increased.*

Although it was not a direct complication of the use of anesthesia in obstetric practice, puerperal fever appeared to be an indirect consequence of it.

Changes in obstetric practice also had unexpected effects on anesthetic complications. During the first decades of the twentieth century, when cesarean deliveries were rare and obstetricians used only inhalation analgesia for delivery, few women were exposed to the risk of aspiration during deep anesthesia. As obstetric practice changed and cesarean deliveries became more common, this risk rose. The syndrome of aspiration was not identified and labeled until 1946, when obstetrician Curtis Mendelson[50] described and named it. The pathophysiology of the syndrome had already been described by Winternitz et al.,[51] who instilled hydrochloric acid into the lungs of dogs to simulate the lesions found in veterans poisoned by gas during the trench warfare of World War I. Unfortunately, the reports of these studies, although excellent, did not initiate any change in practice. Change occurred only after several deaths of obstetric patients were highly publicized in lay, legal, and medical publications. Of course, rapid-sequence induction, currently recommended to reduce the risk of aspiration, creates another set of risks—those associated with a failed intubation.

The third lesson offered by the history of obstetric anesthesia concerns the role of basic science. Modern medicine developed during the nineteenth century after physicians learned to apply principles of anatomy, physiology, and chemistry to the study and treatment of disease. Obstetric anesthesia underwent a similar pattern of development. Studies of placental structure and function called physicians' attention to the transmission of drugs and the potential effects of drugs on the infant. Similarly, studies of the physiology and anatomy of the uterus helped elucidate potential effects of anesthesia on labor. In each instance, lessons from basic science helped improve patient care.

The fourth and perhaps the most important lesson is the role that patients have played in the use of anesthesia for obstetrics. During the nineteenth century it was women who pressured cautious physicians to incorporate routine use of anesthesia into their obstetric practice. A century later, it was women again who altered patterns of practice, this time questioning the overuse of anesthesia for routine deliveries. In both instances the pressure on physicians emanated from prevailing social values regarding pain. In 1900 the public believed that pain, and in particular obstetric pain, was destructive and something that should be avoided. Half a century later, with the advent of the natural childbirth movement, many people began to suggest that the experience of pain during childbirth, perhaps even in other situations, might have some physiologic if not social value. Physicians must recognize and acknowledge the extent to which social values may shape medical "science" and practice.[52,53]

During the past 60 years, scientists have accumulated a wealth of information about many processes integral to normal labor: the processes that initiate and control lactation; neuroendocrine events that initiate and maintain labor; the biochemical maturation of the fetal lung and liver; the metabolic requirements of the normal fetus and the protective mechanisms that it may invoke in times of stress; and the normal mechanisms that regulate the amount and distribution of blood flow to the uterus and placenta. At this point, we have only the most rudimentary understanding of the interaction of anesthesia with any of these processes. Only a fraction of the information available from basic science has been used to improve obstetric anesthesia care. Realizing the rewards from the clinical use of such information may be the most important lesson from the past and the greatest challenge for the future of obstetric anesthesia.

KEY POINTS

- Physicians have debated the safety of obstetric anesthesia since 1847, when James Young Simpson first administered anesthesia for delivery. Two issues have dominated the debate: the effects of anesthesia on labor and the effects of anesthesia on the newborn.
- Despite controversy, physicians quickly incorporated anesthesia into clinical practice, largely because of their patients' desire to avoid childbirth pain.
- Only after obstetric anesthesia was in use for many years did problems become apparent.
- Important milestones in obstetric anesthesia are the introduction of inhalation agents in 1847, the expanded use of opioids in the early decades of the twentieth century, and the refinement of regional anesthesia starting in the mid-twentieth century.
- Outstanding conceptual developments are (1) Zweifel's idea that drugs given to the mother cross the placenta and affect the fetus and (2) Apgar's idea that the condition of the newborn is the most sensitive assay of the quality of anesthetic care of the mother.
- The history of obstetric anesthesia suggests that the major improvements in patient care have followed the application of principles of basic science.

PART II

MATERNAL AND FETAL PHYSIOLOGY

Donald Caton, MD

Metabolism was among the first areas of physiology to influence clinical practice. By the beginning of the twentieth century, physiologists had established many of the principles that we recognize today, including normal rates of oxygen consumption and carbon dioxide production, the relationship between oxygen consumption and heat production, and the relationship between metabolic rate, body weight, and surface area among individuals and species. Almost simultaneously, clinicians began to apply these principles to their studies of patients in different states of health and disease.

In one early study, physiologist Magnus-Levy[1] found an exception to the rule that basal metabolic rate varied in proportion to body surface area. As he measured a woman's oxygen consumption during pregnancy, he observed that her metabolic rate increased out of proportion to increments in her body weight and surface area. Subsequent studies by other investigators established the basis of this phenomenon. Per unit of weight, the fetus, placenta, and uterus together consumed oxygen (and released carbon dioxide and heat) at a higher rate than the mother. In effect, the metabolism of a pregnant woman represented the sum of two independent organisms, each metabolizing at its own rate in proportion to its own surface area. Thus, each kilogram of maternal tissue consumed oxygen at a rate of approximately 4 mL/min, whereas the average rate for the fetus, placenta, and uterus was approximately 12 mL/min, although it could rise as high as 20 mL/min. Therefore, during pregnancy, the mother's metabolism was the sum of her metabolic rate plus that of the fetus, placenta, and uterus.[1-4] Subsequent studies established that the highest rates of fetal metabolism occurred during the periods of most rapid growth, thereby reaffirming another physiologic principle—the high metabolic cost of synthesizing new tissue.[5]

The aforementioned studies gave clinicians estimates of the stress imposed by pregnancy. To maintain homeostasis during pregnancy, a pregnant woman had to make an appropriate adjustment in each of the physiologic mechanisms involved in the delivery of substrates to the fetal placental unit and in the excretion of metabolic wastes. Thus, for every increment in fetal weight, clinicians could expect to find a proportional change in all the mechanisms involved in the delivery of substrate to the fetus and in the excretion of all byproducts. In fact, subsequent clinical studies established predictable changes in uterine blood flow, cardiac output, blood volume, minute ventilation, the dissipation of body heat, and the renal excretion of nitrogenous waste and other materials.

CHAPTER 2

Physiologic Changes of Pregnancy

Robert Gaiser, MD

CHAPTER OUTLINE

Marked anatomic and physiologic changes occur during pregnancy that allow the woman to adapt to the developing fetus and its metabolic demands. The enlarging uterus places mechanical strain on the woman's body. Greater hormonal production by the ovaries and the placenta further alters maternal physiology. The hallmark of successful anesthetic management of the pregnant woman is recognition of these anatomic and physiologic changes and appropriate adaptation of anesthetic techniques to account for them. The physiologic alterations of normal pregnancy and their anesthetic implications are reviewed in this chapter.

BODY WEIGHT AND COMPOSITION

The mean maternal weight increase during pregnancy is 17% of the prepregnancy weight or approximately 12 kg.[1] It results from an increase in the size of the uterus and its contents (uterus, 1 kg; amniotic fluid, 1 kg; fetus and placenta, 4 kg), increases in blood volume and interstitial fluid (approximately 1 kg each), and deposition of new fat and protein (approximately 4 kg). The weight gain during pregnancy recommended by the Institute of Medicine reflects the increased incidence of obesity[2] and depends on the prepregnancy body mass index (BMI; Table 2-1).

TABLE 2-1 Recommended Weight Gain during Pregnancy

Prepregnancy Body Mass Index (kg/m²)	Total Weight Gain in kg (lb)	Rate of Weight Gain during 2nd and 3rd Trimester in kg/wk (lb/wk)
< 18.5	12.7-18.2 (28-40)	0.45 (1)
18.5-24.9	11.4-15.9 (25-35)	0.45 (1)
25.0-29.9	6.8-11.4 (15-25)	0.27 (0.6)
≥ 30	5.0-9.1 (11-20)	0.23 (0.5)

Modified from Institute of Medicine (U.S.) Committee to Reexamine IOM Pregnancy Weight Guidelines, Rasmussen KM, Yaktine AL, editors. Weight Gain During Pregnancy: Reexamining the Guidelines. Washington, DC, National Academies Press, 2009.

BOX 2-1 Changes in the Cardiac Examination in the Pregnant Patient

- Accentuation of first heart sound (S1) and exaggerated splitting of the mitral and tricuspid components
- Typical systolic ejection murmur
- Possible presence of third heart sound (S3) and fourth heart sound (S4); no clinical significance
- Leftward displacement of point of maximal cardiac impulse

The expected weight increase during the first trimester in a nonobese individual is 1 to 2 kg, and there is a 5- to 6-kg increase in each of the last two trimesters. The recommended gain is less in obese individuals. Obesity is a major problem in the United States and has many implications for obstetric anesthesia (see Chapter 50). Excessive weight gain during pregnancy is a risk factor for a long-term increase in BMI.[3]

CARDIOVASCULAR CHANGES

Physical Examination and Cardiac Studies

Pregnancy causes the heart to increase in size, a result of both greater blood volume and increased stretch and force of contraction.[4] These changes, coupled with the elevation of the diaphragm from the expanding uterus, cause several changes in the physical examination and in cardiac studies.

Changes in heart sounds include accentuation of the first heart sound with exaggerated splitting of the mitral and tricuspid components (Box 2-1).[5] The second heart sound changes little, although the aortic-pulmonic interval tends to vary less with respiration during the third trimester, a finding without clinical significance. A fourth heart sound may be heard in 16% of pregnant women, although typically it disappears at term. A grade II systolic ejection murmur is commonly heard at the left sternal border[6]; the murmur is considered a benign flow murmur, attributable to cardiac enlargement from increased intravascular volume, which causes dilation of the tricuspid annulus and regurgitation. Elevation of the diaphragm by the growing uterus shifts the heart anteriorly and to the left. The point of maximal cardiac impulse is displaced cephalad to the fourth intercostal space and also to the left to at least the midclavicular line.

The electrocardiogram typically changes, especially during the third trimester. Heart rate steadily increases during the first and second trimesters, and both the PR interval and the uncorrected QT interval are shortened. This has clinical implications for women with *long QT syndrome* (see Chapter 42). The QRS axis shifts to the right during the first trimester but may shift to the left during the third trimester.[7] Depressed ST segments and isoelectric low-voltage T waves in the left-sided precordial and limb leads are commonly observed.[8]

Echocardiography demonstrates left ventricular hypertrophy by 12 weeks' gestation with a 50% increase in mass at term.[9] This hypertrophy results from an increase in the size of the preexisting cardiomyocytes rather than an increase in the number of cells. The hypertrophy is eccentric, resembling that occurring from exercise.[1] The annular diameters of the mitral, tricuspid, and pulmonic valves increase; 94% of term pregnant women exhibit tricuspid and pulmonic regurgitation, and 27% exhibit mitral regurgitation.[10] The aortic annulus is not dilated.

Central Hemodynamics

For accurate determination of central hemodynamic changes during pregnancy, measurements should be made with the patient in a resting position, tilted to the left, to minimize aortic and vena caval compression. Comparisons must be made with an appropriate control, such as prepregnancy values or a matched group of nonpregnant women. If control measurements are made during the postpartum period, a sufficient interval must have elapsed for hemodynamic parameters to have returned to prepregnancy values; this may take 24 weeks or more.[11]

Cardiac output begins to increase by 5 weeks' gestation and is 35% to 40% above baseline by the end of the first trimester.[9,12] It continues to increase throughout the second trimester until it is approximately 50% greater than nonpregnant values (Figures 2-1 and 2-2).[9,11,13-15] Cardiac output does not change from this level during the third trimester. Some studies have reported a decrease in cardiac output during the third trimester; typically this is when measurements are made in the supine position and thus reflects aortocaval compression rather than a true gestational decline.

The initial increase in cardiac output results from an increase in heart rate, which occurs by the fourth to fifth week of pregnancy.[9] The heart rate increases 15% to 25% above baseline by the end of the first trimester and remains relatively unchanged from that level for the remainder of the pregnancy.[9,11-16] Cardiac output continues to increase during the second trimester because of an increase in stroke volume. Stroke volume increases by approximately 20% during the first trimester and by 25%

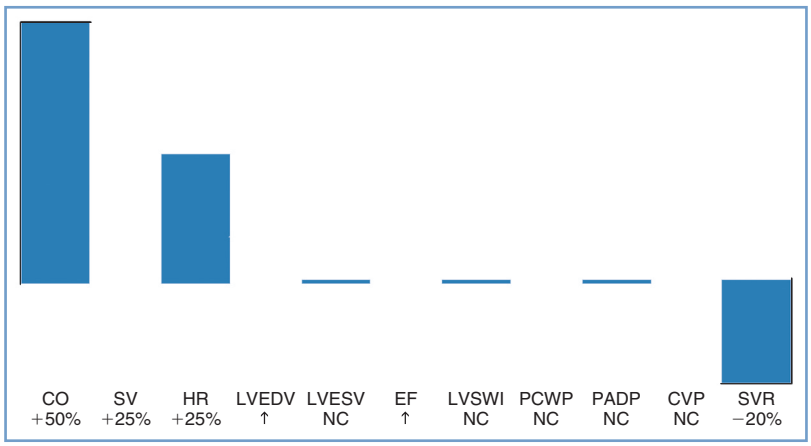

FIGURE 2-1 ■ Central hemodynamic changes at term gestation. Changes are relative to the nonpregnant state. *CO*, cardiac output; *SV*, stroke volume; *HR*, heart rate; *LVEDV*, left ventricular end-diastolic volume; *LVESV*, left ventricular end-systolic volume; *EF*, ejection fraction; *LVSWI*, left ventricular stroke work index; *PCWP*, pulmonary capillary wedge pressure; *PADP*, pulmonary artery diastolic pressure; *CVP*, central venous pressure; *SVR*, systemic vascular resistance; *NC*, no change. (Data from Conklin KA. Maternal physiological adaptations during gestation, labor, and puerperium. Semin Anesth 1991; 10:221-34.)

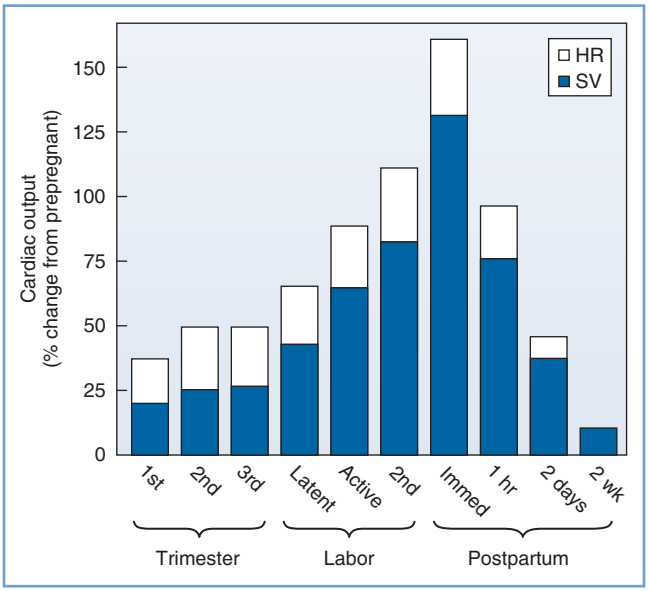

FIGURE 2-2 ■ Cardiac output during pregnancy, labor, and the puerperium. Values during pregnancy are measured at the end of the first, second, and third trimesters. Values during labor are measured between contractions. For each measurement, the relative contributions of heart rate (*HR*) and stroke volume (*SV*) to the change in cardiac output are illustrated.

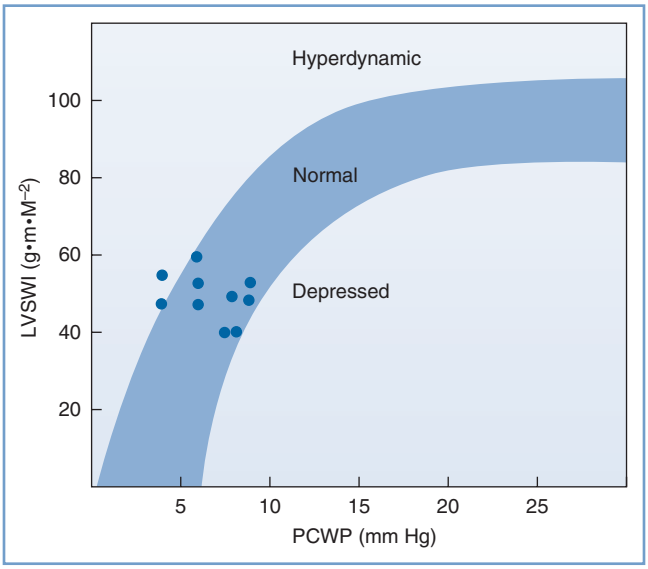

FIGURE 2-3 ■ Left ventricular function in late phase of third-trimester normotensive pregnant patients. *LVSWI*, left ventricular stroke work index; *PCWP*, pulmonary capillary wedge pressure. (Modified from Clark SL, Cotton DB, Lee W, et al. Central hemodynamic assessment of cardiac function. Am J Obstet Gynecol 1989; 161:439-42.)

to 30% above baseline during the second trimester.[9,11,12,16] The increase in stroke volume correlates with increasing estrogen levels.[1] Left ventricular mass increases by 23% from the first to the third trimester.[17] Cardiac output increases to meet the demands of the developing fetus, and the distribution of cardiac output to the uterine circulation increases from 5% to 12% during the second half of pregnancy.[18]

Left ventricular end-diastolic volume increases during pregnancy, whereas end-systolic volume remains unchanged, resulting in a larger ejection fraction.[9,11-14,16] Central venous, pulmonary artery diastolic, and pulmonary capillary wedge pressures are within the normal nonpregnant range.[15] The apparent discrepancy between left ventricular filling pressure and end-diastolic volume is explained by hypertrophy and dilation, with the dilated ventricle accommodating a greater volume without an increase in pressure.

Myocardial contractility increases, as demonstrated by higher velocity of left ventricular circumferential fiber shortening (Figure 2-3).[9,13,16] Tissue Doppler imaging, which is relatively independent of preload, has been used to assess diastolic function.[19] Left ventricular diastolic function is not impaired during pregnancy, whereas systolic function is increased during the second trimester.

The increase in cardiac output during pregnancy results in increased perfusion to the uterus, kidneys, and extremities. Uterine blood flow increases from a baseline value of approximately 50 mL/min to a level at term of 700 to 900 mL/min.[20-24] Approximately 90% of this flow perfuses the intervillous space, with the balance perfusing

the myometrium.[22] At term, skin blood flow is approximately three to four times the nonpregnant level, resulting in higher skin temperature.[25] Renal plasma flow is increased by 80% at 16 to 26 weeks' gestation but declines to 50% above the nonpregnant baseline at term.[26]

The U.S. Department of Health and Human Services recommends that pregnant women have at least 150 minutes of moderate-intensity aerobic activity every week[27]; however, most women do not achieve this goal. Pregnant women are less active, with only half as many meeting guidelines for vigorous activity compared with nonpregnant women.[28] For every two women who exercise before pregnancy, one will not do so during pregnancy. Failure to exercise results in greater gestational weight gain.[29] Exercise is safe for the fetus[29,30]; in a study of 45 women, exercise on a treadmill of moderate intensity (40% to 59% of heart rate reserve) did not affect fetal heart or umbilical artery Doppler indices.[30]

During exercise, maximal oxygen consumption is greater in pregnancy,[31] especially during cardiovascular exercise. The rate of increase in minute ventilation is greater with exercise during pregnancy.[32] Cardiac output is also greater, primarily from increased stroke volume[33] and increased oxygen delivery to the fetus.

Blood Pressure

Positioning, gestational age, and parity affect blood pressure measurements. Brachial sphygmomanometry yields the highest measurements in the supine position and the lowest measurements in the lateral position.[14,34] Blood pressure increases with maternal age, and for a given age, nulliparous women have a higher mean pressure than parous women.[35] Systolic, diastolic, and mean blood pressure decrease during midpregnancy and return toward baseline as the pregnancy approaches term.[36] Diastolic blood pressure decreases more than systolic blood pressure, with early to mid-gestational decreases of approximately 20%.[37] The changes in blood pressure are consistent with changes in systemic vascular resistance, which decreases during early gestation, reaches its nadir (35% decline) at 20 weeks' gestation, and increases during late gestation. Unlike blood pressure, systemic vascular resistance remains approximately 20% below the nonpregnant level at term.[11,15] A postulated explanation for the decreased systemic vascular resistance is the development of a low-resistance vascular bed (the intervillous space) as well as vasodilation caused by prostacyclin, estrogen, and progesterone. The lower blood pressure persists beyond the pregnancy. A longitudinal study of 2304 initially normotensive women over 20 years showed that nulliparous women at baseline who subsequently delivered one or more infants had a blood pressure that was 1 to 2 mm Hg lower than corresponding women who did not have children. This finding demonstrates that pregnancy may create long-lasting vascular changes.[37]

Aortocaval Compression

The extent of compression of the aorta and inferior vena cava by the gravid uterus depends on positioning and gestational age. At term, partial vena caval compression occurs when the woman is in the lateral position, as documented by angiography.[38] This finding is consistent with the 75% elevation above baseline of femoral venous and lower inferior vena cava pressures.[39] Despite caval compression, collateral circulation maintains venous return, as reflected by the right ventricular filling pressure, which is unaltered in the lateral position.[15]

In the supine position, nearly complete obstruction of the inferior vena cava is evident at term.[40] Blood returns from the lower extremities through the intraosseous, vertebral, paravertebral, and epidural veins.[41] However, this collateral venous return is less than would occur through the inferior vena cava, resulting in a decrease in right atrial pressure.[42] Compression of the inferior vena cava occurs as early as 13 to 16 weeks' gestation and is evident from the 50% increase in femoral venous pressure observed when these women assume the supine position (Figure 2-4).[43] By term, femoral venous and lower inferior vena caval pressures are approximately 2.5 times the nonpregnant measurements in the supine position.[39,43]

In the supine position, the aorta may be compressed by the term gravid uterus. This compression accounts for lower pressure in the femoral versus the brachial artery in the supine position.[44,45] These findings are consistent with angiographic studies in supine pregnant women, which show partial obstruction of the aorta at the level of the lumbar lordosis and enhanced compression during periods of maternal hypotension.[46]

At term, the left lateral decubitus position results in less enhancement of cardiac sympathetic nervous system activity and less suppression of cardiac vagal activity than the supine or right lateral decubitus position.[47] Women who assume the supine position at term gestation experience a 10% to 20% decline in stroke volume and cardiac output,[48,49] consistent with the fall in right atrial filling pressure. Blood flow in the upper extremities is normal, whereas uterine blood flow decreases by 20% and lower extremity blood flow decreases by 50%.[50] Perfusion of the uterus is less affected than that of the lower extremities because compression of the vena cava does not obstruct venous outflow via the ovarian veins.[51] The adverse hemodynamic effects of aortocaval compression are reduced once the fetal head is engaged.[44,45] The sitting position has also been shown to result in aortocaval compression, with a decrease in cardiac output of 10%.[52] Flexing the legs rotates the uterus to compress against the vena cava. Short intervals in the sitting position, such as occurs during epidural catheter placement, have no impact on uteroplacental blood flow.

Some term pregnant women exhibit an increase in brachial artery blood pressure when they assume the supine position, which is caused by higher systemic vascular resistance from compression of the aorta. Up to 15% of women at term experience bradycardia and a substantial drop in blood pressure when supine, the so-called *supine hypotension syndrome*.[53] It may take several minutes for the bradycardia and hypotension to develop, and the bradycardia is usually preceded by a period of tachycardia. The syndrome results from a profound drop in venous return for which the cardiovascular system is not able to compensate.

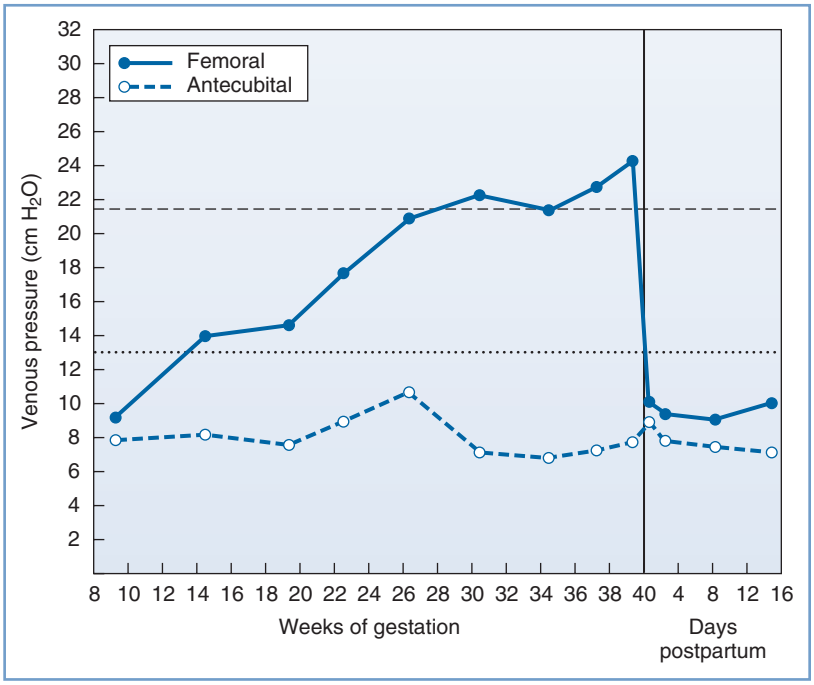

FIGURE 2-4 ■ Femoral and antecubital venous pressures in the supine position throughout normal pregnancy and the puerperium. (Modified from McLennan CE. Antecubital and femoral venous pressure in normal and toxemic pregnancy. Am J Obstet Gynecol 1943; 45:568-91.)

Hemodynamic Changes during Labor and the Puerperium

Cardiac output during labor (but between uterine contractions) increases from pre-labor values by approximately 10% in the early first stage, by 25% in the late first stage, and by 40% in the second stage of labor.[54-56] In the immediate postpartum period, cardiac output may be as much as 75% above pre-delivery measurements.[55] These changes result from an increase in stroke volume due to greater venous return and to alterations in sympathetic nervous system activity. During uterine contractions, 300 to 500 mL of blood is displaced from the intervillous space into the central circulation ("autotransfusion").[57-59] Increased intrauterine pressure forces blood from the intervillous space through the relatively unimpeded ovarian venous outflow system. The postpartum increase in cardiac output results from relief of vena caval compression, diminished lower extremity venous pressure, and a reduction of maternal vascular capacitance.[56] Cardiac output decreases to just below pre-labor values at 24 hours postpartum[57] and returns to prepregnancy levels between 12 and 24 weeks postpartum.[11] Heart rate decreases rapidly after delivery, reaches prepregnancy levels by 2 weeks postpartum, and is slightly below the prepregnancy rate for the next several months.[11,60] Other anatomic and functional changes of the heart are also fully reversible.[18,61]

THE RESPIRATORY SYSTEM

Despite the multiple anatomic and physiologic changes that occur during pregnancy, it is remarkable that pregnancy has a relatively minor impact on lung function.

Anatomy

The thorax undergoes both mechanical and hormonal changes during pregnancy.[62,63] Relaxin (the hormone responsible for relaxation of the pelvic ligaments) causes relaxation of the ligamentous attachments to the lower ribs.[62,63] The subcostal angle progressively widens from 68.5 to 103.5 degrees. The anteroposterior and transverse diameters of the chest wall each increase by 2 cm, resulting in an increase of 5 to 7 cm in the circumference of the lower rib cage. These changes peak at 37 weeks' gestation. The subcostal angle remains about 20% wider than the baseline value after delivery.[64] The vertical measurement of the chest cavity decreases by as much as 4 cm as a result of the elevated position of the diaphragm.

Capillary engorgement of the larynx and the nasal and oropharyngeal mucosa begins early in the first trimester and increases progressively throughout pregnancy.[65] The effect of estrogen on the nasal mucosa leads to symptoms of rhinitis and nosebleeds. Nasal breathing commonly becomes difficult, and epistaxis may occur. Nasal congestion may contribute to the perceived shortness of breath of pregnancy.[66] Throughout the first and second trimesters, the voice has been described as rounded and well carried with good vibration. During the third trimester, vocal cord fatigue is more prevalent with a decrease in the maximum time of phonation. Both of these changes resolve in the immediate postpartum period.[67]

Airflow Mechanics

Inspiration in the term pregnant woman is almost totally attributable to diaphragmatic excursion[68] because of greater descent of the diaphragm from its elevated resting position and limitation of thoracic cage expansion because of its expanded resting position (Table 2-2). Both

TABLE 2-2 Effects of Pregnancy on Respiratory Mechanics

Parameter	Change*
Diaphragm excursion	Increased
Chest wall excursion	Decreased
Pulmonary resistance	Decreased 50%
FEV_1	No change
FEV_1/FVC	No change
Flow-volume loop	No change
Closing capacity	No change

FEV_1, Forced expiratory volume in 1 second; FVC, forced vital capacity.

large- and small-airway function are minimally altered during pregnancy. The shape of flow-volume loops, the absolute flow rates at normal lung volumes,[69] forced expiratory volume in one second (FEV_1), the ratio of FEV_1 to forced vital capacity (FVC), and closing capacity are unchanged during pregnancy.[70] There is no significant change in respiratory muscle strength during pregnancy despite the cephalad displacement of the diaphragm. Furthermore, despite the upward displacement of the diaphragm by the gravid uterus, diaphragm excursion actually increases by 2 cm.[71]

The peak expiratory flow rate achieved with a maximal effort after a maximal inspiration is often considered a surrogate for the FEV_1 and is often used to monitor asthma therapy. Studies of changes in peak expiratory flow rate during pregnancy have had conflicting results, most likely reflecting differences in measurement devices and patient position during measurements. Nonetheless, Harirah et al.[72] found that peak expiratory flow rate declined throughout gestation in all positions and that flow rates in the supine position were lower than those during standing and sitting. The mean rate of decline was 0.65 L/min per week, and peak expiratory flow rate remained below normal at 6 weeks postpartum. By contrast, Grindheim et al.[73] reported that peak expiratory flow rate increased in 100 pregnant women followed longitudinally, starting at an average of 6.7 L/s in the early second trimester and peaking at 7.2 L/s at term (Figure 2-5). These authors also reported that the FVC increased by 100 mL after 14 to 16 weeks' gestation, with the change being greater in parous than in primigravid women.[73] The changes in functional residual capacity (FRC) that occur during pregnancy may persist postpartum.

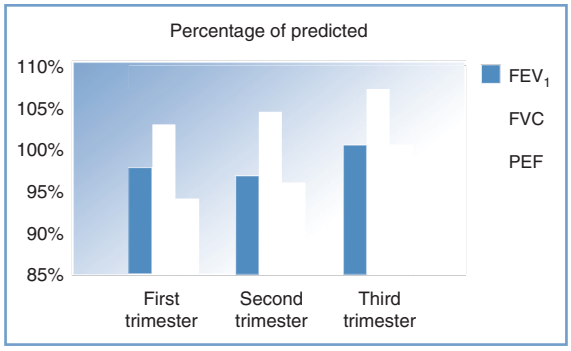

FIGURE 2-5 Changes in airflow mechanics during pregnancy. The magnitude of the increase in flow rates is small. The forced expiratory volume in one second (*FEV_1*) is within the normal range of predictive values for nonpregnant individuals. *FVC,* forced vital capacity; *PEF,* peak expiratory flow. (Based on data from Grindheim G, Toska K, Estensen ME, Rosseland LA. Changes in pulmonary function during pregnancy: a longitudinal study. BJOG 2012; 119:94-101.)

Lung Volumes and Capacities

Lung volumes can be measured using body plethysmography or by inert gas techniques with slightly differing results.[74] During pregnancy, total lung capacity is slightly reduced,[75] whereas tidal volume increases by 45%, with approximately half the change occurring during the first trimester (Table 2-3 and Figure 2-6). The early change in tidal volume is associated with a reduction in inspiratory reserve volume. Residual volume tends to drop slightly, a change that maintains vital capacity. Inspiratory capacity increases by 15% during the third trimester because of increases in tidal volume and inspiratory reserve volume.[76,77] There is a corresponding decrease in expiratory reserve volume.[76,77] The FRC begins to decrease by the fifth month of pregnancy and decreases by 400 to 700 mL to 80% of the prepregnancy value at term.[76,77] This change is caused by elevation of the diaphragm as the enlarging uterus enters the abdominal cavity and is accounted for by a 25% reduction in expiratory reserve volume (200 to 300 mL) and a 15% reduction in residual volume (200 to 400 mL). Assumption of the supine position causes the FRC to decrease further to 70% of the prepregnancy value. The supine FRC can

be increased by 10% (approximately 188 mL) by placing the patient in a 30-degree head-up position.[78]

Ventilation and Blood Gases

During pregnancy, respiratory rate and pattern remain relatively unchanged. Minute ventilation increases via an increase in tidal volume from 450 to 600 mL and a small increase in respiratory rate of 1 to 2 breaths/min.[79] This occurs primarily during the first 12 weeks of gestation with a minimal increase thereafter. The ratio of total dead space to tidal volume remains constant during pregnancy, resulting in an increase in alveolar ventilation of 30% to 50% above baseline. The increase in minute ventilation results from hormonal changes and from an increase in CO_2 production at rest by approximately 30% to 300 mL/min. The latter is closely related to the blood level of progesterone,[80] which acts as a direct respiratory stimulant. The progesterone-induced increase in chemosensitivity results in a steeper slope and a leftward shift of the CO_2-ventilatory response curve. This change occurs early in pregnancy and remains constant until delivery.[69]

Dyspnea is a common complaint during pregnancy, affecting up to 75% of women.[81] Contributing factors include increased respiratory drive, decreased $Paco_2$, the enlarging uterus, larger pulmonary blood volume, anemia, and nasal congestion. Dyspnea typically begins in the first or second trimester but improves as the pregnancy progresses. In a study in which 35 women were observed closely during pregnancy and postpartum, dyspnea was not due to alterations in central ventilatory control or respiratory mechanical factors but rather to the awareness of the increased ventilation.[82] Exercise has no effect on pregnancy-induced changes in ventilation or alveolar gas exchange.[83] The hypoxic ventilatory response is increased during pregnancy to twice the normal level, secondary to elevations in estrogen and progesterone levels.[84] This increase occurs despite blood and cerebrospinal fluid (CSF) alkalosis.

During pregnancy, Pao_2 increases to 100 to 105 mm Hg (13.3 to 14.0 kPa) as a result of greater alveolar ventilation (Table 2-4).[85] The higher Pao_2 results from the decline in $Paco_2$ and a lower arteriovenous oxygen difference, which reduces the impact of venous admixture on Pao_2.[86,87] As pregnancy progresses, oxygen consumption continues to increase, and cardiac output increases to a lesser extent, resulting in a reduced mixed venous oxygen content and increased arteriovenous oxygen difference. After mid gestation, pregnant women in the supine position frequently have a Pao_2 less than 100 mm Hg (13.3 kPa). This occurs because the FRC may be less than closing capacity, resulting in closure of small airways during normal tidal volume ventilation.[85] Moving a pregnant woman from the supine to the erect or lateral decubitus position improves arterial oxygenation and reduces the alveolar-to-arterial oxygen gradient. The increased oxygen tension facilitates the transfer of oxygen across the placenta to the fetus.

$Paco_2$ declines to approximately 30 mm Hg (4.0 kPa) by 12 weeks' gestation but does not change further during the remainder of pregnancy. Although a gradient exists between the end-tidal CO_2 tension and $Paco_2$ in nonpregnant women, the two measurements are equivalent during early pregnancy,[88] at term gestation,[89] and in the postpartum period.[90] This is attributable to a reduction in alveolar dead space, which results from an increase in cardiac output during pregnancy. The mixed venous Pco_2 is 6 to 8 mm Hg (0.8 to 1.1 kPa) below the nonpregnant level from the later first trimester until term.[1]

Metabolic compensation for the respiratory alkalosis of pregnancy reduces serum bicarbonate concentration to approximately 20 mEq/L, the base excess by 2 to 3 mEq/L, and the total buffer base by approximately 5 mEq/L.[91] This compensation is incomplete, as demonstrated by the elevation of venous,[92] capillary,[93] and arterial[85] blood pH by 0.02 to 0.06 units.

Metabolism and Respiration during Labor and the Puerperium

Minute ventilation in the unmedicated parturient increases by 70% to 140% in the first stage of labor and by 120% to 200% in the second stage of labor compared with prepregnancy values.[94] Pain, anxiety, and coached breathing techniques increase minute ventilation. $Paco_2$ may decrease to as low as 10 to 15 mm Hg (1.3 to 2.0 kPa). Oxygen consumption increases above the prelabor value by 40% in the first stage and by 75% in the second stage, secondary to the increased metabolic demands of hyperventilation, uterine activity, and maternal expulsive efforts.[94,95] The maternal aerobic requirement for oxygen exceeds oxygen consumption during labor, as is evident from the progressive elevation of blood lactate concentration, an index of anaerobic metabolism.[95-98] Provision of effective neuraxial analgesia prevents these changes during the first stage of labor and mitigates the changes during the second stage of labor.[95,98]

FRC increases after delivery but remains below the prepregnancy volume for 1 to 2 weeks. Although minute ventilation decreases halfway toward nonpregnant values by 72 hours, oxygen consumption, tidal volume, and minute ventilation remain elevated until at least 6 to 8 weeks after delivery. The alveolar and mixed venous Pco_2 values increase slowly after delivery and are still slightly below prepregnancy levels at 6 to 8 weeks postpartum.[1]

HEMATOLOGY

Blood Volume

Maternal plasma volume expansion begins as early as 6 weeks' gestation and continues until it reaches a net increase of approximately 50% by 34 weeks' gestation (Table 2-5, Figure 2-7).[99-102] After 34 weeks' gestation, the plasma volume stabilizes or decreases slightly. Red blood cell volume decreases during the first 8 weeks of pregnancy, increases to the prepregnancy level by 16 weeks, and undergoes a further rise to 30% above the prepregnancy level at term.[100,102,103] The increase in plasma volume exceeds the increase in red blood cell volume, resulting in the **physiologic anemia of pregnancy.** Hemoglobin concentration, which typically ranges from 12 to 15.8 g/dL in the nonpregnant woman, decreases to 11.6 to 13.9 g/dL in the first trimester, 9.7 to 14.8 g/dL in the second trimester, and 9.5 to 15.0 g/dL in the third trimester.[104] Hematocrit, which ranges from 35.4% to 44.4% in the nonpregnant woman, decreases to 31% to 41% in the first trimester, 30% to 39% in the second trimester, and 28% to 40% in the third trimester.[100] There is an increase in plasma volume from 49 to 67 mL/kg, an increase in total blood volume from 76 to 94 mL/kg, and little change in red cell volume (27 mL/kg) (Figure 2-8).[100] Blood volume is positively correlated with the size of the fetus in singleton pregnancies and is greater in multiple gestations.[101] The

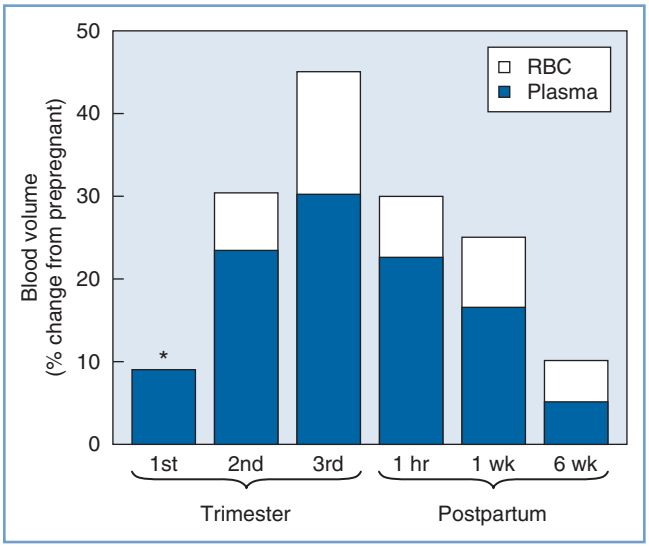

FIGURE 2-7 ■ Blood volume during pregnancy and the puerperium. Values during pregnancy measured at the end of the first, second, and third trimesters. Postpartum values measured after a vaginal delivery. The values for red blood cell volume (*RBC*) and plasma volume (*Plasma*) do not represent the actual percentage of change in these parameters but rather reflect the relative contribution of each to the change in blood volume. The *asterisk* indicates that RBC volume is below the prepregnancy volume at the end of the first trimester.

physiologic hypervolemia facilitates delivery of nutrients to the fetus, protects the mother from hypotension, and reduces the risks associated with hemorrhage at delivery. The decrease in blood viscosity from the lower hematocrit creates lower resistance to blood flow, which may be an essential component of maintaining the patency of the uteroplacental vascular bed.

The increase in plasma volume results from fetal and maternal hormone production, and several systems may play a role. Additionally, the expansion of plasma volume may help to maintain blood pressure in the presence of decreased vascular tone.[103,105] The maternal concentrations of estrogen and progesterone increase nearly 100-fold during pregnancy. Estrogens increase plasma renin activity, enhancing renal sodium absorption and water retention via the renin-angiotensin-aldosterone system. Fetal adrenal production of the estrogen precursor dehydroepiandrosterone may be the underlying control mechanism. Progesterone also enhances aldosterone production. These changes result in marked increases in plasma renin activity and aldosterone level as well as in retention of approximately 900 mEq of sodium and 7000 mL of total body water. The concentration of plasma adrenomedullin, a potent vasodilating peptide, increases during pregnancy and correlates significantly with blood volume.[106]

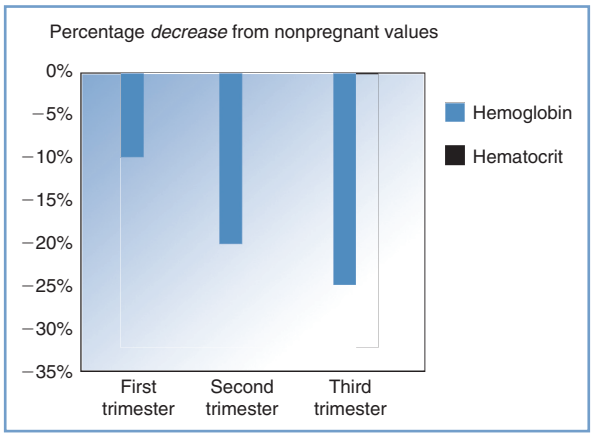

FIGURE 2-8 ■ The decrease in both hemoglobin concentration and hematocrit during pregnancy underlies the physiologic anemia of pregnancy. The decrease is greater for hematocrit and the greatest decreases occur during the third trimester. (Based on data from Abbassi-Ghanavati M, Greer LG, Cunningham FG. Pregnancy and laboratory studies: a reference table for clinicians. Obstet Gynecol 2009; 114:1326-31.)

Red blood cell volume increases in response to elevated erythropoietin concentration[107] and the erythropoietic effects of progesterone, prolactin, and placental lactogen. Both hemoglobin concentration and hematocrit decrease after conception to approximately 11.2 g/dL and 34%, respectively, by mid gestation,[102,103] which is a 15% decrease from prepregnancy levels. During the late third trimester, the hemoglobin concentration and hematocrit increase to approximately 11.6 g/dL and 35.5%, respectively, because red blood cell volume increases more than plasma volume. Women who do not receive iron supplements during pregnancy have greater decreases in hemoglobin concentration and hematocrit.[102]

Plasma Proteins

Plasma albumin concentration decreases from a nonpregnant range of 4.1-5.3 g/dL to 3.1-5.1 g/dL in the first trimester, 2.6-4.5 g/dL in the second trimester, and 2.3-4.2 g/dL in the third trimester (Table 2-6).[104,108,109] The globulin level decreases by 10% in the first trimester and then increases throughout the remainder of pregnancy to 10% above the prepregnancy value at term.[108] The albumin-globulin ratio decreases during pregnancy from 1.4 to 0.9, and the total plasma protein concentration decreases from 7.8 to 7.0 g/dL.[109] Maternal colloid osmotic pressure decreases by approximately 5 mm Hg during pregnancy.[15,110,111] The plasma cholinesterase concentration falls by approximately 25% during the first trimester and remains at that level until the end of pregnancy.[112,113]

Coagulation

Pregnancy is associated with enhanced platelet turnover, clotting, and fibrinolysis (Box 2-2). Thus, pregnancy represents a state of accelerated but compensated intravascular coagulation.

Increases in platelet factor 4 and beta-thromboglobulin signal elevated platelet activation, and the progressive increase in platelet distribution width and platelet volume are consistent with greater platelet consumption during pregnancy.[114-116] Platelet aggregation in response to collagen, epinephrine, adenosine diphosphate, and arachidonic acid is increased.[117] Despite changes in platelet

BOX 2-2 Changes in Coagulation and Fibrinolytic Parameters at Term Gestation*

Increased Factor Concentrations

- Factor I (fibrinogen)
- Factor VII (proconvertin)
- Factor VIII (antihemophilic factor)
- Factor IX (Christmas factor
- Factor X (Stuart-Prower factor)
- Factor XII (Hageman factor)

Unchanged Factor Concentrations

- Factor II (prothrombin
- Factor V (proaccelerin)

Decreased Factor Concentrations

- Factor XI (thromboplastin antecedent)
- Factor XIII (fibrin-stabilizing factor)

Other Parameters

- Prothrombin time: shortened 20%
- Partial thromboplastin time: shortened 20%
- Thromboelastography: hypercoagulable
- Fibrinopeptide A: increased
- Antithrombin III: decreased
- Platelet count: no change or decreased
- Fibrin degradation products: increased
- Plasminogen: increased

*Relative to nonpregnant state.

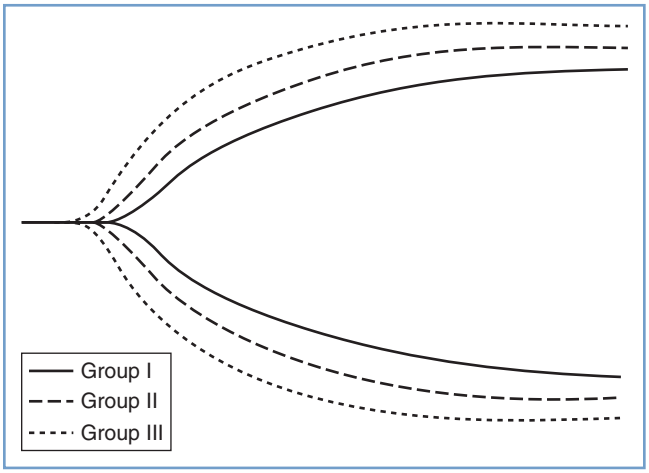

FIGURE 2-9 ■ **Comparative thromboelastographs in nonpregnant (Group I), nonlaboring term pregnant (Group II), and laboring (Group III) women.** (From Steer PL, Krantz HB. Thromboelastrography and Sonoclot analysis in the healthy parturient. J Clin Anesth 1993; 5:419-24.)

count and/or function, the bleeding time measurement is not altered during normal gestation.[118] Some investigators have noted a decrease in platelet count,[116,119] whereas others have noted no change,[114,115] suggesting that increased platelet production compensates for greater activation. The platelet count usually decreases during the third trimester, with an estimated 8% of pregnant women having a platelet count less than 150,000/mm^3 and 0.9% of pregnant women having a platelet count less than 100,000/mm^3.[115,120] The most common causes of thrombocytopenia are gestational thrombocytopenia, hypertensive disorders of pregnancy, and idiopathic thrombocytopenia. The decrease in platelet count in the third trimester is due to increased destruction and hemodilution.[121] Gestational thrombocytopenia is an exaggerated normal response.

The concentrations of most coagulation factors, including fibrinogen (factor I), proconvertin (factor VII), antihemophilic factor (factor VIII), Christmas factor (factor IX), Stuart-Prower factor (factor X), and Hageman factor (factor XII), increase during pregnancy. The increase in factor VIII is generally more marked in the third trimester. The concentrations of some factors increase by more than 100% (factors VII, VIII, IX, and fibrinogen).[121-124] Prothrombin (factor II) and proaccelerin (factor V) concentrations do not change, whereas the concentrations of thromboplastin antecedent (factor XI) and fibrin-stabilizing factor (factor XIII) decrease.[123-125] An increase in most factor concentrations, shortening of the prothrombin time (PT) and activated partial thromboplastin time (aPTT),[122] an increase in fibrinopeptide A concentration, and a decrease in antithrombin III concentration suggest activation of the clotting system (PT decreases from 12.7 to 15.4 seconds in nonpregnant women to 9.6 to 12.9 seconds in the third trimester, and aPTT decreases from 26.3 to 39.4 seconds in nonpregnant women to 24.7 to 35 seconds in the third trimester).[126] Protein S activity decreases steadily during pregnancy, reaching the lowest values at delivery.[127]

Thromboelastrography demonstrates evidence of hypercoagulability in pregnancy. These changes (decrease in R and K values, increase in the α angle and maximum amplitude [MA], and decrease in lysis) are observed as early as 10 to 12 weeks' gestation and are even greater during labor (Figure 2-9).[128-130] *In vitro*, exogenous oxytocin decreases R and K values, while increasing the α angle, thus resulting in an even more hypercoagulable state.[131] The *in vivo* effects of exogenous oxytocin are not known.

The greater concentration of fibrin degradation products signals increased fibrinolytic activity during gestation.[114] The marked elevation in the plasminogen concentration also is consistent with enhanced fibrinolysis.[132]

Hematology and Coagulation during the Puerperium

Blood loss during normal vaginal delivery and the early puerperium is approximately 600 mL.[133] The normal physiologic changes of pregnancy allow the healthy parturient to compensate for this loss. However, blood loss after either vaginal or cesarean delivery is often underestimated and the discrepancy between actual and estimated blood loss is greater with increasing blood loss.[134]

Blood volume decreases to 125% of the prepregnancy level during the first postpartum week,[133] followed by a more gradual decline to 110% of the prepregnancy level

at 6 to 9 weeks postpartum. The hemoglobin concentration and hematocrit decrease during the first 3 postpartum days, increase gradually during the next 3 days (because of a reduction in plasma volume), and continue to increase to prepregnancy measurements by 3 weeks postpartum.[135]

Cesarean delivery results in a blood loss of approximately 1000 mL within the first few hours of delivery.[133] The hematocrit in the immediate postpartum period is lower after cesarean delivery than after vaginal delivery because of the greater blood loss during cesarean delivery.[133]

Albumin and total protein concentrations and colloid osmotic pressure decline after delivery and gradually return to prepregnancy levels by 6 weeks postpartum.[110] The plasma cholinesterase value decreases below the predelivery level by the first postpartum day and remains at that decreased level during the next week.[112,113] Globulin concentrations are elevated throughout the first postpartum week.[108]

Beginning with delivery and during the first postpartum day, there is a rapid decrease in the platelet count and in the concentrations of fibrinogen, factor VIII, and plasminogen and an increase in antifibrinolytic activity.[136] Clotting times remain shortened during the first postpartum day,[137] and thromboelastography remains consistent with a hypercoagulable state.[131] During the first 3 to 5 days postpartum, increases are noted in the fibrinogen concentration and platelet count, changes that may account for the greater incidence of thrombotic complications during the puerperium.[137] The coagulation profile returns to the nonpregnant state by 2 weeks postpartum.[136]

THE IMMUNE SYSTEM

The blood leukocyte count increases progressively during pregnancy from the prepregnancy level of approximately 6,000/mm^3 to between 9,000 and 11,000/mm^3.[119] This change reflects an increase in the number of polymorphonuclear cells, with the appearance of immature granulocytic forms (myelocytes and metamyelocytes) in most pregnant women. The proportion of immature forms decreases during the last 2 months of pregnancy. The lymphocyte, eosinophil, and basophil counts decrease, whereas the monocyte count does not change. The leukocyte count increases to approximately 13,000/mm^3 during labor and increases further to an average of 15,000/mm^3 on the first postpartum day.[135] By the sixth postpartum day, the leukocyte count decreases to an average of 9,250/mm^3, although the count is still above normal at 6 weeks postpartum.

Polymorphonuclear leukocyte function is impaired during pregnancy, as evidenced by depressed neutrophil chemotaxis and adherence.[138] This impairment may account for the greater incidence of infection during pregnancy and improved symptoms in some pregnant women with autoimmune diseases (e.g., rheumatoid arthritis). Levels of immunoglobulins A, G, and M are unchanged during gestation, but humoral antibody titers to certain viruses (e.g., herpes simplex, measles, influenza type A) are decreased.[139]

During pregnancy, the uterine mucosa is characterized by a large number of maternal immune cells found in close contact with the trophoblast. The fetal expression of paternal antigens requires adaptations in the maternal immune system so that the fetus is not perceived by the mother as "foreign."[140,141] This "immune tolerance" occurs because of a lack of fetal antigen expression, because of separation of the mother from the fetus, or from a functional suppression of the maternal lymphocytes.[142] During the first trimester of pregnancy, T lymphocytes express granulysin, a novel cytolytic protein, which provides a protective role at the maternal-fetal interface.[143] Human T cells may be classified into T-helper cells types 1 and 2 (Th1 and Th2) on the basis of their cytokine production. Successful pregnancy is associated with a predominant Th2 cytokine profile. Th1 cytokines are detrimental to pregnancy. These cells also produce natural antimicrobial agents within the uterus, which are important for prevention of uterine infection during pregnancy.[144]

THE GASTROINTESTINAL SYSTEM

Anatomy, Barrier Pressure, and Gastroesophageal Reflux

The stomach is displaced upward toward the left side of the diaphragm during pregnancy, and its axis is rotated approximately 45 degrees to the right from its normal vertical position. This altered position displaces the intra-abdominal segment of the esophagus into the thorax in most women, causing a reduction in tone of the lower esophageal high-pressure zone (LEHPZ), which normally prevents the reflux of gastric contents. Progestins also may contribute to a relaxation of the LEHPZ.[145]

Approximately 30% to 50% of women experience **gastroesophageal reflux disease (GERD)** during pregnancy,[146] with the majority (80%) experiencing regurgitation not heartburn (pyrosis) (20%).[147] The prevalence of GERD is approximately 10% in the first trimester, 40% in the second trimester, and 55% in the third trimester. In the first trimester of pregnancy, basal LEHPZ pressure may not change, but the sphincter is less responsive to physiologic stimuli that usually increase pressure.[148] In the second and third trimesters, LEHPZ pressure gradually decreases to approximately 50% of basal values, reaching a nadir at 36 weeks' gestation and returning to prepregnancy values at 1 to 4 weeks postpartum (Table 2-7). Risk factors for GERD in pregnancy include gestational age, heartburn antecedent to pregnancy, and multiparity. Gravidity, prepregnancy BMI, and weight gain during pregnancy do not correlate with the occurrence of reflux, whereas maternal age has an inverse correlation.[147,149]

Gastrointestinal Motility

Gastric emptying is not altered during pregnancy. This has been demonstrated by studies that measured the absorption of orally administered acetaminophen[150-152] and by studies that assessed the emptying of a test meal

TABLE 2-7 **Changes in Gastrointestinal Physiology during Pregnancy***

Parameter	Trimester			Labor	Postpartum (18 h)
	FIRST	SECOND	THIRD		
Barrier pressure†	Decreased	Decreased	Decreased	Decreased	?
Gastric emptying	No change	No change	No change	Delayed	No change
Gastric acid secretion	No change	No change	No change	?	?
Proportion of women with gastric volume > 25 mL	No change	No change	No change	Increased	No change
Proportion of women with gastric pH < 2.5	No change	No change	No change	No change	No change

*Relative to nonpregnant state.
†Difference between intragastric pressure and tone of the lower esophageal high-pressure zone.

by radiographic,[153] ultrasonographic,[152,154] dye dilution,[155] epigastric impedance,[156] and applied potential tomographic[157] techniques. In a study of morbidly obese women at term, no difference was noted between gastric emptying of 300 mL and 50 mL of water, suggesting that fasting guidelines should not differ for obese versus lean parturients.[158]

Esophageal peristalsis and intestinal transit are slowed during pregnancy,[154,159] which has been attributed to the inhibition of gastrointestinal contractile activity by progesterone. However, this inhibition may be an indirect action that results from a negative effect of progesterone on the plasma concentration of motilin, which declines during pregnancy.[154] Up to 40% of women suffer from constipation at some time during their pregnancy.[160] The prevalence of constipation is greatest in the first two trimesters of gestation and declines in the third trimester.

Gastric Acid Secretion

Early work suggested that both basal and maximal gastric acid secretion decline in mid gestation, reaching a nadir at 20 to 30 weeks' gestation.[161] Van Thiel et al.[162] demonstrated no difference in basal or peak gastric acid secretion in four pregnant women studied in each trimester and at 1 to 4 weeks postpartum, although a plasma gastrin level significantly lower than postpartum levels was observed during the first trimester. Levels of gastric pH and serum gastrin concentration were compared in 100 women who were not in labor but were scheduled for elective cesarean delivery and in 100 nonpregnant women undergoing gynecologic surgery.[163] The pH was lower in the pregnant group (2.4 versus 3.0), but serum gastrin levels were not different despite the fact that gastrin is secreted by the placenta from 15 weeks' gestation onward.[164] Other studies that have examined stomach contents have shown that approximately 80% of both pregnant and nonpregnant women have a gastric pH of 2.5 or less, approximately 50% have gastric volumes of 25 mL or greater, and 40% to 50% exhibit both low pH and gastric volume greater than 25 mL. These results are similar to those obtained from studies of women at a mean gestation of 15 weeks.[165]

Nausea and Vomiting

Approximately 80% of pregnant women will experience nausea and vomiting during pregnancy.[166] The symptoms typically start between 4 to 9 weeks' gestation and may last until 12 to 16 weeks' gestation.[167] Of these women, 1% to 5% will develop symptoms that persist throughout the pregnancy, known as **hyperemesis gravidarum** (see Chapter 16).

Gastric Function during Labor and the Puerperium

Gastric emptying is slowed during labor, as shown by ultrasonographic imaging, emptying of a test meal, and the rate of absorption of oral acetaminophen.[168,169] Direct measurements show that the mean gastric volume increases.[170] However, in one study, postpartum gastric volume was found to be no different in parturients who consumed water in labor compared with those who consumed an isotonic sports drink composed of mixed carbohydrates and electrolytes.[171] Gastric acid secretion may decrease during labor because only 25% of parturients who are in labor have gastric pH of 2.5 or less.[172] Gastric emptying is delayed during the early postpartum period but returns to prepregnancy levels by 18 hours postpartum.[173] Gastric volume and pH values are similar in fasting women more than 18 hours after delivery and in nonpregnant individuals who have fasted before elective surgery.[174-176] The effects of opioids and neuraxial analgesia on gastric emptying are discussed in Chapters 23 and 29.

THE LIVER AND GALLBLADDER

Liver size, morphology, and blood flow do not change during pregnancy, although the liver is displaced upward, posterior, and to the right during late pregnancy.

Serum levels of bilirubin, alanine aminotransferase, aspartate aminotransferase, and lactate dehydrogenase increase to the upper limits of the normal range during pregnancy.[177] The total alkaline phosphatase activity increases twofold to fourfold, mostly from production by the placenta. Excretion of sulfobromophthalein into bile decreases, whereas the hepatic extraction and retention of this compound increases.[178]

Biliary stasis and greater secretion of bile with cholesterol increase the risk of gallbladder disease during pregnancy.[179] The incidence of gallstones is 5% to 12% in pregnant women.[180] One in 1,600 to 1 in 10,000 women undergo cholecystectomy during pregnancy. Progesterone inhibits the contractility of gastrointestinal smooth muscle, leading to gallbladder hypomotility.[181] The size

of the total bile acid pool increases by about 50% during pregnancy, and the relative proportions of the various bile acids change.[182] The changes in the composition of bile revert rapidly after delivery, even in patients with gallstones.

THE KIDNEYS

Owing to an increase in total intravascular volume, both renal vascular and interstitial volume increase during pregnancy. These increases are reflected in enlarged kidneys, with renal volume increased by as much as 30%.[183] Vasodilation of the kidneys contributes to the overall decline in systemic vascular resistance during the first trimester. The collecting system, including the renal calyces, pelvis, and ureters, dilates. Hydronephrosis may occur in 80% of women by mid pregnancy.[184]

Both the glomerular filtration rate (GFR) and the renal plasma flow increase markedly during pregnancy secondary to reduced renal vascular resistance.[26] The renal plasma flow is 75% greater than nonpregnant values by 16 weeks' gestation and is maintained until 34 weeks, when a slight decline occurs. By the end of the first trimester, the GFR is 50% greater than baseline, and this rate is maintained until the end of pregnancy. The GFR does not return to prepregnancy levels until 3 months postpartum. Because the GFR does not increase as rapidly or as much as the renal plasma flow, the filtration fraction decreases from nonpregnant levels until the third trimester.[185] The potential role of nitric oxide in the renal vasodilation was tested and confirmed in a rat model.[186]

Creatinine clearance is increased to 150 to 200 mL/min from the normal baseline values of 120 mL/min.[187] The increase occurs early in pregnancy, reaches a maximum by the end of the first trimester, decreases slightly near term, and returns to the prepregnancy level by 8 to 12 weeks postpartum.[185] These renal hemodynamic alterations are among the earliest and most dramatic maternal adaptations to pregnancy. The increased GFR results in reduced blood concentrations of nitrogenous metabolites. The blood urea nitrogen concentration decreases to 8 to 9 mg/dL by the end of the first trimester and remains at that level until term.[187] Serum creatinine concentration is a reflection of skeletal muscle production and urinary excretion. In pregnancy, skeletal muscle production of creatinine remains relatively constant but the GFR is increased, resulting in a reduced serum creatinine concentration. The serum creatinine concentration decreases progressively to 0.5 to 0.6 mg/dL by the end of pregnancy. The serum uric acid level declines in early pregnancy because of the rise in GFR, to 2.0 to 3.0 mg/dL by 24 weeks' gestation.[188] Subsequently, the uric acid level begins to increase, reaching the prepregnancy level by the end of pregnancy. Tubular reabsorption of urate accounts for this elevated uric acid level during the third trimester.

Total protein excretion and urinary albumin excretion are higher than nonpregnant levels. Average 24-hour total protein and albumin excretion are 200 mg and 12 mg, respectively (upper limits are 300 mg and 20 mg, respectively).[189,190] Proteinuria (> 300 mg/24 h) has been described without the diagnosis of preeclampsia.[191] However, women with isolated proteinuria are more likely to progress to preeclampsia than women with isolated hypertension. The protein-to-creatinine ratio in a random urine sample correlates well with a 24-hour urine protein measurement, and a value of greater than 0.18 has been estimated as indicating significant proteinuria[192]; this test may be an alternative method if time is lacking for a 24-hour urine collection. The degree of proteinuria in normal pregnancy also correlates with gestation. Women with twin pregnancies have greater protein excretion compared with those with singleton pregnancies.[193]

Glucose is filtered and almost completely absorbed in the proximal tubule. In the nonpregnant state, a small amount of glucose is excreted. Pregnancy imposes a change in the glucose resorptive capacity of the proximal tubules, so all pregnant women exhibit an elevation of glucose excretion. Of pregnant women who have normal glucose tolerance to an oral load and normal glucose excretion when not pregnant, approximately half will exhibit a doubling of glucose excretion. Most of the remainder have increases of 3 to 10 times the nonpregnant amount, and a small proportion (< 10%) excrete as much as 20 times the nonpregnant amount.[194] Overall, the amount of glucose excreted in the third trimester is several times greater than that in the nonpregnant state. The normal nonpregnant pattern of glucose excretion is reestablished within a week after delivery.

The kidney is also involved in maintenance of acid-base status during pregnancy. An increase in alveolar ventilation results in respiratory alkalosis. A compensatory response occurs in the kidney, with greater bicarbonate excretion and a decline in serum bicarbonate levels. The decrease in serum bicarbonate affects the pregnant woman's ability to buffer an acid load.

NONPLACENTAL ENDOCRINOLOGY

Thyroid Function

The thyroid gland enlarges by 50% to 70% during pregnancy because of follicular hyperplasia and greater vascularity. The estrogen-induced increase in thyroid-binding globulin results in a 50% increase in total triiodothyronine (T3) and thyroxine (T4) concentrations during the first trimester, which are maintained until term.[195] The concentrations of free T3 and T4 do not change. The concentration of thyroid-stimulating hormone (TSH) decreases during the first trimester but returns to the nonpregnant level shortly thereafter and undergoes no further change during the remainder of pregnancy. The fetal thyroid gland cannot produce thyroid hormone until the end of the first trimester and relies solely on maternal T4 production during this critical time of development and organogenesis.

Approximately 4% to 7% of women of childbearing age are either hypothyroid or at risk of hypothyroidism during pregnancy.[196] Only 20% to 30% of affected women demonstrate symptoms of hypothyroidism, likely because

symptoms of hypothyroidism mimic features of pregnancy.[197] In a large study of 502,036 pregnant women, 15% of tested women had gestational hypothyroidism, with 33% of these women demonstrating symptoms.[198] Based on these results, many physicians advocate universal screening, which appears to be cost effective, given the risk of decreased intelligence in the offspring, miscarriage, and postpartum bleeding if hypothyroidism is left untreated.[199]

Glucose Metabolism

Mean blood glucose concentration remains within the normal range during pregnancy, although the concentration may be lower in some women during the third trimester compared with nonpregnant individuals.[200] This finding is explained by the greater glucose demand of the fetus and the placenta. The relative hypoglycemic state results in fasting hypoinsulinemia. Pregnant women also exhibit exaggerated starvation ketosis.

Pregnant women are insulin resistant because of hormones such as placental lactogen secreted by the placenta.[201] The blood glucose levels after a carbohydrate load are greater in pregnant women than in nonpregnant women, despite a hyperinsulinemic response. These changes resolve within 24 hours of delivery.

Adrenal Cortical Function

The concentration of corticosteroid-binding globulin (CBG) doubles during gestation as a result of an estrogen-induced enhancement of hepatic synthesis.[202] The elevated CBG value results in a 100% increase in the plasma cortisol concentration at the end of the first trimester and a 200% increase at term. The concentration of unbound, metabolically active cortisol at the end of the third trimester is two and one-half times the nonpregnant level. The increase in free cortisol results from greater production and reduced clearance. Protein binding of corticosteroids is affected by an increase in the CBG concentration and a decrease in the serum albumin level. CBG binding capacity usually saturates at low concentrations of glucocorticoids. Clearance of betamethasone is greater during pregnancy, possibly because the drug is metabolized by placental enzymes.[203]

THE MUSCULOSKELETAL SYSTEM

Back pain during pregnancy is common. A cohort of 200 consecutive women without back pain at the start of pregnancy were observed throughout their pregnancy.[204] At 12 weeks' gestation, 19% of the study population complained of backache. The incidence increased to 47% at 24 weeks' gestation and peaked at 49% at 36 weeks' gestation. After delivery, the prevalence of back pain declined to 9.4%. Despite a relatively high prevalence, only 32% of women with low back pain during pregnancy reported this problem to their physicians and only 25% of providers recommended specific therapy.[205]

The etiology of the back pain is multifactorial. One theory is that the enlarging uterus results in exaggerated lumbar lordosis, placing mechanical strain on the lower back. The hormonal changes of pregnancy may also play a role. Relaxin, a polypeptide hormone of the insulin-like growth factor family, is associated with remodeling of collagen fibers and pelvic connective tissue. The primary source of circulating relaxin is the corpus luteum; the placenta is a secondary source. Serum relaxin levels in early pregnancy are positively correlated with the presence of back pain.[206]

Women who develop low back pain during pregnancy may avoid subsequent pregnancy to prevent recurrence. These women have a very high risk of a new episode during a subsequent pregnancy.[207] In the majority of patients, low back pain during pregnancy responds to activity and postural modification. Exercises to increase the strength of the abdominal and back muscles are helpful. Scheduled rest periods with elevation of the feet to flex the hips and decrease the lumbar lordosis help relieve muscle spasm and pain.[208]

The enhancement of the lumbar lordosis during pregnancy alters the center of gravity over the lower extremities (Figure 2-10) and may lead to other mechanical problems. Exaggerated lumbar lordosis tends to stretch the lateral femoral cutaneous nerve, possibly resulting in **meralgia paresthetica,** with paresthesia or sensory loss over the anterolateral thigh. Anterior flexion of the neck and slumping of the shoulders usually accompany the enhanced lordosis, sometimes leading to a brachial plexus neuropathy.

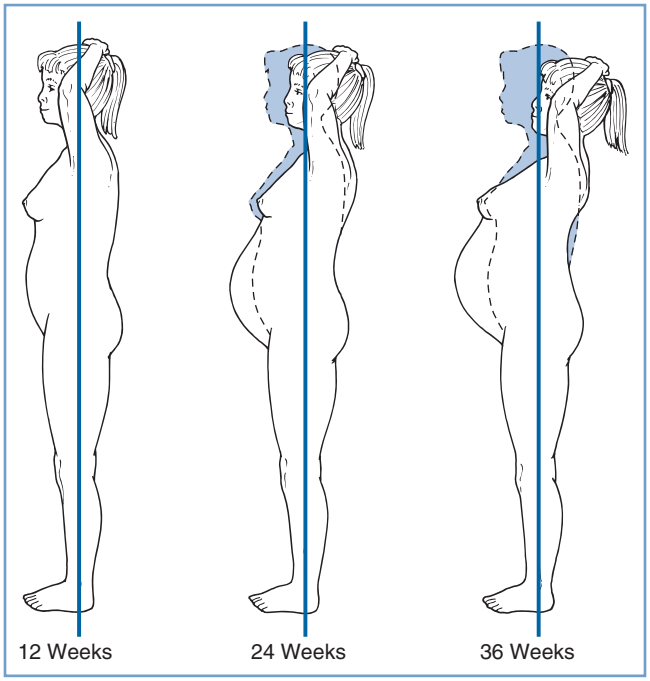

FIGURE 2-10 ■ Changes in posture during pregnancy. The first and the subsequent dotted-line figures represent a woman's posture before growth of the uterus and its contents have affected the center of gravity. The second and third solid figures show that as the uterus enlarges and the abdomen protrudes, the lumbar lordosis is enhanced and the shoulders slump and move posteriorly. (Modified from Beck AC, Rosenthal AH. Obstetrical Practice. Baltimore, Williams & Wilkins, 1955;146.)

Mobility of the sacroiliac, sacrococcygeal, and pubic joints increases during pregnancy in preparation for passage of the fetus. A widening of the pubic symphysis is evident by 30 weeks' gestation. These changes are attributable to relaxin and the biomechanical strain of pregnancy on the ligaments.[209] Relaxin may also contribute to the greater incidence of carpal tunnel syndrome during pregnancy by changing the nature of the connective tissue so that more fluid is absorbed.[210]

The human fetus requires approximately 30 g of calcium for skeletal development by the time of term delivery.[211] Although intestinal absorption of calcium by the mother increases from as early as 12 weeks' gestation to meet this increased demand, it is insufficient to meet fetal demand and thus the maternal skeleton undergoes resorption.[212] This does not cause long-term changes in skeletal calcium content or strength. Pregnant women with a twin gestation have a much higher calcium requirement. Compared with singleton pregnancies, there is a larger increase in bone resorption in twin gestation.[213]

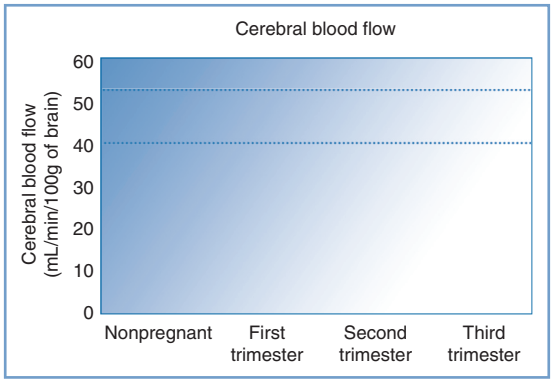

FIGURE 2-11 ■ Cerebral blood flow during pregnancy. Cerebral blood flow increases as pregnancy progresses and is attributable to vasodilation from the hormonal changes of pregnancy. This increase in cerebral blood flow explains the increased risk of complications in patients with intracranial pathology as pregnancy progresses. (Based on data from Nevo O, Soustiel JF, Thaler I. Maternal cerebral blood flow during normal pregnancy: a cross-sectional study. Am J Obstet Gynecol 2010; 203:475.e1-6.)

THE NERVOUS SYSTEM

Sleep

Sleep disturbances from mechanical and hormonal factors occur commonly during pregnancy. Latency and duration of rapid eye movement (REM) sleep are influenced by changes in progesterone and estrogen concentrations. Pregnant women have more complaints of insomnia and daytime sleepiness. The American Academy of Sleep Medicine defined **pregnancy-associated sleep disorder** as the occurrence of insomnia or excessive sleepiness that develops in the course of pregnancy.[214] Progesterone has a strong sedating effect, and cortisol, levels of which are higher in pregnancy, is associated with an increase in REM sleep.[215] In a cohort study of 189 healthy nulliparous women, Facco et al. reported that mean (± SD) sleep duration was shorter in the third trimester (7.0 ± 1.2 hours) compared with the baseline period between 6 and 20 weeks' gestation (7.4 ± 1.2 hours).[216]

The Pittsburgh Sleep Quality Index, a sum of seven components assessing sleep quality, sleep latency, sleep duration, and daytime drowsiness, indicated poor sleep quality as the pregnancy progressed. Polysomnography reveals reduced slow-wave and REM phases of sleep, decreased total sleep time, and increased rate of wakening after sleep onset.[217] Sleep may be poor for up to 3 months postpartum.[218] Upper airway changes lead to increased airflow resistance and snoring. Although only 4% of nonpregnant women snore, as many as 23% of pregnant women snore by the third trimester. Snoring is more common in women with preeclampsia.

Pregnancy is associated with **transient restless leg syndrome,** a disorder in which the patient experiences the need to move her legs. The incidence ranges from 15% in the first trimester to 23% in the third trimester.[219]

Central Nervous System

Cerebral blood flow increases in pregnancy. Nevo et al.[220] measured cerebral blood flow in 210 women at different gestational ages and found that it increased from 44.4 mL/min/100 g during the first trimester to 51.8 mL/min/100 g during the third trimester (Figure 2-11). The increase was secondary to a decrease in cerebrovascular resistance and an increase in internal carotid artery diameter. Two other changes in the brain that occur during pregnancy include (1) an increase in permeability of the blood-brain barrier owing to decreased cerebrovascular resistance with an increase in hydrostatic pressure and (2) an increase in capillary density in the posterior cerebral cortex.[221]

Women experience an elevation in the threshold to pain and discomfort near the end of pregnancy and during labor.[222] The mechanism, although unclear, may be related to the effects of progesterone and endorphins. Elevated concentrations of endorphins and enkephalins are found in the plasma and CSF of parturients,[223] and opioid antagonists abolish pregnancy-induced analgesia to visceral stimulation in experimental animals.[224]

Vertebral Column

Anatomic and mechanical changes occur to the vertebral column during pregnancy. The epidural space can be regarded as a rigid tube that contains two fluid-filled distensible tubes, the dural sac, and epidural veins. The volume of epidural fat and the epidural veins enlarge during pregnancy; spinal CSF volume is reduced.[40]

In the lateral position, lumbar epidural pressure is positive in term pregnant women but negative in more than 90% of nonpregnant women.[225] Turning a parturient from the lateral to the supine position increases the epidural pressure. Epidural pressure also increases during labor because of increased diversion of venous blood through the vertebral plexus secondary to either enhanced compression of the inferior vena cava in the supine position or greater intra-abdominal pressure during pain and pushing. The epidural pressure returns to the nonpregnant level by 6 to 12 hours postpartum.

Despite compression of the dural sac by the epidural veins, the CSF pressure in pregnant women is the same as in nonpregnant women.[226] Uterine contractions and pushing result in an increase in CSF pressure that is secondary to acute increases in epidural vein distention.

Sympathetic Nervous System

Dependence on the sympathetic nervous system for maintenance of hemodynamic stability increases progressively throughout pregnancy and reaches a peak at term.[227-229] The dependence on the sympathetic nervous system returns to that of the nonpregnant state by 36 to 48 hours postpartum.

ANESTHETIC IMPLICATIONS

Positioning

Aortocaval compression, decreased blood pressure and cardiac output, and impairment of uteroplacental blood flow occur when a pregnant woman is placed in the supine position. This may compromise fetal well-being and neonatal outcome during labor or cesarean delivery.[230-232] Therefore, after 20 weeks' gestation, the supine position should be avoided and the uterus should be displaced to the left by placement of a wedge underneath the right hip or by tilting the operating table to the left (Figure 2-12). Anesthetic drugs or techniques that cause venodilation further reduce venous return with caval obstruction. Studies performed with pregnant women placed in the lateral position have not shown major decreases in cardiac output.[233,234]

Blood Replacement

At delivery, maternal vascular capacitance is reduced by the volume of the intervillous space (at least 500 mL). Therefore, during vaginal or cesarean delivery, this volume of blood does not need to be replaced and should not be considered in the estimation of blood loss for replacing red blood cells. Hemoconcentration occurs as maternal blood volume declines from 94 mL/kg at term to 76 mL/kg during the postpartum period; this should be considered in the decision as to whether a parturient should receive crystalloid, colloid, or blood for volume replacement.[100]

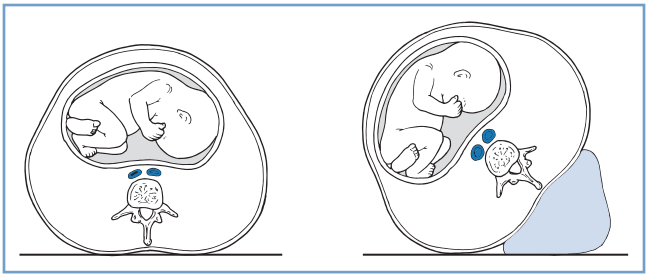

FIGURE 2-12 ■ Compression of the aorta and inferior vena cava in the supine (*left*) and lateral tilt (*right*) positions. (Redrawn from Camann WR, Ostheimer GW. Physiologic adaptations during pregnancy. Int Anesthesiol Clin 1990; 28:2-10.)

General Anesthesia

Airway Management, Oxygenation, and Ventilation

Changes in the maternal airway and respiratory physiology mandate modification of airway management during pregnancy (Box 2-3) (see Chapter 30). The proportion of pregnant women with a Mallampati IV classification increases by 34% between 12 and 38 weeks' gestation.[235] Vascular engorgement of the airway results in edema of the oral and nasal pharynx, larynx, and trachea,[236] which may lead to difficult tracheal intubation and difficult mask ventilation. Airway edema may be exacerbated in patients with upper respiratory tract infection or preeclampsia and in those who have been pushing for a long time during the second stage of labor. Management of the difficult obstetric airway is discussed in Chapter 30.

Because FRC is reduced, oxygen consumption is increased, and FRC is less than closing capacity in up to 50% of supine individuals.[70] Pregnant women become hypoxemic more rapidly than nonpregnant women during episodes of apnea. During apnea accompanying rapid-sequence induction of general anesthesia, Pao_2 decreases twice as rapidly (139 versus 58 mm Hg/min) in pregnant versus nonpregnant women.[237] Denitrogenation is achieved faster in pregnant versus nonpregnant women because of elevated minute ventilation and decreased FRC. However, after

BOX 2-3 Considerations for General Anesthesia during Pregnancy

Drugs

- Propofol
  - Induction dose decreased
  - Elimination half-life unaltered
- Thiopental
  - Induction dose decreased
  - Elimination half-life prolonged
- Volatile anesthetic agents
  - Minimum alveolar concentration (MAC) decreased, but unclear whether hypnotic dose requirement differs from that in nonpregnant women
  - Speed of induction increased
- Succinylcholine
  - Duration of blockade unaltered
- Rocuronium
  - Increased sensitivity
- Chronotropic agents and vasopressors
  - Decreased sensitivity

Tracheal Intubation

- Increased rate of decline of Pao_2 during apnea
- Smaller endotracheal tube required (6.5 or 7.0 mm)
- Increased risk of failed intubation with traditional laryngoscopy
- Increased risk of bleeding with nasal instrumentation

complete denitrogenation via inhalation of 100% oxygen, parturients tolerate only 2 to 3 minutes of apnea, versus 9 minutes in nonpregnant patients, before oxygen saturation decreases to less than 90%.

Ventilation should be adjusted to maintain $Paco_2$ at approximately 30 mm (4 kPa). This can be achieved with minute ventilation of 121 mL/kg/min; in comparison, 77 mL/kg/min is required to maintain a comparable $Paco_2$ in nonpregnant women.[238] Decreased plasma bicarbonate concentration reduces buffering capacity in pregnancy. Allowing the $Paco_2$ to increase to the normal level for nonpregnant women results in respiratory acidosis.

Intravenous and Inhalation Anesthetics

Propofol requirement decreases 10% during the first trimester[239]; this decrease is not accounted for by progesterone because the dose reduction does not correlate with progesterone levels. The elimination half-life of propofol is unaffected by pregnancy, although clearance may be higher.[240] The average induction dose of **thiopental** in pregnant women is 18% lower in the first trimester and 35% lower at term compared with that in nonpregnant women.[241,242] The elimination half-life of thiopental in pregnant women is 26.1 hours, compared with 11.5 hours in nonpregnant women[243]; this is explained by a marked increase in volume of distribution despite increased clearance. Plasma protein binding of thiopental is similar in term pregnant and nonpregnant women.[243]

The rate of rise of alveolar versus inspired anesthetic concentration (F_A/F_I) of **volatile anesthetics**, and thus the speed of induction, is increased during pregnancy because of greater minute ventilation and reduced FRC, despite higher cardiac output.

The minimum alveolar concentration (MAC) for volatile anesthetics is up to 40% lower in pregnancy.[244-246] Although MAC is a spinal nociceptive reflex that involves both sensory and motor components,[247] practitioners have interpreted this decrease in MAC as indicating that pregnant patients have a decreased requirement for inhaled anesthetics. However, this interpretation has been questioned. Ueyama et al.[248] compared bispectral index values in 15 patients undergoing cesarean delivery with sevoflurane general anesthesia versus 15 patients undergoing elective gynecologic surgery and found no difference between groups. This finding suggests that the hypnotic effect of sevoflurane was not enhanced by pregnancy. The investigators concluded that although pregnancy may decrease MAC, it does not decrease volatile anesthetic requirements, and suggested that parturients should be given the same dose of volatile anesthetics as nonpregnant patients. Further work is required to confirm these findings.

Muscle Relaxants

Pseudocholinesterase activity is decreased by 24% before delivery and by 33% on the third postpartum day.[249] It returns to normal 2 to 6 weeks postpartum. The reduced activity does not usually result in clinically relevant prolongation of paralysis after a single dose of **succinylcholine**. Twitch height recovery after administration of succinylcholine is similar between pregnant and nonpregnant women, and recovery may even be faster because the larger volume of distribution results in a lower initial drug concentration and a shorter time before the threshold for recovery is attained. Pregnant women may be less sensitive than nonpregnant women to comparable plasma concentrations of succinylcholine, a feature that also may contribute to more rapid recovery during pregnancy.

Pregnant and postpartum women exhibit enhanced sensitivity to the aminosteroid muscle relaxants **vecuronium** and **rocuronium**.[250,251] The greater sensitivity to vecuronium is not explained by altered pharmacokinetics because the drug exhibits increased clearance and a shortened elimination half-life in pregnant women.[252] The mean onset time and clinical duration of **cisatracurium** are significantly shorter in women immediately after delivery than in nonpregnant women.[253]

Chronotropic Agents and Vasopressors

Pregnancy reduces the chronotropic response to **isoproterenol** and **epinephrine** because of down-regulation of beta-adrenergic receptors.[254] These agents are less-sensitive markers of intravascular injection during administration of an epidural test dose in pregnant patients than in nonpregnant patients. Because of down-regulation of adrenergic receptors, treatment of hypotension requires higher doses of vasopressors such as **phenylephrine** in pregnant women than in nonpregnant women.

Neuraxial Analgesia and Anesthesia

Technical Considerations and Positioning

Increased lumbar lordosis during pregnancy may reduce the vertebral interspinous gap, thus creating technical difficulty in administering neuraxial anesthesia (Box 2-4 and Figure 2-13) (see Chapter 12). Widening of the

BOX 2-4 Neuraxial Anesthesia:

ANESTHETIC IMPLICATIONS OF MATERNAL PHYSIOLOGIC CHANGES

Technical Considerations

- Lumbar lordosis increased
- Apex of thoracic kyphosis at higher level
- Head-down tilt when in lateral position

Treatment of Hypotension

- Decreased sensitivity to vasopressors*

Local Anesthetic Dose Requirements†

- Subarachnoid dose reduced 25%
- Epidural dose unaltered or slightly reduced

*Compared with nonpregnant women.
†Change in the segmental dose requirement compared with nonpregnant women.
Modified from Conklin KA. Maternal physiologic adaptations during gestation, labor, and the puerperium. Semin Anesth 1991; 10:221-34.

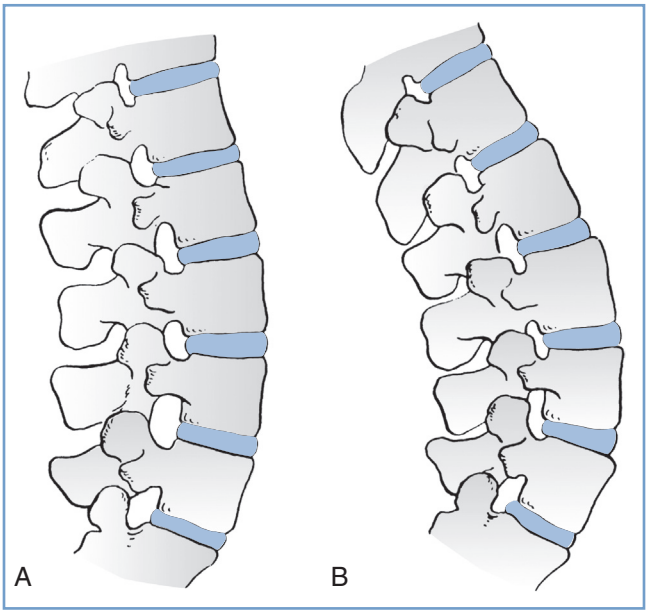

FIGURE 2-13 ■ Effects of pregnancy on the lumbar spine. **A,** Nonpregnant. **B,** Pregnant. There is a marked increase in lumbar lordosis and a narrowing of the interspinous spaces during pregnancy. (Modified from Bonica JJ. Principles and Practice of Obstetric Analgesia and Anesthesia, Volume 1. Philadelphia, FA Davis, 1967:35.)

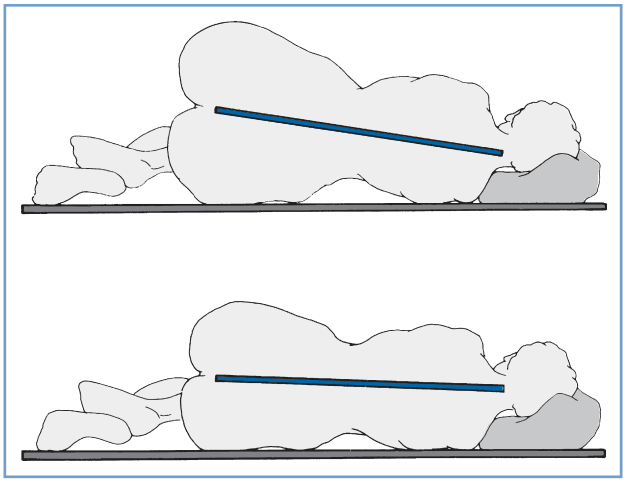

FIGURE 2-14 ■ Pelvic widening and resultant head-down tilt in the lateral position during pregnancy. *Upper panel,* pregnant; *lower panel,* nonpregnant. (Modified from Camann WR, Ostheimer GW. Physiological adaptations during pregnancy. Int Anesthesiol Clin 1990; 28:2-10.)

pelvis results in a head-down tilt when a pregnant woman is in the lateral position (Figure 2-14). This may increase the rostral spread of hyperbaric local anesthetics when injected intrathecally with patients in the lateral position. The flow of CSF from a spinal needle is unchanged throughout gestation because pregnancy does not alter CSF pressure.[226] However, flow rate may increase during a uterine contraction because of increased CSF pressure.

Local Anesthetic Dose Requirements

Pregnant patients show decreased local anesthetic dose requirement in the first trimester. This change occurs well before significant mechanical changes have occurred in the vertebral canal,[255] suggesting that there are pregnancy-induced alterations in nerve tissue sensitivity, either directly or indirectly from changes in hormone concentrations.[256]

Pregnant women exhibit a more rapid onset and a longer duration of spinal anesthesia than nonpregnant women who receive the same dose of local anesthetic. These results are consistent with enhanced neural sensitivity to local anesthetics; pregnancy-associated elevation in CSF pH may contribute to these effects.[257-259] The dose of hyperbaric local anesthetic required in term pregnant women is 25% lower than that in nonpregnant women.[260,261] This is attributed to the following factors: (1) reduction of spinal CSF volume, which accompanies distention of the vertebral venous plexus[40]; (2) enhanced neural sensitivity to local anesthetics; (3) increased rostral spread when injections are made with the patient in the lateral position; (4) inward displacement of intervertebral foraminal soft tissue, resulting from increased abdominal pressure[262]; and (5) a higher level of the apex of the thoracic kyphosis (the lowest point of the thoracic spinal canal in the supine position) during late pregnancy.[263] Spinal dose requirements change rapidly in the postpartum period, with segmental dose requirements returning to those of nonpregnant women within 24 to 48 hours[264] as spinal CSF volume expands with the relief of vena caval compression. In contrast to spinal anesthesia, pregnancy appears to have less effect on the spread of epidural anesthesia.[265,266]

Pregnancy does not enhance the susceptibility of ewes to the neurotoxicity of lidocaine or to the cardiac toxicity of bupivacaine (see Chapter 13). The incidence of lethal ventricular arrhythmias is no greater in pregnant than in nonpregnant ewes treated with bupivacaine, ropivacaine, or levobupivacaine.[267]

Hypotension during Neuraxial Analgesia and Anesthesia

Pregnancy increases dependence on the sympathetic nervous system for the maintenance of venous return and systemic vascular resistance.[228] This, together with the effects of aortocaval compression, means that pregnant patients are particularly prone to hypotension and hemodynamic instability from sympathetic block induced by neuraxial anesthesia. Management of hypotension is discussed in Chapter 26.

Effects of Neuraxial Anesthesia on Respiratory Function

FRC diminishes during neuraxial anesthesia, resulting in an increase in respiratory dead space and ventilation-perfusion mismatch. Abdominal muscles are important for forced expiration and coughing, and paralysis of these muscles during neuraxial anesthesia decreases peak expiratory flow rate, maximum expiratory pressure, and the ability to increase intra-abdominal and intrathoracic pressures during coughing.[268-270]

KEY POINTS

- Pregnancy results in various anatomic and physiologic changes that allow the mother to adapt to the growing fetus and that allow the fetus to develop.
- Cardiac output increases during pregnancy as a result of an increase in stroke volume and heart rate. A pregnant woman with cardiovascular disease may not be able to meet this greater demand.
- Beginning at mid pregnancy, assumption of the supine position may result in compression of the inferior vena cava and aorta by the gravid uterus, which may result in decreases in both cardiac output and uteroplacental perfusion. Severe hypotension and bradycardia in the supine position is called the *supine hypotension syndrome.*
- Pregnant women should not lie supine after 20 weeks' gestation. The uterus should be displaced to the left by placement of a wedge underneath the right hip or by tilting the operating table, or the pregnant women should assume the full lateral position.
- The greater blood volume of pregnancy allows the parturient to tolerate the blood loss of delivery, within limits, with minimal hemodynamic perturbation. Maternal vascular capacitance is reduced at the time of delivery.
- Oxygen demand and delivery are greater during pregnancy.
- Minute ventilation increases whereas functional residual capacity decreases during pregnancy. It is not uncommon for the pregnant women to experience dyspnea.
- Pregnancy is a state of partially compensated respiratory alkalosis.
- Gastric volume, emptying, and pH are unaltered during pregnancy, but lower esophageal sphincter tone may be reduced with possible increased risk of gastroesophageal reflux.
- Mechanical changes in the vertebral column influence neuraxial analgesia and anesthesia.
- Pregnant women have greater sympathetic tone than nonpregnant women.
- Minimum alveolar concentration (MAC) values for the volatile anesthetics are decreased during pregnancy. However, it is unclear whether hypnotic dose requirement is altered during pregnancy.
- Pregnant women have a rapid decrease in Pa_{O_2} during periods of apnea.
- Pregnant women are at increased risk for failed tracheal intubation.
- Pregnant women are less responsive to vasopressors than nonpregnant women.

CHAPTER 3

Uteroplacental Blood Flow

Warwick D. Ngan Kee, BHB, MBChB, MD, FANZCA, FHKCA, FHKAM

CHAPTER OUTLINE

Uteroplacental blood flow is responsible for the delivery of oxygen and nutrients to the fetus. A normal uteroplacental circulation is essential for healthy fetal growth and development. Acute reduction in uteroplacental blood flow may rapidly threaten fetal viability. Chronic reduction in uteroplacental blood flow, as may occur from abnormal development of the placental vasculature, leads to gestational pathologic processes such as preeclampsia and fetal growth restriction (also known as intrauterine growth restriction) and may even predispose the fetus to developing cardiovascular disease during subsequent adulthood.[1] The uteroplacental circulation undergoes circadian changes[2] and may be affected by parturition, disease, and anesthetic techniques and drugs. An understanding of the regulation of uteroplacental circulation is an important foundation for the safe provision of obstetric anesthesia and assists in the management of many pregnancy-related diseases. Research in this area is active but complicated by ethical considerations. Much of the available knowledge comes from studies in animals, particularly sheep but also nonhuman primates and other species. It is important to consider possible interspecies differences and to critically examine the methodology and context of animal research when extrapolating findings into recommendations for clinical care.

ANATOMY AND STRUCTURE

The blood supply to the uterus is derived mainly from the uterine arteries (Figure 3-1) with a smaller, variable contribution from the ovarian arteries. Although the pelvic vasculature shows anatomic variation,[3] the uterine artery arises bilaterally from the anterior division of the internal iliac (hypogastric) artery, whereas the ovarian artery arises from the anterolateral abdominal aorta below the renal arteries. The uterine artery passes medially to the side of the uterus, where it supplies branches to the cervix and vagina and ascends between the two layers of the broad ligament, yielding arcuate arteries that supply the body of the uterus to the junction with the fallopian tubes. During pregnancy, flow may differ between the right and left uterine arteries; Konje et al.[4] estimated that vessel diameter was approximately 11% greater and blood flow was approximately 18% greater in the uterine artery on the same side as the placenta compared with the contralateral artery. Anastomoses are formed with the contralateral uterine artery, the vaginal arteries, and the ovarian arteries. The arcuate arteries give rise to small branches that supply the myometrium and large radial arteries that branch deeply and enter the endometrium to form the convoluted spiral arteries.

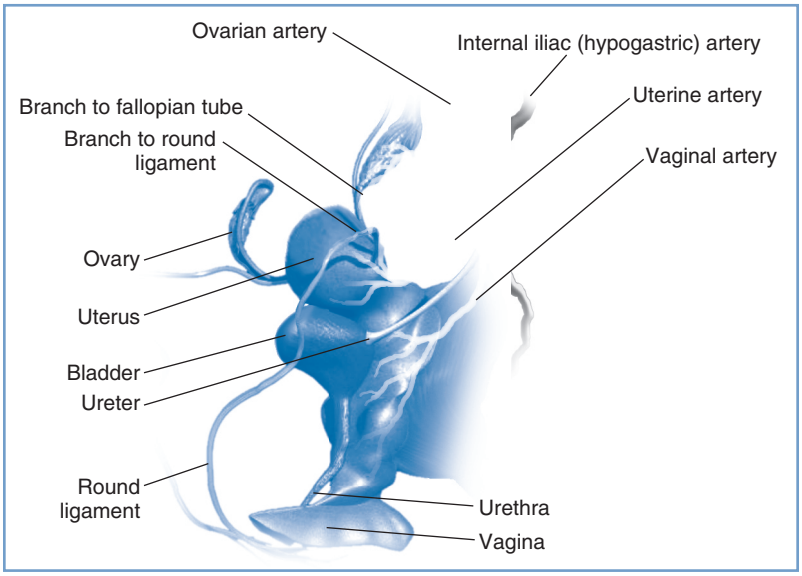

FIGURE 3-1 ■ Arterial supply to the female reproductive tract. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

During gestation, trophoblastic invasion of the spiral arteries results in loss of smooth muscle and loss of contractile ability, leading to vasodilation with decreased resistance and increased blood flow. Abnormal or inadequate trophoblastic invasion is integral to the pathophysiology of preeclampsia (see Chapter 36).[5]

From the spiral arteries, oxygenated maternal blood enters the intervillous space in fountain-like jets. Blood traveling toward the chorionic plate bathes the villi, permitting the exchange of oxygen, nutrients, and wastes between maternal and fetal blood. Maternal blood then returns to the basal plate and drains into multiple collecting veins. Venous drainage of the uterus occurs via the uterine veins to the internal iliac veins and also via the ovarian veins (utero-ovarian plexus) to the inferior vena cava on the right and the renal vein on the left.[6] The uterine artery and other branches of the anterior division of the internal iliac artery, as well as the ovarian artery, may be targeted during angiographic embolization procedures for treatment of obstetric and gynecologic hemorrhage[3] and for the treatment of uterine fibroids.[7]

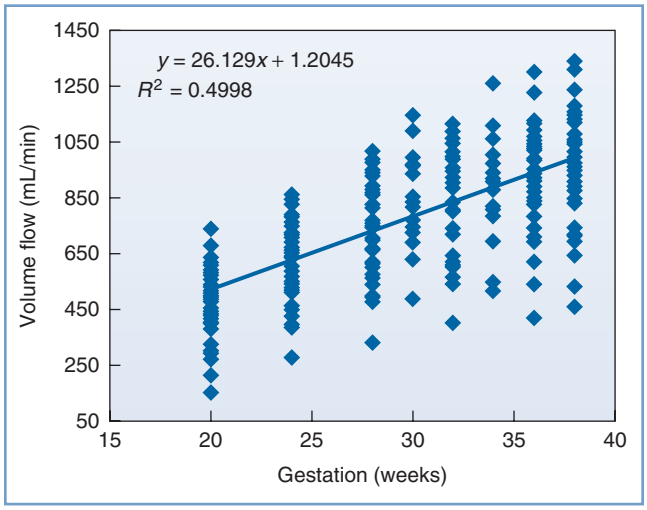

FIGURE 3-2 ■ Changes in uterine artery blood flow with gestation. (From Konje JC, Kaufmann P, Bell SC, Taylor DJ. A longitudinal study of quantitative uterine blood flow with the use of color power angiography in appropriate for gestational age pregnancies. Am J Obstet Gynecol 2001; 185:608-13.)

CHANGES AND FUNCTION DURING PREGNANCY

Pregnancy-Induced Changes

Uterine blood flow increases dramatically during pregnancy, rising from 50 to 100 mL/min before pregnancy to 700 to 900 mL/min at term, depending on the method of measurement (Figure 3-2). Studies in sheep have shown that increases in uterine blood flow can be divided into three phases.[8] An initial phase, most likely controlled by the ovarian hormones estrogen and progesterone, occurs before and during implantation and early placentation. A second phase results from the growth and remodeling of the uteroplacental vasculature to support further placental development. A third and final phase results from progressive uterine artery vasodilation to meet the markedly increased nutrient requirements of the rapidly growing fetus. When expressed in terms of uterine weight, however, uterine flow per gram of tissue is particularly high in early gestation, and this ratio decreases as pregnancy progresses.[8] In comparison, umbilical blood flow, expressed as a function of fetal weight, is relatively constant throughout most of pregnancy and is estimated to be 110 to 120 mL/min/kg.[9] Uterine blood flow is increased in twin pregnancy, but the flow per unit of estimated fetal weight is similar to that in a singleton pregnancy.[10] The progressive increase in uteroplacental blood flow during pregnancy is matched by a concurrent increase in blood flow on the fetal side (fetoplacental blood flow). However, despite suggestions

of the possibility of intrinsic flow matching, it is believed that these circulations are independently regulated.[11]

Distribution of Blood Flow

Uterine blood flow at term represents a greater proportion of cardiac output (approximately 12%) than in early pregnancy (approximately 3.5%).[12] Regional distribution of blood flow within the pelvis also changes during gestation. Palmer et al.[13] observed that increases in common iliac artery blood flow during pregnancy were associated with corresponding increases in uterine artery blood flow but also with decreases in external iliac artery blood flow. This pattern effectively constitutes a "steal" phenomenon, in which blood flow in the pelvis is preferentially redistributed toward the uterus (Figure 3-3).

Primate studies have shown that 80% to 90% of total uterine blood flow perfuses the placenta at term, with the remainder supplying the myometrium and nonplacental endometrium.[14] The placental and nonplacental vasculatures are anatomically and functionally distinct, and regulation of perfusion through these vascular beds differs.[14] Therefore, it is important to differentiate studies that measure total uteroplacental blood flow versus placental blood flow.

Functional Classification

Placental vascular function varies among species. The human multivillous model is commonly believed to function as a "venous equilibrator," in which oxygen tension in the umbilical vein approximates that in the uterine veins. In contrast, the placenta in some species (e.g., rodents) functions as a countercurrent exchanger. The more efficient function of the latter is reflected by the higher fetoplacental weight ratio in rodents (20:1) than in humans (6:1).[15]

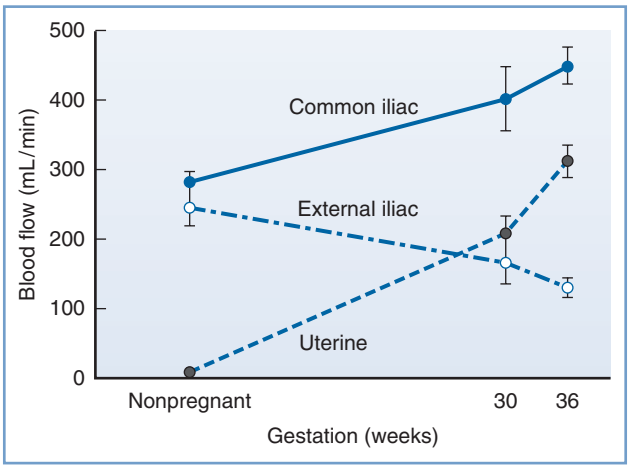

FIGURE 3-3 ■ Redistribution of blood flow in pelvic blood vessels during pregnancy determined unilaterally by Doppler ultrasonography. Blood flow increased in the common iliac and uterine arteries but decreased in the external iliac artery, indicating that redistribution of flow favors uterine perfusion. Data are mean ± SEM. (Adapted from Palmer SK, Zamudio S, Coffin C, et al. Quantitative estimation of human uterine artery blood flow and pelvic blood flow redistribution in pregnancy. Obstet Gynecol 1992; 80:1000-6.)

Autoregulation

Studies of pressure-flow relationships suggest that the nonpregnant uterine circulation exhibits autoregulation, alternately vasoconstricting or vasodilating in response to a number of different stimuli.[16] In contrast, the pregnant uterine circulation is complicated by the properties of both the placental and nonplacental circulations. Animal studies have demonstrated that the uteroplacental circulation is a widely dilated, low-resistance system with perfusion that is largely pressure dependent.[17,18] However, a study in pregnant rabbits found that uteroplacental blood flow was relatively constant over a wide range of perfusion pressures.[19] During hemorrhage in pregnant rats, uterine vascular resistance *increased* as systemic blood pressure and uterine blood flow decreased, thereby demonstrating an absence of autoregulation. Moreover, although the uteroplacental circulation is often considered to be maximally vasodilated with little or no ability for autoregulation,[17] further vasodilation has been observed in response to systemically administered estrogen, prostacyclin, bradykinin, and acetylcholine.[20-22] These discrepancies may be explained by changes in the nonplacental uterine vasculature, which accounts for a small fraction of total uteroplacental blood flow but appears to have similar autoregulatory responses during pregnant and nonpregnant states; this feature contrasts with the limited autoregulatory ability of the placental circulation.[23] Laird et al.[18] found that reducing arterial pressure by 22% with an inflatable aortic occluder in pregnant rabbits produced a reduction in total uteroplacental and placental blood flow but no significant change in myoendometrial blood flow. Clinically, limited autoregulation means that placental blood flow may diminish with reductions in maternal blood pressure (e.g., during neuraxial anesthesia).

Margin of Safety

Studies in animals have demonstrated that, in normal physiologic conditions, uterine blood flow exceeds the minimum required to satisfy fetal oxygen demand.[24] Although this feature confers a margin of safety that protects the fetus from fluctuations in uterine blood flow,[25] decreases in fetal Po_2 and progressive metabolic acidosis can occur with reductions in uteroplacental blood flow, depending on the magnitude and duration.[26] However, the relationship between uterine blood flow and oxygen transfer appears nonlinear and suggests that uteroplacental blood flow can decrease by as much as 50% for limited periods before fetal oxygen uptake decreases and metabolic acidosis occurs.[24]

Studies in sheep have shown that although uterine blood flow varies over a wide range, fetal oxygen uptake remains relatively constant, suggesting that the efficiency of oxygen extraction is greater when perfusion decreases.[27] Using an inflatable balloon occluder around the terminal aorta to reduce uterine blood flow in sheep, Wilkening and Meschia[24] found that at high levels of oxygen

delivery, fetal oxygen uptake was not significantly affected by variations in uterine blood flow; moreover, fetal oxygen uptake became flow dependent only when uterine oxygen delivery was reduced to less than half the baseline value. Boyle et al.,[28] investigating the effects of acute uterine arterial embolization with microspheres in sheep, found a linear decrease in fetal aortic oxygen tension as uterine blood flow decreased. However, uterine oxygen consumption did not decrease and fetal hydrogen ion concentration did not increase until uterine blood flow had decreased to approximately 50% of the baseline value. As uterine blood flow diminished, a reduction in uterine venous oxygen content and a greater arteriovenous oxygen content difference were observed, indicating an increase in oxygen extraction. Gu et al.[29] reported comparable findings with the compression of the common uterine artery by an inflatable occluder in sheep.

Although the preceding experiments were conducted in sheep, the same principles may apply to humans. The human placenta, like the sheep placenta, is a relatively inefficient oxygen exchanger. Thus, in humans and sheep, the transfer rate of oxygen is affected less by decreases in placental perfusion than the transfer rate in animals with more efficient placentas, such as the rabbit and guinea pig. Of interest, this difference may afford some protection in humans, because alterations in placental perfusion in animals with more efficient placentas frequently result in spontaneous abortion.[30] Animal data would also suggest the presence of a significant physiologic buffer that protects the fetus during transient fluctuations in uteroplacental perfusion (e.g., changes in endogenous vasoconstrictor levels, uterine contractions, and parturition).[31] This may partially explain why clinical studies have failed to demonstrate fetal acidosis when alpha-adrenergic agonists are used to maintain maternal blood pressure during neuraxial anesthesia,[32] despite experimental data showing that these agents reduce uteroplacental perfusion in laboratory animals.[33] These observations are based on an assumption of normal physiology; the presence of pathology likely diminishes any margin of safety.

Changes during Parturition

With the onset of the uterine contractions of labor, uteroplacental perfusion undergoes cyclical changes. During uterine contractions, a decrease in perfusion occurs that is inversely related to the strength of the contraction and the increase in intrauterine pressure.[31] Conversely, during uterine relaxation, there is a period of hyperemia when perfusion is increased. Placental perfusion is believed to be more sensitive to these contraction-induced changes than myometrial or endometrial blood flow.[34] Within the first few hours of parturition, uterine blood flow in sheep decreases on average by 50% or more, although there is notable inter-individual variation.[35]

Clinical Determinants of Uterine Blood Flow

In the acute setting, uterine blood flow is related to perfusion pressure (the difference between uterine arterial pressure and uterine venous pressure) and vascular resistance, as represented in the following equation:

$$\text{Uterine blood flow} = \frac{\text{Uterine perfusion pressure}}{\text{Uterine vascular resistance}} \quad (1)$$

Thus, there are several ways that uterine blood flow can decrease (Box 3-1). First, uterine blood flow may decline with reductions in perfusion pressure because of decreased uterine arterial pressure—for example, during systemic hypotension from hemorrhage, aortocaval compression, or sympathetic blockade during neuraxial anesthesia. Second, uterine blood flow may decline with reductions in perfusion pressure caused by increased uterine venous pressure—for example, with vena caval compression, increased intrauterine pressure during uterine contractions, drug effects (e.g., oxytocin, cocaine), and Valsalva maneuvers that accompany maternal expulsive efforts during the second stage of labor. Third, uterine blood flow may decline because of increased uterine vascular resistance, which may be caused by a number of factors, including endogenous vasoconstrictors that are released in response to stress, exogenous vasoconstrictors, and compression of endometrial spiral arterioles with uterine contractions.[34]

BOX 3-1 Causes of Decreased Uterine Blood Flow

Decreased Perfusion Pressure

Decreased uterine arterial pressure:
- Supine position (aortocaval compression)
- Hemorrhage/hypovolemia
- Drug-induced hypotension
- Hypotension during sympathetic blockade

Increased uterine venous pressure:
- Vena caval compression
- Uterine contractions
- Drug-induced uterine tachysystole (oxytocin, local anesthetics)
- Skeletal muscle hypertonus (seizures, Valsalva maneuver)

Increased Uterine Vascular Resistance

Endogenous vasoconstrictors:
- Catecholamines (stress)
- Vasopressin (in response to hypovolemia)

Exogenous vasoconstrictors:
- Epinephrine
- Vasopressors (phenylephrine > ephedrine)
- Local anesthetics (in high concentrations)

MECHANISMS OF VASCULAR CHANGES AND REGULATION

Vascular Changes during Pregnancy

Because mean arterial pressure decreases slightly during pregnancy, the increase in uteroplacental blood flow is

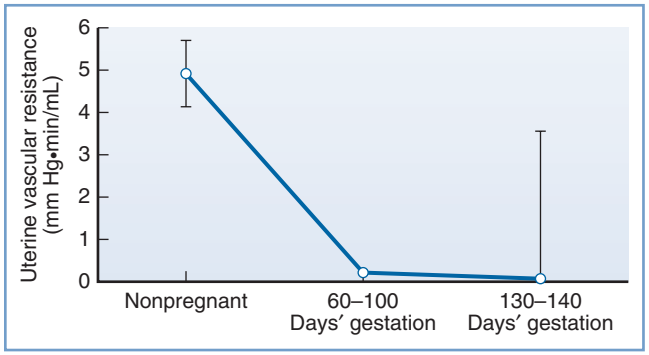

FIGURE 3-4 ■ Changes in uterine vascular resistance with gestation. Data are mean ± SE. (Adapted from Rosenfeld CR. Distribution of cardiac output in ovine pregnancy. Am J Physiol 1977; 232:H231-5.)

dependent on a substantial decrease in uterine vascular resistance (Figure 3-4), together with increased cardiac output and intravascular volume. The main factors contributing to the decrease in vascular resistance include vascular remodeling, changes in vascular reactivity, and the development of the widely dilated placental circulation.

Vascular remodeling of arteries in the uterus during pregnancy is believed to include increases in both vessel diameter and vessel length. In humans, both vessel lengthening and straightening of coiled vessels may occur.[12] According to Poiseuille's law, vascular resistance is decreased in proportion to the fourth power of the radius, whereas resistance is increased in proportion to the first power of vessel length; as such, the effects of changes in vessel diameter dominate, resulting in an overall decrease in resistance. Palmer et al.,[13] using serial Doppler studies during pregnancy, observed that uterine artery diameter is doubled by 21 weeks' gestation, whereas there is no change in the diameter of the common iliac or external iliac arteries. These investigators also showed that uterine artery mean flow velocity increased progressively during pregnancy to values eight times greater than those of nonpregnancy. In parallel with arterial changes, there is also structural remodeling of uterine veins in pregnancy. This includes increases in diameter and distensibility and decreases in elastin content.[36] Although blood viscosity decreases during pregnancy and also contributes to reduced uterine vascular resistance, this is considered a relatively minor effect compared with vascular changes.[37]

Changes in vascular reactivity during pregnancy include a vasodilatory response that is meditated at endothelial and vascular smooth muscle levels.[38] The growth of the placenta creates a low-resistance vascular pathway by eliminating the intramyometrial microcirculation and creating an intervillous space.[39] This has functional characteristics of an arteriovenous shunt.[15]

The mechanisms underlying the vascular changes during pregnancy are incompletely understood. Contributing factors include steroid hormones, decreased response to vasoconstrictors, endothelium-derived vasodilators, increased shear stress, and venoarterial exchange.

Steroid Hormones

Steroids play an integral role in the development and regulation of the uteroplacental circulation. Estrogen and progesterone are especially important, and there is evidence that cortisol may also contribute.

Estrogen has a fundamental role in the short- and long-term uterine vascular changes during pregnancy. Plasma concentrations of estrogen, initially derived from the ovaries and later predominantly from the placenta, rise concomitantly with the increase in uterine blood flow during pregnancy. Exogenously administered estrogen causes uterine vasodilation and a marked rise in uterine blood flow, independent of systemic effects.[40] Angiogenic and vasodilatory effects of estrogen are meditated via estrogen receptors ER-α and ER-β, which are structurally and functionally distinct. The majority of these receptors are located in the nucleus and mediate genomic effects by regulating transcription of genes that are particularly responsible for the longer-term uterine angiogenic responses. There are also membrane receptors that mediate nongenomic effects by up-regulating endothelial production of nitric oxide through the activation of endothelial nitric oxide synthase (eNOS) and the augmentation of eNOS protein expression.[41]

Progesterone modulates the effect of estrogen on uterine blood flow. In a nonpregnant sheep model, exogenous progesterone administered alone had no uterine vasodilatory effect but had an inhibitory effect when combined with estrogen.[38] Progesterone down-regulates expression of estrogen receptors.[42] An increase in the estrogen-progesterone ratio parallels the increase in uterine blood flow in late pregnancy in many species.[43]

Plasma **cortisol** levels approximately double during pregnancy. Cortisol has both systemic and local effects on uterine blood flow. Systemically, cortisol contributes to regulation of uterine blood flow by increasing plasma volume. Although cortisol is believed to decrease eNOS protein expression and decrease nitric oxide release, it potentiates the response to vasoconstrictor agents including angiotensin II, vasopressin, and norepinephrine. Attenuation of these effects occurs during pregnancy.[38]

Decreased Response to Vasoconstrictors

In pregnancy, there is a generalized reduction in response to endogenous and exogenous vasoconstrictors, including angiotensin II, endothelin, thromboxane, epinephrine, norepinephrine, phenylephrine, serotonin, thromboxane, and arginine vasopressin.[44-46] The relative refractoriness of the systemic and uterine circulations varies for different agents, which has important implications for the regulation and maintenance of uteroplacental blood flow.

During pregnancy, concentrations of **angiotensin II** in maternal blood are increased twofold to threefold[47]; however, the vasopressor response to angiotensin II is attenuated.[48] This refractoriness is diminished in patients in whom preeclampsia develops.[48] The uterine circulation is less responsive to angiotensin II than the systemic circulation. Thus, infusion of physiologic doses of

angiotensin II has been shown to have minimal effect on uteroplacental blood flow while increasing systemic blood pressure.[49] The difference in sensitivity of the uterine and systemic circulations to angiotensin II is considered an important physiologic adaptation during pregnancy that contributes to the redistribution of cardiac output, the increase in uterine blood flow, and possibly the maintenance of uterine blood flow during normal fluctuations in blood pressure.[50]

Sensitivity to vasoconstrictors such as **epinephrine**, **norepinephrine**, and **phenylephrine** is attenuated during pregnancy.[51] However, in contrast to the responses to angiotensin II, the uterine circulation is *more* responsive to these agents than the systemic circulation.[51] Thus, during hemorrhage or other major stresses that result in large catecholamine release, it is unlikely that uteroplacental perfusion will be preferentially preserved above essential maternal perfusion.[52]

The mechanism underlying the difference in vascular sensitivity between the uterine and systemic circulations is unclear, but distribution of receptor subtypes is believed to be important.[53] There are two distinct subtypes of angiotensin II receptors: AT_1R and AT_2R. In most tissues, including systemic vascular smooth muscle, AT_1R receptors are predominant and mediate vasoconstriction. However, AT_2R receptors, which do not mediate smooth muscle contraction, account for 75% to 90% of angiotensin II binding in uterine artery and myometrium.[54,55]

Vasodilators

The greater synthesis and higher circulating concentrations of endothelial-derived vasodilators during pregnancy are believed to modulate systemic and uterine vascular responses to angiotensin II and other vasoconstrictors.[56] Uterine vascular production of **prostacyclin** is greater than systemic vascular production, which probably contributes to maintaining uteroplacental blood flow in opposition to the effects of circulating vasoconstrictors.[57] An enhanced response to angiotensin II during pregnancy has been demonstrated with the systemic and local infusion of indomethacin (which blocks prostacyclin production).[58] However, inhibition of prostaglandin synthesis by an infusion of indomethacin induces only a transient decrease in uteroplacental blood flow, indicating that uteroplacental blood flow is not solely dependent on the continued production of prostacyclin.[56]

Nitric oxide is synthesized from arginine in vascular endothelial cells and stimulates soluble guanylate cyclase in vascular smooth muscle, resulting in vascular relaxation through increases in cyclic guanosine monophosphate. Synthesis of nitric oxide is an important mechanism underlying changes in systemic and uterine vascular resistance, attenuated responses to vasoconstrictors, and vascular effects of estrogen during pregnancy.[59] During pregnancy, uterine arteries have increased eNOS activity, higher levels of eNOS messenger ribonucleic acid and eNOS protein, and increased biosynthesis of nitric oxide and cyclic guanosine monophosphate.[59,60] Removal of the vascular endothelium diminishes or eliminates the refractoriness of the uterine artery to vasoconstrictors[45] and inhibition of nitric oxide synthesis by *N*-nitro-L-arginine methyl ester (L-NAME) decreases uterine blood flow and also reverses refractoriness to vasoconstrictors.[61] Long-term inhibition of nitric oxide synthase causes hypertension and fetal growth restriction in rats.[62]

Other Vasoactive Substances

Atrial and brain natriuretic peptides attenuate the response to angiotensin II, and intravenous infusion of atrial natriuretic peptide reduces blood pressure while increasing uterine blood flow in preeclamptic women.[63] **Protein kinase C** activity is decreased in uterine, but not systemic, arteries of pregnant sheep and may cause vasodilation and an increase in uterine blood flow; this may have a regulatory effect on local ovarian and placental estrogen production.[43] Studies in rats have shown a decrease in endogenous endothelin-dependent vasoconstrictor tone in uteroplacental vessels, which may contribute to the increase in placental blood flow in late gestation.[64] Uterine vascular resistance in early pregnancy may be increased by **relaxin,** which may have a role in modulating the effects of estrogen and progesterone.[65]

Shear Stress

Shear stress, the frictional forces on the vessel wall from blood flow, is believed to be an important stimulus for uteroplacental vasodilation and remodeling.[66] The reduction in downstream resistance resulting from the formation of the placenta would be expected to increase the upstream flow velocity and thus shear stress.[39] Nitric oxide is considered an important mediator of this effect because increases in eNOS expression and nitric oxide production are witnessed with shear stress and because stripping the endothelium or pretreatment with L-NAME reduces or abolishes flow-induced vasodilation.[66] Studies *in vitro* have shown that shear stress also increases endothelial production of prostacyclin.

Venoarterial Signaling

It has been postulated that growth factors or signal substances secreted by the placenta and/or myometrium could pass from uterine veins to adjacent uterine arteries; this may provide a system whereby the uterus and placenta regulate their own perfusion.[39] Possible candidates for signal substances include vascular endothelial growth factor and placental growth factor. Confirmation of whether this mechanism is important in humans is awaited.

METHODS OF MEASUREMENT OF UTEROPLACENTAL BLOOD FLOW

Many techniques have been used to measure uteroplacental blood flow in animals and humans. The approaches used in different studies have varied according to the nature of the experimental question, the existing state of technology, and ethical considerations and limitations. All methods have an inherent potential for error.

Many past studies of uterine artery flow have measured flow in only one uterine artery, which may not be an accurate representation of total flow, depending on the location of the placenta (see earlier discussion). The parameter of greatest clinical interest is placental perfusion, but this is not always differentiated from total uterine blood flow, from which it may vary independently. However, in most circumstances, the measurement of intervillous blood flow provides a close approximation of functional placental blood flow. Ovarian arterial blood flow is generally not measured, although studies in primates suggest it may contribute as much as one sixth of placental perfusion.[67]

Early studies of uteroplacental blood flow involved a number of substances that could affect maternal hemodynamics (e.g., nitrous oxide) or myometrial activity (e.g., 4-amino-antipyrine) and relied on the Fick principle. This principle, which calculates blood flow by the measurement of a marker substance entering and leaving an organ, is subject to error in the uterus, where a number of veins are responsible for collecting venous effluent.[68] In animals, placental perfusion can also be measured by the injection of radioactive microspheres. This method allows for the separate calculation of placental and myometrial blood flows but only provides information from a single point in time. Total uterine arterial blood flow can also be measured (or estimated) with the use of surgically implanted electromagnetic or Doppler flow probes.

In humans, placental perfusion can be measured by the injection of trace amounts of radioactive substances, typically xenon-133.[69] During the washout phase, the rapid decrease in measured radioactivity over the placenta is calculated as a biexponential or triexponential process. The most rapid decay constant is ascribed to intervillous perfusion. Alternatively, radioactively tagged proteins (e.g., albumin) can be injected and measured by scintigraphy over the placenta.[70] Although the accuracy of these methods for determining absolute flow is limited, their ability to measure relative change over time is adequate in most cases.

In humans, the most common method of clinically assessing uterine blood flow is Doppler ultrasonography.[71] The uterine artery is identified after it crosses the external iliac artery, before it divides into branches. Color flow aids vessel identification. Blood flow can be quantified by measuring the mean flow velocity and vessel cross-sectional area.

Flow velocity is calculated by applying the principle of Doppler shift. A pulsed ultrasound signal from a stationery transducer is directed toward the vessel with an angle of insonation (θ) less than 60 degrees. Reflections scattered from the red blood cells are received. Because the red blood cells are moving, the frequency of the received signal differs from the transmitted frequency (f_0) by an amount known as the Doppler shift (Δf). This shift is proportional to the red blood cell flow velocity (V_{RBC}) according to the following equation:

$$\Delta f = \frac{2 \times f_0 \times V_{REL}}{c} \quad (2)$$

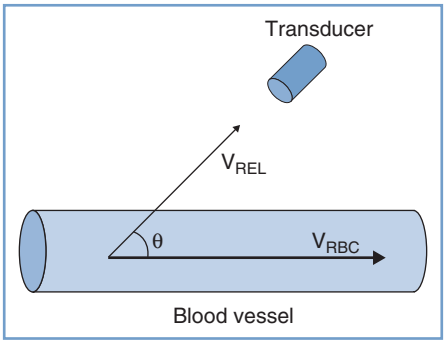

FIGURE 3-5 ■ Principles of use of Doppler ultrasonography to estimate blood flow. Blood flow is calculated as the product of blood vessel cross-sectional area and mean flow velocity in the vessel (V_{RBC}). The latter is derived from the measured flow velocity relative to the direction of the probe (V_{REL}) and requires precise determination of the angle of insonation (θ).

where c is the speed of sound propagation in tissue and V_{REL} is the vector component of the velocity of flow relative to the direction of the transducer. The latter takes into account the difference between the direction of the ultrasound signal from the direction of flow according to θ (Figure 3-5). With the use of basic trigonometry, V_{RBC} is related to the relative velocity of flow in the direction of the probe (V_{REL}) according to the following equation:

$$V_{RBC} = \frac{V_{REL}}{\cos\theta} \quad (3)$$

Combining equations 2 and 3 gives the following equation:

$$V_{RBC} = \frac{\Delta f}{f_0} \times \frac{c}{2 \times \cos\theta} \quad (4)$$

Thus, the flow velocity is estimated from the ratio of the Doppler shift frequency to the transmitted frequency, multiplied by the speed of sound propagation, and divided by two times the cosine of the insonation angle.

An estimation of the volume of blood flow (Q) can be made by multiplying mean velocity by the vessel cross-sectional area (A), which is estimated with two-dimensional (B-mode) ultrasonography:

$$Q = V_{RBC} \times A \quad (5)$$

However, measurement of absolute flow using this technique is prone to difficulty and error, both from inaccurate measurement of vessel cross-sectional area (e.g., arteries pulsate during the cardiac cycle) and from inaccurate measurement of flow (e.g., from inaccuracies in measurement of θ). Therefore, for diagnostic purposes, a number of indices related to vascular impedance can be derived from the flow velocity waveform that are independent of θ.[72] These rely on the fact that the uterine vascular bed normally has low resistance with flow

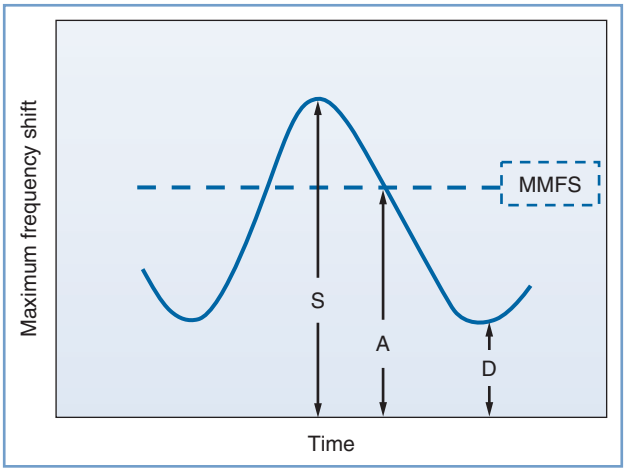

FIGURE 3-6 ■ Schematic diagram showing elements of typical Doppler waveform of the uterine artery. *S,* peak systolic frequency shift (maximum velocity); *D,* end-diastolic frequency shift (minimum velocity); *A,* temporal averaged frequency shift (mean velocity) averaged over one cardiac cycle; *MMFS,* mean maximum frequency shift. Derived indices include systolic/diastolic (S/D) ratio = S/D, pulsatility index (PI) = (S – D)/A, and resistance index (RI) = (S – D)/S.

continuing during diastole. If distal resistance is increased, for example during the development of preeclampsia or fetal growth restriction, diastolic velocity decreases relative to systolic velocity resulting in a waveform showing greater pulsatility. Commonly derived indices (Figure 3-6) are:

$$\text{Systolic} - \text{diastolic}\left(\frac{\text{S}}{\text{D}}\right)\text{ratio} = \frac{\text{Systolic (maximal) velocity}}{\text{Diastolic (minimal) velocity}} \quad (6)$$

$$\text{Pulsatility index (PI)} = \frac{\text{(Systolic [maximum] velocity} - \text{Diastolic [minimum] velocity)}}{\text{Mean velocity}} \quad (7)$$

$$\text{Resistance index (RI)} = \frac{\text{(Systolic [maximum] velocity} - \text{Diastolic [minimum] velocity)}}{\text{Systolic [maximum] velocity}} \quad (8)$$

In addition, the waveform can be described or categorized according to features such as the absence of end-diastolic flow and the presence of post-diastolic notches. Examples of normal and abnormal uterine artery Doppler tracings are shown in Figure 3-7.[73] Doppler velocimetry can be applied to the umbilical vessels for antepartum fetal assessment (see Chapter 6).

There are several potential sources of error in Doppler measurements of absolute flow with regard to both accuracy and reproducibility of measurements. For example, small errors in the estimation of θ can result in blood flow measurement errors as large as 30%.[13] Thus, the methods used in any clinical study that employs Doppler ultrasonography to assess uterine artery blood flow should be examined critically.

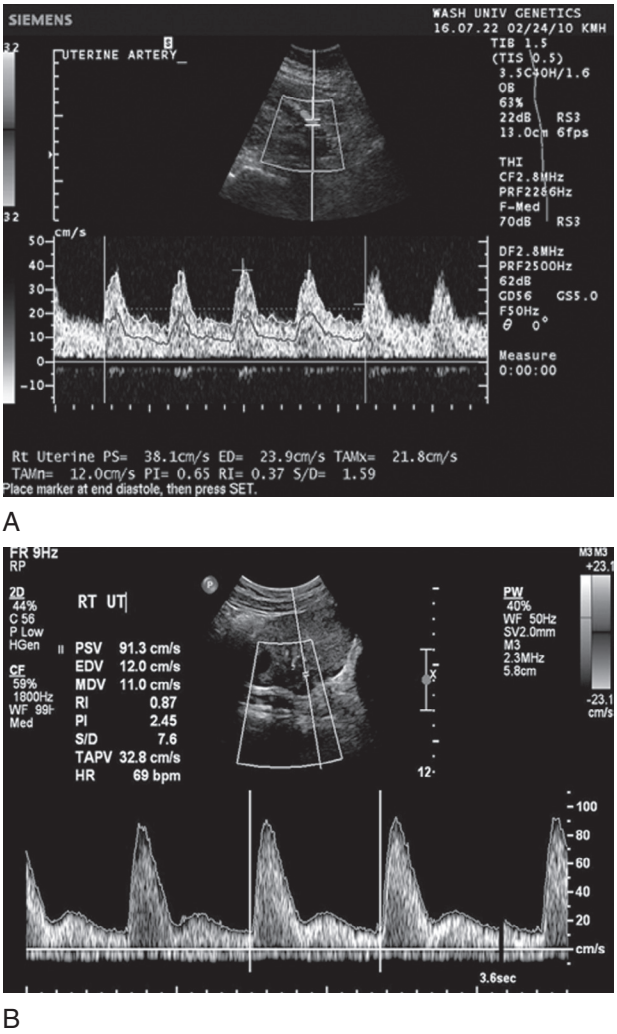

FIGURE 3-7 ■ Normal (**A**) and abnormal (**B**) uterine artery Doppler waveforms. The normal waveform has no notching and normal pulsatility. The abnormal waveform shows notching and increased pulsatility. (From Tuuli M, Odibo AO. The role of serum markers and uterine artery Doppler in identifying at-risk pregnancies. Clin Perinatol 2001; 38:1-19.)

NEURAXIAL ANESTHESIA

The effect of neuraxial anesthesia on uteroplacental blood flow depends on the complex interaction of many factors (Box 3-2). Pain and stress during labor may reduce uteroplacental blood flow through sympathetic stimulation and the release of circulating catecholamines. Shnider et al.[74] observed that acute stress increased plasma norepinephrine concentrations by 25% and decreased uterine blood flow by 50% in gravid ewes. In laboring women, stress is associated with increased plasma epinephrine concentrations and abnormal fetal heart rate patterns. Effective pain relief with neuraxial analgesia decreases circulating concentrations of catecholamines[75] and reduces hyperventilation and therefore may help protect uteroplacental blood flow. In the absence of hypotension, epidural anesthesia does not change uteroplacental blood flow in pregnant sheep.[76] Results from human studies are

BOX 3-2 Effects of Neuraxial Anesthesia on Uterine Blood Flow

Increased uterine blood flow as a result of:
- Pain relief
- Decreased sympathetic activity
- Decreased maternal hyperventilation

Decreased uterine blood flow as a result of:
- Hypotension
- Unintentional intravenous injection of local anesthetic and/or epinephrine
- Absorbed local anesthetic (little effect)

variable, partly because of differences in study design, techniques used, and clinical circumstances. However, most studies have shown no change or an increase in uteroplacental blood flow after administration of epidural analgesia.[77-80] Some studies have shown an increase in uterine vascular resistance indices,[81,82] but with no effect on neonatal outcomes. There is evidence that in women with preeclampsia, epidural analgesia using a plain local anesthetic may reduce uterine artery resistance[78] and increase intervillous blood flow.[83] Ginosar et al.[84] reported that antenatal continuous epidural infusion of ropivacaine in preterm patients with preeclampsia reduced uterine artery resistance. Further work is required to determine whether this might have therapeutic potential for short-term prolongation of pregnancy.

Fetal bradycardia is sometimes observed after combined spinal-epidural techniques and has been attributed to decreases in uteroplacental blood flow; the mechanism for this association is unclear. Although alterations in uteroplacental blood flow have been primarily attributed to maternal hypotension and respiratory depression,[85] another postulated mechanism is uterine tachysystole (hypertonus) caused by a rapid decrease in circulating catecholamine concentrations (see Chapter 23).[86] Additional studies are needed to evaluate the relationship between neuraxial anesthetic techniques, uteroplacental blood flow, and fetal bradycardia.

Hypotension

Hypotension occurring during neuraxial blockade, depending on its magnitude and duration, may decrease uteroplacental blood flow for several reasons—reduction in perfusion pressure,[17] reflex release of endogenous vasoconstrictors, diversion (steal) of blood to the lower limbs,[87] and response to administered vasopressors.[33] The rapid and extensive sympathetic blockade during spinal anesthesia, and some of the methods used to treat hypotension, may account for the observation that umbilical arterial blood pH is lower with spinal anesthesia than with epidural or general anesthesia for cesarean delivery.[88]

Intravenous Fluid Loading

Studies of the effect of intravenous fluid boluses used in conjunction with assessment of the uteroplacental circulation have had mixed results. Most Doppler studies have shown that fluid preload before the initiation of neuraxial analgesia does not change vascular resistance indices,[89] although a decrease has been reported.[90]

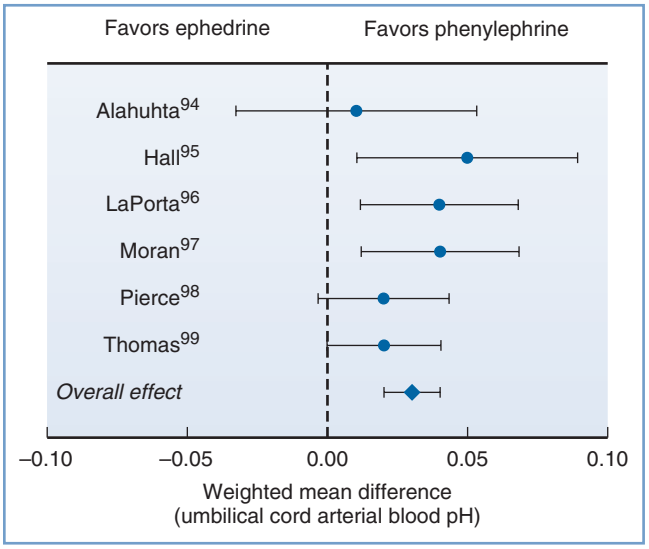

FIGURE 3-8 ■ Results from a meta-analysis of trials comparing phenylephrine and ephedrine for the management of hypotension during spinal anesthesia for cesarean delivery. The chart shows the effect of choice of vasopressor on umbilical cord arterial pH. Data are mean difference with 95% confidence intervals. (Modified from Lee A, Ngan Kee WD, Gin T. A quantitative systematic review of randomized controlled trials of ephedrine versus phenylephrine for the management of hypotension during spinal anesthesia for cesarean delivery. Anesth Analg 2002; 94:920-6.)

Vasopressors

The effects of vasopressors on uteroplacental blood flow and the resulting implications for clinical drug selection are controversial. Animal and *in vitro* studies have observed that uteroplacental blood flow was better maintained using ephedrine versus alpha-adrenergic agonists such as phenylephrine, metaraminol, and methoxamine,[33] which likely reflects the predominant beta-adrenergic effects of ephedrine. In addition, *in vitro* studies in pregnant sheep evaluating the effects of ephedrine on blood vessels have demonstrated enhanced vasoconstrictor activity on the femoral versus uterine vessels and decreased uterine vasoconstriction as a result of nitric oxide release.[91] In contrast, an increase in the uterine arteriolar vasoconstrictor response to phenylephrine has been observed during pregnancy.[92] However, in clinical studies, umbilical arterial blood pH and base excess have been observed to be greater with the use of alpha-adrenergic agonists in comparison to ephedrine to maintain maternal blood pressure during spinal anesthesia for cesarean delivery (Figure 3-8).[93-100] A comparison of different infusion regimens of phenylephrine, titrated to keep maternal systolic blood pressure near baseline, observed no depression of fetal pH and base excess despite very large total doses (up to 2500 µg) before delivery.[32] In contrast, large doses of ephedrine administered to maintain blood pressure during spinal

anesthesia for cesarean delivery depressed umbilical arterial blood pH and base excess in a dose-dependent manner.[101]

The explanation for the discrepancy between experimental and clinical data is complex and incompletely determined. Animal studies are not always appropriate models for clinical situations. Under clinical conditions, Doppler studies have shown some evidence that uterine vascular resistance is increased by alpha-adrenergic agonists,[94] but this finding has not been consistent.[100] Although data suggest that alpha-adrenergic agonists increase uterine vascular resistance more than systemic vascular resistance, the difference may be primarily due to an effect in the myometrium, with relative sparing of the vessels that perfuse the placenta.[102] In addition, uteroplacental blood flow in humans has a margin of safety that appears to allow modest decreases in uterine blood flow (caused by clinically appropriate doses of alpha-adrenergic agonists) to occur without compromising oxygen transfer. Finally, the propensity of ephedrine to worsen fetal acid-base status may be related less to its effects on uteroplacental blood flow and more to direct beta-adrenergic receptor–mediated fetal metabolic effects. When compared with phenylephrine, ephedrine has been observed to cross the placenta to a greater extent and be associated with higher fetal levels of lactate, glucose, epinephrine, and norepinephrine.[103]

Thus, when considering the choice of vasopressor for clinical use, the anesthesiologist should take into account the sum effect on fetal oxygen supply and demand balance rather than the isolated effects on uteroplacental blood flow. In this respect, clinical studies do not favor the use of ephedrine. In addition, the slow onset and long duration of action of ephedrine make it more difficult to titrate than phenylephrine. Conversely, the use of phenylephrine is commonly associated with a reflex slowing of heart rate and a corresponding decrease in cardiac output. At modest doses, this decrease reflects a normalization of the cardiac output that is elevated secondary to decreased afterload after the initiation of spinal anesthesia; at larger doses, alpha-adrenergic agents can cause cardiac output to decrease below baseline.[104] The implications of these findings on uteroplacental blood flow are controversial because the relative importance of maintaining cardiac output versus maintaining uterine perfusion pressure is unknown. Overall, to date, studies comparing ephedrine and other vasopressors in humans have not demonstrated differences in clinical neonatal outcome.

Limited data are available for the comparison of vasopressors in the presence of fetal compromise or placental insufficiency. Erkinaro et al.[105,106] developed a sheep model to compare the effects of phenylephrine and ephedrine after a period of experimental fetal hypoxia. Hypotension was induced by epidural anesthesia and then corrected with either phenylephrine or ephedrine. In an initial study, ephedrine was associated with better restoration of uterine artery blood flow, but no differences in fetal acid-base measurements or lactate concentration were observed.[105] However, in a second study, these investigators embolized the placenta with microspheres to model placental insufficiency and found that phenylephrine and ephedrine had similar effects on uterine blood flow, fetal pH, and base excess as found in the initial study, with the exception that fetal lactate concentration was greater in the phenylephrine group.[106] Although the investigators speculated that this exception might reflect impaired fetal clearance of lactate, the placental embolization may have narrowed the margin of safety for uteroplacental blood flow and increased fetal lactate production in the phenylephrine group. Ngan Kee et al.[107] compared phenylephrine and ephedrine for maintaining blood pressure in patients receiving spinal anesthesia for nonelective cesarean delivery, 24% of whom had evidence of fetal compromise. The results showed that although umbilical arterial and venous blood lactate concentrations were lower in the phenylephrine group, umbilical arterial blood pH and base excess values were similar in the two groups. However, umbilical arterial and venous blood Po_2 measurements were lower in the phenylephrine group, suggesting that although phenylephrine may have caused some reduction in uteroplacental perfusion, adequate oxygen supply was likely maintained by increased oxygen extraction.

In summary, ephedrine and phenylephrine both continue to be used clinically for maintaining maternal blood pressure during the administration of neuraxial anesthesia. Although most experimental data suggest that uteroplacental perfusion is likely to be better maintained with ephedrine than with alpha-adrenergic agonists, this advantage may be outweighed by other considerations, such as differences in efficacy for maintaining blood pressure and direct fetal effects that occur from the placental transfer of the drug.

Local Anesthetics

Studies *in vitro* have shown that local anesthetics constrict arteries directly and inhibit endothelium-mediated vasodilation.[108] High concentrations of local anesthetic can decrease uteroplacental blood flow by stimulating vasoconstriction and myometrial contractility.[109,110] A comparative study in pregnant sheep showed that bupivacaine was more potent than either lidocaine or 2-chloroprocaine in decreasing uterine blood flow.[110] However, the adverse effects of local anesthetics were seen only at concentrations in excess of those observed clinically, with two possible exceptions: (1) the unintentional intravenous injection of local anesthetic and (2) the use of local anesthetics for a paracervical block. At clinically relevant doses, no adverse effect on uteroplacental blood flow was reported.[111] Although initially the inherent vasoconstrictor properties of ropivacaine were a matter of concern, studies in animals[111] and humans[112] have not shown that administration of ropivacaine results in a reduction in uterine blood flow.

Epinephrine and α_2-Adrenergic Agonists

Epinephrine is often combined with local anesthetic agents in obstetric anesthesia. Wallis et al.[76] found that the epidural injection of 1.5% 2-chloroprocaine with epinephrine (10 μg/mL) produced a small, brief reduction

in uterine blood flow in pregnant sheep. In contrast, Alahuhta et al.[113] reported that epidural bupivacaine with epinephrine (5 μg/mL) had no effect on intervillous blood flow in women undergoing cesarean delivery. Studies have not shown a reduction in uteroplacental blood flow as a result of the absorption of epinephrine from local anesthetic solutions given epidurally to healthy women during labor.[114] However, one study observed that the addition of epinephrine (85 to 100 μg) to epidural bupivacaine increased Doppler indices of uteroplacental vascular resistance in hypertensive parturients with chronic fetal asphyxia.[115] Therefore, some anesthesia providers avoid epidural administration of epinephrine-containing local anesthetic solutions to women with preeclampsia. Commonly, epinephrine (10 to 15 μg) is included in the epidural test dose. Marcus et al.[116] reported that repeated epidural injections of epinephrine (10 to 15 μg) did not decrease uterine blood flow in pregnant sheep; however, the same dose injected intravenously reduced uterine blood flow, with a maximum decrease of 43% observed at 1 minute.

The epidural and intrathecal administration of α_2-adrenergic agonists (e.g., clonidine, dexmedetomidine) has been a subject of clinical investigations. Intravenous, but not epidural, administration of clonidine decreased uterine blood flow in gravid ewes.[117,118]

Opioids

Opioids are often combined with local anesthetic agents for epidural and intrathecal analgesia during labor and the peripartum period. Intrathecal opioids have been implicated as contributing to a greater risk for fetal bradycardia when used for labor analgesia compared with non-intrathecal opioid neuraxial analgesic techniques.[119] The mechanism for this effect has been postulated as an increase in uterine tone and a resulting decrease in uteroplacental blood flow, although further research is needed. Craft et al.[120,121] observed that neither epidural fentanyl nor morphine had a significant effect on uterine blood flow in gravid ewes. Alahuhta et al.[122] reported that epidural sufentanil 50 μg did not alter uterine artery blood flow velocity waveform indices in laboring women. Intrathecal meperidine and sufentanil, however, may be associated with hypotension that may potentially decrease uterine blood flow.[123,124]

GENERAL ANESTHESIA

Induction Agents

Available data suggest that the commonly used induction agents have minimal or no direct adverse effect on uteroplacental blood flow. Allen et al.[125] found that thiopental inhibited the response of human myometrial arteries to contractile agents *in vitro* but had no effect on relaxation induced by prostacyclin. Alon et al.[126] reported that uterine blood flow did not change significantly during induction and maintenance of propofol anesthesia in pregnant sheep. Craft et al.[127] reported that uterine tone increased but uterine blood flow remained constant after an intravenous bolus of ketamine in pregnant sheep. Similarly, Strümper et al.[128] reported that neither racemic nor S^+-ketamine affected uterine perfusion in pregnant sheep. Few data are available on the direct effects of etomidate on uteroplacental blood flow.

During the intravenous induction of general anesthesia, uteroplacental perfusion may be affected by indirect mechanisms such as blood pressure changes and the sympathetic response to laryngoscopy and endotracheal intubation. Jouppila et al.[129] reported that intervillous blood flow decreased by 22% to 50% during induction of general anesthesia for cesarean delivery with thiopental 4 mg/kg, succinylcholine 1 mg/kg, and endotracheal intubation. Gin et al.[130] compared thiopental 4 mg/kg and propofol 2 mg/kg in patients undergoing elective cesarean delivery. These investigators found that venous plasma concentrations of epinephrine and norepinephrine increased after endotracheal intubation in both groups, but maximum norepinephrine concentrations were lower in the propofol group. No differences in neonatal outcomes were observed. Levinson et al.[131] found that intravenous ketamine increased blood pressure with a concomitant rise in uterine blood flow in pregnant sheep. Addition of a rapid-acting opioid (e.g., alfentanil, remifentanil) during induction of general anesthesia may minimize the increase in circulating catecholamines that occurs after laryngoscopy and endotracheal intubation.[132,133] Although the use of such opioids might attenuate any decrease in uterine blood flow, the potential for neonatal respiratory depression should be considered.

Inhalational Agents

Studies in pregnant sheep have shown that usual clinical doses (i.e., 0.5 to 1.5 minimum alveolar concentration) of the volatile anesthetic agents, including isoflurane, desflurane, and sevoflurane, have little or no effect on uterine blood flow, although deeper planes of anesthesia are associated with reductions in cardiac output, maternal blood pressure, and uterine blood flow.[134,135] Nonetheless, high concentrations of inhalational agents (approximately 2 minimum alveolar concentration) have been used during *ex utero* intrapartum treatment procedures without evidence of impaired fetal gas exchange.[136] A dose-dependent reduction in uterine tone caused by inhalational agents would be expected to increase uterine blood flow in clinical circumstances in which tone is increased (e.g., hyperstimulation with oxytocin, cocaine overdose, placental abruption). Overall, there is little reason to choose one inhalational agent over another on the basis of an agent's effects on uterine blood flow.

Ventilation

Although moderate levels of hypoxemia and hypercapnia do not affect uteroplacental blood flow,[137] marked alterations may reduce blood flow indirectly by mechanisms most likely involving sympathetic activation and catecholamine release. The effect of hypocapnia on uteroplacental blood flow is controversial. Some investigators have noted that hyperventilation with hypocapnia caused

fetal hypoxia and metabolic acidosis in animals,[138] whereas others have found no effect.[139] Levinson et al.[140] observed that positive-pressure ventilation decreased uterine blood flow in pregnant sheep; however, because the addition of carbon dioxide did not improve uterine blood flow, the reduction in blood flow was attributed to the mechanical hyperventilation rather than the hypocapnia. In general, most authorities recommend that hyperventilation be avoided in pregnancy, in part because of concerns about uterine blood flow.

EFFECTS OF OTHER DRUGS

Magnesium Sulfate

Magnesium sulfate increases uterine blood flow in normotensive and hypertensive pregnant sheep.[141,142] Although hypermagnesemia was found to exacerbate maternal hypotension during epidural anesthesia in pregnant sheep, no reduction in uterine blood flow was observed.[141] In women in preterm labor[143] and with severe preeclampsia,[144] magnesium sulfate caused a modest decrease in Doppler indices of uterine vascular resistance. Infusion of magnesium caused an increase in uterine blood flow, which was associated with an improvement in red blood cell deformability in women with preeclampsia or fetal growth restriction.[145]

Antihypertensive Agents

In patients with pregnancy-induced hypertension, the effects of antihypertensive drugs on uteroplacental perfusion depend on the interaction of their effects on uterine vascular resistance and systemic maternal blood pressure. In animal models of pharmacologically induced hypertension, hydralazine reduced maternal blood pressure but increased uteroplacental blood flow, reflecting a decrease in uterine vascular resistance.[146,147] Similar studies with labetalol have had varying results, showing increased,[148] decreased,[149] and no change[150] in uteroplacental blood flow. A study in preeclamptic women observed an increase in uterine artery resistance indices after hydralazine but not labetalol.[151] However, previous studies have generally demonstrated no significant change in uteroplacental blood flow with either drug,[152-155] indicating that other considerations are probably more important for guiding drug selection. Studies of methyldopa in patients with preeclampsia have found either a reduction[156] or no change[157] in indices of uterine and placental vascular resistance.

Calcium Entry–Blocking Agents

Verapamil 0.2 mg/kg was shown to decrease maternal blood pressure and uterine blood flow in pregnant sheep.[158] Studies with nifedipine have yielded conflicting results. Some animal studies have shown that nifedipine decreases uteroplacental blood flow and worsens the fetal condition, whereas human studies have shown either no change in uteroplacental blood flow or vascular resistance[159] or a decrease in vascular resistance.[160]

Vasodilators

Nitroglycerin was shown to relax human uterine arteries *in vitro*.[161] In women with abnormal uterine artery blood flow at 24 to 26 weeks' gestation, infusion of intravenous nitroglycerin decreased uterine resistance indices.[162] Similarly, transdermal nitroglycerin administered for 3 days to patients with preeclampsia and fetal growth restriction decreased uterine resistance indices.[163] However, Grunewald et al.[164] reported that an infusion of nitroglycerin in women with severe preeclampsia did not change the pulsatility index of the uterine artery. When interpreting such studies, clinicians should remember that increases in total uterine blood flow do not necessarily result in enhanced placental perfusion.[165] Further work is required to define the utility of systemic vasodilators for improving uteroplacental blood flow in clinical practice.

Inotropic Drugs

Positive inotropic drugs are rarely indicated in obstetric patients. On the basis of studies of normal pregnant sheep, milrinone and amrinone may increase uterine blood flow, whereas dopamine and epinephrine may diminish it.[166,167] The choice of an inotropic agent should be based primarily on the desired efficacy (i.e., maternal considerations) rather than the potential direct effects on uterine blood flow. This is especially important during maternal resuscitation or cardiac arrest, when maternal welfare is the overriding priority and standard resuscitation drugs should be given. Restoration of spontaneous circulation and adequate uterine perfusion pressure is far more important than avoidance of uterine vasoconstriction.

KEY POINTS

- Growth and development of the uteroplacental vasculature and progressive vasodilation allow uteroplacental blood flow to increase during pregnancy. Uteroplacental blood flow constitutes approximately 12% of maternal cardiac output at term.
- Many factors modulate the maintenance and regulation of uteroplacental blood flow, including altered responses to vasoconstrictors, increases in endothelium-derived vasodilators, and the effects of steroid hormones and shear stress.
- The uteroplacental circulation is a dilated, low-resistance vascular bed with limited ability for autoregulation. Flow may be reduced by a decrease in uterine arterial pressure, an increase in uterine venous pressure, or an increase in uterine vascular resistance.
- The uteroplacental circulation is composed of placental and nonplacental circulations that are anatomically and functionally dissimilar.
- Acute or chronic reductions in uteroplacental blood flow may threaten fetal viability and

predispose to disorders such as preeclampsia and fetal growth restriction. In situations of acute reduction in uteroplacental perfusion, there is a limited margin of safety; exceeding this limit may decrease fetal oxygen uptake with resultant metabolic acidosis.

- Animal studies are the principal source of uteroplacental blood flow data; thus, clinicians should carefully consider interspecies differences and study methodology when extrapolating experimental findings to clinical practice.
- Doppler ultrasonography is the method most commonly used to estimate uterine blood flow in humans. Estimates of absolute flow and indices of resistance can be derived, but there are many potential sources of inaccuracy.
- Neuraxial anesthesia can increase uterine blood flow by reducing pain and stress or can decrease uterine blood flow by causing hypotension.
- Although animal studies show that ephedrine protects uteroplacental blood flow better than alpha-adrenergic agonists such as phenylephrine, umbilical arterial blood pH and base excess are lower after administration of ephedrine. This effect may be related to a greater propensity of ephedrine to cross the placenta and have direct metabolic effects on the fetus. Thus, a growing number of obstetric anesthesia providers recommend phenylephrine as a first-line vasopressor for treatment of hypotension associated with neuraxial anesthesia in obstetric patients.
- The doses of general anesthetic agents used clinically have minimal direct effects on uterine blood flow. General anesthesia may reduce uterine blood flow by causing decreased cardiac output as well as hypotension. Conversely, noxious stimulation during light anesthesia may precipitate the release of catecholamines, which results in decreased uterine blood flow.
- For cardiovascular emergencies in pregnant women, the choice of inotropic drug should depend primarily on the efficacy of the drugs to optimize the maternal condition, rather than on minor differences in uterine blood flow. Standard resuscitation drugs should be used in an emergency.

CHAPTER 4

The Placenta: Anatomy, Physiology, and Transfer of Drugs

Mark I. Zakowski, MD • Andrew Geller, MD

CHAPTER OUTLINE

The placenta is a critical organ of great importance to obstetric anesthesia. Revered by ancient cultures as "the seat of the external soul" or "the bundle of life," the placenta is involved in many cultural rituals.[1] However, understanding of the indispensable role of the placenta in the development of the fetus did not start to evolve until the 17th century and continues today via microanatomic, biochemical, and molecular biologic techniques. The concept of the placenta as a passive sieve (acting only as a conduit for oxygen, nutrients, and waste) has been dispelled with the realization that the placenta is a complex and dynamic organ. Indeed, new studies show the critical importance of placental function in the metabolism, nutrition, and hormonal maintenance of pregnancy. Maternal-placental conditions can affect the fetus not only during pregnancy but also in adulthood and beyond into the next generation via epigenetic mechanisms.[2]

The placenta brings the maternal and fetal circulations into close apposition without substantial interchange of maternal and fetal blood for the physiologic transfer of gases, nutrients, and wastes. This important exchange is accomplished within a complex structure that is almost entirely of fetal origin.

ANATOMY

Embryology

The blastocyst initially attaches to endometrial pinopodes (uterodomes), which express markers of endometrial receptivity (e.g., galectin-9).[3] The remodeling of uterine extracellular matrix starts with serine proteases and metalloproteinases (e.g., MMP-2 and MMP-9). The developing blastocyst erodes the surrounding decidua, leaving the cellular debris on which it survives. The syncytiotrophoblasts (invasive cells located at the margin of the growing conceptus) continue to erode the surrounding decidua and its associated capillaries and arterioles until the blastocyst is surrounded by a sea of circulating maternal blood (trophoblastic lacunae). The vitelline vein system develops in the yolk sac of the embryo to enhance the transport of nutrients, which diffuse from the maternal blood through the trophoblast layer and chorionic plate into the chorionic cavity. The embryo undergoes a dramatic acceleration in growth as its dependence on simple diffusion diminishes.[4]

At 2 weeks of development, the primitive extraembryonic mesoderm (cytotrophoblast layer) begins to

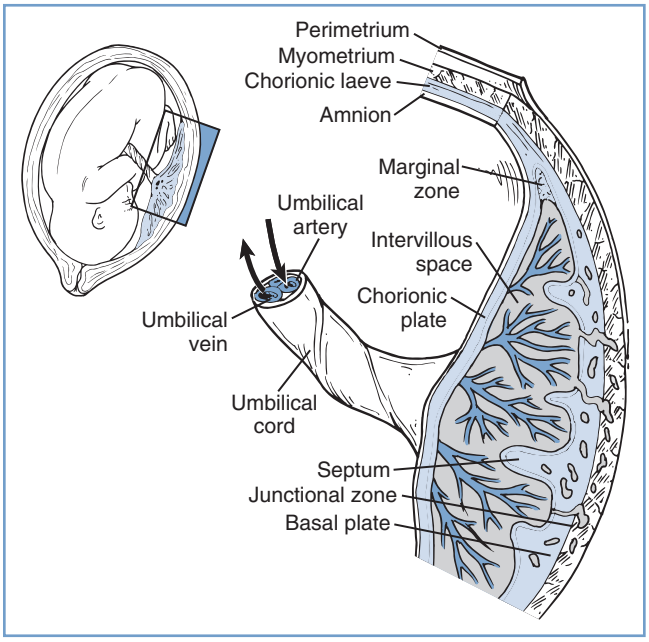

FIGURE 4-1 ■ The placenta is a complex structure that brings the maternal and fetal circulations into close apposition for exchange of substances. (Redrawn from Kaufmann P, Hans-Georg F. Placental development. In Polin RA, Fox WW, Abman SH, editors. Fetal and Neonatal Physiology. 3rd edition. Philadelphia, Saunders, 2004:85-96.)

proliferate as cellular columns into the syncytiotrophoblast. These columns with their syncytiotrophoblast covering extend into the maternal blood lacunae and represent *primary* villi. Further mesodermal invasion into the core of these primary villi marks the metamorphosis into *secondary* villi. Cellular differentiation of the villi mesoderm results in the formation of a network of blood cells and vessels; this transition allows their classification as *tertiary* villi. The vascular components of each villus develop connections within the chorionic plate and into the stalk that connects the developing embryo and primitive placenta. Penetration of the cytotrophoblast continues through the syncytiotrophoblastic layer until many of the villi reach the decidua and form *anchoring* villi (Figure 4-1).[4,5]

Villi continue to develop and undergo extensive branching into treelike structures; the branches, which extend into the lacunar (or intervillous) spaces, enlarge the surface area available for exchange. Further villous maturation results in a marked reduction in the cytotrophoblastic component and a shortening of the distance between the fetal villi and maternal intervillous blood.[4]

The growing embryo within the blastocyst attaches to the chorion through a connecting or body stalk. Mesodermal components of this stalk coalesce to form the allantoic (or rudimentary umbilical) vessels. As the embryo continues its exponential growth phase, the connecting stalk shifts ventrally from its initial posterior attachment. The expansive open region at the ventral surface of the embryo constricts as the body wall grows and closes. By so doing, the body wall surrounds the yolk stalk, allantois, and developing vessels within the connecting stalk to form the primitive umbilicus. As the expanding amnion surrounds and applies itself over the connecting stalk and yolk sac, the cylindrical umbilical cord takes on its mature form.[4]

Placental development is a dynamic process influenced by many factors. **Nitric oxide** plays an important role in embryo development, implantation, and trophoblast invasion in diverse species.[6] Human endothelial nitric oxide synthase (eNOS) expression in the syncytiotrophoblast and early endothelium occurs in the first trimester. Later in pregnancy, eNOS increases and becomes more prominent in the syncytiotrophoblast and endothelial cells. Vasculogenesis and angiogenesis depend on vascular endothelial growth factor (VEGF) and its receptors VEGFR-1 (Flt-1) and VEGFR-2 (Flk-2), transforming growth factor-β_1 (TGF-β_1), and angiopoietin 1 and 2, which exert their effects in part through nitric oxide. Hypoxia also plays an important role in placental development and angiogenesis by stimulating trophoblast invasion and differentiation via hypoxia-inducible factor-alpha, which activates VEGF and eNOS. Relative hypoxia must be maintained in early placental development because the placental-fetal unit cannot tolerate the oxidative stress of reactive oxygen species during organogenesis.[7] Oxygen levels influence the placental vascular sensitivity to vasodilators and constrictors. *In vitro* studies have shown that NOS inhibition and hypoxia independently increase placental perfusion pressure. Both of these effects are prevented by nitric oxide donors, suggesting a common pathway with the effect of hypoxia mediated partly by low NOS activity.[6]

The development of preeclampsia is related, at least in part, to abnormal placental growth and implantation at this early stage of development (see Chapter 36). In patients with preeclampsia, the villous tree has longer capillaries with fewer branches.[6] Vascular dysfunction occurs mainly from changes in vascular structure and activation of nitric oxide synthesis rather than from altered responses to nitric oxide and vasoconstrictors.

DNA, gene expression, and manipulation of gene expression control placental development, fetal development, adult phenotype expression, and clinical diseases, even into subsequent generations.[2,8] The evolving field of epigenetics explores the prolonged effect of maternal and paternal environmental influences; gene expression becomes altered by DNA methylation, histone modification, and noncoding RNA. At fertilization, global DNA methylation is erased so at the blastocyst stage (implantation) the genome is hypomethylated.[8] DNA methylation occurs in a specific manner so the trophectoderm (which becomes the placenta) remains relatively hypomethylated (50% to 70%) compared with the inner cell mass tissue (which becomes somatic human tissue). Genomic imprinting causes the silencing of one allele-specific copy of a gene. DNA methylation of imprinted genes occurs at the germ cell stage but is not involved in the methylation remodeling. Indeed, the human placenta exhibits extensive intraplacental mosaicism in an X-chromosome inactivation pattern. Individual placental cotyledons are derived from only a few cells, leading to cotyledon mosaicism. Even the process of *in vitro* fertilization produces an altered imprinted gene methylation pattern in the placenta.

Altered gene methylation has been linked to clinical disease states.[8] Increased long interspersed nuclear element-1 (*LINE1*) gene methylation is associated with early-onset preeclampsia. Compared with disease-free matched tissue, early-onset preeclampsia is associated with hypomethylation of 34 specific genes, whereas only 4 hypomethylated genes were associated with late-onset preeclampsia.[9] Thus, DNA and DNA regulatory changes influence not only early placental development but also the occurrence of pregnancy-associated disease.

Human studies have demonstrated fetal programming of childhood and adult disease. For example, a study showed that adults who were exposed *in utero* to episodes of malnutrition developed reduced glucose tolerance, atherogenic lipid profiles, and a doubled rate of cardiovascular diseases; these disease states were associated with hypomethylation of regulatory areas for insulin-like growth factor-2 and other genes.[2] *In utero* exposure to a high-fat diet can lead to an increased incidence of diabetes in offspring. Maternal stress during pregnancy can lead to infant neurodevelopmental disorders.[2]

The placenta grows dramatically from the third month of gestation until term, with a direct correlation between placental growth and fetal growth. By term, the mature placenta is oval and flat, with an average diameter of 18.5 cm, weight of 500 g, and thickness of 23 mm. At term, the human fetal-placental weight constitutes 6% of maternal weight. Placental weight increases 0.7% per day, with active fetal growth contributing up to 1.5% of fetal body mass per day.[10] The allocation of nutrient and metabolic resources for fetal growth potentially come at the expense of the mother. The growth of the placenta and fetus is influenced by maternal anabolic status, placental growth hormone, insulin-like growth factor-1, leptin, and glucocorticoids.[11] Whether maternal or fetal in origin, increased glucocorticoids signal adverse environmental conditions and result in reduced glucose and amino acid transfer to the fetus. Indeed, competition between mother and fetus for resource allocation has been termed the *kinship theory*, in which imprinted genes influence the balance of nutrient allocation in a context-specific manner.[11]

Comparative Anatomy

The placentas of different species differ greatly, beginning with their method of uterine attachment, which can include adhesion, interdigitation, and fusion. In addition, the number of tissue layers between the maternal and fetal circulations differ. The most commonly used placental categorization system, the Grossner classification, uses the number of tissue layers in the placental barrier to help differentiate species (Figure 4-2).[12]

The ability of the placenta to transfer various substances differs among species. The markedly thicker epitheliochorial placenta found in sheep, a species commonly used for placental transfer studies, has three maternal layers (epithelium, connective tissue, and endothelium) that separate maternal from fetal blood. By contrast, the human hemochorial placenta lacks these maternal layers, which allows maternal blood to bathe fetal tissues directly (see Figure 4-2). As a result, species

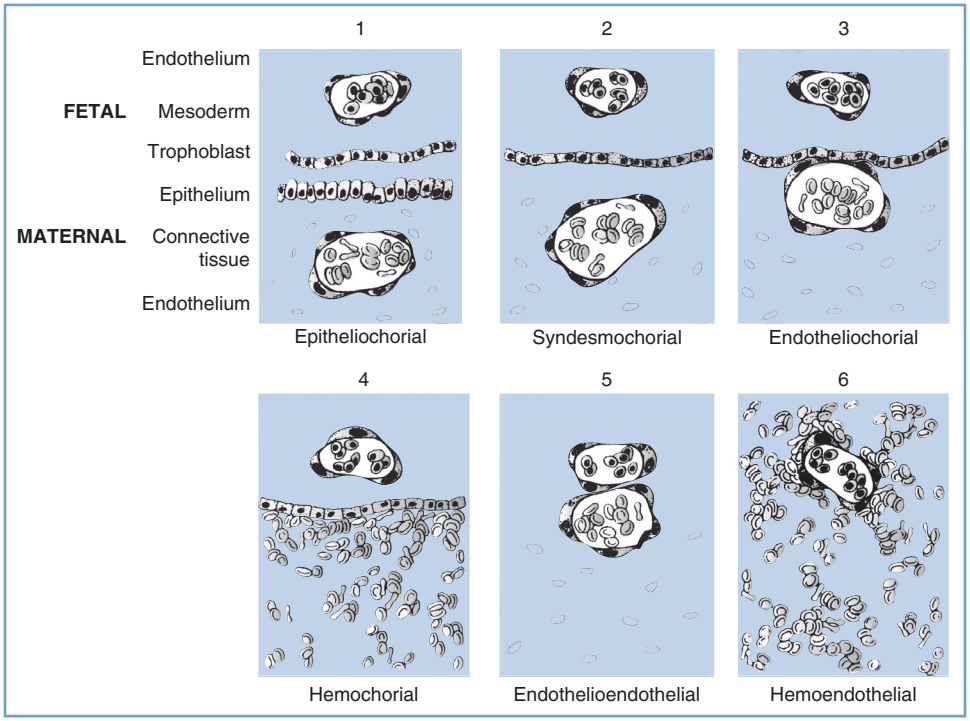

FIGURE 4-2 ■ Modification of Grossner's original classification scheme, showing the number and types of tissue layers between the fetal and maternal circulations. Examples of each are as follows: (1) epitheliochorial, sheep; (2) syndesmochorial, no known examples; (3) endotheliochorial, dogs and cats; (4) hemochorial, human and hamster; (5) endothelioendothelial, bandicoot (Australian opossum); and (6) hemoendothelial, Rocky Mountain pika. (Modified from Ramsey EM. The Placenta: Human and Animal. New York, Praeger Publishers, 1982.)

differ in the transfer of substances through the placenta; for example, fatty acids cannot cross through the placenta in sheep as they do in humans.[13] This wide diversity in placental structure and function among species makes extrapolation from animal investigations to clinical medicine tenuous.

Vascular Architecture

Maternal

Under the initial hormonal influences of the corpus luteum, the spiral arteries of the uterus become elongated and more extensively coiled. In the area beneath the developing conceptus, the compression and erosion of the decidua induces lateral looping of the already convoluted spiral arteries,[14] accessing the intervillous spaces. In late pregnancy, the growing demands of the developing fetus use approximately 200 spiral arteries that directly feed the placenta to handle a blood flow of approximately 600 mL/min.[14] The vasodilation required to accommodate this flow is the result of the replacement of the elastic and muscle components of the artery, initially by cytotrophoblast cells and later by fibroid cells. This replacement reduces the vasoconstrictor activity of these arteries and exposes the vessels to the dilating forces of the greater blood volume of pregnancy, especially at the terminal segments, where they form funnel-shaped sacs that enter the intervillous space.[14] The increased diameter of the vessels decreases blood velocity and reduces blood pressure.

The **intervillous space** is a large cavernous expanse that develops from the fusion of the trophoblastic lacunae and the erosion of the decidua by the expanding blastocyst, forming a huge blood sinus bounded by the chorionic plate and the decidua basalis (i.e., the maternal or basal plate). Folds in the basal plate form septa that separate the space into 13 to 30 anatomic compartments known as *lobules*. Each lobule contains numerous villous trees that are also known as *cotyledons* or *placentomes*. Although tightly packed with highly branched villous trees, the intervillous space of the mature placenta can accommodate approximately 350 mL of maternal blood.

Maternal arterial blood leaves the funnel-shaped spiral arteries and enters the intervillous space. The blood moves into the nearly hollow, low-resistance area, where villi are very loosely packed (the intercotyledonary space), before entering another region of densely packed intermittent and *terminal* villi (Figure 4-3).[15] The terminal villi represent the areas where placental exchange predominates. After passing through this dense region, maternal venous blood collects between neighboring villous trees in an area called the *perilobular zone*.[16] Collecting veins penetrate the maternal plate at the periphery of the villous trees to drain perilobular blood from the intervillous space.

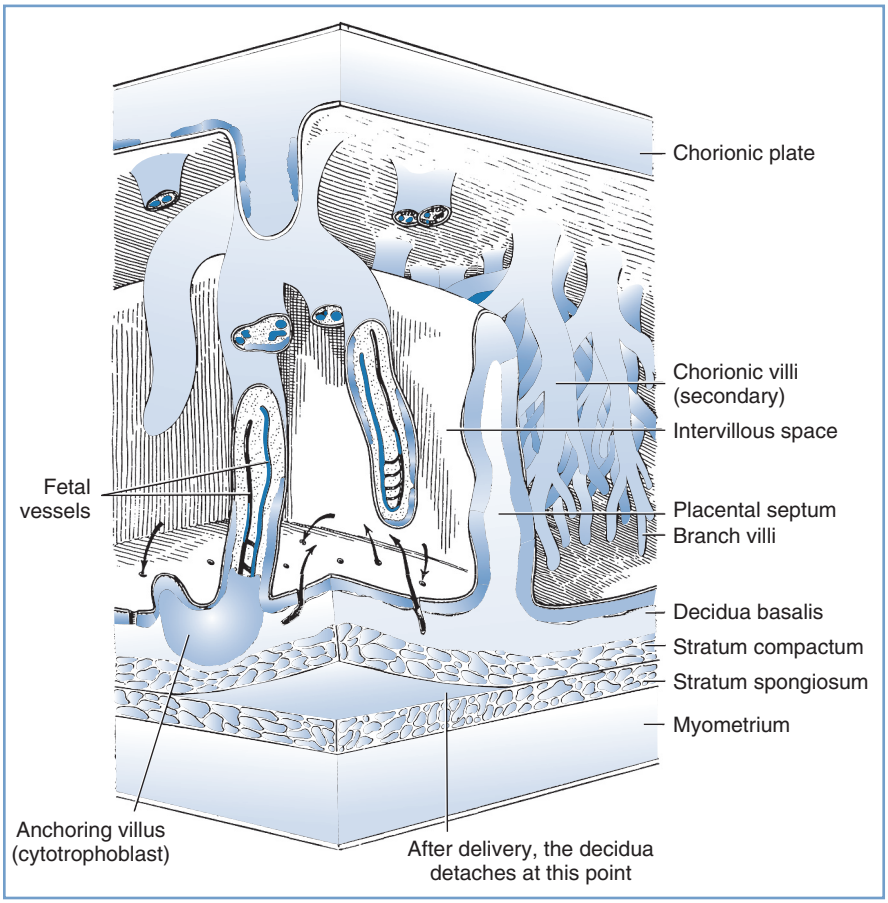

FIGURE 4-3 ■ The relationship between the villous tree and maternal blood flow. *Arrows* indicate the maternal blood flow from the spiral arteries into the intervillous space and out through the spiral veins. (Modified from Tuchmann-Duplessis H, David G, Haegel P. Illustrated Human Embryology. Volume 1. Embryogenesis. New York, Springer Verlag, 1972:73.)

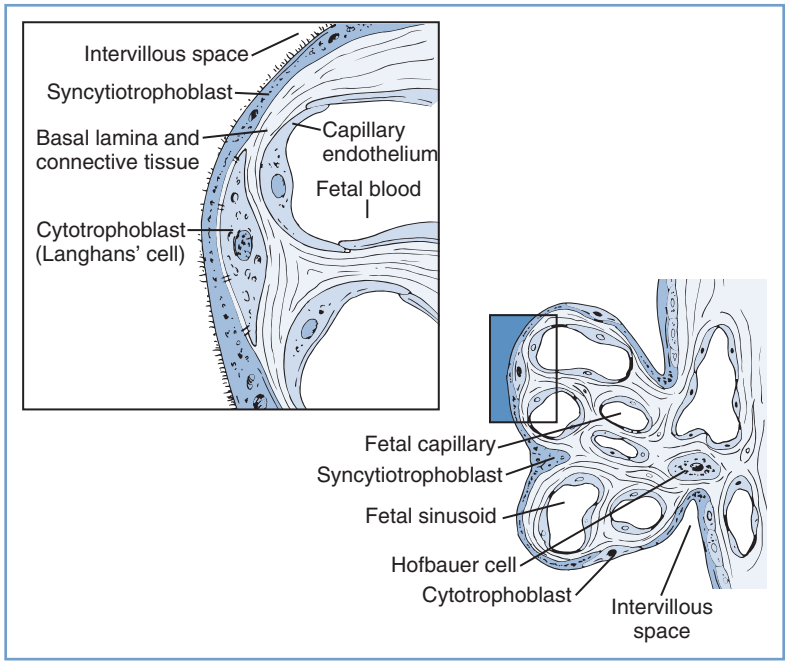

FIGURE 4-4 ■ *Left,* Cellular morphology of two terminal villi. *Right,* Higher magnification of the boxed region exhibiting the placental barrier between fetal and maternal blood. (Redrawn from Kaufmann P. Basic morphology of the fetal and maternal circuits in the human placenta. Contrib Gynecol Obstet 1985; 13:5-17.)

Fetal

Two coiled arteries bring fetal blood within the umbilical cord toward the placenta. On the placental surface, these arteries divide into **chorionic arteries** that supply the 50 villous trees located in the placental lobules. At the base of each villous tree, the chorionic arteries are considered the *main villous stem* or *truncal arteries* (first-order vessels), which in turn branch into four to eight *ramal* or *cotyledonary arteries* (second-order vessels); as they pass toward the maternal plate, they further subdivide into *ramulus chorii* (third-order vessels) and, finally, *terminal arterioles.* The terminal arterioles lead through a neck region into a bulbous enlargement where they form two to four narrow capillary loops. Here the large endothelial surface area and the near-absence of connective tissue allow optimal maternal-fetal exchange (Figure 4-4).[16,17]

The **venous end of the capillaries** loops, narrows, and returns through the neck region to the collecting venules, which coalesce to form the larger veins in the stem of the villous trees. Each villous tree drains into a large vein, which, as it perforates the chorionic plate, becomes a **chorionic vein.** All of the venous tributaries course toward the umbilical cord attachment site, where they empty into the one umbilical vein that delivers blood back to the fetus.

PHYSIOLOGY

Barrier Function

The placenta is an imperfect barrier that allows many substances to cross from the maternal to the fetal circulation and from the fetal to the maternal circulation. The rate and amount of placental transfer depend on the permeability and the ability of various mechanisms to restrict movement. A vast array of cytochrome P450 isoenzymes and transporters are found within the placenta; some of these are inducible, whereas others are constitutive. In addition, a number of substances undergo specific or nonspecific binding within the placental tissues, thereby minimizing fetal exposure to and accumulation of the substances. Finally, the thickness of the placental membranes, which diminishes as gestation progresses, may influence the rate of diffusion.[18] Of interest, the rate of transfer of certain substances (e.g., glucose, water) differs very little among species, even though the placental thickness varies greatly.[19]

Fetal cells have been detected in maternal circulation, before organogenesis and full maternal arterial perfusion of the placenta, and maternal cells have also been shown to enter the fetal circulation.[20] Maternal-fetal cell transfer may occur by disruption of the trophoblastic layer or by active adhesion and transmigration (similar mechanism to blood-brain barrier migration). Fetal cells may be pluripotent, and the DNA may be found in maternal organs for decades. Murine fetal progenitor cells have been found to migrate and assist with maternal wound healing.[21] These microchimeric fetal cells may contribute to maternal immunomodulation, development or worsening of autoimmune diseases (e.g., thyroiditis, lupus, and asthma), and healing of wounds, including neuronal tissue.[22] Indeed, placental exosomes, nanovesicles 30 to 100 nm in size found in maternal circulation that contain proteins and transcription-related materials, exert a maternal immunosuppressive effect. Placental microparticles, vesicular products of syncytiotrophoblast greater than 100 nm, also contain RNA and DNA fragments and affect fetal and maternal apoptosis, angiogenesis, and inflammation. An excess of microparticles has been observed in early-onset preeclampsia. The placenta and fetal-maternal interactions are certainly complex and worthy of further study.

Cell-free fetal DNA has been shown to be present in the plasma of pregnant women.[23] This discovery has facilitated the development of a range of noninvasive diagnostic investigations, including tests for fetal sex assessment, fetal rhesus D blood group genotyping, fetal chromosomal aneuploidy detection, and other genetic abnormalities.[24]

Hormonal Function

A sophisticated transfer of precursor and intermediate compounds in the maternal-fetal-placental unit allows placental enzymes to convert steroid precursors into estrogen and progesterone. This steroidogenic function of the placenta begins very early in pregnancy; by 35 to 47 days after ovulation, the placental production of estrogen and progesterone exceeds that of the corpus luteum (i.e., the ovarian-placental shift).[25]

The placenta also produces a wide array of enzymes, binding proteins, and polypeptide hormones. For example, the placenta produces human chorionic gonadotropin, human placental lactogen (a growth hormone also known as human chorionic somatomammotropin), and factors that control hypothalamic function.[25] This ability to produce proteins and steroid hormones allows the placenta to influence and control the fetal environment.[26]

Regulation of Placental Blood Flow

Maternal Blood Flow

The trophoblastic invasion and functional denervation of the musculoelastic lining of the spiral arteries may represent adaptive mechanisms to decrease vascular reactivity and promote vasodilation. These alterations allow the spiral arteries to vasodilate as much as 10 times their normal diameter, thereby lowering resistance for the passage of blood through the intervillous spaces.[27]

Maternal blood enters the intervillous cotyledon space at a pressure of 70 to 80 mm Hg in an area that has relatively few villi.[14] The pressure and velocity of blood flow rapidly diminishes to approximately 10 mm Hg as the blood passes into an area of higher resistance created by the densely packed villi of the placentome.[18]

Fetal Blood Flow

In contrast to maternoplacental blood flow, the gestational increases in fetoplacental blood flow primarily results from vascular growth rather than vasodilation of the villous beds. Fetal perfusion of the placenta is not classically autoregulated; the placental vasculature has no innervation by the sympathetic nervous system. However, the fetus can modulate fetoplacental perfusion in a number of ways: (1) via endocrine effects of adrenomedullin, (2) via net efflux/influx of water regulated by fetal blood pressure, and (3) via local autoregulatory effects mediated by the paracrine vasodilators nitric oxide and acetylcholine.[28,29] Adrenomedullin release by the fetal adrenal glands assists in maintenance of tone in placental vessels. Fetal blood pressure changes cause net influx/efflux of water across the placenta that affects fetal intravascular volume and perfusion. Maternal hyperglycemia[30] and hypoxemia[31] are examples of derangements that can alter regional fetal blood flow, probably through vascular mediators. Endothelium-derived relaxing factors, especially prostacyclin[32] and nitric oxide,[33] are important in the control of fetoplacental circulation. Hypoxia-induced fetoplacental vasoconstriction is mediated by a reduction in the basal release of nitric oxide.[34] This vasoconstrictor activity is functionally similar to that found in the lung (i.e., hypoxic pulmonary vasoconstriction) and allows optimal fetal oxygenation through redistribution of fetal blood flow to better-perfused lobules.[31] The placental vasculature constricts in response to graded hypoxia.[35]

Transport Mechanisms

Substances are transferred across the placenta by one of several mechanisms.

Passive Transport

The passive transfer of molecules across a membrane depends on (1) concentration and electrochemical differences across the membrane, (2) molecular weight, (3) lipid solubility, (4) degree of ionization, and (5) membrane surface area and thickness. This process requires no expenditure of cellular energy, with transfer driven principally by the concentration gradient across a membrane. Simple transmembrane diffusion can occur either through the lipid membrane (e.g., lipophilic molecules and water) or within protein channels that traverse the lipid bilayer (e.g., charged substances such as ions) (Figure 4-5).[36,37] Drugs with a molecular weight less than 600 daltons cross the placenta by passive diffusion.[38]

Facilitated Transport

Carrier-mediated adenosine triphosphate (ATP)–independent transport of relatively lipid-insoluble molecules down their concentration gradient is called *facilitated diffusion*.[36] Facilitated diffusion differs from simple diffusion in several ways. Specifically, this mode of transfer exhibits (1) saturation kinetics, (2) competitive and noncompetitive inhibition, (3) stereospecificity, and (4) temperature influences (e.g., a higher temperature results in greater transfer). With *simple diffusion*, the net rate of diffusion is proportional to the difference in concentration between the two sides of the membrane. This rate limitation is valid for facilitated diffusion only when transmembrane concentration differences are small. At higher concentration gradients, a maximum rate of transfer (V_{max}) is reached; thereafter, further increases in the concentration gradient do not affect the rate of transfer. The rate of transfer is determined by the number of membranous carrier protein complexes and the extent of interaction between the carrier and the substance undergoing transport.[37] An example of facilitated diffusion is the transplacental transfer of glucose.

A special type of facilitated diffusion involves the "uphill" transport of a molecule linked to another substance traveling down its own concentration gradient. As

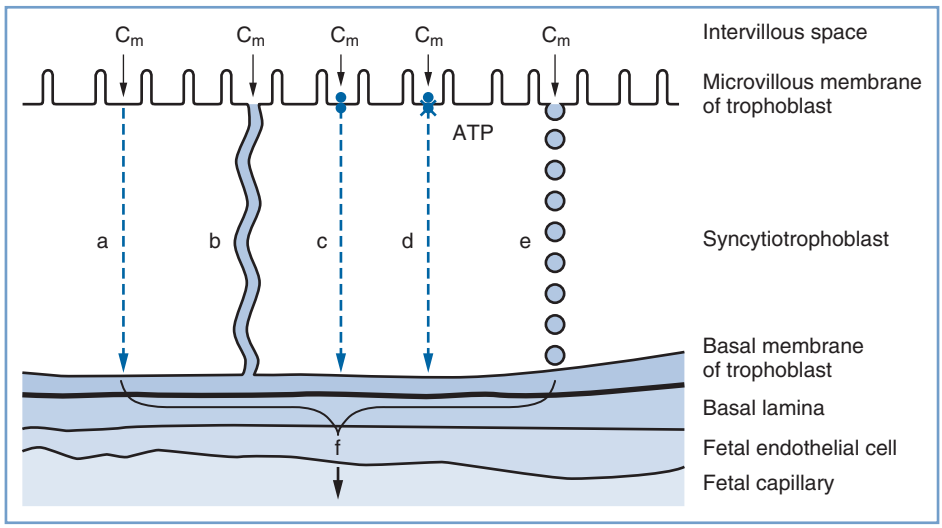

FIGURE 4-5 ■ The transfer mechanisms used for the transfer of substances across the placental barrier: *a*, simple diffusion; *b*, simple diffusion through channels; *c*, facilitated diffusion; *d*, active transport; *e*, endocytosis; *f*, substance available for transfer into fetal circulation; C_m, intervillous concentration of substance at the trophoblastic membrane. (Modified from Atkinson DE, Boyd RDH, Sibley CP. Placental transfer. In Neill JD, Plant TM, Pfaff DW, et al., editors. Knobil and Neill's Physiology of Reproduction. 3rd edition. St. Louis, Academic Press, 2006:2787-846.)

such, the transfer is not directly driven by cellular energy expenditure. In most cases, sodium is the molecule that facilitates transport. For the membrane-bound carrier to transfer these molecules, both molecules must be bound to the carrier. This hybrid system is called *secondary active transport* or *co-transport*.[37] The transplacental transport of amino acids appears to occur principally through secondary active transport. Transporters may be affected by disease states (e.g., preeclampsia) or signaling molecules (e.g., elevated steroid levels).[39]

Active Transport

Active transport involves the movement of any substance across a cell membrane; the process requires cellular energy. In general, active transport occurs against a concentration, electrical, or pressure gradient.

Like facilitated diffusion, active transport requires a protein membrane carrier that exhibits saturation kinetics and competitive inhibition.[36] However, unlike secondary active transport, the movement of a substance against its concentration gradient is directly linked to the hydrolysis of high-energy phosphate bonds of ATP. The best known example of primary active transport is the translocation of sodium and potassium through the sodium-potassium adenosine triphosphatase (Na^+/K^+ ATPase) pump.

Active transport proteins include P-glycoprotein, breast cancer resistance protein, multidrug resistance protein, and the sodium/multivitamin transporter, as well as the many proteins involved in monoamine transport and xenobiotics.[39] These transport proteins play an important role in protecting the fetus from foreign and potentially teratogenic compounds. Drugs may compete with endogenous compounds of similar shape and charge for active transport.[39] P-glycoprotein transports many lipophilic drugs and antibiotics and removes cytotoxic compounds from the fetus; it exists on the maternal side of the trophoblastic cell membrane of the placenta and prevents compounds such as methadone and saquinavir (a protease inhibitor) from leaving the maternal blood, thus limiting fetal exposure.[40] Inhibition of these transporter proteins (e.g., inhibition of P-glycoprotein by verapamil) can significantly increase the fetal transfer of certain drugs, including midazolam, which is a substrate for P-glycoprotein. DNA transcription of transporters may be induced by drugs or disease states. Expression of transporters may change with gestational age.[41]

Pinocytosis

Large macromolecules (e.g., proteins that exhibit negligible diffusion properties) can cross cell membranes via the process of pinocytosis (a type of endocytosis). Pinocytosis is an energy-requiring process in which the cell membrane invaginates around the macromolecule. Although the contents of pinocytotic vesicles are subject to intracellular digestion, electron microscopic studies have demonstrated that vesicles can move across the cytoplasm and fuse with the membrane at the opposite pole. This appears to be the mechanism by which immunoglobulin G is transferred from the maternal to the fetal circulation.[36]

Other Factors That Influence Placental Transport

Other factors that affect maternal-fetal exchange include (1) maternal and fetal blood flow, (2) placental binding, (3) placental metabolism, (4) diffusion capacity, (5) maternal and fetal plasma protein binding, and (6) gestational age (the placenta is more permeable in early pregnancy).[42] Lipid solubility, pH gradients between the maternal and fetal environments for certain basic drugs ("ion trapping"), and alterations in maternal or fetal plasma protein

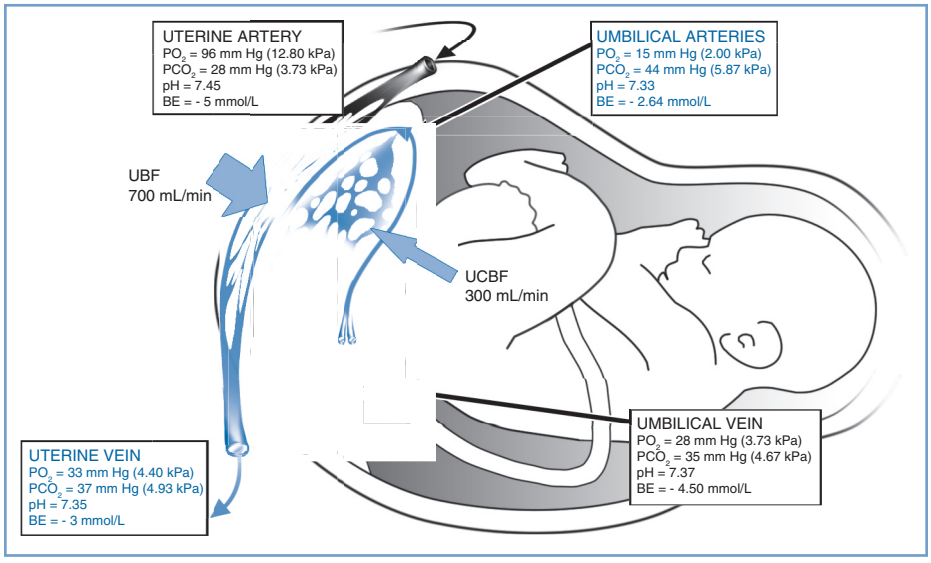

FIGURE 4-6 ■ The concurrent relationship between the maternal and fetal circulations within the placenta and the way this arrangement affects gas transfer. These values were obtained from patients' breathing room air during elective cesarean delivery. *BE,* base excess; *Po_2,* partial pressure of oxygen; *Pco_2,* partial pressure of carbon dioxide; *UBF,* uterine blood flow; *UCBF,* umbilical cord blood flow. concentrations found in normal pregnancy[43] and other disease states (e.g., preeclampsia) may also alter placental transport.

Transfer of Respiratory Gases and Nutrients

Oxygen

Our knowledge of oxygen transfer physiology in the placenta is largely derived from the lung. The placenta must provide approximately 8 mL O_2/min/kg fetal body weight for fetal growth and development, while adults only require 3 to 4 mL O_2/min/kg at rest.[44] As the "lung" for the fetus, the placenta has only one fifth the oxygen transfer efficiency of the adult lung.[45] The human lung, with a surface area of 50 to 60 m^2 and a thickness of only 0.5 µm, has a very large oxygen diffusion capacity; in comparison, the placenta has a lower diffusion capacity because of its smaller surface area of 16 m^2 and a thicker membrane of 3.5 µm. Furthermore, 16% of uterine blood flow and 6% of umbilical blood flow are shunted through the placenta.[18]

Oxygen transfer across the placenta depends on the membrane surface area, membrane thickness, oxygen partial pressure gradient between maternal blood and fetal blood, affinity of maternal and fetal hemoglobin, and relative maternal and fetal blood flows. As physically dissolved oxygen diffuses across the villous membranes, bound oxygen is released by maternal hemoglobin in the intervillous space and diffuses across the placenta. Several factors affect the fetal blood Po_2 once it reaches equilibration in the villi end-capillaries. First, the concurrent and countercurrent arrangements of maternal and fetal blood flow play a key role for placental oxygen transfer in various species. The almost complete equilibration of maternal and fetal Po_2 values suggests that a concurrent (or parallel) relationship between maternal blood and fetal blood exists within the human placenta (Figure 4-6),[18,46] although others have described a multivillous, cross-current flow pattern.

Much of the literature in this area is based on animal studies. Because the functional anatomy of the placenta in many mammals involves more layers than the human placenta (e.g., the epitheliochorial placenta of the sheep has three layers), results of animal models can only provide evidence for trends, not values, in humans.

In humans, oxygen solubility is 10^{-4} M in plasma and 10^{-2} M in hemoglobin; thus, 99% of the oxygen content in blood is bound to hemoglobin. With an inspired oxygen fraction of 1.0, the maximum maternal arterial Po_2 was 425 mm Hg, but the fetal umbilical venous Po_2 was only 47 mm Hg, indicating a low diffusion capacity of oxygen across the placenta.[47] In addition, the placenta receives less than 50% of the fetal cardiac output, and blood returning from the placenta admixes with the nonoxygenated blood in the fetal inferior vena cava, thus limiting fetal arterial Po_2.

Although some have called the human placenta "diffusion limited" because of the decreased ability of oxygen to cross the intervillous membrane, the delivery of oxygen to the fetus is predominantly flow limited. Maternal delivery of blood (i.e., oxygen) to the uterus is the predominant factor controlling fetal oxygen transfer. The high fetal hemoglobin concentration (17 mg/dL) accounts for the large oxygen content and the net delivery of large quantities of oxygen to the fetus. Fetal hemoglobin has a higher oxygen affinity and therefore a lower partial pressure at which it is 50% saturated (P_{50}: 18 mm Hg) than maternal hemoglobin (P_{50}: 27 mm Hg). This gradient produces a "sink" effect that enhances oxygen uptake by

fetal red blood cells, keeping fetal Po_2 lower and promoting the transfer of additional oxygen across the placenta (see Figure 5-7). The **Bohr effect** also augments the transfer of oxygen across the placenta. Specifically, fetal-maternal transfer of carbon dioxide makes maternal blood more acidic and fetal blood more alkalotic. These alterations of pH cause shifts in the maternal and fetal oxyhemoglobin dissociation curves, further enhancing the maternal oxygen transfer to the fetus in what is termed the "double" Bohr effect. This accounts for 2% to 8% of the transplacental transfer of oxygen.[48]

The placenta normally has a 50% reserve for changes in maternal or fetal blood flow by increasing venous extraction, a mechanism similar to that in adults. Based on umbilical venoarterial difference, human fetal oxygen uptake at term is 0.25 mmol/kg/min.[49] The metabolic activity of the placenta itself consumes up to 40% of the oxygen uptake. Placental oxygen consumption is stable even with changes in maternal blood pressure and Po_2; 30% of placental oxygen is used for protein synthesis and almost 30% for Na^+/K^+ ATPase. The human placenta has a villous structure, which may be an adaptation for greater maternal flow and thus oxygen delivery, but at the expense of a smaller surface area and cross-current exchange mechanism.[50] However, the placenta does change in response to chronic hypoxia found at high altitudes, with an increased capillary volume and decreased capillary thickness providing a near-doubling of the oxygen diffusion capacity.[51]

Carbon Dioxide

The transfer of CO_2 occurs through a number of different forms, including dissolved CO_2, carbonic acid (H_2CO_3), bicarbonate ion (HCO_3^-), carbonate ion (CO_3^{2-}), and carbaminohemoglobin. Equilibrium between CO_2 and HCO_3^- is maintained by a reaction catalyzed by carbonic anhydrase in red blood cells. The Pco_2 gradient between fetal and maternal blood (i.e., 40 versus 34 mm Hg, respectively) drives fetal-maternal transfer. Carbon dioxide is 20 times more diffusible than oxygen and readily crosses the placenta,[52] although dissolved CO_2 is the form that actually crosses. The rapid movement of CO_2 from fetal capillary to maternal blood invokes a shift in the equilibrium of the carbonic anhydrase reaction **(La Chatelier's principle)** that produces more CO_2 for diffusion. The transfer of CO_2 is augmented further by the production of deoxyhemoglobin in the maternal blood, which has a higher affinity for CO_2 than oxyhemoglobin (the **Haldane effect**). The resulting affinity may account for as much as 46% of the transplacental transfer of carbon dioxide.[46] Although a significant fetal-maternal concentration gradient exists for HCO_3^-, its charged nature impedes its transfer and contribution to CO_2 transport except as a source for CO_2 production through the carbonic anhydrase reaction.[53]

Glucose

Simple diffusion alone cannot account for the amount of glucose required to meet the demands of the placenta and fetus. To assist the movement of glucose down its concentration gradient, stereospecific-facilitated diffusion systems have been described with glucose transporters such as GLUT1 and GLUT3; the system is independent of insulin, a sodium gradient, or cellular energy.[54] Insulin does not cross the placenta; however, insulin receptors in the maternal side of the syncytiotrophoblast regulate nutrient transport through a signaling cascade involving the mammalian target of rapamycin complex (mTORC). Nutrient sensors for glucose, amino acids, oxygen, cytokines, growth factors, and energy levels stimulate mTORC1, a key sensing and signaling protein in the syncytiotrophoblast that regulates nutrient transport and growth.[55]

Amino Acids

Concentrations of amino acids are highest in the placenta, followed by umbilical venous blood and then maternal blood. The maternal-fetal transplacental transfer of amino acids is an active process that occurs principally through a linked translocation with sodium. The energy required for this transfer comes from the large sodium gradient established by the Na^+/K^+ ATPase pump, resulting in increased intracellular concentrations of amino acids, which then "leak" down their gradients into the fetal circulation. This transport mechanism may not apply to all amino acids and may be susceptible to inhibitors. Transport also occurs via transport exchangers of amino acids on both maternal and fetal sides of the placenta as well as facilitated diffusion. Pregnancies with fetal growth restriction (also known as intrauterine growth restriction) have reduced amino acid transport with an inability to increase transport in spite of higher maternal levels of essential amino acids than occur in healthy pregnancies.[56]

Fatty Acids

Free fatty acids readily cross the human, but not ovine, placenta. The essential fatty acids, linoleic and alpha-linolenic acid, must be transferred across the placenta. Lipid transfer to the fetus reaches a peak of 7 g/day at term. The placental basal membrane has specific binding sites for very low-density, low-density, and high-density lipoproteins. Lipase activity in the placenta is responsible for converting triglycerides to nonessential fatty acids. The placenta does not elongate fatty acid chains, whereas the fetus does. Fatty acid transport occurs primarily by simple diffusion; however, fatty acid–binding proteins (FABPpm, FAT/CD36, and FATP), which facilitate transport, have been discovered. Nonessential fatty acids are albumin bound and may displace other protein-bound substances.[57]

DRUG TRANSFER

Placental permeability and pharmacokinetics determine the fetal exposure to maternal drugs. Animal models (e.g., pregnant ewes, guinea pigs) have been used to assess the placental transport of drugs; however, interspecies differences in placental anatomy and physiology limit the

application of these data to humans.[58] Human placental transport mechanisms have been studied in placental slices, isolated villi, membrane vesicles, homogenates, and tissue culture cells. The direct application of these data, however, is in question because these methods do not account for the dual (i.e., maternal and fetal) perfusion of the intact placenta *in situ*.[58]

The inaccessibility of the placenta *in situ* and concerns for maternal and fetal safety have limited direct studies of the placenta in humans. Data regarding the transplacental transfer of anesthetic agents have been extrapolated primarily from single measurements of drug concentrations in maternal and umbilical cord blood samples obtained at delivery. Most studies have reported fetal-to-maternal (F/M) ratios of drug concentration. In these studies, the umbilical vein blood concentration represents the fetal blood concentration of the drug. Maternal and fetal concentrations of a drug are influenced by drug metabolism in the mother, the placenta, and the fetus and also by changes during delivery (e.g., altered uteroplacental blood flow).[58]

A dual-perfused, *in vitro* human placental model has been developed to allow for the independent perfusion of the maternal and fetal sides of the placenta and thereby investigate maternal-fetal (or fetal-maternal) transport.[58] Equilibration studies (i.e., recirculating maternal and fetal perfusates) using this model are not directly applicable to the placenta *in vivo*. However, when a nonrecirculating design is used, steady-state drug clearance can be determined for either direction (maternal to fetal *or* fetal to maternal) and may have direct clinical application. This method has been used to assess the placental transfer of anesthetic agents (e.g., thiopental,[59] methohexital,[60] propofol,[61] bupivacaine,[62] ropivacaine,[63] alfentanil,[64] and sufentanil[65,66]). Transfer across the placenta may be reported as drug clearance or as a ratio referred to as the **transfer index** (i.e., drug clearance/reference compound clearance). The use of a transfer index allows for interplacental comparisons by accounting for differences between placentas (e.g., lobule sizes). Commonly used reference compounds are either flow limited (e.g., antipyrine, tritiated water) or membrane limited (e.g., creatinine). These studies have enhanced our understanding of the placental transfer of anesthetic drugs (Box 4-1).

BOX 4-1 Transplacental Transfer of Anesthetic Drugs

Drugs That Readily Cross the Placenta

- Anticholinergic agents
  - Atropine
  - Scopolamine
- Antihypertensive agents
  - Beta-adrenergic receptor antagonists
  - Nitroprusside
  - Nitroglycerin
- Benzodiazepines
  - Diazepam
  - Midazolam
- Induction agents
  - Propofol
  - Ketamine
  - Etomidate
  - Thiopental
- Inhalation anesthetic agents
  - Halothane
  - Isoflurane
  - Sevoflurane
  - Desflurane*
  - Nitrous oxide
- Local anesthetics
- Opioids
- Vasopressor
  - Ephedrine

Drugs That Do Not Readily Cross the Placenta

- Anticholinergic agent
  - Glycopyrrolate
- Anticoagulants
  - Heparin
- Muscle relaxants
  - Depolarizing: succinylcholine
  - Nondepolarizing agents
- Vasopressor
  - Phenylephrine

*Experimental data for desflurane are lacking but, based on physical characteristics similar to other halogenated anesthetics, placental transfer is assumed.

Pharmacokinetic Principles

Factors affecting drug transfer across the human placenta include lipid solubility, protein binding, tissue binding, pKa, pH, and blood flow (Table 4-1). High lipid solubility may readily enable cell membrane (lipid bilayer) penetration but may also cause the drug (e.g., sufentanil) to be trapped within the placental tissue.[66] Highly protein-bound drugs are affected by the concentration of maternal and fetal plasma proteins, which varies with gestational age and disease. Some drugs (e.g., diazepam) bind to albumin, whereas others (e.g., sufentanil, cocaine) bind predominantly to α_1-acid glycoprotein (AAG) (Table 4-2). Although the free, unbound fraction of drug equilibrates across the placenta, the total drug concentration is greatly affected by both the extent of protein binding and the quantity of maternal and fetal proteins; fetal blood typically contains less than half the concentration of AAG than maternal blood.[67] One study of the placental transfer of sufentanil *in vitro* noted different results when fresh frozen plasma, rather than albumin, was used as a perfusate. Albumin binds primarily acidic and lipophilic compounds, whereas AAG binds more basic compounds. Indeed, the fetal levels of both albumin and AAG increase from first trimester to term.[68]

The pKa of a drug determines the fraction of drug that is non-ionized at physiologic pH. Thus, fetal acidemia greatly enhances the maternal-fetal transfer (i.e., "ion trapping") of many basic drugs, such as local anesthetics and opioids (Figure 4-7) (see Chapter 13).[69] Most anesthetic drugs are passively transferred, with the rate of blood flow (hence drug delivery) affecting the amount of drug that crosses the placenta.[70] One of the authors (M.I.Z.) has used the *in vitro* perfused human placenta model to perform a number of studies of the placental transfer of opioids (Table 4-3).

TABLE 4-1 Factors Affecting Placental Transfer of Drug (Maternal to Fetal)

	Increased Transfer	Decreased Transfer
Size: molecular weight (Da)	<1000	>1000
Charge of molecule	Uncharged	Charged
Lipid solubility	Lipophilic	Hydrophilic
pH versus drug pKa*	Higher proportion of un-ionized drug in maternal plasma	Higher proportion of ionized drug in maternal plasma
Placental efflux transporter† proteins (e.g., P-glycoprotein)	Absent	Present
Binding protein type	Albumin (lower binding affinity)‡	α_1-Acid glycoprotein (AAG) (higher binding affinity)
Free (unbound) drug fraction	High	Low

Da, dalton.
*The pH relative to the pKa determines the amount of drug that is ionized and un-ionized in both maternal and fetal plasma. Fetal acidemia enhances the maternal-to-fetal transfer (i.e., "ion trapping") of basic drugs such as local anesthetics and opioids.
†The efflux transporter pumps substances in a fetal-to-maternal direction.
‡*Note:* albumin concentration is higher in the fetus, and AAG concentration is higher in the maternal circulation.

TABLE 4-2 Concentrations of Proteins That Bind Drugs

	Maternal	Umbilical Cord
Albumin	33.1 g/L	37.1 g/L*
Alpha$_1$-acid glycoprotein (AAG)	0.77 g/L	0.26 g/L*

*$P < .05$.

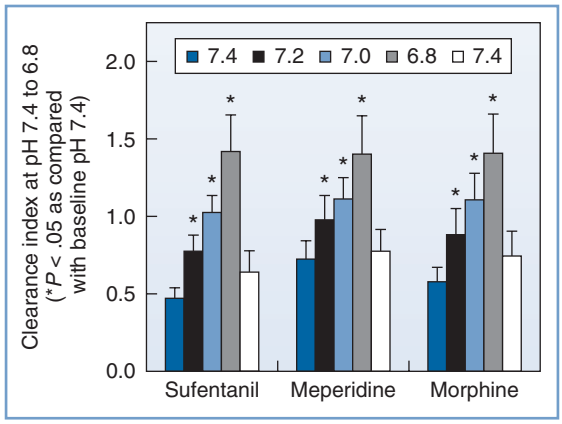

FIGURE 4-7 ■ The effects of changes in fetal pH on the transfer of opioids during *in vitro* perfusion of the human placenta. This figure demonstrates the "ion trapping" of opioids, which is similar to that of local anesthetics. Clearance index = clearance drug/clearance creatinine (a reference compound). (Modified from Zakowski MI, Krishna R, Grant GJ, Turndorf H. Effect of pH on transfer of narcotics in human placenta during in vitro perfusion. Anesthesiology 1995; 85:A890.)

TABLE 4-3 Opioid Transfer during *In Vitro* Perfusion of the Human Placenta

	Morphine	Meperidine	Alfentanil	Fentanyl	Sufentanil
Lipid solubility	1.4	39	129	816	1727
Percent non-ionized at pH 7.4	23%	7.4%	89%	8.5%	20%
Percent protein binding	30%	70%	93%	84%	93%
Placenta drug ratio	0.1	0.7	0.53	3.4	7.2
F/M ratio, MTF	0.08	0.27	0.22	0.19	0.14
F/M ratio, FTM	0.08	0.13	0.11	0.08	0.18
Minutes to steady state	30	20	20	40-60	40-60
Clearance index, MTF	0.4	0.95	0.75	0.76	0.41
Clearance index, FTM	0.5	0.91	0.78	0.61	0.76

Clearance index, clearance drug/clearance antipyrine (a flow-limited reference compound); *FTM,* fetal-to-maternal (direction); *MTF,* maternal-to-fetal (direction); *placenta drug ratio,* placenta drug concentration/g placental tissue/maternal drug concentration.
Data from non-recirculated experiments, using perfusate Media 199 without protein, with maternal flow 12 mL/min and fetal flow 6 mL/min.[64,66,102,105,110]

Inhalation Anesthetic Agents

The lipid solubility and low molecular weight of inhalation anesthetic agents facilitate rapid transfer across the placenta. A prolonged induction-to-delivery interval results in lower Apgar scores.[71]

When administered during cesarean delivery, **halothane** is detectable in both umbilical venous blood and arterial blood within 1 minute. Even with a relatively short induction-to-delivery time, an F/M ratio of 0.71 to 0.87 is established.[72,73] **Isoflurane** distributes rapidly across the placenta during cesarean delivery, resulting in an F/M ratio of approximately 0.71.[73] **Sevoflurane** has an F/M ratio of 0.38, similar to that of other inhaled agents.[74] Sevoflurane causes a dose-dependent vasodilation of the placental vessels that is not mediated by nitric oxide.[75] To our knowledge, there are no published data regarding the placental transfer of **desflurane.**

Nitrous oxide also rapidly crosses the placenta, with an F/M ratio of 0.83 within 3 minutes.[76] Maternal administration of nitrous oxide decreases fetal central vascular resistance by 30%,[77] and a prolonged induction to delivery interval may cause neonatal depression. Diffusion hypoxia may occur during the rapid elimination of nitrous oxide from the neonate; supplemental oxygen for any neonate exposed to nitrous oxide immediately before delivery appears prudent.

Induction Agents

The lipophilic characteristics that make anesthetic agents ideal for the induction of anesthesia also enhance their transfer across the placenta. The understanding of the transplacental transfer of these drugs is better than for any other group of anesthetic agents.

Propofol

A 2- to 2.5-mg/kg bolus dose of propofol, the most widely used induction agent for general anesthesia, results in a mean F/M ratio between 0.65 and 0.85.[78-80] A bolus dose of 2 mg/kg followed by a continuous infusion of 6 mg/kg/h or 9 mg/kg/h of propofol resulted in mean F/M ratios of 0.50 and 0.54, respectively.[81] These F/M ratios are similar to those found when propofol is given in early gestation (at 12 to 18 weeks).[82] Propofol may have sedative effects on the neonate; in a randomized trial of propofol compared with thiopental for the induction of anesthesia for elective cesarean delivery, the maternal administration of propofol (2.8 mg/kg) resulted in lower 1- and 5-minute Apgar scores than thiopental (5 mg/kg).[83] Plasma levels of propofol in the neonate depend on the maternal dose and the time elapsed between drug administration and delivery of the neonate. In one study, when delivered within 10 minutes of induction, neonates whose mothers were given propofol (2 mg/kg) had an average umbilical vein propofol concentration of 0.32 μg/mL.[84]

Several factors that affect propofol transfer have been investigated with *in vitro* human placental perfusion models.[85-87] Increased maternal blood flow and reduced protein binding increase both placental tissue uptake and transplacental transfer of propofol.[81] Propofol is highly protein bound to albumin. Thus, altered albumin concentrations in mother or fetus will affect transplacental transfer and the total, but not free, concentration in umbilical vein.[87] Propofol causes calcium channel-dependent vasodilation of human placental vessels *in vitro.*[88]

Ketamine

Ketamine, a phencyclidine derivative, rapidly crosses the placenta. Ketamine 2 mg/kg reached a mean F/M ratio of 1.26 in as little as 97 seconds when administered to the mother for vaginal delivery.[89] In a sheep study, fetal concentration was 25% less than maternal concentration at 10 minutes.[90]

Etomidate

Etomidate, a carboxylated imidazole, has long been used for the induction of general anesthesia in obstetric patients. A dose of 0.3 to 0.4 mg/kg administered for cesarean delivery resulted in an F/M ratio of approximately 0.5,[91] which is similar to the ratio found in sheep.[92]

Barbiturates

Previously a popular agent for the induction of general anesthesia in parturients, **thiopental** is the most extensively studied barbiturate. An extremely short-acting agent, it quickly appears in umbilical venous blood after maternal injection, with a mean F/M ratio between 0.4 and 1.1.[93,94] The high F/M ratios suggest that thiopental is freely diffusible; however, there is wide intersubject variability in umbilical cord blood concentration at delivery. Both maternal-fetal and fetal-maternal transfer of thiopental are strongly influenced by maternal and fetal protein concentrations.[59]

The rapid transfer of the oxybarbiturate **methohexital** into the fetal circulation, with simultaneous peak concentrations in maternal blood and fetal blood, has been demonstrated by *in vivo* studies.[95] Human *in vitro* placental perfusion studies in which the concentration of albumin was equal in the maternal and fetal perfusates confirm that methohexital rapidly crosses the placenta in both maternal-to-fetal and fetal-to-maternal directions, with transfer indices of less than 0.5 at 30 minutes.[60]

Dexmedetomidine

In humans, **dexmedetomidine**, an α_2-adrenergic agonist, has an F/M ratio of 0.12, with evidence of significant placental tissue binding due to high lipophilicity.[96] At 10 minutes, fetal concentration of medetomidine was about 28% less than maternal concentration in the sheep model.[90]

Benzodiazepines

Highly un-ionized, lipophilic, and 95% protein-bound **diazepam** is associated with an F/M ratio of 1 within

minutes of maternal administration and a ratio of 2 at 60 minutes after maternal administration.[97] Less lipophilic, **lorazepam** requires almost 3 hours after administration for the F/M ratio to reach unity.[98] **Midazolam** is more polar, with an F/M ratio of 0.76 at 20 minutes after administration. The F/M ratio of midazolam, unlike that of other benzodiazepines, decreases rapidly; by 200 minutes it is only 0.3.[99]

Opioids

Meperidine has been associated with neonatal central nervous system and respiratory depression. Intravenous administration results in rapid transfer across the human placenta within 90 seconds after maternal administration.[100] F/M ratios for meperidine may exceed 1.0 after 2 to 3 hours; maternal levels fall more rapidly than fetal levels because of the mother's greater capacity for metabolism of the drug.[101] This same time interval is associated with the greatest likelihood of neonatal depression, in part because of the active drug metabolite normeperidine. Human placental perfusion studies *in vitro* have demonstrated rapid placental transfer in both maternal-to-fetal and fetal-to-maternal directions with equal clearance profiles, minimal placental tissue binding, and no placental drug metabolism.[102] As maternal levels fall, the meperidine and normeperidine will transfer from the fetus back to the mother, correlating with the clinically observed decrease in neonatal sedation 4 hours after maternal administration.

Morphine also rapidly crosses the placenta. One study demonstrated a mean F/M ratio of 0.61, a mean umbilical venous blood concentration of 25 ng/mL, and a significant reduction in the biophysical profile score (primarily as a result of decreased fetal breathing movements and fewer fetal heart rate accelerations) within 20 to 30 minutes of maternal administration.[103] Intrathecal administration of morphine results in a high F/M ratio (0.92), although the absolute fetal concentrations are less than those associated with fetal and neonatal side effects.[104] Human placental perfusion studies *in vitro* have demonstrated that morphine, which is a hydrophilic compound, exhibits membrane-limited transfer with a low placental tissue content and a fast washout.[105] Concurrent naloxone administration does not affect the placental transfer of morphine.[106]

Fentanyl and its analogues are administered via the epidural, intrathecal, and intravenous routes. Fentanyl has a high lipophilicity and albumin binding (74%).[107] Maternal epidural administration results in an F/M ratio between 0.37 and 0.57.[108] During early pregnancy, fentanyl is rapidly transferred and may be detected not only in the placenta but also in the fetal brain.[109] Perfusion of the human placenta *in vitro* results in rapid transfer in both maternal-to-fetal and fetal-to-maternal directions, with the placenta acting as a moderate drug depot.[110,111]

Despite a relatively low F/M ratio (0.30),[112] maternal administration of **alfentanil** has been associated with a reduction of 1-minute Apgar scores when administered to the mother immediately before the induction of anesthesia.[113] Perfusion of the human placenta *in vitro* shows rapid and symmetric maternal-fetal and fetal-maternal transfers of alfentanil, with low placental drug uptake and rapid washout.[64]

Maternal administration of **sufentanil** results in a high F/M ratio, 0.81. Compared with fentanyl, sufentanil has higher lipid solubility and more rapid uptake by the central nervous system, resulting in less systemic absorption from the epidural space; lower maternal and umbilical vein concentrations reduce fetal exposure and the associated potential risk for neonatal respiratory depression.[108] Human placental perfusion studies *in vitro* have confirmed the rapid transplacental transfer of sufentanil, which is influenced by differences in maternal and fetal plasma protein binding and fetal pH. High placental tissue uptake suggests that the placenta serves as a drug depot.[65,66]

Remifentanil undergoes rapid placental transfer. During cesarean delivery, average F/M ratios were 0.88 when remifentanil was administered by intravenous infusion (0.1 μg/kg/min) during epidural anesthesia[114] and 0.73 when it was given as a single bolus (1 μg/kg) at induction of general anesthesia.[115] Excessive maternal sedation without adverse neonatal effects has been reported with the use of remifentanil during labor; presumably, the rapid metabolism of remifentanil by nonspecific esterases (context-sensitive half-time of 3 minutes) results in minimal fetal exposure.[116] When remifentanil was used for patient-controlled analgesia during labor, bolus doses of 0.5 μg/kg resulted in an F/M ratio of approximately 0.5 and a 20% incidence of fetal heart rate changes.[117] With continuous infusion of 0.33 μg/kg/min, the F/M ratio in plasma rapidly reached 0.1 to 0.3 in sheep.[116]

The systemic administration of an opioid agonist/antagonist for labor analgesia has been associated with few maternal, fetal, and neonatal side effects. Both **butorphanol** and **nalbuphine** rapidly cross the placenta, with mean F/M ratios of 0.84 and 0.74 to 0.97, respectively.[118,119] In one study, maternal administration of nalbuphine resulted in "flattening" of the fetal heart rate tracing in 54% of cases.[119]

Local Anesthetics

Local anesthetic agents readily cross the placenta (see Chapter 13). The enantiomers of bupivacaine cross the placenta at the same rate as racemic bupivacaine.[120]

Muscle Relaxants

As fully ionized, quaternary ammonium salts, muscle relaxants do not readily cross the placenta; however, single doses of muscle relaxants can result in detectable fetal blood concentrations. Maternal administration of muscle relaxants for the induction of general anesthesia for cesarean delivery rarely affects neonatal muscle tone at delivery.

After a standard induction dose, **succinylcholine** is not detectable in umbilical venous blood at delivery; maternal doses larger than 300 mg are required before the drug can be detected.[121] Neonatal neuromuscular blockade can occur when high doses are given repeatedly

or when both the parturient and fetus are homozygous for atypical pseudocholinesterase deficiency.[122]

The administration of nondepolarizing muscle relaxants results in low F/M ratios: 0.19 to 0.26 for **pancuronium,**[123-125] 0.06 to 0.11 for **vecuronium,**[125,126] 0.16 for **rocuronium,**[127] and 0.07 for **atracurium.**[128] The F/M ratio may be the result of expedient fetal/neonatal blood sampling; in a study in rats, the F/M ratio of vecuronium nearly doubled as the induction-to-delivery interval increased from 180 to 420 seconds.[126] No published study has investigated the placental transfer of the atracurium isomer **cisatracurium.** However, laudanosine, a metabolite of atracurium and cisatracurium, has an F/M ratio of 0.14.[129]

Although nondepolarizing muscle relaxant transfer rates are low, the fetal blood concentrations increase over time.[126] Fetal blood concentrations of nondepolarizing muscle relaxants can be minimized by giving succinylcholine to facilitate intubation, followed by a nondepolarizing muscle relaxant to maintain paralysis.[124]

Anticholinergic Agents

The placental transfer rate of anticholinergic agents directly correlates with their ability to cross the blood-brain barrier. **Atropine** is detected in the umbilical circulation within 1 to 2 minutes of maternal administration, and an F/M ratio of 0.93 is attained at 5 minutes.[130] **Scopolamine** also crosses the placenta easily; intramuscular administration results in an F/M ratio of 1.0 within 55 minutes.[131] By contrast, **glycopyrrolate** is poorly transferred across the placenta, with maternal intramuscular administration resulting in a mean F/M ratio of only 0.22.[132] Maternal intravenous administration of glycopyrrolate does not result in a detectable fetal hemodynamic response, whereas atropine and scopolamine may directly increase fetal heart rate.

Anticholinesterase Agents

Neostigmine, **pyridostigmine**, and **edrophonium** are quaternary ammonium compounds that are ionized at physiologic pH and consequently undergo limited transplacental transfer.[133] For example, maternal administration of neostigmine does not reverse atropine-induced fetal tachycardia. However, small amounts of these agents do cross the placenta, and fetal bradycardia after maternal administration of neostigmine and glycopyrrolate has been reported.[134] Because neostigmine may cross the placenta to a greater extent than glycopyrrolate, the combination of neostigmine and atropine should be considered for the reversal of nondepolarizing muscle relaxants in pregnant patients.[134] **Physostigmine** crossed the placenta in 9 minutes and reversed the fetal heart rate effect of scopolamine.[135]

Antihypertensive Agents

Beta-adrenergic receptor antagonists have been commonly used as antihypertensive agents in pregnancy, despite early investigations noting an association with fetal growth restriction and neonatal bradycardia, hypoglycemia, and respiratory depression.[136] Although a single dose of **propranolol** administered 3 hours before cesarean delivery has been shown to lead to an F/M ratio of 0.26,[137] long-term administration during pregnancy results in F/M ratios greater than 1.0.[138] Maternal administration of **atenolol** and **metoprolol** leads to mean F/M ratios of 0.94 and 1.0, respectively.[139,140]

Labetalol, the most commonly used antihypertensive during pregnancy, has a low F/M ratio of 0.38 with long-term oral administration, despite reports of mild neonatal bradycardia.[141,142] National data from Denmark showed that use of beta-adrenergic receptor antagonists during pregnancy, including labetalol, approximately doubles the risk for small-for-gestational-age preterm births and for perinatal mortality, even after adjusting for preeclampsia.[143] Preterm hypertensive women receiving labetalol had no acute change in umbilical artery or fetal middle cerebral resistance indices of flow.[144]

The ultra-short-acting beta-adrenergic receptor antagonist **esmolol** has been used to attenuate the hypertensive response to laryngoscopy and intubation. A mean F/M ratio of 0.2 after maternal administration of esmolol was observed in gravid ewes.[145] However, a few cases of significant and prolonged fetal bradycardia requiring the performance of emergency cesarean delivery have been reported.[146]

Clonidine and **methyldopa** act through the central stimulation of α_2-adrenergic receptors; studies have reported mean F/M ratios of 0.89[147] and 1.17,[148] respectively, for these agents. In concentrations likely to be present in maternal blood during clinical use, **magnesium** and **nifedipine**, but not clonidine, produce fetal vasodilation in human placental perfusion studies *in vitro*.[149] **Phenoxybenzamine**, an alpha-adrenergic receptor antagonist, is commonly used to treat hypertension in patients with pheochromocytoma and has an F/M ratio of 1.6 with long-term maternal administration.[150]

Direct-acting vasodilators are used for short-term management of severe hypertension in pregnant women. Administration of **hydralazine**, which is often given to lower blood pressure in preeclampsia, results in an F/M ratio of 1.0[151] and causes fetal vasodilation in *in vitro* studies.[152] Hydralazine increased the umbilical artery resistance index, indicating vasodilation, in hypertensive women.[144]

Sodium nitroprusside is lipid soluble, rapidly crosses the placenta, and can produce cyanide as a byproduct.[153] Sodium thiosulfate, the agent used to treat cyanide toxicity, does not cross the placenta in gravid ewes; it can be used to treat fetal cyanide toxicity by lowering maternal cyanide levels, thereby enhancing fetal-maternal transfer of cyanide.[154]

Glyceryl trinitrate (nitroglycerin) crosses the placenta to a limited extent, with an F/M ratio of 0.18, and results in minimal changes in fetal umbilical blood flow, blood pressure, heart rate, and blood gas measurements in gravid ewes.[155] However, dinitrate metabolites found in both maternal and fetal venous blood indicate the capacity for placental biotransformation.[156] Indeed, placental tissue production of nitric oxide enhances the uterine relaxation caused by nitroglycerin *in vivo*.[157] In one *in vitro* study, in which prostaglandin $F_{2\alpha}$ was used to

create fetal vasoconstriction, the following order of nitrovasodilator compound potency was observed: glyceryl trinitrate ≥ sodium nitroprusside ≥ sodium nitrite ($NaNO_2$) ≥ S-nitroso-*N*-acetylpenicillamine (SNAP) = S-nitroso-*N*-glutathione (SNG).[158] SNG and $NaNO_2$ were significantly more potent under conditions of low oxygen tension. The antioxidants cysteine, glutathione, and superoxide dismutase significantly enhanced the vasodilatory effects of $NaNO_2$ only.[158]

Placental transfer of angiotensin-converting enzyme inhibitors may adversely affect fetal renal function. **Enalaprilat** rapidly crosses the placenta, and its maternal administration in high doses resulted in a 20% reduction in fetal arterial pressure in rhesus monkeys.[159]

Vasopressor Agents

Vasopressor agents are often administered to prevent or treat hypotension during the administration of neuraxial anesthesia in obstetric patients. **Ephedrine** readily crosses the placenta and results in an F/M ratio of approximately 0.7.[160] In an *in vitro* human perfusion model that required supraphysiologic doses to obtain any effect, **phenylephrine** increased placental arterial pressure, but less so than ephedrine, whereas **epinephrine**, **norepinephrine**, and **methoxamine** had no effect.[161]

Ephedrine possesses 10 times greater lipid solubility than phenylephrine, with F/M ratios of 1.1 versus 0.17, respectively, in humans.[162] Indeed, when either ephedrine or phenylephrine was given during spinal anesthesia for cesarean delivery, the ephedrine group had lower pH and base excess, higher Pco_2, and higher glucose, lactate, epinephrine, and norepinephrine concentrations in umbilical arterial blood than the phenylephrine group.[162] These differences may be due to the beta-adrenergic agonist effects of ephedrine in the fetus.[162,163]

Cocaine, a common drug of abuse during pregnancy (see Chapter 54), has potent vasoconstrictor activity. Human placenta perfusion studies *in vitro* have demonstrated the rapid transfer of cocaine in both maternal-to-fetal and fetal-to-maternal directions; transfer is constant over a wide range of concentrations.[164] The active cocaine metabolites norcocaine and cocaethylene, but not the inactive metabolite benzoylecgonine, are also rapidly transferred across the placenta.[165] Chronic maternal exposure to cocaine increases fetal concentrations; however, they remain lower than maternal peak levels.[166]

In a study using the *in vitro* dually perfused human placental lobule, fetal-side administration of vasoconstrictors was found to raise fetal placental perfusion pressure, thus causing a shift of fluid from the fetus to the maternal circulation.[167]

Anticoagulants

Anticoagulation therapy is often necessary during pregnancy. Maternal administration of **warfarin** in the first trimester results in placental transfer to the fetus, causing a higher rate of fetal loss and congenital anomalies.[168] After the first trimester, warfarin may be used in the setting of stroke or mechanical heart valves.[169] In contrast, **heparin** does not appear to cross the placenta, as measured by neonatal coagulation studies and the measurement of radiolabeled heparin in fetal lambs.[170] **Low-molecular-weight heparin** appears to have limited placental transfer; maternal administration of enoxaparin does not alter fetal anti-IIa or anti-Xa activity.[171] Even when **enoxaparin** or **fondaparinux** (a pentasaccharide that selectively inhibits factor Xa) was given at doses used for acute thromboembolic therapy, human placental perfusion studies *in vitro* demonstrated no placental transfer.[172,173] Several case reports discussed use of direct thrombin inhibitors as early as 9 weeks' gestation with successful delivery of normal neonates.[174,175] Antiplatelet therapy (e.g., **aspirin**, **clopidogrel**) has been used successfully in the first trimester in dual therapy for coronary artery disease in the setting of drug-eluting stents.[176] **Abciximab,** a glycoprotein IIb/IIIa platelet inhibitor, did not transfer across the *in vitro* perfused human placenta but did bind to the trophoblastic layer of the placenta.[177]

Drug Delivery Systems

New drug delivery systems may influence drug transfer and distribution across the human placenta. Liposome encapsulation, depending on the type and ionic charge, can affect placental transfer; anionic and neutral liposomes increase placental transfer, whereas cationic liposomes decrease placental transfer and placental tissue uptake.[178] Liposome encapsulation of valproic acid significantly reduces drug transfer and placental uptake.[179]

Disease States

Disease states, such as diabetes, may affect the placental transfer of drugs. **Glyburide**, a second-generation sulfonylurea, is partially dependent on a P-glycoprotein active transport mechanism and demonstrates a lower F/M ratio (0.3) than the first-generation agents, even in the presence of a P-glycoprotein inhibitor.[180] A high level of protein binding (99.8%) may also contribute to the low transplacental transfer of glyburide; when protein levels are reduced *in vitro*, higher transfer rates are observed.[181,182] Some investigators have speculated that the thickened placenta found in diabetic patients is a cause of low transfer rates; however, no difference in maternal-fetal transfer of **metformin** has been observed between placentas from parturients with gestational diabetes and those from healthy parturients.[183]

Gestational age may alter placental transfer, although the direction of the alteration requires further evaluation. Although traditional belief holds that placentas from younger fetuses are more likely to transfer substances, one study has demonstrated that **methadone** transfer is 30% lower in human preterm placentas than in term placentas.[184] **Dexamethasone** and **betamethasone**, corticosteroids that are often given to accelerate fetal lung maturity, increase *ABCB1* gene expression fourfold. ABCB1 is an efflux transporter protein; hence increased gene expression may increase fetal-maternal transfer of substrate molecules.[185]

Oxidative stress increases in preeclampsia, fetal growth restriction, and diabetes. New studies have shown that

nitrative stress, the covalent modification of proteins and DNA by peroxynitrite (formed by nitric oxide reacting with superoxide), also occurs.[186] Peroxynitrite reacts with tyrosine to form nitro-tyrosine, a negatively charged group, which may mimic phosphorylation. Nitration may result in loss or gain of protein function.

Vitamin D helps modulate cytokines, inflammation, and insulin sensitivity, and a deficiency leads to increased risk for gestational diabetes and preeclampsia.[187]

PLACENTAL PATHOLOGY

There has been a growing interest in the clinicopathologic correlation between placental abnormalities and adverse obstetric outcomes. In some cases, a skilled and systematic examination of the umbilical cord, fetal membranes, and placenta may provide insight into antepartum pathophysiology; in most of these cases, examination of the placenta confirms the clinical diagnosis (e.g., chorioamnionitis). When adverse outcomes occur, often the "disorder that was not suspected clinically may be revealed by placental pathology."[188] Drugs may produce placental abnormalities (e.g., cocaine causes chorionic villus hemorrhage and villous edema).[189] The significance of many findings (e.g., villous edema, hemorrhagic endovasculitis, chronic villitis), however, is unclear.

The following factors limit the assessment of placental pathology: (1) "the paucity of properly designed studies of adequate size with appropriate outcome parameters,"[188] which impairs the correlation of placental abnormalities with adverse clinical outcomes; (2) the limited number of pathologists with expertise in the recognition and interpretation of subtle abnormalities of the placenta; and (3) the cost associated with a routine assessment of placental pathology.

KEY POINTS

- The placenta is a dynamic organ with a complex structure. It brings two circulations close together for the exchange of blood gases, nutrients, and other substances (e.g., drugs).
- During pregnancy, anatomic adaptations result in substantial (near-maximal) vasodilation of the uterine spiral arteries; this leads to a low-resistance pathway for the delivery of blood to the placenta. Therefore, adequate uteroplacental blood flow depends on the maintenance of a normal maternal perfusion pressure.
- The marked diversity in placental structure and function among various animal species limits clinicians' ability to extrapolate the results of animal investigations to human pregnancy and clinical practice.
- Placental transfer involves all of the physiologic transport mechanisms that exist in other organ systems.
- Physical factors (e.g., molecular weight, lipid solubility, level of ionization) affect the placental transfer of drugs and other substances. In addition, other factors affect maternal-fetal exchange, including changes in maternal and fetal blood flow, placental binding, placental metabolism, diffusion capacity, and extent of maternal and fetal plasma protein binding.
- Lipophilicity, which enhances the central nervous system uptake of general anesthetic agents, also heightens the transfer of these drugs across the placenta. However, the placenta itself may take up highly lipophilic drugs, thereby creating a placental drug depot that limits the initial transfer of drug.
- Fetal acidemia can result in the "ion trapping" of both local anesthetics and opioids.
- Vasoactive drugs cross the placenta and may affect the fetal circulation and may have effects on fetal metabolism.

CHAPTER 5

Fetal Physiology

Mieke Soens, MD • Lawrence C. Tsen, MD

CHAPTER OUTLINE

Fetal life *in utero* differs significantly from postnatal life. The fetus relies completely on the mother and the placenta for basic metabolic needs such as nutrient delivery, gas exchange, acid-base balance, and electrolyte homeostasis. During gestation, the fetus gradually assumes the responsibility for many of the vital physiologic functions that must be assumed after the abrupt transition to physiologic independence at birth. Knowledge of fetal physiology, and the timing associated with these developmental changes, is necessary for the optimal provision of analgesia and anesthesia during pregnancy and childbirth.

FETAL ENVIRONMENT

Amniotic Fluid

The fetus is surrounded by amniotic fluid, a complex fluid that changes as the pregnancy progresses. Amniotic fluid serves a number of vital roles, including the facilitation of fetal growth, the provision of a microgravity environment that cushions the fetus, and the generation of a defense mechanism against invading microbes.[1,2] The formation and maintenance of amniotic fluid is an intricate process that depends on fetal maturation and maternal hydration, hormonal status, and uteroplacental perfusion.

Amniotic fluid during early embryogenesis is principally derived from maternal plasma by the passage of water and solutes through fetal membranous and placental layers. Between 10 and 20 weeks' gestation, the volume of amniotic fluid increases in a predictable and linear manner from approximately 25 mL to 400 mL. During this period, the composition of amniotic fluid is similar to fetal extracellular fluid, owing to the absence of keratin in the fetal skin. After this period, the volume of amniotic fluid is a function of production, from fetal urine (600 to 1200 mL/day near term) and respiratory tract secretions (60 to 100 mL/kg fetal body weight/day), and removal through fetal swallowing (200 to 250 mL/kg fetal body weight/day).[3] Amniotic fluid volume is also influenced by intramembranous (between amniotic fluid and fetal blood within the placenta) and transmembranous (between amniotic fluid and maternal blood within the uterus) pathways in both physiologic and pathophysiologic states.[4] Finally, the status of maternal hydration and the amount of decidual prolactin may alter the transfer of amniotic fluid through fetal and maternal tissues.

The *composition* of amniotic fluid undergoes more marked variation than its volume.[5,6] Keratinization of the fetal skin is complete by 25 weeks' gestation and decreases the permeability of fetal tissues to water and solutes. The impact of this process, coupled with the ability of the fetal kidneys to produce urine, results in increased amniotic fluid concentrations of urea and creatinine, decreased concentrations of sodium and chloride, and reduced osmolality. A variety of carbohydrates, proteins, lipids, electrolytes, enzymes, and hormones, which vary in concentration depending on the gestational age, are also present; some of these elements, particularly the amino acids taurine, glutamine, and arginine, serve a nutritive function for mitotic cells involved in trophoblastic growth and placental angiogenesis.[1] An abundance of growth factors are found in amniotic fluid, including epidermal growth factor, transforming growth factor-alpha, transforming growth factor-beta 1, insulin-like growth

factor-1, erythropoietin, and granulocyte colony-stimulating factor; many of these growth factors play an important role in fetal intestinal development.[1,7]

Antimicrobial defenses within the amniotic fluid are primarily composed of humoral mediators such as alpha-defensins, which are released from neutrophils, especially in the setting of preterm labor and/or chorioamnionitis. Other humoral mediators include lactoferrin, calprotectin, leukocyte protease inhibitor, and cathelicidin, which have significant activity against bacteria, viruses, and fungi.[8-10] Cellular mediators of the immune response are poorly characterized in amniotic fluid, and it remains unclear if the macrophages that are present serve a scavenging or an antimicrobial role. Neutrophils are usually absent from the amniotic fluid of a healthy fetus, and their presence typically signifies an inflammatory or infectious process.[1]

Biochemical and cellular analyses of amniotic fluid provide valuable information on chromosomal abnormalities, neural tube defects, prenatal infections, and most inborn errors of metabolism.[11,12] Several amniotic fluid–based indices, including the lecithin-sphingomyelin ratio, the phosphatidylglycerol level, and the lamellar body count, are commonly used to assess fetal lung maturity.[13,14] Bilirubin levels can be determined by measuring the optical density of amniotic fluid, which assists in the monitoring of fetal hemolysis. Estimation of the amniotic fluid levels of S100-β (a protein released from injured astrocytes) and cell-free fetal nucleic acids may serve as early screening tests for perinatal neurologic damage and fetal development, respectively.[15,16] Finally, amniotic fluid is a valuable reservoir for cell types of multiple lineages at different maturational ages; approximately 1% of these cells are pluripotent, thereby representing a novel source of stem cells.[17,18]

Oxygen Supply and Transport

The fetus has almost no oxygen reserve and thus depends on maternal sources of oxygen delivery. Oxygen is an essential substrate for cell survival, because it is the final electron acceptor in the electron transport chain. When oxygen is scarce, the electron transport chain is compromised, resulting in decreased oxidative phosphorylation and adenosine triphosphate (ATP) production.[19] Hypoxia ensues when the demand for oxygen exceeds the available supply, and it occurs more frequently in the presence of low oxygen tensions. In adult tissues, hypoxia occurs at oxygen tensions less than 20 mm Hg (normal, 40 mm Hg). By contrast, in fetal tissues, hypoxia occurs at oxygen tensions less than 17 mm Hg (normal, 20 to 25 mm Hg).[20,21] This implies that fetal development occurs in an environment that exhibits a smaller margin of safety before reaching a state of oxygen insufficiency and highlights the importance of ensuring fetal oxygen delivery through the maintenance of adequate uteroplacental perfusion and fetal cardiac output. Ultimately, oxygenation of fetal tissues depends principally on the partial pressure of oxygen gradient between maternal and fetal blood as well as on the difference in the types of hemoglobin that exist in maternal and fetal blood.

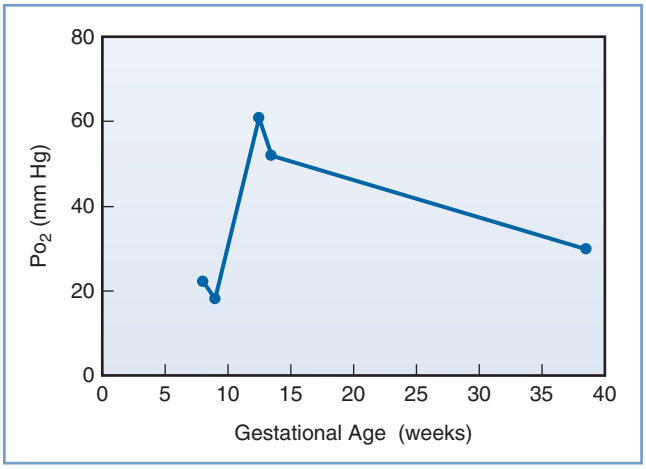

FIGURE 5-1 ■ **The mean oxygen partial pressure (Po_2) throughout gestation in the human intervillous space.** (Data from Jauniaux E, Kiserud T, Ozturk O, et al. Amniotic gas values and acid-base status during acute maternal hyperoxemia and hypoxemia in the early fetal sheep. Am J Obstet Gynecol 2000; 182:661-5; Rodesch F, Simon P, Donner C, Jauniaux E. Shunting the intervillous space: new concepts in human uteroplacental vascularization. Am J Obstet Gynecol 2005; 192:323-32.)

Placental oxygen concentrations change with gestation. In early pregnancy, the placental intervillous space is free of maternal blood cells, thereby requiring the embryo to rely on endometrial secretions and maternal plasma for its energy requirements.[22,23] The first trimester placenta has (1) an oxygen partial pressure (Po_2) of approximately 20 mm Hg; (2) only a few capillaries, which are located mainly in the center of the mesenchymal core; and (3) a trophoblastic layer that is twice the thickness of that in the second trimester.[24] Moreover, the fetal red blood cells are nucleated and the exocoelomic cavity does not contain an oxygen transport system, but rather it contains antioxidant molecules. These anatomic features, which limit the transfer of oxygen and the creation of free radicals, protect the highly sensitive embryo from the effects of oxidative stress.[25] At the end of the first trimester, an exponential increase in fetal growth creates significant demands for oxygen and nutrients (Figure 5-1). In response, cytotrophoblastic cells interact with the smooth muscle of maternal spiral arteries, resulting in vessel dilation (Figure 5-2). This allows oxygen-rich maternal blood to flow to the placenta.[26]

The placenta acts as both a conduit and consumer of oxygen. The placenta is metabolically active and performs important roles in carbohydrate and amino acid metabolism, protein synthesis, and substrate transport. Almost 40% of the oxygen delivered to the pregnant uterus is needed to support the metabolic processes of the placenta.[27] During periods of hypoxia, the placenta appears to alter its metabolism to diminish its consumption of oxygen, most likely by increasing glycolysis.[28,29] This process can maintain fetal oxygen supply but, if ongoing, may result in fetal growth restriction (also known as intrauterine growth restriction). When the oxygen supply is compromised, the fetus shunts blood flow from peripheral tissues to vital organs (see later discussion), converts

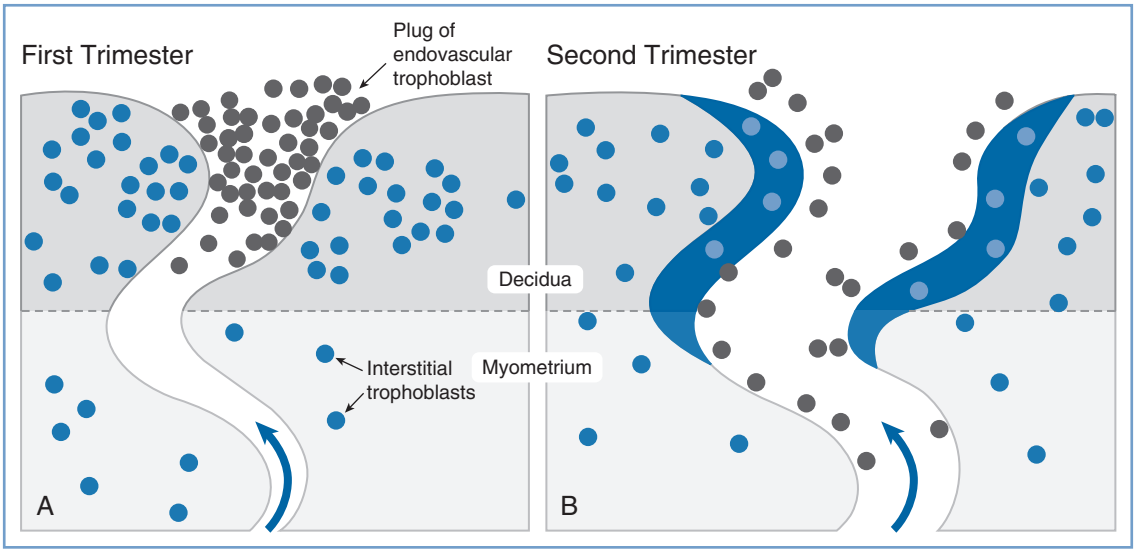

FIGURE 5-2 ■ Invasion and remodeling of the spiral arteries by endovascular and interstitial extravillous trophoblasts. **A,** In the first trimester, the terminal portion of the spiral artery is blocked by a plug of endovascular trophoblast. Early placental and embryonic development occurs in a state of low oxygen tension, and nutrition at this early stage is derived from secretions from maternal endometrial glands. **B,** After 10 to 12 weeks' gestation, the endovascular trophoblast plug dissolves and the endovascular trophoblast migrates into the myometrium, replacing endothelial cells, which undergo apoptosis. Maternal blood is now able to enter the intervillous space, the oxygen tension increases to 60 mm Hg, and nutrition changes from histotrophic to hemotrophic. (Modified from Pijnenborg R, Vercruysse L, Hanssens M. The uterine spiral arteries in human pregnancy: facts and controversies. Placenta 2006; 27:939-58.)

to greater use of anaerobic pathways, and undergoes an induction of gene expression that enables improved survival in a low-oxygen environment.[19] The presence of fetal hemoglobin (hemoglobin F), with its greater affinity for oxygen than adult hemoglobin (see later discussion), and a hemoglobin concentration higher than that of adults (approximately 18 g/dL) result in a fetal arterial blood oxygen content that is only marginally lower than that in the adult, despite a lower oxygen tension.[30]

Glucose and Lactate Metabolism

Under normal conditions, gluconeogenesis does not occur to any significant extent in mammalian fetuses; the only source of glucose is that which is transferred across the placenta.[31] Fetal glucose concentrations are linearly related to maternal concentrations over a range of 3 to 5 mmol/L (54 to 90 mg/dL; Figure 5-3); studies in isolated placentas suggest that this relationship continues up to a glucose concentration of 20 mmol/L (360 mg/dL).[32] The placenta uses the majority of glucose delivered to the uterus for oxidation, glycogen storage, and conversion to lactate, with the remainder being transferred to the umbilical venous blood by facilitated, carrier-mediated diffusion. The amount of glucose supplied to the fetus appears more than adequate during normal conditions; ovine uterine blood flow must be reduced by greater than 50% before a decrease in fetal glucose uptake or fetal arterial glucose concentration is observed.[33,34]

The umbilical cord blood glucose uptake is approximately 5 mg/kg/min at normal maternal arterial plasma glucose concentrations.[35] Because the umbilical glucose/oxygen quotient varies from approximately 0.5 in sheep[36] to 0.8 in human fetuses during labor,[37] it is assumed that

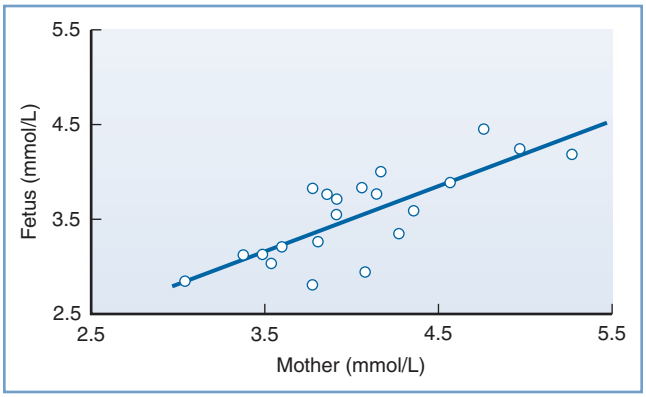

FIGURE 5-3 ■ The linear relationship between maternal and fetal blood glucose concentrations during the third trimester. Fetal blood was obtained by percutaneous umbilical cord blood sampling. (From Kalhan SC. Metabolism of glucose and methods of investigation in the fetus and newborn. In Polin RA, Fox WW, editors. Fetal and Neonatal Physiology. Vol I. Philadelphia, WB Saunders, 1992:477-88.)

substrates other than glucose are used to support fetal oxidative metabolism; it is estimated that lactate and amino acids each provides approximately 25% of the total fetal energy requirements.[38,39]

Lactate is produced even in well-oxygenated fetal lambs, with total lactate production being approximately 4 mg/kg/min.[40] Although the exact origin of fetal lactate is unclear, skeletal muscles and bones have been identified as sources of lactate production under resting conditions. Lactate production increases during episodes of acute hypoxemia, although this response may be blunted in fetuses previously exposed to oxidative stress.[41] Lactate

consumption occurs in the fetal myocardium and liver.[42] Short-term exogenous lactate infusion in fetal lambs (sufficient to lower the pH to 7.20) results in transient fetal bradycardia and increased fetal breathing movements but no other adverse effects.[43]

Amino Acid and Lipid Metabolism

The fetus uses amino acids for protein synthesis, growth, and oxidation. Most maternal-to-fetal amino acid transfer occurs against a concentration gradient and involves energy-dependent transfer mechanisms. Under conditions in which fetal aerobic metabolism is decreased, amino acid uptake by the placenta and fetus may be reduced because it involves an expenditure of energy. Hypoxia results in a large reduction in nitrogen uptake in fetal lambs.[44] During maternal fasting, fetal amino acid uptake does not change; however, enhanced fetal proteolysis may occur, which subsequently results in amino acid oxidation or gluconeogenesis.

Lipid products are transferred from the mother to the fetus. The fetus requires free fatty acids for growth, brain development, and the deposition of body fat for postnatal life. Fatty acids are transferred across the placenta by simple diffusion. Ketones are also transferred by simple diffusion; in humans, the maternal/fetal ketone ratio is approximately 2.0.[45] The fetus can use ketones as lipogenic substrates or as energy substrates in the brain, kidney, heart, liver, and placenta.[46] Beta-hydroxybutyrate (fatty acid) metabolism can occur in the placenta, brain, and liver during episodes of fetal hypoglycemia that result from maternal fasting.[46] Cholesterol synthesis or free cholesterol diffusion does not appear to occur in the placenta.[47] However, there is a significant correlation between maternal and fetal concentrations of lipoprotein(a), implying that diffusion of lipoprotein(a) may occur.[47]

Thermoregulation

Intrauterine fetal temperature largely depends on maternal temperature. However, owing to the high metabolic rate in the fetus, the net flow of heat is from the fetus to the mother. When compared with the mother during the third trimester, the fetus produces approximately twice as much heat (on a weight-adjusted basis) and maintains a temperature 0.5° C higher.[48,49] This maternal-fetal difference in temperature remains relatively constant and is referred to as the "heat clamp."[50]

The placental circulation is responsible for approximately 85% of the heat exchange between the mother and fetus. The remaining 15% is dissipated through the fetal skin and transferred through the amniotic fluid and the uterine wall to the maternal abdomen.[51] As a consequence, fetal temperature may be rapidly affected by changes in umbilical blood flow; fetal temperatures rise quickly on occlusion of umbilical blood flow in both baboons and sheep.[52,53] In humans, fetal temperatures increase during uterine contractions, which may be a result of intermittent obstruction of umbilical cord blood flow.[54] Whether this rise in fetal temperature contributes to acute hypoxic-ischemic brain damage in the setting of umbilical cord prolapse is currently unknown. However, relatively small increases in temperature increase the sensitivity of the fetal brain to hypoxic injury (see Chapter 10).[55]

Although the fetus generates heat through high metabolic activity, the ability of the fetus to generate heat through thermogenic mechanisms is not developed until the end of gestation and is largely inactive *in utero*. Newborns are at high risk for rapid heat loss due to amniotic fluid evaporation and a sudden decrease in ambient temperature.[49] They are not capable of significant heat production through shivering owing to their small muscle mass. As a consequence, nonshivering thermogenesis plays an important role in maintaining neonatal temperature. Nonshivering thermogenesis occurs in brown adipose tissue, which is unique from other adipocytes owing to the significant presence of mitochondria, fat vacuoles, sympathetic innervation, and blood vessels. In the mitochondria of brown adipose tissue, ATP production is uncoupled from the oxidative process, resulting in an increase in heat production and oxygen consumption.[56] Nonshivering thermogenesis is inhibited *in utero*, most likely owing to the presence of adenosine and prostaglandin E_2, which have strong antilipolytic actions on brown tissue.[57-59] Inadequate oxygen levels and low levels of intrauterine catecholamines and thyroid hormones may also inhibit nonshivering thermogenesis. The inhibition of nonshivering thermogenesis is believed to be beneficial to the health of the fetus, in that it allows for conservation of fetal oxygenation and accumulation of brown adipose tissue.[50]

FETAL CARDIOVASCULAR SYSTEM

The cardiovascular system is one of the first functional organ systems in the developing fetus. The morphologic development of the human heart, from its first appearance as a heart tube to its development as a four-chambered structure, occurs between 20 and 44 days' gestation. Even before the development of the four-chambered heart, the valveless heart tube generates unidirectional flow, typically around 21 days' gestation.

Circulatory Pattern

Fetal circulation differs significantly from the postnatal circulation. The fetal cardiovascular system is anatomically arranged in such a way as to allow blood to bypass the lungs and provide maximal perfusion of the placenta, where gas and nutrient exchange occur. The fetal systemic circulation receives cardiac output from both the left and the right ventricle, with the ventricles working in *parallel*. In contrast, during postnatal life, the left and right circulations are separated and the ventricles work in *series*.

Fetal blood flow is characterized by three anatomic communications between the left and right circulations: the **ductus venosus**, the **foramen ovale**, and the **ductus arteriosus** (Figure 5-4). Oxygenated blood travels from the placenta through the umbilical vein to the **ductus venosus**, which connects the umbilical vein with the inferior vena cava, thus bypassing the portal circulation and the liver. At mid gestation, approximately 30% of the

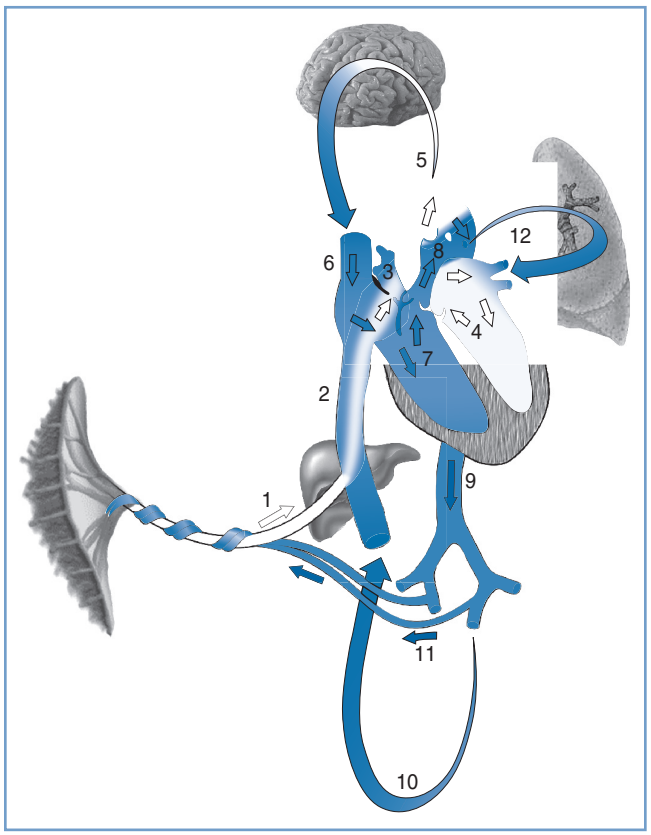

FIGURE 5-4 ■ Oxygenated blood leaves the placenta via the fetal umbilical vein (*1*), enters the liver where flow divides between the portal sinus and the ductus venosus, and then empties into the inferior vena cava (*2*). Inside the fetal heart, blood enters the right atrium, where most of the blood is directed through the foramen ovale (*3*) into the left atrium and ventricle (*4*), and then enters the aorta. Blood is then sent to the brain (*5*) and myocardium, ensuring that these cells receive the highest oxygen content available. Deoxygenated blood returning from the lower extremities and the superior vena cava (*6*) is preferentially directed into the right ventricle (*7*) and pulmonary trunk. The majority of blood passes through the ductus arteriosus (*8*) into the descending aorta (*9*), which in turn supplies the lower extremities (*10*) and the hypogastric arteries (*11*). Blood returns to the placenta via the umbilical arteries for gas and nutrient exchange. A small amount of blood from the pulmonary trunk travels through the pulmonary arteries (*12*) to perfuse the lungs. *Arrows* in this figure depict the direction and oxygen content [*white* (oxygenated), *blue* (deoxygenated)] of the blood in circulation. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

umbilical venous blood is shunted through the ductus venosus; from 30 to 40 weeks' gestation, this fraction decreases to approximately 20%, although a significant increase can occur in response to hypoxia (see later discussion).[60] Once in the right atrium, oxygenated blood preferentially flows through the **foramen ovale** to the left atrium and left ventricle, before entering the aorta and the systemic circulation. This mechanism ensures the delivery of well-oxygenated blood to the brain and the heart, which are the two organs with the highest oxygen requirements. The preferential shunting of ductus venosus blood through the foramen ovale into the left atrium is related to the umbilical venous pressure and the portocaval pressure gradient.

Deoxygenated blood from the head and upper extremities enters the right atrium through the superior vena cava and is preferentially directed into the right ventricle and the pulmonary artery. Because fetal pulmonary vascular resistance is higher than systemic vascular resistance, the majority of pulmonary artery blood flow crosses the **ductus arteriosus** into the descending aorta, which in turn supplies the lower extremities and hypogastric arteries. Deoxygenated blood returns to the placenta via the umbilical arteries for gas and nutrient exchange; only a small percentage travels through the lungs into the left atrium, the left ventricle, and the ascending aorta.

At birth, the fetus undergoes a significant and abrupt transition to a state of physiologic independence (see Chapter 9). Clamping of the umbilical cord results in a sudden increase in systemic vascular resistance, whereas expansion of the lungs and an increased alveolar oxygen tension result in decreased pulmonary vascular resistance. This allows for greater blood flow through the lungs, resulting in a decrease in right atrial pressure and an increase in left atrial pressure, ultimately leading to the functional closure of both the foramen ovale and the ductus arteriosus.

Blood Volume

Human fetal intravascular volume is approximately 110 mL/kg, which is higher than that in postnatal life. However, approximately 25% of this blood volume is contained within the placenta; the blood volume within the fetal body is estimated to be approximately 80 mL/kg.[61,62] Fetal intravascular volume is regulated through a complex interplay between the fetal heart, kidneys, and circulation and the placenta.[63] The fetus can adapt more quickly to changes in intravascular volume than the adult, owing to higher diffusion rates between fetal compartments.[64]

Transplacental transfer of water from mother to fetus depends on hydrostatic and osmotic pressures. The hydrostatic pressure is determined by the difference in pressures between the maternal intervillous space or capillaries and the fetal capillaries. The osmotic pressure is mainly determined by the presence of plasma proteins (i.e., colloid osmotic pressure). Transplacental water transfer is further regulated by angiotensin II. Adamson et al.[65,66] found that angiotensin II lowered the pressures in fetal placental exchange vessels, thereby promoting fluid transfer from the maternal to the fetal circulation. The production of angiotensin II is under control of the renin-angiotensin-aldosterone system in the fetal kidneys. A reduction in fetal arterial pressure results in an increase in fetal plasma renin activity, which results in subsequent increases in angiotensin I and II. The resulting expansion of intravascular volume augments fetal cardiac output and arterial pressure.

Cardiac Development

During gestation the fetal heart grows quickly and adapts to the continuously changing demands. The fetal myocardium grows primarily through cell division, whereas

after delivery, cardiac mass increases as a result of cell enlargement.[67] This growth correlates with a pre-birth transition from mononucleated cardiomyocytes, which contribute to heart growth by hyper*plasia*, to binucleated cardiomyocytes, which contribute to heart growth by hyper*trophy*.

The number of cardiac myofibrils and the transition in the type of cardiac troponins that are present during prenatal development can alter fetal heart contractility.[68] The change from fetal to adult troponin is associated with decreased sensitivity of the contractile apparatus to calcium. A heightened calcium sensitivity is important in the early development of the fetal heart, when the sarcoplasmic reticulum is immature.[69] With advancing gestational age, ejection fraction declines but cardiac output (per unit of fetal weight) does not change owing to increasing ventricular volume. The fetal heart rate decreases over the course of gestation from 140 to 150 beats per minute at 18 weeks' gestation to 120 to 140 beats per minute at term.[70,71]

Ventricular Responses to Changes in Preload and Afterload

It is unclear whether fetal and adult hearts possess similar responses to preload and afterload. The adult heart responds in accordance to the Frank-Starling curve, which indicates that ventricular distention lengthens the diastolic fibers and results in augmented contractility. A number of studies have indicated that the fetal heart has a limited capacity to increase its stroke volume in response to an increase in preload (e.g., intravenous fluid infusion).[72,73] By contrast, other studies have observed that the fetal heart can accommodate increases in preload and afterload in a manner consistent with the Frank-Starling curve.[74,75] These seemingly contradictory findings may be partially explained if the fetal heart functions *in vivo* near the peak of the Frank-Starling curve. However, the left ventricular stroke volume is known to double at birth, which would not be in agreement with this hypothesis. A more plausible explanation is that ventricular constraint, arising from tissues that surround the heart (chest wall, pericardium, and lungs), limits fetal ventricular preload and overall cardiac function *in utero*. Relief of this constraint at birth, as a result of lung aeration and clearance of liquid from the lungs, may then allow for an increase in left ventricular preload and subsequent stroke volume in the newborn.[76]

Studies investigating the effects of afterload on fetal ventricular function have observed a significant decrease in right ventricular stroke volume in response to increases in arterial pressure.[72] The same phenomenon occurs in the left ventricle, although to a lesser degree. In a study of fetal lambs, in which gradual constriction of the descending aorta was applied, stroke volume was maintained until high mean arterial pressures were achieved, after which decreases were observed. This decrease in stroke volume in the presence of high mean arterial pressure may represent the exhaustion of "preload reserve," which will typically allow the maintenance of stroke volume in the setting of increased afterload.[77]

Cardiac Output and Distribution

In postnatal life, the right and left ventricles operate in series and their output is approximately equal; as a consequence, cardiac output is defined through measurements of output from either ventricle. However, in the fetus, the systemic circulation receives blood from both the left and right ventricle in parallel (i.e., the sum of the right and left ventricular outputs, with the exception of a proportion of the right ventricular output that is delivered to the fetal lungs). At mid gestation, the combined ventricular output (CVO) is approximately 210 mL, and it increases to approximately 1900 mL at 38 weeks' gestation (500 mL/min/kg).[73,78,79] During fetal life, the right ventricular volume is greater than the left ventricular volume during both systole and diastole, but stroke volume does not differ significantly between the two ventricles.[70]

Fetal cardiac output is sensitive to changes in fetal heart rate. As heart rate increases, cardiac output increases. As fetal heart rate decreases, fetal stroke volume increases only slightly, in part because of low fetal myocardial compliance. Although fetal bradycardia results in an extended diastolic filling time, the stiff fetal cardiac ventricles have limited ability to distend. Therefore, fetal bradycardia is associated with a marked drop in fetal cardiac output.

The distribution of the CVO in near-term fetal lambs and resting adult humans is shown in Figure 5-5. The fetal lamb CVO is distributed to the placenta (41%), the bone and skeletal muscle (38%), the gastrointestinal system (6%), the heart (4%), the brain (3%), and the kidneys (2%). In both fetal and adult animals, approximately equal volumes of blood are delivered to

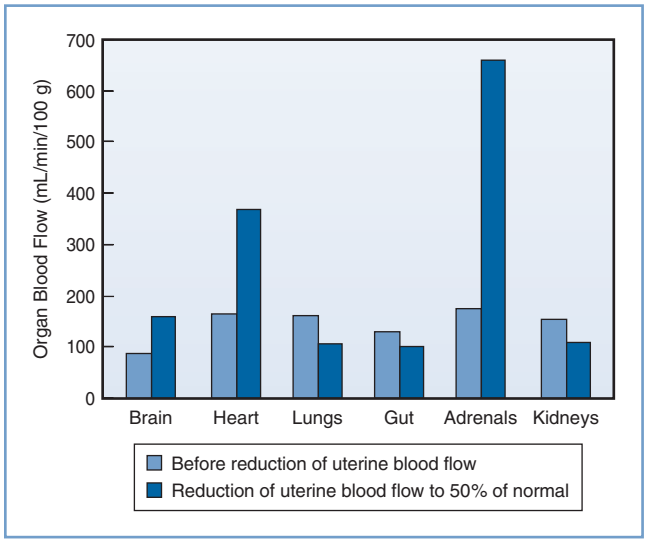

FIGURE 5-5 ■ **Redistribution of combined ventricular output in fetal lambs during hypoxemia caused by reduced uterine blood flow.** (Modified from Jensen A, Roman C, Rudolph AM. Effects of reducing uterine blood flow on fetal blood flow distribution and oxygen delivery. J Dev Physiol 1991; 15: 309-23.)

oxygen-uptake organs (i.e., the placenta before delivery, the lungs after delivery) and the oxygen-consuming organs.

The distribution of the CVO changes over the course of gestation and in certain conditions, such as hypoxia and hypovolemia. Interpretation of CVO data should be evaluated with the understanding that significant interspecies differences exist. For example, in humans the fetal lungs receive approximately 20% of CVO, whereas in the fetal lamb the lungs receive 10% or less of CVO. In human fetuses at 10 to 20 weeks' gestation, the brain receives approximately 15% of CVO,[80] but this fraction may be increased during circumstances of decreased placental perfusion, acidosis, and increased Pco_2. In the rhesus monkey, the fraction of CVO devoted to cerebral blood flow was observed to increase from 16% to 31% during a hypoxic challenge.[81]

Fetal Blood Pressure

Fetal blood pressure increases with gestational age. Intracardiac (intraventricular) pressure recordings in the human fetus suggest that systolic pressure increases from 15 to 20 mm Hg at 16 weeks' gestation to 30 to 40 mm Hg at 28 weeks' gestation.[67] Substantial variation in blood pressure may be observed. The diastolic ventricular pressures undergo similar, albeit slower and smaller increases, from 5 mm Hg or less at 16 to 18 weeks' gestation to 5 to 15 mm Hg at 19 to 26 weeks' gestation.[67]

Regulation of Fetal Circulation

Fetal cardiovascular function continuously adapts to varying metabolic and environmental conditions through regulation by the neurologic and endocrine systems. The predominant form of neuroregulation occurs in response to baroreceptor and chemoreceptor afferent input to the autonomic nervous system and through modulation of myocardial adrenergic receptor activity. Thus, the autonomic nervous system functions to reversibly redirect blood flow and oxygen delivery as required.

Arterial baroreceptor function has been demonstrated in several different fetal animal models. The predominant baroreceptors are located within the vessel walls of the aortic arch and at the bifurcation of the common carotid arteries. These receptors project signals to the vasomotor center in the medulla, from which autonomic responses emanate. The baroreceptors are functional early in fetal development and undergo continuous adaptation to the increases in blood pressure observed over time.[82] A sudden increase in fetal mean arterial pressure—as occurs with partial or complete occlusion of the umbilical arteries—results in cholinergic stimulation and subsequent fetal bradycardia.

Peripheral chemoreceptors are present within the vessel walls of the aortic arch and at the bifurcation of the common carotid arteries. In some animal species, peripheral chemoreceptors are transiently present in the adrenal gland but disappear after birth.[83] The fetal aortic chemoreceptors are responsive to even small changes in arterial oxygenation,[84,85] which contrasts to the less active fetal carotid chemoreceptors. Dawes et al.[86] concluded that the carotid chemoreceptors are important for postnatal respiratory control, whereas the aortic chemoreceptors are more involved in the control of cardiovascular responses and the regulation of oxygen delivery. Central chemoreceptors, located in the medullar oblongata, appear to play little if any role in fetal circulatory responses.

The neural control of the fetal circulation is far more dependent on chemoreceptor-mediated responses than neural control of the adult circulation.[87] Acute fetal hypotension often stimulates a reflex response, which can include both bradycardia and vasoconstriction. Vasoconstriction is dependent on increases in both sympathetic autonomic activity and the rate of secretion of several vasoactive hormones, including arginine vasopressin, renin, angiotensin, and aldosterone. Fetal bradycardia is most likely caused by activation of peripheral chemoreceptors.[87]

Autonomic Nervous System

The autonomic nervous system is present early in gestation and plays a critical role in maintaining cardiovascular homeostasis. In the fetal chick heart, evidence of cholinergic innervation occurs as early as 3 days after fertilization (average incubation, 22 days). In the mammalian heart, inotropic and chronotropic responses to adrenergic agents have been measured as early as 4 to 5 weeks' gestation,[88] and the fetal myocardial pacemaker can be inhibited at this time by the cholinergic agonists carbamylcholine and acetylcholine.[89]

In comparing the parasympathetic cholinergic and sympathetic adrenergic nervous systems during gestation, the majority of studies indicate that the parasympathetic system appears earlier (8 weeks' gestation versus 9 to 10 weeks' gestation),[88,90,91] becomes more dominant as pregnancy progresses, and is more functionally complete at birth (Figure 5-6). As a result, the baseline fetal heart rate is slower at term than at 26 weeks' gestation. The administration of atropine can result in fetal tachycardia by 15 to 17 weeks' gestation, which occurs before fetal bradycardia can be demonstrated with the administration of a beta-adrenergic receptor antagonist.[88]

Both parasympathetic and sympathetic systems undergo significant maturation during postnatal life, and full maturation of the vagal response is not observed until 1 to 2 months after delivery.[92-94] Similarly, although the contractile response of the fetal vasculature is less functional than the adult response, the fetal administration of an alpha-adrenergic agonist can result in the redistribution of blood flow away from the kidneys, skin, and splanchnic organs and toward the heart, brain, placenta, and adrenal glands.[95] At birth, the autonomic nervous system can mediate a number of hemodynamic adjustments, including changes in heart rate and peripheral vascular resistance, as well as a redistribution of blood flow.[88]

FETAL PULMONARY SYSTEM

The lungs begin as small, saccular outgrowths of the ventral wall foregut. Although sacculi with type I and II

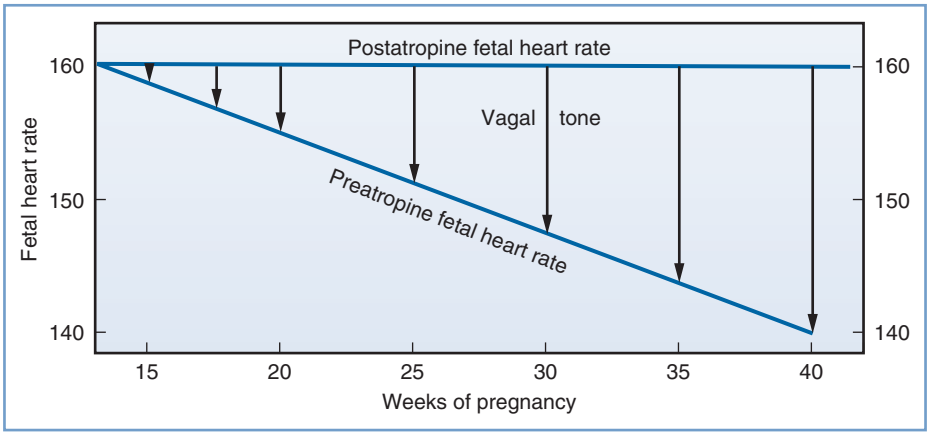

FIGURE 5-6 ■ The growing influence of the parasympathetic nervous system on fetal heart rate as gestation progresses. This parasympathetic activity is reversible with administration of atropine. (From Schifferli P, Caldeyro-Barcia R. Effects of atropine and beta-adrenergic drugs on the heart rate of the human fetus. In Boréus LO, editor. Fetal Pharmacology. New York, Raven Press, 1973:264.)

pneumocytes and ventilatory capacity are present during the last trimester, true alveoli develop at approximately 36 weeks' gestation. The majority of alveolar development occurs postnatally, within the first 6 to 18 months of life, when further maturation of the microvasculature and the air-blood barrier occurs.[96]

The pulmonary vasculature develops early in gestation, with continuous circulation being documented at 34 days' gestation.[97,98] The size and number of pulmonary arteries and veins increases over time; however, vessel reactivity to local and hormonal influences is not detectable until after 20 weeks' gestation.[99,100] From 20 to 30 weeks' gestation, an increase in the size of the pulmonary vascular bed combined with a decrease in the pulmonary vascular resistance results in an increase in pulmonary blood flow (i.e., from 10% to 15% of the CVO to 25% of the CVO). During this time, alterations in maternal oxygenation have no effect on the fetal pulmonary vasculature.[80,99] However, after 30 weeks' gestation, blood flow to the lung decreases slightly owing to a significant increase in pulmonary vascular resistance, diminishing the fraction of CVO to approximately 20%. Contemporaneously, the vasomotor tone and reactivity of the fetal circulation begins to respond to maternal hyperoxygenation with a decrease in pulmonary vascular resistance and an increase in pulmonary blood flow.[80,99] A study in near-term fetal lambs observed a 10-fold increase in pulmonary blood flow when fetal oxygen tension was increased from 24 to 46 mm Hg[101]; this finding emphasizes the importance of ventilation and oxygenation in the newborn to assist in the transition to postnatal circulation.

The reduction in pulmonary vascular resistance at birth is also attributed to a number of mechanical and molecular processes. *In utero*, the fetal lungs are filled with fluid to maintain an appropriate level of expansion for normal pulmonary development.[102] The expulsion of lung liquid, particularly with a vaginal birth, likely decreases extraluminal pressure on the pulmonary vasculature and leads to a decrease in pulmonary vascular resistance.[103] Breathing movements, shear stress created by an abrupt surge in pulmonary blood flow, and the creation of alveolar surface tension are other mechanical factors that can decrease pulmonary vascular resistance.[104] Finally, the relative predominance of vasodilators (e.g., endothelium-derived nitric oxide, prostacyclin) versus vasoconstrictors (e.g., platelet activating factor) at birth may also significantly decrease pulmonary vascular resistance.[105-109]

The pulmonary **surfactant system** is one of the last systems to develop before birth.[110] Surfactant is a lipoprotein complex (phospholipoprotein) that reduces and regulates the surface tension at the air-liquid interface to prevent alveolar collapse and reduces the work associated with breathing.[111] Pulmonary surfactant is composed predominantly (> 90%) of lipids (i.e., phospholipids and neutral lipids [primarily cholesterol]), with the remaining fraction being proteins.[112,113] Surfactant assembly occurs in the endoplasmic reticulum and the Golgi apparatus of the type II alveolar cells, and it is stored in the lamellar bodies. The primary stimuli for surfactant secretion (i.e., exocytosis from the lamellar bodies) are signals from the autonomic nervous system (β_2-adrenergic receptor mediated) and mechanical factors (e.g., stretching of the basement membrane of alveolar type II cells with ventilation).[114] Dipalmitoylphosphatidylcholine, an important component of surfactant, is present in amniotic fluid and can be found in alveolar lavage samples from human fetuses between 24 and 28 weeks' gestation.

The amount and composition of surfactant changes over the course of gestation. For example, the ratio of phosphatidylglycerol to phosphatidylinositol, as well as the ratio of lecithin to sphingomyelin, increases with gestation and may be used as markers of fetal lung maturity.[115-117] Fetal surfactant production can be accelerated by a number of factors, including glucocorticoids, thyroid hormones, and autonomic neurotransmitters. The maternal administration of glucocorticoids such as betamethasone or dexamethasone has been associated with a 35% to 40% reduction in respiratory distress syndrome in preterm infants.[118]

FETAL RENAL SYSTEM

Although fluid and electrolyte balance, as well as acid-base homeostasis, are primarily regulated and maintained by the placenta, the fetal kidneys play an important role in fetal development through amniotic fluid production. Fetal glomeruli begin to develop at 8 to 9 weeks' gestation and start producing urine at 10 weeks' gestation, which contributes significantly to amniotic fluid production.[119,120] By 20 weeks' gestation, greater than 90% of amniotic fluid is provided by the kidneys. Fetal oliguria and anuria can lead to lung hypoplasia and skeletal and tissue deformities (e.g., Potter sequence).[121] Glomerular filtration rate (GFR) increases over the course of gestation but remains low during fetal and early neonatal life. At birth, term newborns have a GFR of approximately 20 mL/min/1.73m^2,[122,123] which increases to approximately 50 mL/min/1.73 m^2 by 1 month of age.[123] This early increase in GFR is believed to result from a large increase in the glomerular capillary surface area and the ultrafiltration coefficient, together with a small increase in the filtration pressure.[124,125] Thereafter, the GFR undergoes progressive increases and reaches adult levels between 1 and 2 years of age.[126]

The ability of the fetal kidneys to perform filtration, reabsorption, and secretion (i.e., tubular function) begins by 14 weeks' gestation and continues to develop postnatally. Immaturity of tubular function in preterm infants can lead to acidosis and salt wasting.[127,128] Renal function *in utero* is regulated by a variety of factors that control renal blood flow, glomerular filtration, and tubular function. The renin-angiotensin system is particularly important for normal fetal renal growth and development[129]; angiotensin II helps regulate blood pressure as well as the volume of fluid in the extravascular space.[130]

FETAL HEMATOLOGIC SYSTEM

Red blood cells, platelets, neutrophils, monocytes, and macrophages are all derived from a common progenitor cell.[131] In the developing embryo, hematopoiesis occurs at several anatomic sites in multiple waves. The first wave occurs in the yolk sac and produces mostly primitive erythroid cells, but also macrophages and megakaryocytes. The second wave also arises in the yolk sac but creates the same cells found in the adult human (i.e., erythroid, megakaryocyte, and several myeloid lineages). The third wave emerges from hematopoietic stem cells located within the major arteries of the embryo, yolk sac, and placenta. Hematopoietic stem cells migrate to the fetal liver and eventually seed the bone marrow. The final wave of hematopoiesis produces all hematopoietic cell lineages, including B- and T-lymphocyte progenitor cells.[132,133]

Erythroid (red blood cells) are the first blood cells to develop. There are two developmentally and morphologically distinct erythroid lineages: primitive (embryonic) and definitive (adult). Cells of the primitive lineage support the transition from the rapidly growing embryo to fetus; primitive megaloblastic erythrocytes are much larger than definitive erythrocytes, express different globin genes, and differ in their oxygen-carrying capacity and response to low oxygen tension. By contrast, definitive erythrocytes function during the transition from fetal to extrauterine life at birth are produced continuously from hematopoietic stem cells in the bone marrow and participate in a variety of normal physiologic processes throughout postnatal life.[131,134]

Fetal and adult human erythrocytes can be distinguished by their hemoglobin (hemoglobin F and A, respectively). The tetramer for hemoglobin F consists of two alpha (α) chains and two gamma (γ) chains (α2γ2), whereas the tetramer for hemoglobin A includes two alpha (α) chains and two beta (β) chains ($\alpha_2\beta_2$). The gamma chain and the beta chain contain the same number of amino acids (146), but their sequences differ by a total of 39 amino acids.[135] The change in expression from fetal to adult beta-globin genes begins at approximately 32 weeks' gestation and is completed after birth.[136]

Hemoglobin F has a greater affinity for oxygen and a lower affinity for 2,3-disphosphoglycerate (DPG) and exhibits a leftward shift in the oxyhemoglobin dissociation curve compared with hemoglobin A (Figure 5-7).[137-139] These differences result in greater arterial oxygen saturation in fetal versus maternal blood for any given arterial oxygen pressure. This difference in oxygen affinity can be explained by a decreased interaction between the gamma chains of hemoglobin F and intraerythrocyte 2,3-DPG, which acts to lower oxygen affinity by binding and stabilizing the deoxygenated hemoglobin tetramer. As a consequence, 2,3-DPG decreases the oxygen affinity of hemoglobin F less than that of hemoglobin A.[140,141] Although fetuses and adults have similar intraerythrocyte

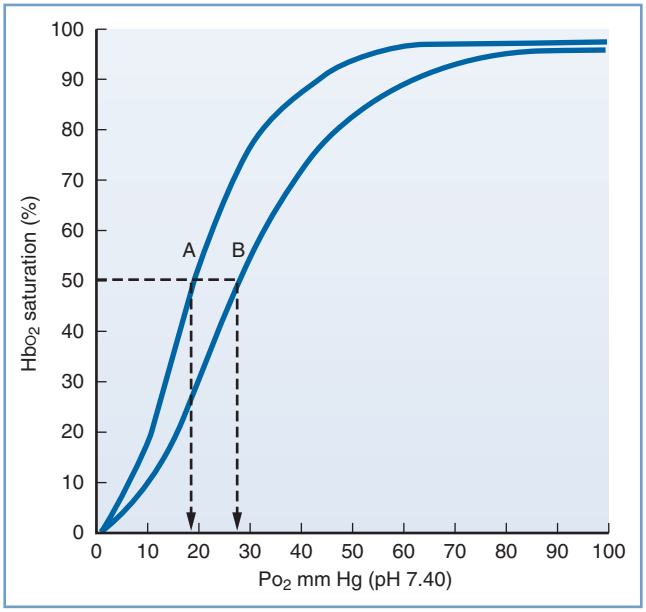

FIGURE 5-7 ■ Oxyhemoglobin saturation curves for fetal (**A**) and adult (**B**) human blood. The P_{50} is indicated by the *dashed vertical line.* (Modified from Delivoria-Papadopoulos M, DiGiacomo JE. Oxygen transport. In Polin RA, Fox WW, editors. Fetal and Neonatal Physiology. Vol 1. Philadelphia, WB Saunders, 1992:807.)

2,3-DPG concentrations, fetal blood exhibits a lower oxygen tension at which hemoglobin is 50% saturated (P_{50}). Hemoglobin F levels begin to decrease toward the end of pregnancy, resulting in a corresponding increase in the P_{50}. At term, hemoglobin A accounts for approximately 25% of total hemoglobin and the P_{50} is approximately 19 mm Hg.[142,143]

Hemoglobin A levels begin to increase and 2,3-DPG concentrations transiently increase above usual fetal and adult levels during the first few months of life. During this time, the affinity of neonatal blood for oxygen is equivalent to that of the adult despite the persistence of 25% fetal hemoglobin.[137,142,143]

FETAL GASTROINTESTINAL SYSTEM

The gastrointestinal tract develops from the primitive digestive tube, which includes the foregut, midgut, and hindgut. The foregut receives its vascular supply from the celiac axis and gives origin to the oral cavity, pharynx, esophagus, stomach, and upper duodenum. The midgut, which receives its vascular supply from the superior mesenteric artery, develops into the distal duodenum, jejunum, ileum, cecum, appendix, and transverse colon. The hindgut receives its vascular supply from the inferior mesenteric artery, and it differentiates into the descending colon, the sigmoid colon, and the upper two thirds of the rectum.[144] Intestinal villi appear by 7 weeks' gestation, and active absorption of glucose and amino acids occurs by 10 and 12 weeks' gestation, respectively.[145] Peristaltic waves and gastrointestinal motility are initiated by 8 weeks' gestation. Teniae, the three longitudinal ribbons of smooth muscle on the outside of the colon, appear by 12 weeks' gestation and contract to produce the haustra (bulges) in the colon.[146] In the small intestine, Auerbach's and Meissner's plexuses of parasympathetic nerves provide motor and secretomotor innervation, respectively; the two plexuses are present as early as 8 weeks' gestation.[145] Aggregations of lymphoid nodules (i.e., Peyer patches) develop by 20 weeks' gestation in the ileum.[147]

Swallowing

The fetus starts swallowing at approximately 15 weeks' gestation, and at term the fetus ingests 500 to 750 mL of amniotic fluid per day.[148] Fetal swallowing plays an important role in amniotic fluid homeostasis,[148] and the swallowed fluid appears to provide nutritional support for mucosal development within the gastrointestinal tract.[149] Avila et al.[150] found that surgical obstruction of ingested fluid within the upper gastrointestinal tract resulted in restricted development of the gastrointestinal tract, liver, and pancreas. In addition, the ingestion and intestinal absorption of nutrient-rich amniotic fluid appears to play an important role in general fetal growth and development. In the fetal rabbit model, disorders of the upper gastrointestinal tract (e.g., esophageal obstruction, gastroschisis) lead to decreased intestinal nutrient absorption and decreased birth weight and crown-rump length.[151,152] Similar findings have been reported in human neonates with congenital esophageal atresia.[153]

Meconium

Meconium, which consists of water, intestinal secretions, squamous cells, lanugo hair, bile pigments, and blood, first appears in the fetal intestine between 10 and 12 weeks' gestation.[154] By 16 weeks' gestation, meconium moves into the colon.[155] Between 14 and 22 weeks' gestation, fetal colonic contents, as indicated by the presence of high levels of intestinal enzymes (disaccharidases, alkaline phosphatase), appear in the amniotic fluid.[156] After 22 weeks' gestation, a subsequent decline in the concentration of these gastrointestinal enzymes within the amniotic fluid is observed, which coincides with the development of anal sphincter tone.[156,157]

Meconium is continually cleared by fetal swallowing, leading to relatively clear amniotic fluid in the majority of pregnancies. The presence of meconium-stained amniotic fluid may therefore represent either decreased meconium clearance or increased meconium passage, which is observed in the presence of fetomaternal stress factors such as hypoxia and infection, independent of fetal maturation.[154] Meconium-stained amniotic fluid occurs more frequently with advanced gestational age and is common in post-term pregnancies.[158]

Although many fetuses with meconium-stained amniotic fluid are born without adverse sequelae, meconium can have detrimental effects on fetal organs and the placenta. Meconium may cause umbilical cord vessel constriction, vessel necrosis, and the production of thrombi, which can lead to altered coagulation, cerebral palsy, and neonatal seizures.[159] In addition, meconium may reduce the antibacterial properties of amniotic fluid by altering zinc levels.[154] Fetal aspiration of meconium also may neutralize the action of surfactant, promote lung tissue inflammation through the activation of neutrophils, and possibly result in meconium aspiration syndrome (see Chapter 9). Finally, in the presence of perinatal hypoxia, meconium also may contribute to vascular hypertrophy and possible pulmonary hypertension.[154]

FETAL NERVOUS SYSTEM

Over the course of gestation, the human brain and central nervous system begin to develop from a few embryonic cells to a complex system in which billions of neurons are arranged and interconnected; small, seemingly minor changes may have profound implications. For example, animal studies suggest that intrauterine exposure to a variety of anesthetic agents at specific time intervals appears to result in anatomic, functional, and behavioral changes following birth (see Chapter 10).

Structural and Functional Brain Development

Primary neuromodulation and neural tube formation occur by 4 weeks' gestation. Between 8 and 12 weeks' gestation, prosencephalon development is initiated, which

is accompanied by neuronal proliferation and migration. Simultaneously, the subplate layer is created to fulfill a critical, albeit transient, role as a location for synapses with cortical and thalamic projections; the subplate layer disintegrates between 24 and 28 weeks' gestation. A significant increase in cortical development, organization, and synapse formation begins by 20 weeks' gestation and continues postnatally; during the third trimester alone, the cerebral cortex volume increases fourfold.[160-163]

The first fetal movements are witnessed near the end of the first trimester. These initial movements have simple patterns and originate from spontaneous discharges within the spine and brainstem. The fetal movements become more organized and complex as the pregnancy progresses, with higher brain centers modulating the activity of the brainstem and spine.

The exact onset of electrocortical activity is unknown, but electroencephalographic (EEG) activity can be recorded in preterm infants as early as 24 weeks' gestation. Fetal EEG activity differs from that in the adult and is characterized by the presence of intermittent bursts of activity separated by periods of complete suppression. With maturation, these suppressed episodes become shorter and less frequent before completely disappearing in postnatal life. The early electrical activity within the nervous system controls several developmental processes, such as neuronal differentiation, migration, synaptogenesis, and formation of neuronal networks. For example, the initial spontaneous spinal and subcortical discharges are believed necessary for somatosensory development. As they elicit movements in the periphery, afferent signals establish topographic representation on the sensory cortex.[164-166]

Cerebral Metabolism

The immature brain, similar to the adult brain, relies mostly on oxidative metabolism for the production of energy. However, owing to the limited capacity for mitochondrial oxidative phosphorylation and the lower partial pressures of oxygen observed *in utero*, anaerobic glycolysis exhibits a greater role during this developmental period than after delivery.[167,168] In the presence of aerobic conditions, glucose is converted to pyruvic acid (glycolysis), which enters the Krebs cycle and the mitochondrial cytochrome system to create chemical energy; this process converts 1 mole of glucose into 36 moles of ATP. By contrast, during anaerobic conditions, glycolysis is much less efficient, yielding only 2 moles of ATP for each mole of glucose.[169]

Although glucose represents the primary and predominant source of cerebral energy, the perinatal brain is uniquely capable of metabolizing other substrates, such as lactic acid and ketone bodies (β-hydroxybutyrate and acetoacetate). Lactic acid concentrations in the peripartum period are significantly elevated and may support over 50% of total cerebral oxidative metabolism in certain conditions such as hypoglycemia and hypoxia.[170,171] During hypoxic conditions, the fetal brain will also significantly decrease its energy consumption, as evidenced by fewer fetal movements and a slower EEG wave pattern.[172]

Cerebral Blood Flow

The development of the neural tube begins with formation of endothelium-lined vascular channels; by 10 weeks' gestation, an extensive network of leptomeningeal arteries covers the fetal brain, allowing vessels to sprout and penetrate the brain parenchyma. Subsequent vascular growth is most pronounced in rapidly developing areas of the brain.[167]

The fetal systemic circulation has unique features that ensure optimal oxygen delivery to the brain. Well-oxygenated blood from the umbilical vein and ductus venosus is preferentially shunted through the foramen ovale to the left side of the heart and the ascending aorta to supply the cerebral and coronary circulations. Hypoxia results in acute changes in fetal and placental vascular resistance, which leads to intense peripheral vasoconstriction (likely mediated by stimulation of chemoreceptors) and further shunting of umbilical venous blood through the ductus venosus. The fetal circulatory system is much more sensitive to hypoxemia than that in the adult, which helps maintain oxygen delivery to the developing brain and myocardium (Figure 5-8).[173-175]

The redistribution of blood flow to the most actively developing regions of the fetal brain is at least partially the result of an adenosine-mediated mechanism. Adenosine, the breakdown product of ATP, accumulates during failure of ATP resynthesis and causes vasodilation of blood vessels and suppression of neuronal activity.[172] Other substances (e.g., nitric oxide, endogenous opioids, adrenomedullin) may also play a role in cerebral blood redistribution, but the exact mechanisms are incompletely understood.[176]

Nociception

Cutaneous sensory receptors are present in the human fetus at approximately 7 weeks' gestation, and a widespread network is established by 20 weeks. At term gestation, the density of cutaneous nociceptive receptors in the fetus is comparable to, and may even exceed, that of the adult. Although the development of sensory fiber-to-dorsal horn interneuron synapses has been reported to occur as early as 6 weeks' gestation,[177] differentiation of dorsal horn neurons begins at approximately 13 weeks' gestation; the laminar arrangement of dorsal horn neurons, replete with synaptic interconnections and neurotransmitter vesicles, is present in some regions of the spinal cord by 30 weeks' gestation.[178] At this time, the A-delta and C fibers make connections at the spinal cord level and with the surrounding dermatomes.

The neurons of the cerebral cortex develop by 20 weeks' gestation, and synaptogenesis of the thalamocortical connections is established between 20 and 24 weeks' gestation. Thalamocortical axons reach the somatosensory cortex at 24 to 26 weeks' gestation. Myelination of the pain pathways of the spinal cord and brainstem is completed during the second and third trimesters of gestation[179]; however, the process continues postnatally in other areas of the brain and in peripheral

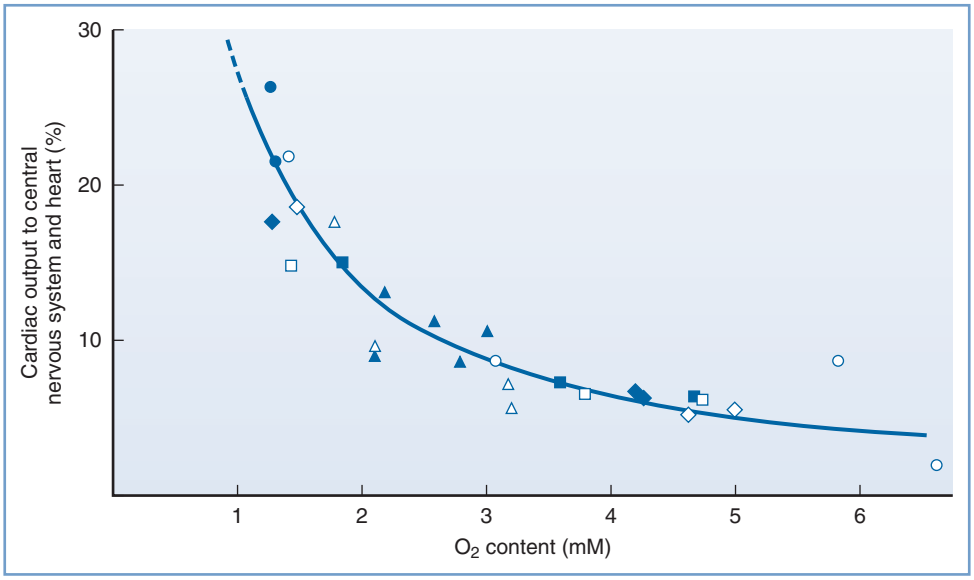

FIGURE 5-8 ■ The redistribution of cardiac output to the heart and central nervous system during hypoxemia in fetal lambs. Each symbol represents a measurement from an individual fetal lamb. (Modified from Sheldon RE, Peeters LLH, Jones MD Jr, et al. Redistribution of cardiac output and oxygen delivery in the hypoxic fetal lamb. Am J Obstet Gynecol 1979; 135:1071-8.)

nerve fibers. Although optimal pain processing requires myelination of pain pathways, cortical maturation, dendritic arborization, and thalamocortical fiber synaptogenesis, it is unclear when nociception, the capacity to feel pain, develops within the fetus. As early as 18 weeks' gestation, human fetuses demonstrate pituitary-adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli.[180-182] In studies of intrauterine blood transfusion in the human fetus, surgical needling of the intrahepatic vein (compared with needling of the insensate umbilical cord) is associated with evidence of a stress response, including increases in plasma beta-endorphin and cortisol levels and a diminution in the middle cerebral artery pulsatility index.[183] Administration of fentanyl 10 μg/kg blunts this stress response to intrahepatic needling.[184]

Near-infrared spectroscopy has demonstrated cortical activity in response to noxious stimuli in preterm neonates born and studied as early as 25 weeks' postmenstrual age.[185,186] Similarly, facial responses to painful stimuli (similar to those seen in adults) can be provoked in preterm neonates born and assessed as early as 25 weeks' gestation, which suggests the development of functional pathways from the spinal cord to the brain.[187,188] However, the withdrawal from noxious stimuli or an increased release of stress hormones does not necessarily reflect an *awareness* of pain, because local spinal reflexes and hormonal release can occur without cortical involvement.[189] The experience of pain is a conscious subjective experience with emotional and affective components that requires higher-level cortical processing. Nociceptive processing begins in the peripheral neurons, which relay signals through the spinothalamic tract, the thalamus, and ultimately the cerebral cortex, where conscious perception of pain occurs.[190]

After birth, neonates appear to be more sensitive to pain, with lower pain thresholds, poor discriminative abilities, and a greater tendency to exhibit central sensitization in response to later noxious stimuli than adults. Early sensory experiences in the neonate can influence the development of nociceptive pathways.[191] Neonates and especially preterm infants who undergo numerous procedures in the neonatal intensive care unit and/or surgery have been observed to demonstrate altered pain perceptions later in life.[192] In the rodent model, tissue injury in early neonatal life results in an increased magnitude and duration of hyperalgesia after reinjury in later life, compared with those with no early life pain experience.[191] Collectively, these observations have prompted some investigators to conclude that noxious events in neonates, when pain pathways are still undergoing a learning or "tuning process," may result in structural functional and behavioral alterations in adult pain processing. Some of these long-term consequences may be attenuated by preemptive analgesia.[193]

The foregoing neuroanatomic and neurochemical evidence, in addition to the well-characterized behavioral and physiologic responses to pain, indicate that both the fetus and newborn infant have nociceptive pathways capable of communicating nociceptive stimuli from the periphery to the cerebral cortex and regulating the response via efferent inhibitory pathways. Current evidence suggests that fetal nociception at the level of the cortex occurs after the midpoint of pregnancy (i.e., between 24 and 30 weeks' gestation). Of note, maternal administration of general anesthesia does not guarantee the presence of fetal anesthesia or analgesia (see Chapter 7). For example, most infants are clearly awake and cry loudly immediately after cesarean delivery during maternal administration of general anesthesia.

KEY POINTS

- Amniotic fluid serves a number of vital roles, including the facilitation of fetal growth, the provision of a microgravity environment that cushions the fetus, and the generation of a defense mechanism against invading microbes.
- The fetus depends on the mother and the placenta for its basic metabolic needs, such as nutrient delivery, gas exchange, and electrolyte and acid-base homeostasis.
- Fetal arterial blood P_{O_2} ranges from 20 to 30 mm Hg, and fetal development exists in a state of relative hypoxia compared with adult oxygen tension.
- Despite a lower fetal oxygen tension, the fetal arterial blood oxygen content is not much lower than that of the adult. This results from a higher oxygen-carrying capacity (hemoglobin concentration of 18 g/dL) and a higher affinity of hemoglobin F for oxygen, when compared with hemoglobin A.
- The fetus produces approximately twice as much heat (on a weight-adjusted basis) and maintains a temperature 0.5°C higher than the mother during the third trimester.
- The fetal circulation receives output from both the left and the right ventricle, with the ventricles working in parallel. Systemic blood flow consists of the sum of the right and left ventricular outputs, with the exception of the small amount of blood delivered to the fetal lungs by the right ventricle.
- Fetal blood flow is characterized by three important communications between the left and right circulation: the ductus venosus, the foramen ovale, and the ductus arteriosus.
- Acute hypotension in the fetus stimulates a reflex response, which includes both bradycardia and vasoconstriction.
- The sympathetic nervous system at birth is not as well developed as the parasympathetic nervous system; however, it plays an important role in the hemodynamic adjustments at birth.
- Although fetal fluid and electrolyte balance, as well as acid-base homeostasis, are primarily regulated and maintained by the placenta, the fetal kidneys play an important role in fetal development through amniotic fluid production.
- The pulmonary surfactant system is one of the last systems to develop before birth. Surfactant assembly occurs in the type II alveolar cells, and components of surfactant are first detected between 24 and 28 weeks' gestation.
- Fetal hemoglobin has a greater oxygen affinity than adult hemoglobin, owing to a decreased interaction between hemoglobin F and 2,3-DPG. The P_{50} of fetal blood is significantly lower than that of adult blood.
- Fetal hypoxemia leads to a significant redistribution of cardiac output to the heart and the brain. This results in both a global increase in cerebral blood flow and a redistribution of blood flow within the fetal brain.
- Fetal swallowing plays an important role in amniotic fluid homeostasis, and the swallowed fluid appears to provide nutritional support for mucosal development within the gastrointestinal tract.
- The fetus has nociceptive pathways capable of communicating painful stimuli from the periphery to the cerebral cortex. Current evidence suggests that fetal nociception at the level of the cortex occurs after the midpoint of pregnancy (i.e., between 24 and 30 weeks' gestation).

PART III

FETAL AND NEONATAL ASSESSMENT AND THERAPY

Donald Caton, MD

Ostensibly, concern for the neonate began in 1861, when London physician W. J. Little published a paper entitled "On the influence of abnormal parturition, difficult labors, premature birth, and asphyxia neonatorum, on the mental and physical condition of the child, especially in relation to deformities."[1] Hailed as "an original field of observation," Little's paper was among the first to identify antepartum asphyxia as the cause of problems in the neonate.

Almost half a century passed, however, before clinicians developed a sustained interest in fetal oxygenation. This development came through the influence of Sir Joseph Barcroft and his book *Researches on Prenatal Life*.[2] A professor of physiology at Cambridge University, Barcroft was already highly respected for his studies of respiration when this book was published.

From his laboratory studies, Barcroft discovered a progressive decrease in fetal oxygen saturation during the last half of pregnancy. He attributed this finding to the fetal demands for oxygen, which slowly increased until the capacity of the placenta was exhausted. Barcroft compared the fetus to a mountaineer climbing Mt. Everest, in that the oxygen environment of the fetus became progressively less dense. He suggested that the term fetus faced either asphyxia *in utero* or escape through the initiation of labor. Barcroft's depiction of the fetal environment disturbed clinicians who were already well aware of the additional stress imposed by labor.

Ironically, one of Barcroft's own students proved him wrong. D. H. Barron, professor of physiology at Yale, suggested that Barcroft's data had been skewed by the conditions of his experiments, all of which had been conducted on animals anesthetized for immediate surgery. Barron and his colleagues developed methods to sample fetal blood in awake, unstressed animals. Under these circumstances, they observed no deterioration in the fetal environment until the onset of labor. Oxygen saturation, hemoglobin concentration, and pH remained stable and normal.[3]

Barcroft's data have had the greatest impact on clinical practice. Virtually all current methods of fetal monitoring grew out of the belief that oxygen availability is the single most important factor influencing the well-being of the newborn. However, Barron's studies affected physiologists, who began to study the mechanisms that maintained the stability of the intrauterine environment in the presence of increasing fetal demands.

CHAPTER 6

Antepartum Fetal Assessment and Therapy

Teresa Marino, MD • Joong Shin Park, MD, PhD • Errol R. Norwitz, MD, PhD

CHAPTER OUTLINE

Obstetric care providers have two patients, the mother and the fetus. Although assessment of maternal health is relatively straightforward, assessment of fetal well-being is far more challenging. Several tests have been developed to assess the fetus during pregnancy, including some that are recommended for all pregnancies (e.g., ultrasonography for pregnancy dating) and others that are reserved only for women with pregnancy complications (e.g., middle cerebral artery Doppler velocimetry in pregnancies with isoimmunization). In addition, a limited number of fetal interventions are employed to improve fetal outcome, including some that are used frequently, such as maternal corticosteroid administration, and others that are used much more rarely, such as intrauterine fetal procedures. A review is presented here of the tests available to assess fetal well-being in both low- and high-risk pregnancies and of the fetal therapies used during the antepartum period.

PRENATAL CARE IN LOW-RISK PREGNANCIES

Determination of Gestational Age

The mean duration of a singleton pregnancy is 280 days (40 weeks) from the first day of the last normal menstrual period in women with regular 28-day menstrual cycles. *Term*, defined as the period from 37 weeks' (259 days') to 42 weeks' (294 days') gestation, is the optimal time for delivery. Both preterm births (defined as delivery before 37 weeks' gestation) and post-term births (delivery after 42 weeks' gestation) are associated with increased perinatal and neonatal morbidity and mortality. Evaluation of fetal growth, efficient use of screening and diagnostic tests, appropriate initiation of fetal surveillance, and optimal timing of delivery all depend on accurate dating of the pregnancy.

A number of clinical, biochemical, and radiologic tests are available to determine gestational age (Box 6-1).[1,2] Determination of gestational age is most accurate in early pregnancy, and the estimated date of delivery (EDD) should be established at the first prenatal visit. Embryo transfer dating in women undergoing *in vitro* fertilization (IVF) is the most accurate clinical dating criterion. Among women with regular menstrual cycles who conceive spontaneously, if the first day of the last menstrual period (LMP) is known and if uterine size is consistent with dates by clinical examination, then Naegele's rule (subtract 3 months and add 7 days to the LMP) can be used to determine the EDD. Menstrual dating is known to be inaccurate in women taking oral contraceptives, in women who conceive in the immediate postpartum period, and in women who have irregular menstrual cycles or a history of intermenstrual bleeding. Moreover, clinical examination of uterine size can be inaccurate in

BOX 6-1 Clinical Criteria Commonly Used to Confirm Gestational Age

- Reported date of last menstrual period (estimated due date can be calculated by subtracting 3 months and adding 7 days to the first day of the last normal menstrual period [Naegele's rule]) or date of assisted reproductive technology (intrauterine insemination or embryo transfer)
- The size of the uterus as estimated on bimanual examination in the first trimester, which should be consistent with dates
- The perception of fetal movement ("quickening"), which usually occurs at 18 to 20 weeks in nulliparous women and at 16 to 18 weeks in parous women
- Fetal heart activity, which can be detected with a nonelectronic fetal stethoscope by 18 to 20 weeks and with Doppler ultrasonography by 10 to 12 weeks
- Fundal height; at 20 weeks, the fundal height in a singleton pregnancy should be approximately 20 cm above the pubic symphysis (usually corresponding to the umbilicus)
- Ultrasonography, involving crown-rump length measurement of the fetus during the first trimester, or fetal biometry (biparietal diameter, head circumference, and/or femur length) during the second trimester

Data from American College of Obstetricians and Gynecologists. Antepartum fetal surveillance. ACOG Practice Bulletin No. 9. Washington, DC, 1999 (reaffirmed 2009); and American College of Obstetricians and Gynecologists. Management of postterm pregnancy. ACOG Practice Bulletin No. 55. Washington, DC, 2004 (reaffirmed 2009).

women with a high body mass index (BMI), uterine fibroids, or a multifetal pregnancy. For these reasons, reliance on standard clinical criteria alone to determine the EDD will lead to an inaccurate diagnosis, with a tendency to overestimate gestational age.[3-6] One study reported that reliance on LMP alone leads to a false diagnosis of preterm birth and post-term pregnancy in one fourth and one eighth of cases, respectively.[7] Use of other historic factors (e.g., the date of the first positive pregnancy test result or the first perceived fetal movements ["quickening"]) and physical findings (e.g., the date when fetal heart sounds are first audible) may help obstetric providers determine the EDD more accurately (see Box 6-1).

Most early pregnancy tests involve the identification and quantification of human chorionic gonadotropin (hCG), a hormone produced by the syncytiotrophoblast of the fetoplacental unit.[8,9] Levels in the maternal circulation increase exponentially to a peak of 80,000 to 100,000 mIU/mL at 8 to 10 weeks' gestation and then decrease to a level of 20,000 to 30,000 mIU/mL for the remainder of the pregnancy. Commercially available hCG test kits can detect concentrations as low as 25 to 50 mIU/mL in serum or urine, which are typically evident 8 to 9 days after conception.

Uncertainty in dating parameters should prompt ultrasonographic assessment of gestational age. Transabdominal ultrasonography can identify an intrauterine sac in 94% of eutopic (intrauterine) pregnancies once the serum hCG concentration is 6000 mIU/mL or higher.[10] With the use of transvaginal ultrasonography, an intrauterine pregnancy can typically be confirmed at a serum hCG level of 1500 to 2000 mIU/mL.[11] Failure to confirm an intrauterine sac at these hCG levels should raise concerns about an abnormal pregnancy (e.g., ectopic pregnancy, missed abortion) and requires further evaluation. A fetal pole and cardiac activity should be visible at a serum hCG concentration of approximately 1700 mIU/mL (5 to 6 weeks) and 5400 mIU/mL (6 to 8 weeks), respectively. The EDD derived from ultrasonographic evaluation should be used when there is a 5- to 7-day discrepancy from LMP dating in the first trimester.[11]

In the first trimester, the fetal crown-rump length (CRL) is the most accurate determinant of gestational age (± 3 to 5 days). In the second trimester, the biparietal diameter (BPD) and length of the long bones (especially femur length) are the ultrasonographic measurements used most often to determine gestational age. Of these, the BPD is the more accurate indicator with a variation of ± 7 to 10 days.[12] Two large clinical studies of approximately 50,000 pregnancies demonstrated that a second-trimester BPD measurement, when used instead of menstrual dating to establish the EDD, resulted in a significant increase in the number of women who delivered within 7 days of their due dates and a 60% to 70% reduction in the number of pregnancies continuing post term.[13,14] After 26 weeks' gestation, the variation in the BPD measurement is greater (± 14 to 21 days), thereby making it less valuable in estimating gestational age.[12] Both femur length and humerus length correlate strongly with the BPD and gestational age and are sometimes used for additional confirmation.[15] By contrast, because abdominal circumference (AC) reflects fetal nutritional status and growth, it is less accurate than either BPD or femur length. All fetal biometric measurements are subject to some degree of error, so a number of techniques have been used to predict gestational age more accurately. Serial determinations of gestational age at 2- to 3-week intervals may be more accurate than a single determination in the third trimester to confirm dating and eliminate the possibility of fetal growth restriction.

Routine Ultrasonography

Routine early ultrasonography significantly improves the accuracy of gestational age dating.[3-6,16-19] Early ultrasonography can also detect pregnancy abnormalities (e.g., molar pregnancy), major fetal structural abnormalities (e.g., anencephaly), and multiple pregnancy. Although recommended in Europe, the practice of routine ultrasonography for pregnancy dating has not been recommended as a standard of prenatal care in the United States.[20,21]

The usefulness of routine second-trimester ultrasonography in all pregnant women remains a subject of debate. Early studies suggested an improvement in perinatal outcome with its use.[17,22-25] For example, one prospective clinical trial in Helsinki, Finland, randomly assigned 9310 low-risk women either to a single screening ultrasonographic examination at 16 to 20 weeks' gestation or to ultrasonography for obstetric indications only; a significantly lower perinatal mortality rate was

found in the screening ultrasonography group (4.6 versus 9.0 per 1000 births, respectively).[18] This difference was due in part to earlier detection of major fetal malformations (which prompted elective abortion) and multiple pregnancies (which resulted in more appropriate antenatal care) with the screening examination. As expected, routine ultrasonography also led to improved pregnancy dating and a lower rate of induction of labor for postterm pregnancy.[18]

In contrast, a subsequent large multicenter randomized clinical trial involving 15,151 low-risk women in the United States (designated as the RADIUS study) concluded that screening ultrasonography did *not* improve perinatal outcomes and had no impact on the management of the anomalous fetus.[19,26,27] Although this trial was adequately powered, it has been criticized for the highly selective entry criteria (by one estimate, less than 1% of pregnant women in the United States would have been eligible[28]) and the selection of primary outcomes (perinatal morbidity and mortality) that were inappropriate for the low-risk population studied. In addition, only 17% of major congenital anomalies were detected before 24 weeks' gestation in the routine ultrasonography group, so the rate of elective pregnancy termination for fetal anomalies was significantly lower than that in the Helsinki study. The skill and experience of the ultrasonographer is also an important variable in these studies.

Evaluation of Fetal Growth

Normal fetal growth is a critical component of a healthy pregnancy and the subsequent long-term health of the child. Maternal weight gain during pregnancy is at best an indirect measure of fetal growth, because much of the weight gain during pregnancy is the result of fluid (water) retention. Earlier recommendations for weight gain in pregnancy were based on the Institute of Medicine (IOM) guidelines published in 1990.[29] In 2009, the IOM revised their 1990 recommendations to include an upper limit of weight gain for obese women (9 kg [20 lb]), and they altered the lower limit of weight gain from 6.8 kg (15 lb) to 5 kg (11 lb) (Table 6-1); they also recommended that all women try to be within the normal BMI range when they conceive.[30]

The size, presentation, and lie of the fetus can be assessed with abdominal palpation. A systematic method of examination of the gravid abdomen was first described by Leopold and Sporlin in 1894.[31] Although the abdominal examination has several limitations (especially in the setting of a small fetus, maternal obesity, multiple pregnancy, uterine fibroids, or polyhydramnios), it is safe, is well tolerated, and may add valuable information to assist in antepartum management. Palpation is divided into four separate Leopold's maneuvers (Figure 6-1). Each maneuver is designed to identify specific fetal landmarks or to reveal a specific relationship between the fetus and mother. The first maneuver, for example, involves measurement of the fundal height. The uterus can be palpated above the pelvic brim at approximately 12 weeks' gestation. Thereafter, fundal height should increase by approximately 1 cm per week, reaching the level of the umbilicus at 20 to 22 weeks' gestation (Figure 6-2). Between 20 and 32 weeks' gestation, the fundal height (in centimeters) is approximately equal to the gestational age (in weeks) in healthy women of average weight with an appropriately growing fetus. However, there is a wide range of normal fundal height measurements. In one study, a 6-cm difference was noted between the 10th and 90th percentiles at each week of gestation after 20 weeks.[32] Moreover, maximal fundal height occurs at approximately 36 weeks' gestation, after which time the fetus drops into the pelvis in preparation for labor. For all of these reasons, reliance on fundal height measurements alone fails to identify more than 50% of fetuses with fetal growth restriction (also known as intrauterine growth restriction).[33] Serial fundal height measurements by an experienced obstetric care provider are more accurate than a single measurement and will lead to better diagnosis of fetal growth restriction, with reported sensitivities as high as 86%.[34]

If clinical findings are not consistent with the stated gestational age, ultrasonography is indicated to confirm gestational age and provide a more objective measure of fetal growth. Ultrasonography may also identify an

TABLE 6-1 Recommendations for Weight Gain in Pregnancy

Mother's Body Mass Index	Recommended Weight Gain
18.5 to 24.9 kg/m^2 (normal weight)	11.2 to 15.9 kg (25 to 35 lb)
25 to 29.9 kg/m^2 (overweight)	6.8 to 11.2 kg (15 to 25 lb)
>30 kg/m^2 (obesity)	5.0 to 9.0 kg (11 to 20 lb)

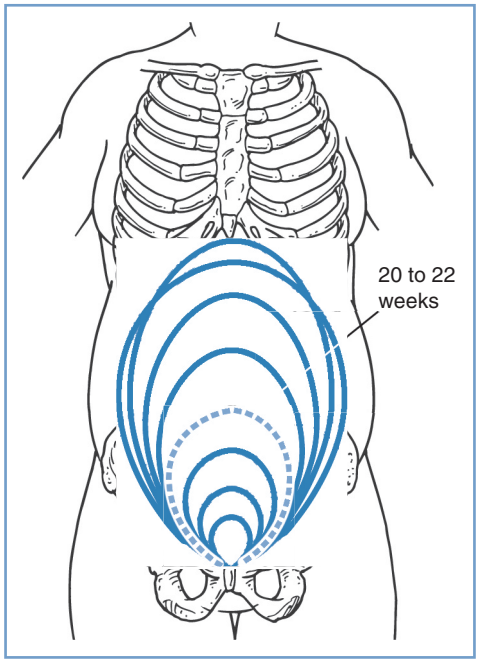

FIGURE 6-2 ■ Fundal height measurements in a singleton pregnancy with normal fetal growth.

alternative explanation for the discrepancy, such as multifetal pregnancy, polyhydramnios, fetal demise, and uterine fibroids. For many years, obstetric ultrasonography has used fetal biometry to define fetal size by weight estimations. This approach has a number of limitations. First, regression equations used to create weight estimation formulas are derived primarily from cross-sectional data for infants being delivered within an arbitrary period after the ultrasonographic examination. Second, these equations assume that body proportions (fat, muscle, bone) are the same for all fetuses.[34-45] Finally, growth curves for "normal" infants between 24 and 37 weeks' gestation rely on data collected from pregnancies delivered preterm, which are abnormal and probably complicated by some element of uteroplacental insufficiency, regardless of whether the delivery was spontaneous or iatrogenic. Despite these limitations, if the gestational age is well validated, the prevailing data suggest that prenatal ultrasonography can be used to verify an alteration in fetal growth in 80% of cases and to exclude abnormal growth in 90% of cases.[46]

Ultrasonographic estimates of fetal weight are commonly derived from mathematical formulas that use a combination of fetal measurements, especially the BPD, AC, and femur length.[47] The AC is the single most important measurement and is weighted more heavily in these formulas. Unfortunately, the AC is also the most difficult measurement to acquire, and small differences in the measured value result in large changes in the estimated fetal weight (EFW). The accuracy of the EFW depends on a number of variables, including gestational age (in absolute terms, EFW is more accurate in preterm or growth-restricted fetuses than in term or macrosomic fetuses), operator experience, maternal body habitus, and amniotic fluid volume (measurements are more difficult to acquire if the amniotic fluid volume is low). Objective ultrasonographic EFW estimations have an error of 15% to 20%, even in experienced hands.[48] Indeed, an ultrasonographic EFW at term is no more accurate than a clinical estimate of fetal weight made by an experienced obstetric care provider or the mother's estimate of fetal weight if she has delivered before.[49] Ultrasonographic estimates of fetal weight must therefore be evaluated within the context of the clinical situation and balanced against the clinical estimate. Serial ultrasonographic evaluations of fetal weight are more useful than a single measurement in diagnosing abnormal fetal growth. The ideal interval for fetal growth evaluations is every 3 to 4 weeks, because more frequent determinations may be misleading. Similarly, the use of population-specific growth curves, if available, improves the ability of the obstetric care provider to identify abnormal fetal growth. For example, growth curves derived from a population that lives at high altitude, where the fetus is exposed to lower oxygen tension, will be different from those derived from a population at sea level. Abnormal fetal growth can be classified as insufficient (fetal growth restriction) or excessive (fetal macrosomia).

Fetal Growth Restriction

The definition of *fetal growth restriction* has been a subject of long-standing debate. Distinguishing the healthy, constitutionally small-for-gestational-age (SGA) fetus, defined as having an EFW below the 10th percentile for a given week of gestation, from the nutritionally deprived, truly growth-restricted fetus has been particularly difficult. Fetuses with an EFW less than the 10th percentile are not necessarily pathologically growth restricted. Conversely, an EFW above the 10th percentile does not necessarily mean that an individual fetus has achieved its growth potential, and such a fetus may still be at risk for perinatal mortality and morbidity. Therefore, fetal growth restriction is best defined as either (1) an EFW less than the 5th percentile for gestational age in a well-dated pregnancy or (2) an EFW less than the 10th percentile for gestational age in a well-dated pregnancy with evidence of fetal compromise, such as oligohydramnios or abnormal umbilical artery Doppler velocimetry.

Fetal growth restriction has traditionally been classified as either asymmetric or symmetric fetal growth restriction. **Asymmetric fetal growth restriction,** characterized by normal head growth but suboptimal body growth, is seen most commonly in the third trimester. It is believed to result from a late pathologic event (e.g., chronic placental abruption leading to uteroplacental insufficiency) in an otherwise uncomplicated pregnancy and normal fetus. In cases of **symmetric fetal growth restriction,** both the fetal head size and body weight are reduced, indicating a global insult that likely occurred early in gestation. Symmetric fetal growth restriction may reflect an inherent fetal abnormality (e.g., fetal chromosomal anomaly, inherited metabolic disorder, early congenital infection) or long-standing severe placental insufficiency due to an underlying maternal disease (e.g., hypertension, pregestational diabetes mellitus, or

collagen vascular disorder). In practice, the distinction between asymmetric and symmetric fetal growth restriction is not particularly useful.

Early and accurate diagnosis of fetal growth restriction coupled with appropriate intervention leads to an improvement in perinatal outcome. If fetal growth restriction is suspected clinically and on the basis of ultrasonography, a thorough evaluation of the mother and fetus is indicated. Referral to a maternal-fetal medicine specialist should be considered. Every effort should be made to identify the cause of the fetal growth restriction and to modify or eliminate contributing factors. Up to 20% of cases of severe fetal growth restriction are associated with fetal chromosomal abnormalities or congenital malformations, 25% to 30% are related to maternal conditions characterized by vascular disease, and a smaller proportion are the result of abnormal placentation. Other causes of fetal growth restriction include exposure to teratogens, alcohol, and substance abuse. In a substantial number of cases (>50% in some studies), the etiology of the fetal growth restriction remains unclear even after a thorough investigation.[50]

Fetal Macrosomia

Fetal macrosomia is defined as an EFW (not birth weight) of 4500 g or greater measured either clinically or by ultrasonography and is independent of gestational age, diabetic status, and actual birth weight.[51] Fetal macrosomia should be differentiated from the large-for-gestational age (LGA) fetus, in whom the EFW is greater than the 90th percentile for gestational age. By definition, 10% of all fetuses are LGA at any given gestational age. Fetal macrosomia is associated with an increased risk for cesarean delivery, instrumental vaginal delivery, and birth injury to both the mother (including vaginal, perineal, and rectal trauma) and the infant (orthopedic and neurologic injury).[52-56] Shoulder dystocia with resultant brachial plexus injury (Erb's palsy) is a serious consequence of fetal macrosomia; it is more likely in the setting of diabetes because of the larger diameters of the fetal upper thorax and neck.

Fetal macrosomia can be determined clinically (e.g., Leopold's maneuvers) or with ultrasonography, and these two techniques appear to be equally accurate.[57] Estimated fetal weight measurements are less accurate in macrosomic fetuses than in normally grown fetuses, and factors such as low amniotic fluid volume, advancing gestational age, maternal obesity, and fetal position can compound these inaccuracies. Indeed, clinical examination has been shown to underestimate the birth weight by more than 0.5 kg in almost 80% of macrosomic fetuses.[58] For all these reasons, prediction of fetal macrosomia is not particularly accurate, with a false-positive rate of 35% and a false-negative rate of 10%.[57,58] A number of alternative ultrasonographic measurements have therefore been proposed in an attempt to better identify the macrosomic fetus, including fetal AC alone,[59] umbilical cord circumference,[60] cheek-to-cheek diameter,[61] and subcutaneous fat in the mid humerus, thigh, abdominal wall, and shoulder.[62] However, these measurements remain investigational.

Despite the inaccuracy in the prediction of fetal macrosomia, an EFW should be documented by either clinical estimation or ultrasonography in all high-risk women at approximately 38 weeks' gestation. Suspected fetal macrosomia is not an indication for induction of labor, because induction does not improve maternal or fetal outcomes and may increase the risk for cesarean delivery.[51] The American College of Obstetricians and Gynecologists (ACOG) recommends performance of an elective cesarean delivery when the suspected birth weight exceeds 4500 g in a diabetic woman or 5000 g in a nondiabetic woman.[51,52,63]

Assessment of Fetal Well-Being

All pregnant women should receive regular antenatal care throughout their pregnancy, and fetal well-being should be evaluated at every visit. Fetal heart activity should be assessed and the fetal heart rate (FHR) estimated. A low FHR (<100 bpm) is associated with an increased risk for pregnancy loss, although congenital complete heart block should be excluded. In the latter half of pregnancy, physical examination of the abdomen should be performed to document fetal lie and presentation.

Fetal movements ("quickening") are typically reported at 18 to 20 weeks' gestation by nulliparous women and at 16 to 18 weeks' gestation by parous women; the presence of fetal movements is strongly correlated with fetal health. Although the mother appreciates only 10% to 20% of total fetal movements,[64-67] such movements are almost always present when she does report them.[67] Factors associated with a diminution in perceived fetal movements include increasing gestational age, smoking, decreased amniotic fluid volume, anterior placentation, and antenatal corticosteroid therapy. Decreased fetal movements may also be a harbinger of an adverse pregnancy event (e.g., stillbirth) that can be averted if detected early. For these reasons, a subjective decrease in perceived fetal movements in the third trimester should prompt an immediate investigation.

Published studies support the value of **fetal movement** charts ("kick counts") in the detection and prevention of fetal complications (including stillbirth) in both high- and low-risk populations.[68-73] The normal fetus exhibits an average of 20 to 50 (range of 0 to 130) gross body movements per hour, with fewer movements during the day and increased activity between 9:00 PM and 1:00 AM.[74] Several different schemes have been proposed to determine the baseline fetal activity pattern for an individual fetus after 28 weeks' gestation and to evaluate activity patterns that may represent fetal compromise. One commonly used scheme ("count-to-10") instructs the mother to rest quietly on her left side once each day in the evening (between 7:00 PM and 11:00 PM) and to record the time interval required to feel 10 fetal movements. Most patients with a healthy fetus will feel 10 movements in approximately 20 minutes; 99.5% of women with a healthy fetus feel this amount of activity within 90 minutes.[75] Under this scheme, failure to appreciate 10 fetal movements in 2 hours should prompt immediate fetal assessment. In one large clinical trial, institution of this fetal activity monitoring scheme

BOX 6-2 High-Risk Pregnancies

Maternal Factors

- Preeclampsia (gestational proteinuric hypertension)
- Chronic hypertension
- Diabetes mellitus (including gestational diabetes)
- Maternal cardiac disease
- Chronic renal disease
- Chronic pulmonary disease
- Active thromboembolic disease

Fetal Factors

- Nonreassuring fetal testing (fetal compromise)
- Fetal growth restriction
- Isoimmunization
- Intra-amniotic infection
- Known fetal structural anomaly
- Prior unexplained stillbirth
- Multiple pregnancy

Uteroplacental Factors

- Premature rupture of fetal membranes
- Unexplained oligohydramnios
- Prior classic (high vertical) hysterotomy
- Placenta previa
- Placental abruption
- Vasa previa

resulted in a significant increase in hospital visits, labor induction, and cesarean deliveries, but also in a reduction in perinatal mortality from 44.5 to 10.3 per 1000 births.[75] Taken together, these data suggest that daily or twice-daily fetal "kick counts" should be performed after 32 weeks' gestation in high-risk pregnancies. Currently there is insufficient evidence to recommend this practice in low-risk pregnancies.

PRENATAL CARE IN HIGH-RISK PREGNANCIES

Approximately 20% of all pregnancies should be regarded as high risk (Box 6-2). Because of the attendant risks to both the mother and fetus, additional efforts should be made to confirm fetal well-being throughout such pregnancies. In addition to the testing outlined previously, high-risk pregnancies should be monitored closely and regularly by a multidisciplinary team, including subspecialists in maternal-fetal medicine and neonatology, if indicated.

Goals of Antepartum Fetal Testing

The goal of antepartum fetal surveillance is the early identification of a fetus at risk for preventable neurologic injury or death. Numerous causes of neonatal cerebral injury exist, including congenital abnormalities, chromosomal abnormalities, intracerebral hemorrhage, hypoxia, infection, drugs, trauma, hypotension, and metabolic derangements (e.g., hypoglycemia, thyroid dysfunction). Antenatal fetal testing cannot reliably predict or detect all of these causes; however, those specifically associated with uteroplacental vascular insufficiency should be identified when possible. Antenatal fetal testing makes the following assumptions: (1) pregnancies may be complicated by progressive fetal asphyxia that can lead to fetal death or permanent neurologic handicap; (2) current antenatal tests can adequately discriminate between asphyxiated and nonasphyxiated fetuses; and (3) detection of asphyxia at an early stage can lead to an intervention that is capable of reducing the likelihood of an adverse perinatal outcome.

Of interest, it is not clear whether any of these assumptions are true, and nonreassuring fetal test results may reflect existing but not ongoing neurologic injury. At most, 15% of cases of cerebral palsy are thought to result from antepartum or intrapartum hypoxic-ischemic injury.[75-78] Despite these limitations, a number of antepartum tests have been developed in an attempt to identify fetuses at risk. These include the nonstress test (NST), biophysical profile (BPP), and contraction stress test (CST). Such tests can be used either individually or in combination. There is no consensus as to which of these modalities is preferred, and no single method has been shown to be superior.[1]

Antepartum Fetal Tests

All antepartum fetal tests should be interpreted in relation to the gestational age, the presence or absence of congenital anomalies, and underlying clinical risk factors.[79] For example, a nonreassuring NST in a pregnancy complicated by severe fetal growth restriction and heavy vaginal bleeding at 32 weeks' gestation has a much higher predictive value in identifying a fetus at risk for subsequent neurologic injury than an identical tracing in a well-grown fetus at 40 weeks, because of the higher prevalence of this condition in the former situation. It should be remembered that, in many cases, the efficacy of antenatal fetal testing in preventing long-term neurologic injury has not been validated by prospective randomized clinical trials. Indeed, because of ethical and medicolegal concerns, there are no studies of pregnancies at risk that include a nonmonitored control group, and it is highly unlikely that such trials will ever be performed.

Nonstress Test

The fetal nonstress test, also known as fetal cardiotocography, investigates changes in the FHR pattern with time and reflects the maturity of the fetal autonomic nervous system. For this reason, it is less useful in the extremely premature fetus (< 28 weeks) before the autonomic nervous system has matured sufficiently to influence the FHR. The NST is noninvasive, simple to perform, inexpensive, and readily available in all obstetric units. However, interpretation of the NST is largely subjective. Although a number of different criteria have been used to evaluate these tracings, most obstetric care providers have used the definitions for FHR interpretation established in 1997 by the National Institute of Child Health and Human Development (NICHD) Research Planning Workshop (Table 6-2).[80] A 2008 NIH report summarized

TABLE 6-2 Interpretation of Antepartum Nonstress Test Results

Criterion	Definition
Baseline fetal heart rate (FHR)	Defined as the approximate mean FHR during a 10-min segment and lasting at least 2 min. The normal FHR is defined as 110 to 160 bpm.
Baseline FHR variability	Described as fluctuations in the baseline FHR of ≥ 2 cycles/min. It is quantified visually as the amplitude of peak-to-trough in bpm. Variability is classified as follows: • Absent: amplitude range undetectable • Minimal: amplitude range detectable but ≤ 5 bpm • Moderate: amplitude range 6 to 25 bpm • Marked: amplitude range > 25 bpm The normal baseline FHR variability is defined as moderate variability.
Accelerations	Defined as an abrupt increase in FHR above baseline. • At and after 32 weeks' gestation, an acceleration is defined as ≥ 15 bpm above baseline for ≥ 15 sec but < 2 min. • Before 32 weeks' gestation, an acceleration is defined as ≥ 10 bpm above baseline for ≥ 10 sec but < 2 min. A **prolonged acceleration** is defined as an acceleration lasting ≥ 2 min but < 10 min. If the duration is longer than 10 min, it is referred to as a "change in baseline" and not a prolonged acceleration.
Decelerations	Decelerations are not normal. However, some decelerations are a more serious sign of fetal compromise than others. The following three types of decelerations are recognized: • **Early decelerations** are characterized by a gradual decrease and return to baseline FHR associated with a uterine contraction. The onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the uterine contraction. • **Variable decelerations** are characterized by an abrupt decrease in the FHR to ≥ 15 bpm below the baseline and lasting for ≥ 15 sec but < 2 min. Abrupt is defined as < 30 sec from baseline to the nadir of the deceleration. When variable decelerations are associated with uterine activity, their onset, depth, and duration commonly vary with successive contractions. • **Late decelerations** are characterized by a gradual decrease and return to baseline FHR associated with a uterine contraction. Importantly, the deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction. Onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the uterine contraction. A **prolonged deceleration** is defined as a deceleration lasting ≥ 2 min but < 10 min. If the duration is longer than 10 min, it is referred to as a "change in baseline" and not a prolonged deceleration. **Recurrent decelerations** describe the presence of decelerations with more than 50% of uterine contractions in any 20-min period.

Data from the National Institute of Child Health and Human Development Research Planning Workshop. Electronic fetal heart rate monitoring: research guidelines for interpretation. Am J Obstet Gynecol 1997; 177:1385-90.

terminology and nomenclature used in contemporary clinical practice. This report described a three-tier system for FHR tracing interpretation: category I (normal), category II (indeterminate), and category III (abnormal).[81]

By definition, an NST is performed before the onset of labor and does not involve invasive (intrauterine) monitoring. The test is performed by recording the FHR for a period of 20 to 40 minutes; the recording is then evaluated for the presence of periodic changes. The FHR is determined externally with use of Doppler ultrasonography, in which sound waves emitted from the transducer are deflected by movements of the heart and heart valves. The shift in frequency of these deflected waves is detected by a sensor and converted into heart rate. The FHR is printed on a strip-chart recorder running at 3 cm/min. A single mark on the FHR tracing therefore represents the average rate in beats per minute (bpm) of 6 fetal heart beats. The presence or absence of uterine contractions is typically recorded at the same time with an external tonometer. This tonometer records myometrial tone and provides information about the timing and duration of contractions, but it does not measure intrauterine pressure or the intensity of the contractions. Results of the NST are interpreted as reactive or nonreactive. An FHR tracing is designated *reactive* if there are two or more accelerations of at least 15 bpm for 15 seconds in a 20-minute period (Figure 6-3).[80-82] For preterm fetuses (<32 weeks' gestation), an FHR tracing is designated as reactive if there are two or more accelerations of at least 10 bpm for 10 seconds.

An NST is performed when formal documentation of the fetal condition is necessary. Because most healthy fetuses move within a 75-minute period, the testing period for an NST should not exceed 80 minutes.[83] The NST is most useful in cases of suspected uteroplacental insufficiency. A reactive NST is regarded as evidence of fetal health,[84,85] but the interpretation of a nonreactive NST remains controversial. Determination of a nonreactive NST must consider the gestational age, the underlying clinical circumstance, and the results of previous FHR tracings. Only 65% of fetuses have a reactive NST by 28 weeks' gestation, whereas 95% do so by 32 weeks.[79,86] However, once a reactive NST has been documented in a given pregnancy, the NST should remain reactive throughout the remainder of the pregnancy. A nonreactive NST at term is associated with poor

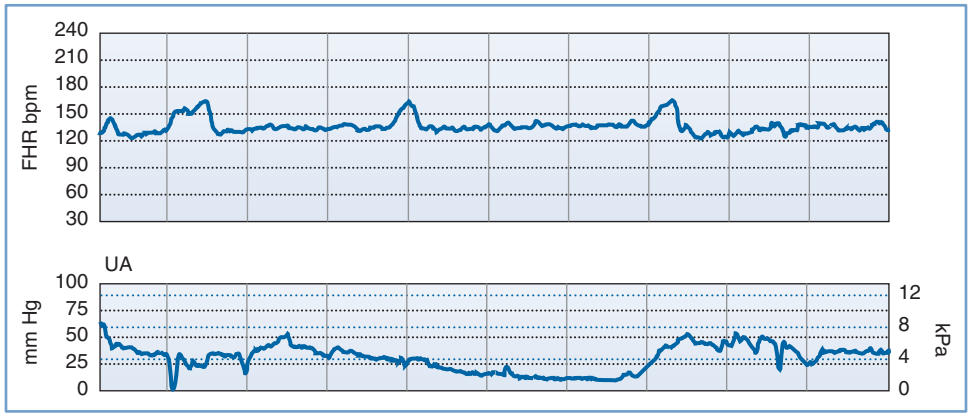

FIGURE 6-3 ■ A normal (reactive) fetal heart rate (FHR) tracing. The baseline FHR is normal (between 110 and 160 bpm), there is moderate variability (defined as 6 to 25 bpm from peak to trough), there are no decelerations, and there are two or more accelerations (defined as an increase in FHR of ≥ 15 bpm above baseline lasting at least 15 seconds) in a 20-minute period.

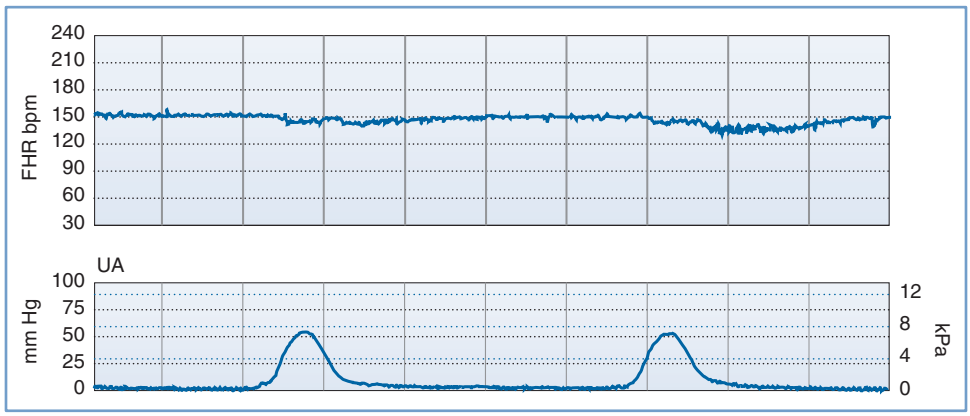

FIGURE 6-4 ■ An "at risk" fetal heart rate (FHR) tracing. The baseline FHR is normal (between 110 and 160 bpm), but the following abnormalities can be seen: minimal baseline FHR variability (defined as 0 to 5 bpm from peak to trough), no accelerations, and decelerations that are late in character (start after the peak of the contraction) and repetitive (occur with more than half of the contractions).

perinatal outcome in only 20% of cases. The significance of such a result at term depends on the clinical endpoint under investigation. If the clinical endpoint of interest is a 5-minute Apgar score less than 7, a nonreactive NST at term has a sensitivity of 57%, a positive predictive value of 13%, and a negative predictive value of 98% (assuming a prevalence of 4%). If the clinical endpoint is permanent neurologic injury, a nonreactive NST at term has a 99.8% false-positive rate.[87]

Visual interpretation of the FHR tracing involves the following components: (1) baseline FHR, (2) baseline FHR variability, (3) presence of accelerations, (4) presence of periodic or episodic decelerations, and (5) changes of FHR pattern over time. The definitions of each of these variables are summarized in Table 6-2.[80,81] The patterns are categorized as baseline, periodic (i.e., associated with uterine contractions), or episodic (i.e., not associated with uterine contractions). Periodic changes are described as *abrupt* or *gradual* (defined as onset-to-nadir time < 30 seconds or > 30 seconds, respectively). In contrast to earlier classifications, this classification makes no distinction between short-term and long-term variability, and certain characteristics (e.g., the definition of an acceleration) depend on gestational age (see Table 6-2).[80,81]

A normal FHR tracing is defined as having a normal baseline rate (110 to 160 bpm), normal baseline variability (i.e., moderate variability, defined as 6 to 25 bpm from peak to trough), presence of accelerations, and absence of decelerations. The FHR typically accelerates in response to fetal movement. Therefore, FHR accelerations usually indicate fetal health and adequate oxygenation.[80-82] At-risk FHR patterns demonstrate recurrent late decelerations with absence of baseline variability, recurrent variable decelerations with absence of baseline variability, or substantial bradycardia with absence of baseline variability (Figure 6-4). Intermediate FHR patterns have characteristics between the two extremes of normal and at risk already described.[80,81]

Persistent fetal tachycardia (defined as an FHR > 160 bpm) may be associated with fetal hypoxia, maternal fever, chorioamnionitis (intrauterine infection), administration of an anticholinergic or beta-adrenergic receptor agonist, fetal anemia, or tachyarrhythmia. Persistent fetal bradycardia (FHR < 110 bpm) may be a result of congenital heart block, administration of a beta-adrenergic receptor antagonist, hypoglycemia, or hypothermia (Table 6-3). However, it may also indicate fetal hypoxia.[80,81] Both tachyarrhythmias and bradyarrhythmias require immediate evaluation.

TABLE 6-3 Drugs That Affect the Fetal Heart Rate Tracing

Effect on the Fetus	Drug
Fetal tachycardia	Atropine
	Epinephrine (adrenaline)
	Beta-adrenergic agonists (ritodrine, terbutaline)
Fetal bradycardia	Antithyroid medications (including propylthiouracil)
	Beta-adrenergic antagonists (e.g., propranolol)
	Intrathecal or epidural analgesia
	Methylergonovine (contraindicated prior to delivery)
	Oxytocin (if associated with excessive uterine activity)
Sinusoidal fetal heart rate pattern	Systemic opioid analgesia
Diminished variability	Atropine
	Anticonvulsants (but not phenytoin)
	Beta-adrenergic antagonists
	Antenatal corticosteroids (betamethasone, dexamethasone)
	Ethanol
	General anesthesia
	Hypnotics (including diazepam)
	Insulin (if associated with hypoglycemia)
	Magnesium sulfate
	Systemic opioid analgesia
	Promethazine

Baseline FHR variability, perhaps the most important component of the NST, is determined on a beat-to-beat basis by the competing influences of the sympathetic and parasympathetic nervous systems on the fetal sinoatrial node. A variable FHR, characterized by fluctuations that are irregular in both amplitude and frequency,[80,81] indicates that the autonomic nervous system is functioning and that the fetus has normal acid-base status. *Variability* is defined as absent, minimal, moderate, or marked (see Table 6-2) (Figure 6-5).[80,81] The older terms *short-term variability* and *long-term variability* are no longer used.[81] Normal (moderate) variability indicates the absence of cerebral hypoxia. With acute hypoxia, variability may be minimal or marked. Persistent or chronic hypoxia is typically associated with loss of variability. Reduced variability also may be the result of other factors, including maternal drug administration (see Table 6-3), fetal arrhythmia, and neurologic abnormality (e.g., anencephaly).[1,80,81]

Vibroacoustic Stimulation

Fetal vibroacoustic stimulation (VAS) refers to the response of the FHR to a vibroacoustic stimulus (82 to 95 dB) applied to the maternal abdomen for 1 to 2 seconds in the region of the fetal head. An FHR acceleration in response to VAS represents a positive result and is suggestive of fetal health. VAS is a useful adjunct to shorten the time needed to achieve a reactive NST and to decrease the proportion of nonreactive NSTs at term, thereby precluding the need for further testing. In one study of low-risk women at term, VAS reduced the proportion of nonreactive NSTs over a 30-minute period by 50% (from 14% to 9%) and shortened the time needed to achieve a reactive NST by an average of 4.5 minutes.[88] VAS has no adverse effect on fetal hearing. The absence of an FHR acceleration in response to VAS at term is associated with an 18-fold higher risk for nonreassuring fetal testing in labor[89] and a 6-fold higher risk for cesarean delivery.[90]

Biophysical Profile

An NST alone may not be sufficient to confirm fetal well-being. In such cases, a biophysical profile (BPP) may be performed. The BPP is an ultrasonographic scoring system performed over a 30- to 40-minute period designed to assess fetal well-being. Initially described for testing of the post-term fetus, the BPP has since been validated for use in both term and preterm fetuses, but not during active labor.[91-97] The five variables described in the original BPP were (1) gross fetal body movements, (2) fetal tone (i.e., flexion and extension of limbs), (3) amniotic fluid volume, (4) fetal breathing movements, and (5) the NST.[97] More recently, the BPP has been interpreted without the NST (Table 6-4).

The individual variables of the BPP become apparent in the normal fetus in a predictable sequence: fetal tone appears at 7.5 to 8.5 weeks' gestation, fetal movement at 9 weeks, fetal breathing at 20 to 22 weeks, and FHR reactivity at 24 to 28 weeks. In the setting of antepartum hypoxia, these characteristics typically disappear in the reverse order of their appearance (i.e., FHR reactivity is lost first, followed by fetal breathing, fetal movements, and finally fetal tone).[93] The amniotic fluid volume, which is composed almost entirely of fetal urine in the second and third trimesters, is not influenced by acute fetal hypoxia or acute fetal central nervous system dysfunction. Rather, oligohydramnios (decreased amniotic fluid volume) in the latter half of pregnancy and in the absence of ruptured membranes is a reflection of chronic uteroplacental insufficiency and/or increased renal artery resistance leading to diminished urine output.[98] It predisposes to umbilical cord compression, thus leading to intermittent fetal hypoxemia, meconium passage, or meconium aspiration. Adverse pregnancy outcome (including a nonreassuring FHR tracing, low Apgar scores, and/or admission to the neonatal intensive care unit) is more common when oligohydramnios is present.[98-101] Weekly or twice-weekly screening of high-risk pregnancies for oligohydramnios is important because amniotic fluid can become drastically reduced within 24 to 48 hours.[102]

Although each of the five features of the BPP are scored equally (2 points if the variable is present or normal and 0 points if absent or abnormal, for a total of 10 points), they are not equally predictive of adverse

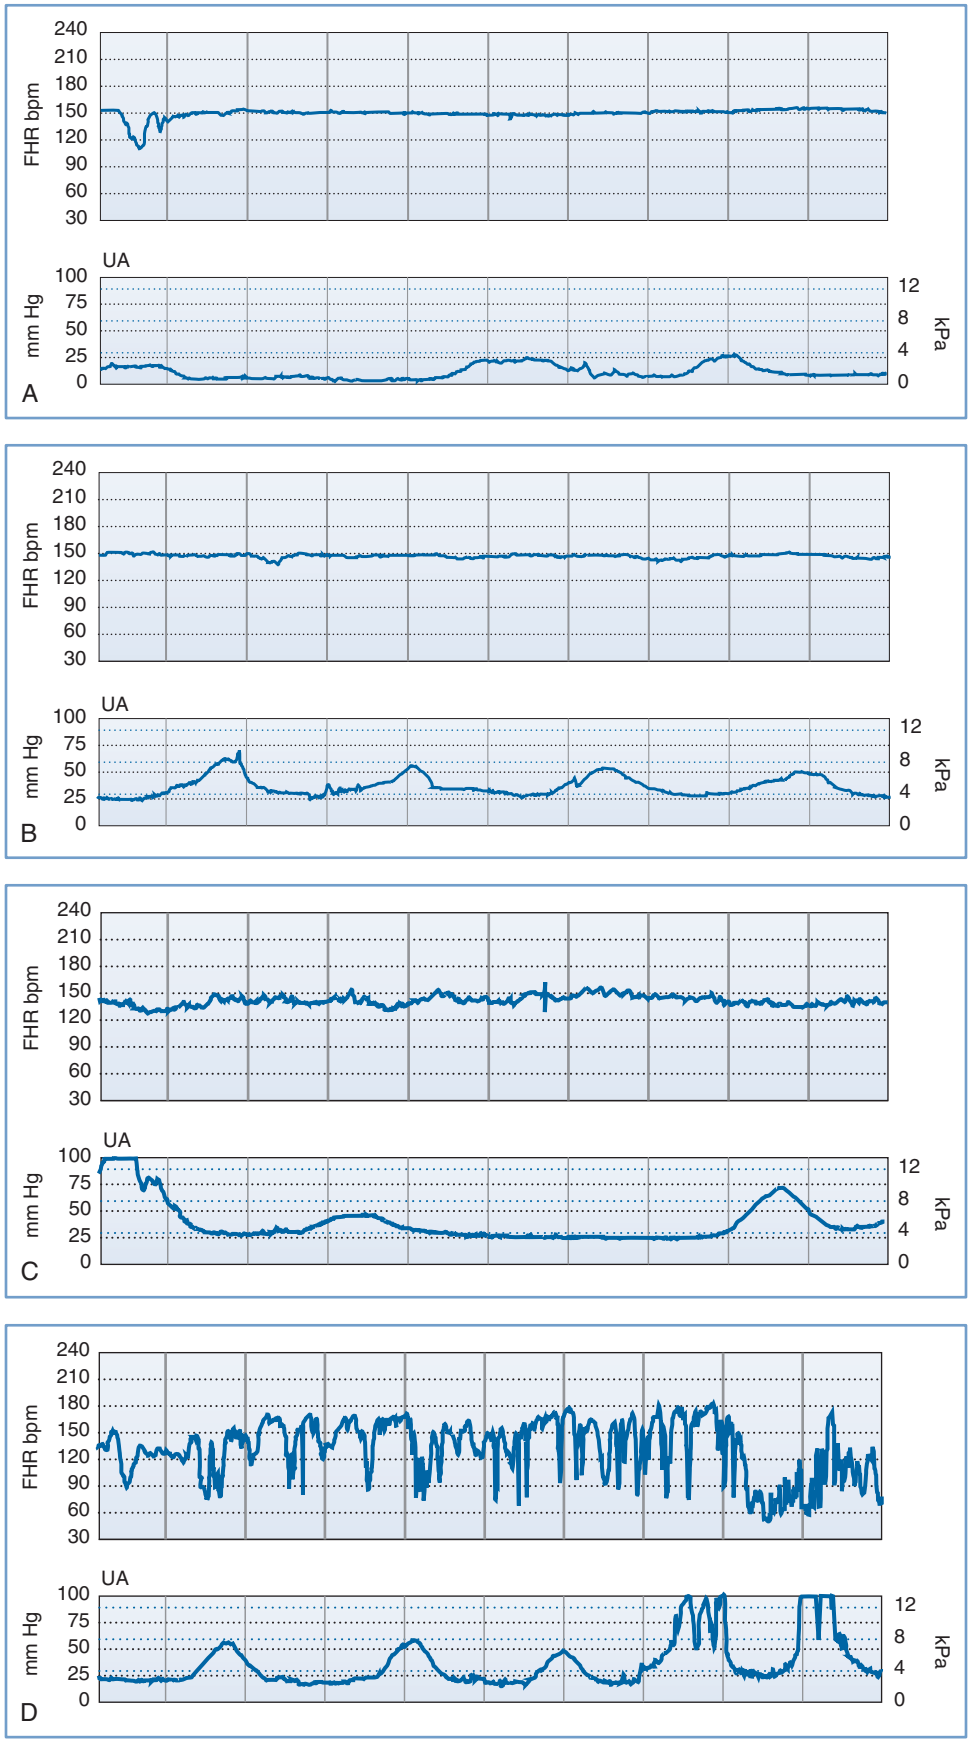

FIGURE 6-5 ■ Components of baseline fetal heart rate (FHR) variability. **A,** Absence of variability. **B,** Minimal variability (0 to 5 bpm from peak to nadir). **C,** Moderate variability (6 to 25 bpm from peak to nadir). **D,** Marked variability (> 25 bpm from peak to nadir).

TABLE 6-4 Characteristics of the Biophysical Profile

Biophysical Variable	Normal Score (Score = 2)	Abnormal Score (Score = 0)
Fetal breathing movements (FBMs)	At least one episode of FBM lasting at least 30 sec	Absence of FBM altogether or no episode of FBM lasting ≥ 30 sec
Gross body movements	At least three discrete body/limb movements in 30 min (episodes of active continuous movements should be regarded as a single movement)	Fewer than three episodes of body/limb movements over a 30-min period
Fetal tone	At least one episode of active extension with return to flexion of fetal limbs or trunk; opening and closing of hand are considered normal tone	Slow extension with return to partial flexion, movement of limb in full extension, or absence of fetal movements
Qualitative amniotic fluid (AF) volume	At least one pocket of AF that measures ≥ 1 cm in two perpendicular planes	No AF pockets or an AF pocket measuring < 1 cm in two perpendicular planes
Reactive nonstress test	At least two episodes of FHR acceleration of ≥ 15 bpm lasting ≥ 15 sec associated with fetal movements over 30 min of observation	Fewer than two episodes of FHR accelerations or accelerations of < 15 bpm over 30 min of observation

TABLE 6-5 Recommended Management Based on Biophysical Profile

Score	Interpretation	Recommended Management
8 or 10	Normal	No intervention
6	Suspect asphyxia	Repeat in 4 to 6 h Consider delivery for oligohydramnios
4	Suspect asphyxia	If ≥ 36 weeks' gestation or mature pulmonary indices, deliver immediately If < 36 weeks' gestation, repeat BPP in 4 to 6 h versus delivery with mature pulmonary indices If score persistently ≤ 4, deliver immediately
0 or 2	High suspicion of asphyxia	Evaluate for immediate delivery

Data from Manning FA. Fetal biophysical assessment by ultrasound. In Creasy RK, Resnik R, editors. Maternal-Fetal Medicine: Principles and Practice. 2nd edition. Philadelphia, WB Saunders, 1989:359.

pregnancy outcome. For example, amniotic fluid volume is the variable that correlates most strongly with adverse pregnancy events. The management recommended on the basis of the BPP score is summarized in Table 6-5.[97] A score of 8 or 10 is regarded as reassuring; a score of 4 or 6 is suspicious and requires reevaluation; and a score of 0 or 2 suggests nonreassuring fetal status (previously referred to as "fetal distress").[91,92] Evidence of nonreassuring fetal status should prompt evaluation for immediate delivery.[93,94]

Contraction Stress Test

Also known as the oxytocin challenge test (OCT), the contraction stress test is an older test of uteroplacental function. It assesses the response of the FHR to uterine contractions induced by either intravenous oxytocin administration or nipple stimulation (which causes release of endogenous oxytocin from the maternal neurohypophysis). A minimum of three contractions of minimal-to-moderate strength in 10 minutes is required to interpret the test. A negative CST (no decelerations with contractions) is reassuring and suggestive of a healthy, well-oxygenated fetus. A positive CST (repetitive late or severe variable decelerations with contractions with at least 50% of the contractions) is suggestive of a fetus suffering from impaired maternal-to-fetal oxygen exchange during uterine contractions and is associated with adverse perinatal outcome in 35% to 40% of cases (Figure 6-6). The combination of a positive CST and absence of FHR variability is especially ominous. Consideration should be given to immediate and urgent delivery of a fetus with a positive CST, with or without FHR variability. It should be noted, however, that the false-positive rate of this test exceeds 50%.[84] If the CST is uninterpretable or equivocal, the test should be repeated in 24 to 72 hours. Studies suggest that more than 80% of results of repeated tests are negative. The rate of antepartum intrauterine fetal demise within 1 week of a negative CST is 0.04%.[84,97]

Because this test is time consuming, requires skilled nursing care, and necessitates an inpatient setting owing to the possibility of precipitating fetal compromise requiring emergency cesarean delivery, the CST is reserved for specific clinical indications. Moreover, there are a number of contraindications to its use, including placenta previa, placental abruption, prior classic (high-vertical) cesarean delivery, and risk for preterm labor. Despite these limitations, the CST allows for indirect evaluation of fetal oxygenation during periods of uterine contractions and diminished uteroplacental perfusion and may therefore provide a better assessment of fetal well-being and fetal reserve than either the NST or the BPP (Table 6-6).[1,84,95,103]

Umbilical Artery Doppler Velocimetry

Doppler velocimetry shows the direction and characteristics of blood flow and can be used to examine the maternal, uteroplacental, or fetal circulation. The umbilical artery is one of the few arteries that normally has diastolic flow and consequently is one of the vessels most frequently evaluated during pregnancy. Umbilical artery

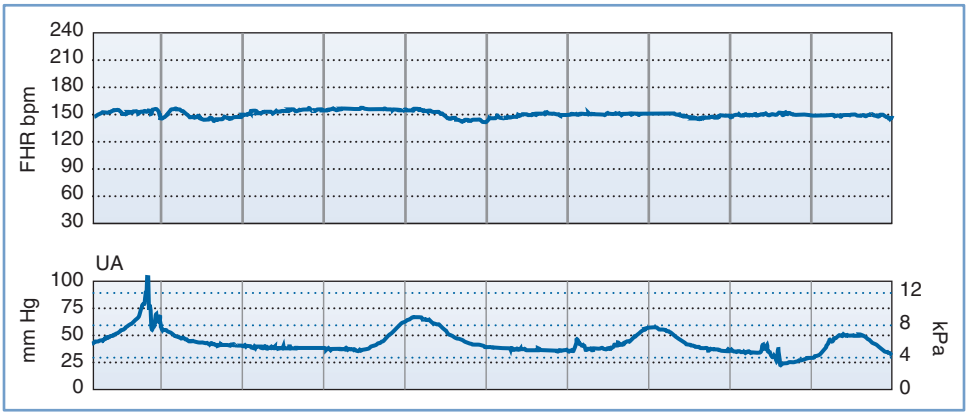

FIGURE 6-6 ■ A positive contraction stress test (CST) result. There are at least three contractions in a 10-minute period. The baseline fetal heart rate (FHR) is 130 bpm, there is minimal baseline FHR variability (defined as 0 to 5 bpm from peak to trough), and there are decelerations that are late in character (start after the peak of the contraction) and repetitive (occur with more than half of the contractions).

TABLE 6-6 False-Positive and False-Negative Rates for the Nonstress Test, Biophysical Profile, and Contraction Stress Test

Test	False-Positive Rate (%)	False-Negative Rate (per 1000 live births)*
Nonstress test (NST)	58	1.4 to 6.2
Biophysical profile (BPP):		0.7 to 1.2
• Score 6/10	45	
• Score 0/10	0	
Contraction stress test (CST)	30	0.4 to 0.6

*Data are presented as perinatal mortality rate within 1 wk of a reactive NST, a BPP score of 8 or 10, or a negative CST after adjustments for congenital anomalies and known causes.

Data from references 1, 84, 95, and 103.

Doppler velocimetry measurements reflect resistance to blood flow from the fetus to the placenta. Normally, umbilical artery resistance falls progressively throughout pregnancy, reflecting the increase in number of tertiary stem vessels. Factors that affect placental vascular resistance include gestational age, placental location, pregnancy complications (e.g., placental abruption, preeclampsia), and underlying maternal disease (chronic hypertension).

Doppler velocimetry of umbilical artery blood flow provides an indirect measure of fetal status. Decreased diastolic flow with a resultant increase in the systolic-to-diastolic (S/D) ratio suggests an increase in placental vascular resistance and fetal compromise. Severely abnormal umbilical artery Doppler velocimetry (defined as absence of or reversed diastolic flow) is an especially ominous observation and is associated with poor perinatal outcome in the setting of fetal growth restriction (Figure 6-7).[104-108] The role of ductus venosus and/or middle cerebral artery (MCA) Doppler velocimetry in the management of fetal growth restriction pregnancies is not well defined. Preparation for delivery—including administration of corticosteroids for fetal lung maturity and transfer to a tertiary delivery center—should be considered when Doppler findings are severely abnormal in the setting of fetal growth restriction, regardless of gestational age. However, in the presence of a normally grown fetus, it is unclear how to interpret such findings. For these reasons, umbilical artery Doppler velocimetry should not be performed routinely in women at low risk for fetal abnormalities. Appropriate indications include fetal growth restriction, cord malformations, unexplained oligohydramnios, suspected or established preeclampsia, and, possibly, fetal cardiac anomalies.

Umbilical artery Doppler velocimetry has not been shown to be useful in the evaluation of some high-risk pregnancies, including diabetic and post-term pregnancies, primarily owing to a high false-positive rate.[2,109-112] Thus, in the absence of fetal growth restriction, obstetric management decisions are not usually made on the basis of Doppler velocimetry findings alone. New applications for Doppler technology include the use of MCA peak systolic velocity for the noninvasive evaluation of fetal anemia resulting from isoimmunization. When severe anemia develops in a fetus, blood is preferentially shunted to the vital organs, such as the brain, and the shunt can be demonstrated by an increase in MCA peak systolic flow velocity.[113] This finding can help the perinatologist counsel affected patients about the need for cordocentesis and fetal blood transfusion. Doppler studies of other vessels (including the uterine artery, fetal aorta, ductus venosus, and fetal carotid arteries) have contributed to our knowledge of maternal-fetal physiology but as yet have resulted in few clinical applications.

Multiple Modalities to Assess Fetal Well-Being

All standard tests to assess antepartum fetal well-being (i.e., NST, BPP, CST) are evaluated according to their ability to predict the absence of fetal death during the 1-week period after the test. The false-negative rate (defined as a reassuring test result with a subsequent bad outcome) and false-positive rate (an abnormal result with a subsequent normal outcome) for each of these tests are listed in Table 6-6.[1,84,95,103] The false-negative rates for all

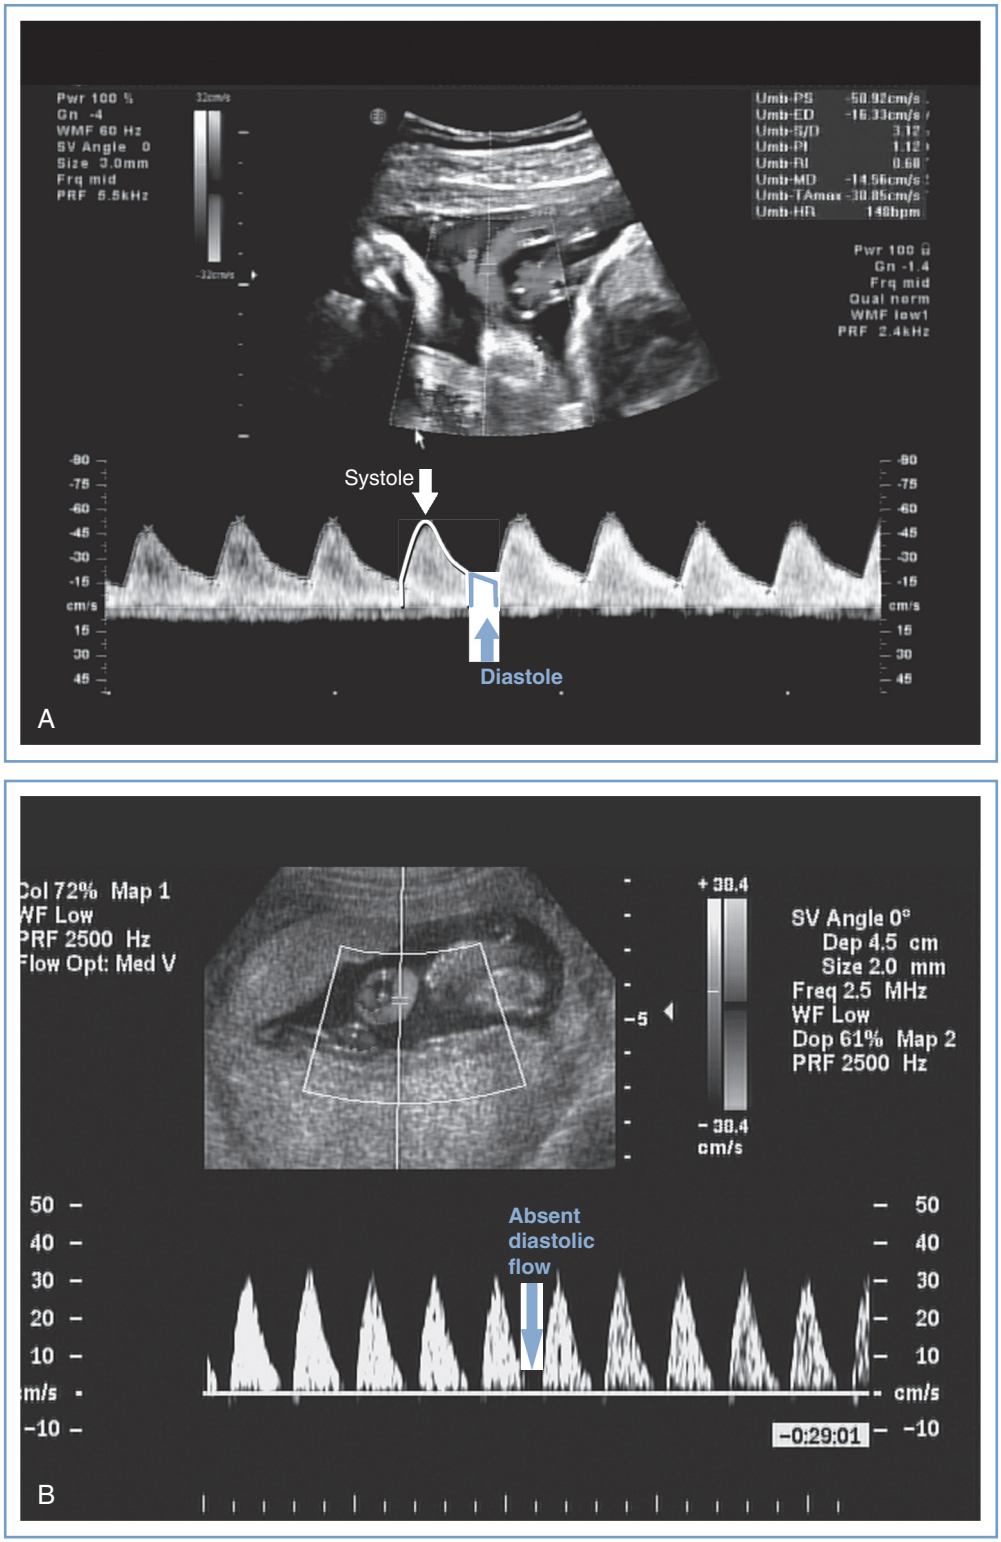

FIGURE 6-7 ■ Umbilical artery Doppler velocimetry. **A,** Normal waveform in the umbilical artery as shown on Doppler velocimetry. Forward flow can be seen during both fetal systole and diastole. **B,** Absent end-diastolic flow. Forward flow can be seen during systole, but there is no flow during diastole.

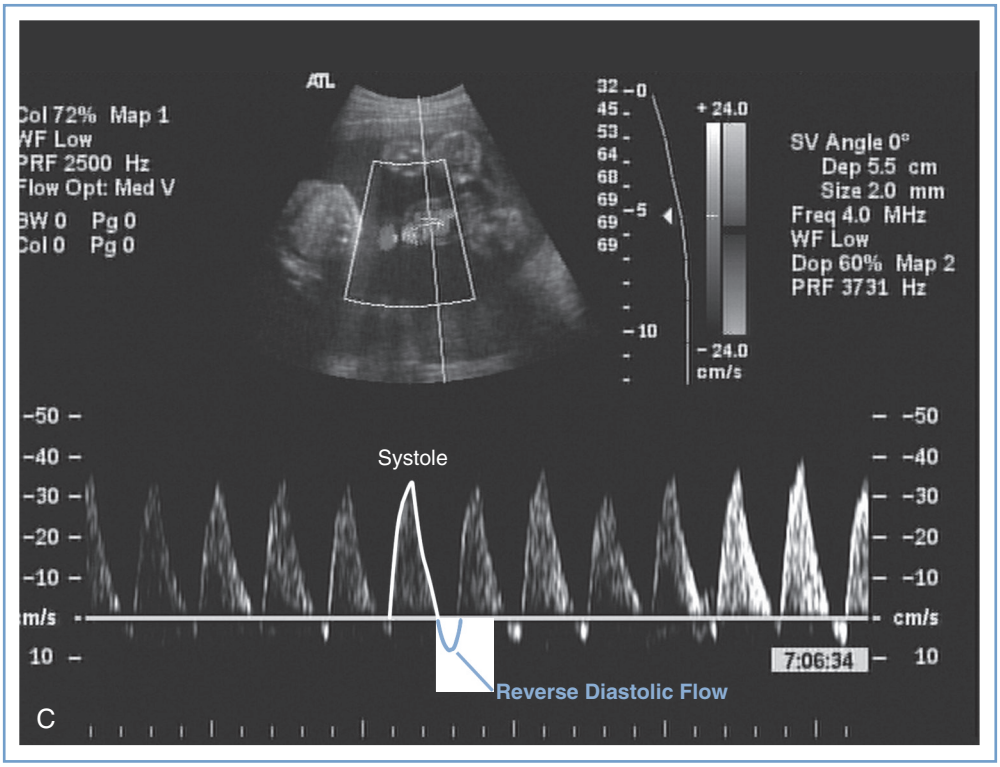

FIGURE 6-7, cont'd ■ C, Reverse diastolic flow. Forward flow can be seen during systole, but there is reverse flow in the umbilical artery during diastole, which is suggestive of high resistance to blood flow in the placenta.

three tests are relatively low. Because the NST has a high false-positive rate, some authorities consider it a screening test to identify fetuses requiring further assessment with either a BPP or a CST. No method of fetal assessment is perfect, and clinical judgment plays a large role in any management decision.

SPECIAL TECHNIQUES FOR ANTEPARTUM FETAL SURVEILLANCE

Perinatal Ultrasonography

Ultrasonography uses high-frequency sound waves (3.5 to 5 MHz for transabdominal transducers and 5 to 7.5 MHz for transvaginal transducers) that are directed into the body by a transducer, reflected by maternal and fetal tissue, detected by a receiver, processed, and displayed on a screen. Increasing the wave frequency results in greater display resolution at the expense of diminished tissue penetration. Interpretation of images requires operator experience. Widespread clinical application of two-dimensional ultrasonography began in the 1960s after pioneering work by researchers in the United States and Great Britain.[114] Although no deleterious biologic effects have been associated with obstetric ultrasonography, the rates of false-positive and false-negative diagnoses based on the images are a major limitation.

Perinatal ultrasonography can be classified broadly into three types of examinations: basic, targeted (comprehensive), and limited. The **basic examination** (level I) involves determination of fetal number, viability, position, gestational age, and gross malformations. Placental location, amniotic fluid volume, and the presence of abnormal maternal pelvic masses can be evaluated as well.[20] Most pregnancies can be evaluated adequately with this type of examination alone. If the patient's history, physical findings, or basic ultrasonographic results suggest the presence of a fetal malformation, an ultrasonographer who is skilled in fetal evaluation should perform a **targeted** or **comprehensive examination** (level II). During a targeted ultrasonographic examination, which is best performed at 18 to 20 weeks' gestation, fetal structures are examined in detail to identify and characterize any fetal malformation. Ultrasonographic markers of fetal aneuploidy (see later discussion) can be evaluated as well. In some situations, a **limited examination** may be appropriate to answer a specific clinical question (e.g., fetal viability, amniotic fluid volume, fetal presentation, placental location, cervical length) or to provide ultrasonographic guidance for an invasive procedure (e.g., amniocentesis).

Current debate centers on identifying those patients who would benefit from an ultrasonographic evaluation and determining what type of evaluation would be optimal. Advocates of the universal application of ultrasonography cite the advantages of more accurate dating of pregnancy (see earlier discussion) and earlier and more accurate diagnosis of multiple gestation, structural malformations, and fetal aneuploidy (see later discussion). Opponents of routine ultrasonographic examination view it as an expensive screening test ($100 to $250 for a basic

examination) that is not justified by published research, which suggests that routine ultrasonography does not change perinatal outcome significantly.[19,26,27] Although routine ultrasonography for all low-risk pregnant women is controversial, few would disagree that the benefits far outweigh the costs for selected patients. The ACOG[20] has recommended that the benefits and limitations of ultrasonography should be discussed with all pregnant women.

First-trimester ultrasonography is indicated to confirm an intrauterine pregnancy (i.e., exclude ectopic pregnancy), confirm fetal viability, document fetal number, estimate gestational age, and evaluate the maternal pelvis and ovaries.

Second-trimester ultrasonography is indicated in patients with an uncertain LMP date, uterine size larger or smaller than expected for the estimated gestational age, a medical disorder that can affect fetal growth and development (e.g., diabetes, hypertension, collagen vascular disorders), a family history of an inherited genetic abnormality, and suspected fetal malformation or growth disturbance.[20] Most patients undergo a detailed fetal anatomic survey at 18 to 20 weeks' gestation to screen for structural defects. An understanding of normal fetal physiology is critical to the diagnosis of fetal structural anomalies. Placental location should be documented with the maternal bladder empty, because overdistention of the bladder or a lower uterine contraction can give a false impression of placenta previa. If placenta previa is identified at 18 to 22 weeks' gestation, serial ultrasonographic examinations should be performed to follow placental location. Only 5% of cases of placenta previa identified in the second trimester persist to term.[115] The umbilical cord should also be imaged and the number of vessels, placental insertion, and fetal insertion should be noted. Evaluation of the amniotic fluid volume should also be done. In pregnancies at high risk for fetal cardiac anomalies or preterm birth, fetal echocardiography and cervical length measurements, respectively, should be performed.

The indications for **third-trimester ultrasonography** are similar to those for second-trimester ultrasonography. Fetal anatomic surveys and EFW become less accurate with greater gestational age, especially in obese women or pregnancies complicated by oligohydramnios. Fetal biometry and detailed anatomic surveys are still performed in late gestation, because certain fetal anomalies (e.g., achondroplasia, duodenal atresia) may become evident for the first time during this period. Transvaginal ultrasonographic measurement of cervical length (performed to identify women at risk for preterm birth) is of little use after 30 to 32 weeks' gestation.[116]

Screening for Fetal Chromosomal Abnormalities

Fetal chromosomal abnormalities are a major cause of perinatal morbidity and mortality, accounting for 50% of first-trimester spontaneous abortions, 6% to 12% of all stillbirths and neonatal deaths, and 10% to 15% of structural anomalies in live-born infants.[117] The most common aneuploidy encountered during pregnancy (autosomal trisomy) results primarily from nondisjunction during meiosis I, an event that occurs with growing frequency in older women. Women of advanced maternal age (> 35 years or older at EDD) are at higher risk for having a pregnancy complicated by fetal aneuploidy and are routinely offered noninvasive prenatal screening as well as an invasive diagnostic procedure, either amniocentesis or chorionic villus sampling (CVS). However, because only 8% to 12% of all births occur in women age 35 and older, at most 20% to 25% of all cases of trisomy 21 (Down syndrome) would be identified if all women of advanced maternal age agreed to amniocentesis.[118] Many older women are now opting for serum analyte screening for fetal aneuploidy, which is equally accurate in older women.[119] All women, regardless of age, should be offered aneuploidy screening during early gestation.[117]

Second-Trimester Fetal Aneuploidy Screening

Methods have been developed to help identify women at high risk for fetal aneuploidy. The major focus of attention has been the detection of Down syndrome, because it is the most common chromosomal abnormality manifesting at term and because, unlike the less common disorders trisomy 13 and 18, its diagnosis can be very difficult to make with ultrasonography. In all of these screening tests, one or more serum analytes are used to adjust the *a priori* risk for fetal aneuploidy in a given pregnancy, which depends primarily on maternal age. The maternal serum analytes used most commonly in second-trimester aneuploidy screening protocols are maternal serum alpha-fetoprotein (MS-AFP), total or free β-subunit hCG (β-hCG), unconjugated estriol, and dimeric inhibin A (collectively known as the quadruple or "quad" screen). Screening results are reported as positive or negative. If the adjusted risk for fetal aneuploidy exceeds the age-related risk at age 35 or the rate of amniocentesis procedure-related pregnancy loss, which is currently defined as 1 in 300 to 500 (i.e., if the chance of finding a chromosomal abnormality on fetal karyotype is higher than the risk of the invasive procedure), then genetic amniocentesis is recommended.[120] If all screen-positive women undergo amniocentesis and if the fetal karyotype analysis is successful in all cases, this protocol can identify 60% of all Down syndrome cases with a screen-positive (amniocentesis) rate of approximately 5%. Older women are more likely to be screen positive but also have higher detection rates. In women older than 35 years, this protocol identifies 75% of aneuploid fetuses with a screen-positive rate of approximately 25%.[118,121,122]

Second-Trimester Ultrasonographic Screening for Fetal Aneuploidy

Second-trimester ultrasonographic markers, such as intracardiac echogenic focus and echogenic bowel (Table 6-7), are not generally incorporated into standard algorithms to predict risk for fetal aneuploidy; however, a risk adjustment based on ultrasonographic markers can be made. Multiple major structural abnormalities, such as those often found in fetuses with trisomy 13 or 18,

TABLE 6-7 **Accuracy Measurements of Second-Trimester Ultrasonographic "Soft Markers" for Trisomy 21 (Down Syndrome) When Identified as Isolated Anomalies**

Ultrasonographic Marker	Sensitivity (95% CI)	Specificity (95% CI)	Positive LR (95% CI)	Negative LR (95% CI)
Thickened nuchal fold	0.04 (0.02-0.10)	0.99 (0.99-0.99)	17 (8.0-38.0)	0.97 (0.94-1.00)
Choroid plexus cyst	0.01 (0.00-0.03)	0.99 (0.97-1.00)	1.00 (0.12-9.40)	1.00 (0.97-1.00)
Short femur length	0.16 (0.05-0.40)	0.96 (0.94-0.98)	2.7 (1.2-6.0)	0.87 (0.75-1.00)
Short humeral length	0.09 (0.00-0.60)	0.97 (0.91-0.99)	7.5 (4.7-12.0)	0.87 (0.67-1.10)
Echogenic bowel	0.04 (0.01-0.24)	0.99 (0.97-1.00)	6.1 (3.0-12.6)	1.00 (0.98-1.00)

CI, confidence interval; LR, likelihood ratio.
Data from Smith-Bindman P, Hosmer W, Feldstein VA, et al. Second-trimester ultrasound to detect fetuses with Down syndrome: a meta-analysis. JAMA 2001; 285:1044-55; and Vintzeleos AM, Campbell WA, Rodis JF, et al. The use of second-trimester genetic sonogram in guiding clinical management of patients at increased risk for fetal trisomy 21. Obstet Gynecol 1996; 87:948-52.

can be detected reliably by perinatal ultrasonography. Approximately 50% of fetuses with Down syndrome appear structurally normal on ultrasonography.[123] Several major structural ultrasonographic abnormalities (e.g., endocardial cushion defect) may be associated with trisomy 21 in more than 30% of cases.[123-125] The clinical significance of an isolated "soft" ultrasonographic marker for Down syndrome in a low-risk population is unclear.

First-Trimester Fetal Aneuploidy Screening

First-trimester fetal aneuploidy screening is a more recent development. The screening protocol involves the following three steps undertaken at 11 to 14 weeks' gestation: (1) maternal serum analyte screening for pregnancy-associated placental protein-A (PAPP-A) and total or free β-hCG, (2) ultrasonographic assessment of nuchal translucency, and (3) genetic counseling.[126] The measurement of free rather than total β-hCG provides a small statistical advantage without apparent clinical benefit.[127] First-trimester aneuploidy screening appears to be as good as second-trimester serum analyte screening in identifying fetuses with Down syndrome.[128,129] The serum analytes in the first trimester associated with an increased risk for Down syndrome include a decrease in PAPP-A (< 0.4 multiples of the median [MoM]) and an increase in free hCG (> 1.8 MoM). *Nuchal translucency* is defined as the fluid-filled space between the back of the fetal neck and the overlying skin. Proper training and technique are needed to obtain this measurement. There is a correlation between an increased nuchal translucency measurement and a risk for Down syndrome.

The advantage of first-trimester aneuploidy screening is that it is performed early in pregnancy, allowing for more counseling, the option of CVS, and early pregnancy termination if desired. The screening test most commonly used in Europe for identifying pregnancies at risk for Down syndrome is the "integrated" test, which combines first-trimester aneuploidy screening with second-trimester serum analyte screening into a single adjusted risk in the mid to late second trimester. The integrated test can identify 85% to 90% of fetuses with Down syndrome with a false-positive rate of 2% (Table 6-8).[129-135] However, the true application of the integrated screening test requires that the first-trimester test results, *even if abnormal*, be withheld from the patient until combined with the second-trimester test results; this practice of withholding information has generated controversy, particularly in the United States. To overcome this objection, *sequential* and *contingent* integrated screening tests have been developed, whereby the second-trimester test is performed after disclosure of the first-trimester screening result or if the first test result is abnormal, respectively. It remains unclear, however, whether the detection rates for these integrated tests are any better than those of the first-trimester screening test alone (see Table 6-8).[129-132] Indeed, if the first-trimester aneuploidy screen result is negative (indicating low risk), the sensitivity of second-trimester serum analyte screening is reduced fivefold.[136] For this reason, many authorities suggest that no further aneuploidy screening be done if the first-trimester screen result is negative, with the exception of the second-trimester fetal anatomic survey and possibly isolated MS-AFP serum screening for open neural tube defects at 15 to 20 weeks' gestation.

In addition to the nuchal translucency measurement, absence of the nasal bone on first-trimester ultrasonography has been correlated with Down syndrome. However, whether this ultrasonographic marker adds to the predictive value of first-trimester risk assessment in either low- or high-risk populations has been questioned.[137,138] At this time, the presence or absence of the nasal bone is not included in the first-trimester screening test.

Risk assessment for Down syndrome can be performed in twin pregnancies using either first- or second-trimester serum analyte measurements but is less accurate than in singleton pregnancies.[132] Such screening has not been validated for use in higher-order multiple pregnancies (triplets and up) or in multiple pregnancies with a nonviable fetus (either due to spontaneous demise or following a multifetal pregnancy reduction). In such cases, Down syndrome risk assessment can be achieved using first-trimester nuchal translucency measurements only, although this is not a particularly good screening test and has a lower sensitivity even than nuchal translucency alone in singleton pregnancies.[132]

TABLE 6-8 **Detection Rate of Down Syndrome Screening Tests**

Screening Test	Detection Rate (%)*	False-Positive Rate (%)†
Maternal age > 35 yr	30-40	10-15
First Trimester		
NT assessment	64-70	5-10
NT assessment, PAPP-A, and total or free β-hCG measurements	82-87	5-6
Second Trimester		
Triple screen (measurements of MS-AFP, total or free β-hCG, unconjugated estriol)	69-77	9
Quadruple screen (measurements of MS-AFP, total or free β-hCG, unconjugated estriol, inhibin A)	79-83	6
Combined First and Second Trimesters		
Integrated (NT assessment, PAPP-A measurement, quadruple screen)	93-96	1-2
Serum integrated (APP-A measurement, quadruple screen)	84-88	2-3
Stepwise sequential: • If first-trimester test result positive, diagnostic test offered • If first-trimester test result negative, second-trimester test offered, and final risk assessment incorporates both first- and second-trimester results	84-95	1
Contingent sequential: • If first-trimester test result positive, diagnostic test offered • If first-trimester test result negative, no further testing • If first-trimester test result intermediate, second-trimester test offered, and final risk assessment incorporates both first- and second-trimester results	88-94	1

β-hCG, beta-human chorionic gonadotropin; *MS-AFP,* maternal serum level of alpha-fetoprotein; *NT,* nuchal translucency; *PAPP-A,* pregnancy-associated placental protein-A.

Definitive Diagnosis of Fetal Chromosomal Abnormalities

Although an abnormal screening test result or the presence of ultrasonographic abnormalities may signal an increased risk for Down syndrome or other chromosomal abnormality, the majority of fetuses with such findings are chromosomally normal. To provide a definitive diagnosis, an invasive procedure is needed to obtain the fetal karyotype; generally amniocentesis or CVS is used, although in rare cases a cordocentesis is performed.

All invasive procedures are associated with risks to the pregnancy. Risks common to all invasive procedures include the chance of bleeding, isoimmunization (especially in women who are Rh negative), and infection. All women who are Rh negative should receive Rh_0(D) immune globulin before or after the procedure. Although the risk for vertical transmission of viral infections (e.g., hepatitis B, hepatitis C, human immunodeficiency virus) with invasive procedures is believed to be low,[139] every effort should be made to avoid invasive procedures in such patients, especially if there is a high viral load in the maternal circulation.

Amniocentesis

Amniotic fluid is composed of fetal urine, lung fluid, skin transudate, and water that is filtered across the amniotic membranes. It contains electrolytes, proteins, and desquamated fetal cells (amniocytes). Sampling of amniotic fluid **(amniocentesis)** can be used to measure various substances such as lecithin and sphingomyelin for assessing fetal lung maturity, to look for pathogenic bacteria for confirmation of an intra-amniotic infection, and to obtain fetal cells for determination of fetal karyotype or performance of specific genetic analyses.

Cell culture with karyotype analysis typically takes 10 to 14 days, although a small chance exists that the cells will fail to grow, resulting in an inconclusive result. Fluorescence *in situ* hybridization (FISH) does not require that the cells be cultured for any length of time, and its results can be obtained within a few days. This technique uses a series of chromosome-specific fluorescent probes to analyze the metaphase spread in fetal cells to determine fetal gender and detect common trisomies (21, 18, 13, X, and Y). It can also be used to identify chromosome deletions or duplications in pregnancies at risk for a specific genetic disorder because of a family history or suspicious ultrasonographic findings, such as the 22q11 deletion in DiGeorge's syndrome.[140-142] Although FISH is highly sensitive (trisomy present on FISH testing is invariably present in the fetus), it is not particularly specific, with a false-negative rate of approximately 15%. For this reason, the American College of Medical Genetics (ACMG) and the American Society of Human Genetics (ASHG) recommend that all FISH results be confirmed by complete karyotype analysis.[142]

The most common indication for second-trimester amniocentesis is cytogenetic analysis of fetal cells, although on occasion it is performed to determine amniotic fluid AFP levels and acetylcholinesterase activity for the diagnosis of fetal open neural tube defects. Amniocentesis later in pregnancy is usually performed for nongenetic indications, such as (1) documentation of fetal

pulmonary maturity prior to elective delivery before 39 weeks' gestation, (2) for amnioreduction in pregnancies complicated by severe polyhydramnios, (3) to confirm preterm premature rupture of membranes (PROM) (amniodye test), or (4) to exclude intra-amniotic infection.

Genetic amniocentesis typically involves the insertion of a 22-gauge spinal needle through the maternal abdominal wall and into the uterine cavity at 15 to 20 weeks' gestation. The procedure is now commonly performed under ultrasonographic guidance, which allows the operator to choose the safest site, preferably away from the fetal face and umbilical cord and when possible without passage of the needle through the placenta. The greatest risk of amniocentesis is spontaneous abortion; however, the procedure-related pregnancy loss rate for genetic amniocentesis appears to be only 1 in 300 to 500.[120,143-145] Of interest, the pregnancy loss rate is not influenced by operator experience or needle placement through the placenta[145,146] but is higher in the presence of first-trimester bleeding or recurrent miscarriage, ultrasonographic demonstration of chorioamniotic separation, discolored amniotic fluid at the time of the procedure, and an unexplained elevation in MS-AFP.[144,147] Whether this risk is higher in twin pregnancies is not clear. Transient leakage of amniotic fluid can be seen in 1% to 2% of procedures. This leakage usually stops after 48 to 72 hours, infection is extremely rare (< 0.1% of cases), and the perinatal survival rate after mid-trimester fluid leakage may be as high as 90%.[117,148-152]

Compared with late second-trimester amniocentesis, early amniocentesis (before 15 weeks' gestation) is associated with significantly higher procedure-related pregnancy loss rates, ranging from 2.2% to 4.8%.[148-151] This rate is fourfold higher than that of late amniocentesis and twice as high as that of CVS. Early amniocentesis has also been shown to be associated with higher rates of rupture of membranes, club foot, and amniocyte culture failures (2% to 5%) than late amniocentesis.[148-153] For these reasons, amniocentesis before 15 weeks' gestation is not recommended.

If early karyotyping is desired, CVS is preferred over early amniocentesis (see later discussion). Amniocentesis in the third trimester is technically easier and is associated with fewer complications. If a late amniocentesis is being performed for any reason (e.g., to confirm fetal pulmonary maturity), consideration should be given to obtaining the karyotype if indicated, even though the pregnancy is too far along to be ended electively.

Amniocentesis in multiple gestations can be performed safely. Care must be taken to carefully map the fetal sacs so that the amniotic fluid for each fetus is sampled separately. A small amount of indigo carmine (3 to 5 mL) is typically inserted into the first sac after the fluid is sampled to ensure that the same sac is not sampled twice.

Chorionic Villus Sampling

Like that of amniocentesis, the goal of CVS is to provide fetal cells for genetic analysis, although in this case the cells are trophectoderm (placental) cells rather than amniocytes. The technique entails ultrasound-guided aspiration of chorionic villi by means of a 16-gauge catheter inserted transcervically or a 20-gauge spinal needle inserted transabdominally into the placenta. The 15 to 30 mg of villous material collected can be examined in two ways: (1) by direct cytogenetic analysis after an overnight incubation, which yields results in 2 to 3 days; and (2) by longer-term culture followed by cytogenetic analysis, which yields results in 6 to 8 days.[154] To provide rapid and accurate results, many centers report the results of both methods. The main advantage of CVS over amniocentesis is that it allows for fetal karyotyping results in the first trimester, thereby allowing decisions about pregnancy termination to be made earlier if chromosomal abnormalities are detected. Moreover, although rare, certain genetic disorders (e.g., osteogenesis imperfecta) can be diagnosed antenatally only through analysis of placental tissue.

CVS is best performed between 10 and 12 weeks' gestation. CVS performed before 10 weeks' gestation has been associated with limb reduction defects,[155,156] whereas no such association exists if the procedure is performed after 66 days' gestation.[157] Transabdominal CVS can also be performed in the second or third trimester and is a reasonable alternative to cordocentesis for obtaining tissue for an urgent fetal karyotype.[158]

The most common complication of CVS is vaginal spotting, which occurs in 10% to 25% of patients within the first few days after the procedure. Fortunately, the bleeding is usually mild and resolves spontaneously with no long-term sequelae. The incidences of amnionitis (0.3%) and rupture of membranes (0.3%) after CVS do not differ significantly from those seen with late amniocentesis and are significantly lower than those reported after early amniocentesis.[157] As with amniocentesis, the most serious complication of CVS is spontaneous abortion. CVS appears to be associated with a higher risk for pregnancy loss than late amniocentesis; the procedure-related loss rate in CVS is reported as 1.0% to 1.5%.[157,159-164] This rate is significantly higher (0.6% to 0.8%) than that seen after late amniocentesis, with an adjusted odds ratio of 1.30 (95% confidence interval [CI], 1.17 to 1.52).[163] Factors that increase the procedure-related loss rate are operator inexperience, number of needle passes, and a history of bleeding prior to the procedure.[163] By contrast, the risk does not appear to be increased in twin gestations or with the anatomic approach used (i.e., transabdominal versus transcervical catheter placement).[162,165] Some investigators have suggested that the apparently higher pregnancy loss related to CVS (compared with amniocentesis) is a function of the earlier gestational age at which the procedure is performed.[120]

One complication unique to CVS involves the interpretation of the genetic test results. Because the fetus and placenta both arise from the same cell, it is assumed that the genetic complements of these two tissues are identical, but this is not always the case. **Confined placental mosaicism** refers to the situation in which the karyotype of the chorionic villus is a mosaic (i.e., it contains two or more populations of cells with different karyotypes, usually one normal and one trisomic) but the karyotype of the fetus is normal. The incidence of confined placental mosaicism may be as high as 1% to 2% with the direct

cytogenetic analysis method, but most cases are not confirmed by the long-term tissue-culture method,[157,161] suggesting a methodologic error. For this reason, many centers report only the long-term culture results. On occasion, it may be necessary to repeat the fetal karyotype, either with a second CVS or with amniocentesis, to resolve the dilemma. The reverse situation, in which the CVS result is normal but the fetus has aneuploidy (a false-negative result), has also been reported[166] but is rare. It may occur from contamination with maternal cells or from inadvertent sampling of a twin placenta.

Cordocentesis

In cases in which pregnancy complications or fetal abnormalities are discovered late in gestation, **cordocentesis** (also known as percutaneous umbilical blood sampling) is an option for rapid evaluation of the fetal karyotype. Cordocentesis involves the insertion of a 22-gauge spinal needle through the maternal abdominal and uterine walls and into the umbilical vein, preferably at the insertion site on the placenta, under direct ultrasonographic guidance. Considerable training and expertise are needed to perform this procedure. Karyotype analysis results can be obtained in 24 to 48 hours.

The first cordocentesis was reported in 1983.[167] Although this procedure was originally considered superior to amniocentesis for a number of diagnostic indications, advances in laboratory analysis have allowed more information to be obtained through amniocentesis.[168] For example, cordocentesis was commonly used to obtain a sample of fetal blood for rapid karyotyping when a major structural anomaly or severe fetal growth restriction was identified late in pregnancy; however, this sample can be obtained as rapidly from amniocentesis or CVS samples using FISH analysis. Similarly, DNA analysis of amniocytes can rapidly and accurately determine the fetal Rh status as well as the presence of other red cell and platelet antigens,[169] which in the past was an absolute indication for cordocentesis. Now employed primarily for therapeutic indications, cordocentesis is most commonly used to transfuse fetuses with severe anemia from isoimmunization, parvovirus infection, or fetal-maternal hemorrhage (spilling of fetal blood cells into the maternal circulation). This intravascular route of fetal transfusion is preferred to the older technique of intraperitoneal transfusion.[170] Other rare indications for cordocentesis are to measure drug concentrations in the fetal circulation, to document response to pharmacologic therapy, and to administer drugs directly to the fetus (e.g., adenosine to treat resistant fetal tachydysrhythmia).[171]

When skilled operators perform cordocentesis, complications are infrequent and similar to those encountered with amniocentesis. Specifically, there is risk for bleeding, cord hematoma, infection, and preterm PROM. The risk for pregnancy loss as a result of the procedure is estimated to be 1.2% to 4.9%,[172] although fetuses with severe fetal growth restriction, hydrops or major structural anomalies may be at higher risk compared with well-grown, structurally normal fetuses. Operator experience is an important determinant of success, as are logistical issues (e.g., volume of amniotic fluid, placental position, location of the cord insertion site within the placenta). A transient fetal bradycardia may occur during the procedure, often resulting from unintentional placement of the needle into one of the umbilical arteries and leading to arterial vasospasm. Although this bradycardia invariably resolves, if the fetus is at a favorable gestational age (> 24 weeks), the procedure should be performed at a facility with the capacity to perform an emergency cesarean delivery. No consistent data or recommendations exist regarding the use of prophylactic antibiotics, tocolysis, and maternal sedation during cordocentesis.

Other Tests

Three-Dimensional Ultrasonography

Compared with standard two-dimensional ultrasonography, three-dimensional (3D) ultrasonography (or four-dimensional, if fetal movements are included) allows for concurrent visualization of fetal structures in all three dimensions for improved characterization of complex fetal structural anomalies. Unlike two-dimensional ultrasonographic images, 3D images are greatly influenced by fetal movements and are subject to more interference from structures such as fetal limbs, umbilical cord, and placental tissue. Because of movement interference, visualization of the fetal heart with 3D ultrasonography is suboptimal.

In addition to rapid acquisition of images that can be later reconstructed and manipulated, 3D ultrasonography has the following potential advantages:

1. The ability to provide clearer images of soft tissue structures through surface rendering. Such images may improve the diagnosis of certain fetal malformations, especially craniofacial anomalies (e.g., cleft lip and palate, micrognathia, ear anomaly, facial dysmorphism, intracranial lesions), club foot, finger and toe anomalies, spinal anomalies, ventral wall defects, and fetal tumors.
2. The ability to provide more accurate measurements of the gestational sac, yolk sac, and crown-rump length and to obtain a midsagittal view for measuring nuchal translucency.
3. The ability to measure tissue volume. Preliminary data suggest that assessment of cervical volume may identify women at risk for cervical insufficiency,[173] and measurement of placental volume in the first trimester may determine fetuses at risk for fetal growth restriction.[174]

Despite these advantages, 3D ultrasonography has been used primarily as a complementary technique rather than the standard technique for ultrasonographic imaging. In the future, technical improvements should provide higher-quality images, perhaps similar to those offered by computed tomography and magnetic resonance imaging (MRI).

Complementary Radiographic Imaging

Ultrasonography remains the first-line imaging modality during pregnancy. In certain situations, however, enhanced imaging may be required to better define a

particular fetal anomaly. For example, radiographic imaging is superior to ultrasonography in evaluating the fetal skeleton and may provide valuable information in the evaluation of a fetus with a suspected bony dystrophy. At least 25 different forms of skeletal dysplasias are identifiable at birth, 11 of which are lethal in the peripartum period.[175] Although some of these forms can be identified from their unusual appearance on ultrasonography (e.g., cloverleaf skull and small thorax in thanatophoric dysplasia), the majority are difficult to identify. Timely radiographic imaging may allow an experienced pediatric radiologist to more thoroughly evaluate the fetal skeleton and determine the correct diagnosis. A simple maternal abdominal radiograph may be all that is required, because ossification is sufficient by 20 weeks' gestation to allow good visualization of the fetal bones.

Although computed tomography is best avoided in pregnancy because it exposes the fetus to ionizing radiation (albeit at small doses), MRI is regarded as safe. This latter technology relies on the interaction between an applied magnetic field and the inherent nuclear magnetism of atomic nuclei within the patient's tissues to generate a high-resolution anatomic image. Because MRI is particularly good at visualizing soft tissue rather than bony structures, it is uniquely suited to the evaluation of fetal intracranial defects and the soft tissues of the maternal pelvis (Figure 6-8).[176,177] Although fetal motion artifact has previously been a major limitation in the use of MRI, new ultrafast technology allows for rapid image acquisition and has largely overcome this problem.

Fetal Echocardiography

Cardiac anomalies are the most common major congenital defects encountered in the antepartum period. A four-chamber ultrasonographic view of the heart during the fetal anatomic survey at 18 to 20 weeks' gestation detects only 30% of congenital cardiac anomalies, although the detection rate can be increased to 60% to 70% if the outflow tracts are adequately visualized.[178] Owing to the number of congenital cardiac anomalies that would be missed, however, fetal echocardiography should be performed by a skilled and experienced sonologist at 20 to 22 weeks' gestation in all pregnancies at high risk for a fetal cardiac anomaly. Indications for fetal echocardiography include (1) pregnancies complicated by pregestational diabetes mellitus, (2) a personal or family history of congenital cardiac disease (regardless of the nature of the lesion or whether it has been repaired), (3) maternal exposure to certain drugs (e.g., lithium, paroxetine),[179] and (4) conception by *in vitro* fertilization (but not if the pregnancy was conceived through the use of clomiphene citrate or ovarian stimulation/intrauterine insemination alone).[180]

Fetal Cells or DNA in the Maternal Circulation

To minimize the risks associated with invasive prenatal diagnosis (amniocentesis and CVS), improved noninvasive tests are being developed for fetal aneuploidy genetic testing. Fetal cells are known to be present in the maternal circulation throughout pregnancy at a concentration of approximately 1 fetal cell for every 10,000 to 1 million maternal cells.[181] However, we do not currently have the technology to isolate these cells with sufficient purity to develop a reliable prenatal test. Recent efforts have focused on genetic analysis of cell-free DNA in the maternal circulation. It is now apparent that fetal DNA (most of which comes from the placenta) accounts for 3% to 10% of all cell-free DNA in maternal serum, and it may account for as much as 20% of cell-free DNA in women with preeclampsia or after major fetal-maternal hemorrhage. Because of its relative abundance, purity, and short half-life (precluding contamination from a prior pregnancy), high-throughput sequencing of cell-free DNA provides new opportunities for noninvasive prenatal testing.[182] Several commercial tests are now available that rely on analysis of cell-free DNA in the maternal circulation to screen for fetal aneuploidy as early as 10 weeks' gestation. Recent publications have shown that such noninvasive prenatal testing can increase the detection rate for trisomy 21 (Down syndrome) to approximately 99.8% with a 0.2% false-positive rate in high-risk pregnancies [183-186]; these results have not yet

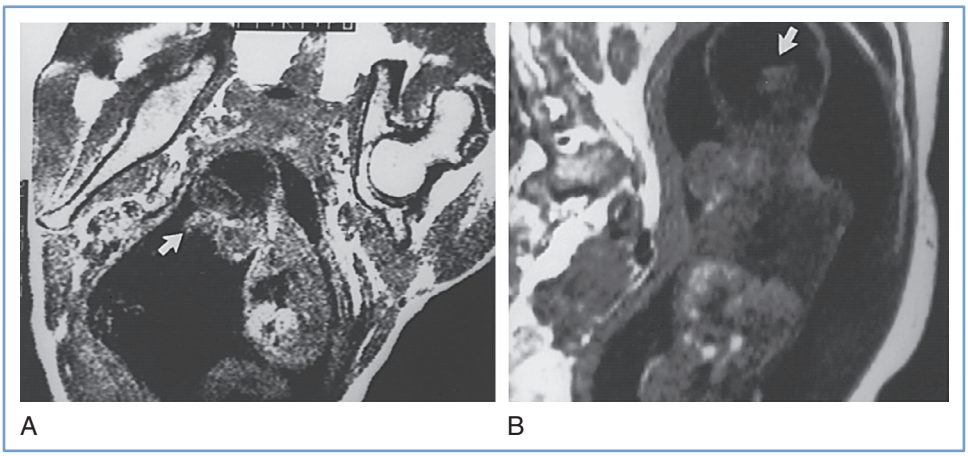

FIGURE 6-8 ■ Magnetic resonance images of a fetus with holoprosencephaly. **A,** Sagittal view showing the proboscis (*arrow*). **B,** Coronal view showing the single ventricle and fused thalami (*arrow*). (Reprinted from Wenstrom KD, Williamson RA, Weiner CP, et al. Magnetic resonance imaging of fetuses with intracranial defects. Obstet Gynecol 1991; 77:529-32.)

been validated in low-risk pregnancies. Because of the small but finite false-positive rate, these tests should be considered screening and not diagnostic tests, and confirmatory CVS or amniocentesis is still recommended before acting on a positive test. The detection of trisomy 18 (98%) and trisomy 13 (65%) is also possible using this technology.[184,186]

An alternative approach under investigation for definitive genetic testing is the isolation of trophoblast cells from the cervicovaginal discharge of women in early pregnancy.[187,188] Provisional studies have isolated these cells from the maternal cervix with cervical canal lavage at 7 to 10 weeks' gestation[187] or with the use of a brush-type collection device at 5 to 12 weeks (the "genetic Pap smear").[188] With this technique, such cells have been isolated in 86% (195/227) of samples by immunocytochemistry with trophoblast-specific antibodies, and results agreed with those of placental tissue karyotyping via CVS in 95% (186/195) of cases.[188] The ability to successfully collect trophoblast cells from the cervicovaginal discharge of women in early pregnancy may provide a simple, reliable, noninvasive, yet definitive genetic test for fetal aneuploidy in a singleton pregnancy with no risk to the mother or fetus.

SPECIAL CIRCUMSTANCES REQUIRING ADDITIONAL FETAL SURVEILLANCE

Under certain circumstances, additional antenatal fetal surveillance may be required (see Box 6-2). If appropriate, early consultation with a specialist (e.g., a maternal-fetal medicine specialist, medical geneticist, pediatric surgeon, pediatric urologist, pediatric cardiologist, or infectious disease specialist) and delivery at a tertiary care center should be considered.

Abnormal Serum Analyte and Nuchal Translucency Screening with Normal Fetal Karyotype

Pregnancies with abnormal serum analyte screening in the first or second trimester are at increased risk for adverse outcomes, including preterm birth, preeclampsia, and stillbirth, *even if the karyotype is normal* (Tables 6-9 and 6-10).[189-191] Such pregnancies therefore require more intensive fetal monitoring (Table 6-11), including serial growth evaluation and NST. Fetuses with a nuchal translucency measurement of 3.0 mm or more in the first trimester have a higher risk for congenital heart defects and other chest abnormalities, even with a negative aneuploidy screening test result and normal fetal chromosomes.[132,192] Women with such pregnancies should be offered a fetal echocardiogram at 20 to 22 weeks' gestation in addition to a routine targeted fetal anatomic survey at 18 to 20 weeks.

Hydrops Fetalis

Hydrops fetalis ("edema of the fetus") is a rare pathologic condition that complicates approximately 0.05% of all pregnancies. It is an ultrasonographic diagnosis requiring the presence of an abnormal accumulation of fluid in more than one fetal extravascular compartment, including ascites, pericardial effusion, pleural effusion, subcutaneous edema, and/or placental edema. Polyhydramnios is seen in 50% to 75% of cases. Although classically seen in fetuses with severe anemia resulting from Rh isoimmunization, the introduction of Rh_0(D) immune globulin has led to a substantial decrease in the incidence of immune hydrops. Indeed, 90% of hydrops fetalis cases

TABLE 6-9 Relationship between First-Trimester PAPP-A Level at or below Fifth Percentile (0.42 MoM) and Risks of Adverse Pregnancy Outcomes

Adverse Outcome	Adjusted Odds Ratio	95% Confidence Interval
Spontaneous loss < 24 weeks	2.50	1.76-3.56
Fetal death ≥ 24 weeks	2.15	1.11-4.15
Preterm birth ≤ 37 weeks	1.87	1.61-2.17
Preterm birth ≤ 32 weeks	2.10	1.59-2.76
Preeclampsia	1.54	1.16-2.03
Gestational hypertension	1.47	1.20-1.82
Placental abruption	1.80	1.15-2.84
Fetal growth restriction	3.22	2.38-4.36

MoM, multiple of the median; *PAPP-A,* pregnancy-associated placental protein-A test.

Data from Dugoff L, Hobbins JS, Malone FD, et al. First-trimester maternal serum PAPP-A and free beta-subunit human chorionic gonadotropin concentrations and nuchal translucency are associated with obstetric complications: a population-based screening study (the FASTER Trial). Am J Obstet Gynecol 2004; 191:1446-51.

TABLE 6-10 Second-Trimester Serum Analyte (Marker) Screening and Adverse Pregnancy Outcome

Adverse Outcome	Marker	Odds Ratio
Spontaneous loss < 24 weeks	MS-AFP	7.8
Fetal death ≥ 24 weeks	Inhibin A	3.7
Preterm birth ≤ 32 weeks	Inhibin A	5.0
Preterm premature rupture of membranes	MS-AFP	1.9
Preeclampsia	Inhibin A	3.8
Gestational hypertension	Inhibin A	1.7
Placental abruption	MS-AFP	1.9
Placenta previa (confirmed at delivery)	MS-AFP	3.1
Fetal growth restriction	Inhibin A	3.0
Birth weight ≤ 5th percentile	Inhibin A	2.3
• Delivery < 37 weeks	Inhibin A	8.0
• Delivery < 32 weeks	Inhibin A	18.6

MS-AFP, maternal serum level of alpha-fetoprotein.

are due to nonimmune causes, such as maternal infection (e.g., with parvovirus B19, cytomegalovirus, syphilis), massive fetal-maternal hemorrhage, and fetal abnormalities (e.g., congenital cardiac defects, fetal thalassemia, twin-to-twin transfusion syndrome). Although the overall perinatal mortality rate in the setting of hydrops fetalis exceeds 50%, the prognosis depends on the underlying cause, severity, and gestational age.

Immune hydrops occurs when fetal erythrocytes express a protein that is not present on maternal erythrocytes. The maternal immune system can become sensitized and produce antibodies against these "foreign" proteins. These immunoglobulin (Ig) G antibodies can cross the placenta and destroy fetal erythrocytes, leading to fetal anemia and high-output cardiac failure. Immune hydrops is typically associated with a fetal hematocrit less than 15% (normal fetal hematocrit is 50%). The most antigenic protein on the surface of fetal erythrocytes is the D antigen of the Rhesus protein complex, also known as Rh(D). Other antigens that can cause severe immune hydrops are Kell ("Kell kills"), Rh(E), Rh(c), and Duffy ("Duffy dies"). Antigens causing less severe hydrops are ABO, Rh(e), Rh(C), Ce, k, and s. Lewis a and b (Le^a, Le^b) incompatibility can cause mild anemia but not hydrops, because this condition primarily results in production of IgM antibodies, which do not cross the placenta ("Lewis lives"). For identification of women at risk for isoimmunization, every pregnant woman should undergo blood type and antibody screening at the first prenatal visit and again in the third trimester.

Sixty percent of cases of immune hydrops result from ABO incompatibility; however, only Rh(D) isoimmunization can be prevented. The Rh(D) antigen is expressed only on primate erythrocytes and becomes evident by 38 days of intrauterine life. A mutation in the Rh(D) gene on chromosome 1 results in lack of expression of Rh(D) antigen on circulating erythrocytes (Rh[D] negative). This mutation arose in the Basque region of Spain, and the difference in prevalence of Rh(D)-negative individuals between the races likely reflects the amount of Spanish blood in their ancestry: Caucasian, 15%; African-American, 8%; African, 4%; Native American, 1%; and Asian, less than 1%.[193] If the fetus of an Rh(D)-negative woman is Rh(D) negative, Rh(D) sensitization will not occur. However, 60% of Rh(D)-negative women have Rh(D)-positive fetuses, and exposure of these women to as little as 0.25 mL of Rh(D)-positive blood may induce an antibody response. Because the initial immune response is production of IgM, the index pregnancy is rarely affected. However, immunization in subsequent pregnancies triggers an IgG response that crosses the placenta and causes hemolysis. Risk factors for Rh(D) sensitization include a mismatched blood transfusion (95% sensitization rate), ectopic pregnancy (< 1%), abortion (3% to 6%), amniocentesis (1% to 3%), and pregnancy itself. Indeed, the sensitization rate is 16% to 18% after a normal pregnancy without Rh_0(D) immune globulin administration, 1.3% with Rh_0(D) immune globulin at delivery only, and 0.13% with anti-Rh_0(D) immune globulin at 28 weeks and again after delivery.[193,194] The risk for isoimmunization depends on the volume of fetal-maternal hemorrhage (Table 6-12). Passive immunization with Rh_0(D) immune globulin can destroy fetal erythrocytes before they evoke a maternal immune response, thereby preventing sensitization. Therefore, Rh_0(D) immune globulin should be given within 72 hours of potential exposure; 300 µg given intramuscularly is

TABLE 6-12 **Fetal-Maternal Transfusion Volume and Risk for Rh(D) Isoimmunization in an Rh(D)-Negative Woman**

Transfusion Volume	Incidence at Delivery (%)	Risk for Isoimmunization (%)*
Unmeasurable	50	Minimal
< 0.1 mL	45-50	3
> 5.0 mL	1	20-40
> 30 mL	0.25	60-80

*Without Rh_0(D) immune globulin.

Data from American College of Obstetricians and Gynecologists. Prevention of Rh D alloimmunization. ACOG Practice Bulletin No. 4. Int J Gynaecol Obstet 1999; 66:63-70 (reaffirmed 2009); and Moise KJ. Red blood cell alloimmunization in pregnancy. Semin Hematol 2005; 42:169-78.

adequate for exposure to as much as 30 mL of fetal whole blood or 15 mL of fetal red blood cells.

Once isoimmunization has occurred, passive immunoglobulin is not useful. Such pregnancies should be observed closely for evidence of fetal compromise. Fetal hemolysis results in release of bile pigment into the amniotic fluid, which can be quantified as a change in optical density measured at wavelength 450 nm. Traditionally, the extent of hemolysis had been measured with serial amniocenteses, with amniotic fluid optical density plotted against gestational age; increased density (upper 80% of zone 2 or zone 3 of the Liley curve) is associated with a poor prognosis,[195,196] and prompt intervention is indicated. Measurements of peak systolic velocity in the fetal MCA by means of noninvasive Doppler velocimetry have now emerged as the best tool to accurately identify fetuses with severe anemia requiring urgent intervention, regardless of the cause of the anemia.[113,194,197] The sensitivity of an elevated MCA peak systolic velocity (i.e., >1.5 MoM for a given gestational age) for predicting moderate to severe anemia approaches 100%.[113] Depending on gestational age, these interventions may include immediate delivery or intrauterine blood transfusion.

Post-Term Pregnancy

Post-term (prolonged) pregnancy is defined as any pregnancy that continues to or beyond 42 weeks (294 days) from the first day of the last normal menstrual period or 14 days beyond the best obstetric estimate of the EDD.[2,198] The prevalence of post-term pregnancy depends on the patient population (e.g., percentage of primigravidas, incidence of pregnancy complications, frequency of spontaneous preterm births) and the local practice patterns (e.g., use of ultrasonographic assessment of gestational age, cesarean delivery rates, use of labor induction). Approximately 10% (range, 3% to 14%) of all pregnancies continue beyond 42 weeks, and 4% (range, 2% to 7%) continue beyond 43 weeks in the absence of obstetric intervention.[2] Compared with delivery at 40 weeks, post-term pregnancies pose significant risks to both the mother (including higher risk for cesarean delivery, severe perineal injury, and postpartum hemorrhage) and the fetus (including stillbirth, fetal macrosomia, birth injury, and meconium aspiration syndrome).[2,198-201] The risks to the fetus can be largely prevented by routine induction of labor for all low-risk pregnancies at 40 to 41 weeks' gestation.[2,199]

Post-term pregnancy is a universally accepted indication for antenatal fetal surveillance,[2] although the efficacy of this approach has not been validated by prospective randomized trials. Options for evaluating fetal well-being include NST with or without amniotic fluid volume assessment, BPP, CST, and a combination of these modalities. There is no consensus as to which of these modalities is preferred, and no single method has been shown to be superior.[2] The ACOG has recommended that antepartum fetal surveillance be initiated by 42 weeks' gestation at the latest, without making a specific recommendation about the type of test or frequency.[2] Many investigators would advise twice-weekly testing with some evaluation of amniotic fluid volume at least weekly. Doppler ultrasonography has no benefit in monitoring the post-term fetus and is not recommended for this indication.[109,110] Although the data are inconsistent, there is a suggestion that antenatal testing at 40 to 42 weeks' gestation may be associated with improvements in perinatal outcome. In one retrospective study, women with routine antenatal testing beginning at 41 weeks had lower rates of cesarean delivery for nonreassuring fetal test results than women in whom testing was started at 42 weeks (2.3% versus 5.6%, respectively; $P < .01$).[202] In addition, the group with delayed antenatal testing experienced three stillbirths and seven other neonatal major morbidity events, compared with none in the group who had antenatal testing from 41 weeks ($P < .05$).[202]

In the post-term period, evidence of fetal compromise (nonreassuring fetal test results) or **oligohydramnios** (e.g., low amniotic fluid volume) should prompt delivery.[2] Oligohydramnios may result from uteroplacental insufficiency or increased renal artery resistance and may predispose to umbilical cord compression, thus leading to intermittent fetal hypoxemia, meconium passage, and meconium aspiration. A uniform definition for oligohydramnios has not been established; however, options are as follows: (1) a depth of less than 2 cm for the maximum vertical fluid pocket; (2) amniotic fluid index less than 5 cm (i.e., < 5 cm for the sum of the depths in cm of the largest vertical pocket in each of four uterine quadrants); and (3) product of length times width times depth of the largest pocket (in cm) less than 60. Adverse pregnancy outcomes (nonreassuring FHR tracing, low Apgar score, and neonatal intensive care unit admission) are more common when oligohydramnios is present. Frequent (twice-weekly) screening of post-term patients for oligohydramnios is important, because amniotic fluid can become dramatically reduced within 24 to 48 hours. One prospective double-blind cohort study of 1584 women after 40 weeks' gestation found that an amniotic fluid index less than 5 cm with no largest vertical fluid pocket depth greater than 2 cm was associated with birth asphyxia and meconium aspiration, although the sensitivity for adverse outcomes was low.[203]

Intrauterine Fetal Demise

Intrauterine fetal demise (IUFD), also known as stillbirth, is defined in the United States as demise of the fetus after 20 weeks' gestation and prior to delivery.[204-206] In Europe, only fetuses more than 24 weeks' gestation are included. The stillbirth rate in the United States diminished from 15.8 per 1000 total births in 1960 to 7.5 per 1000 births in 1990.[205,206] However, it remains a vastly underappreciated clinical problem, with antepartum stillbirths accounting for more perinatal deaths than either complications of prematurity or sudden infant death syndrome.[207] Risk factors for stillbirth include extremes of maternal age, chromosomal disorders, congenital malformations, antenatal infection, multiple pregnancy, prior unexplained IUFD, post-term pregnancy, fetal macrosomia, male fetus, umbilical cord and placental abnormalities, and underlying maternal medical conditions (e.g., chronic hypertension, pregestational or gestational diabetes mellitus, autoimmune disorders, inherited or acquired thrombophilia).[204,208,209]

Although older studies observed that approximately 50% of cases of IUFD were unexplained, an aggressive

TABLE 6-13 Causes of Intrauterine Fetal Demise

Maternal causes	Underlying medical conditions (diabetes mellitus, thyroid disease, antiphospholipid antibody syndrome)
	Preeclampsia
	Isoimmunization
	Illicit drug use (cocaine)
	Antepartum drug/toxin exposure
Uteroplacental causes	Placental abruption
	Placenta previa
	Vasa previa
	Fetomaternal hemorrhage
	Cord accident
Fetal causes	Fetal chromosomal/genetic anomalies
	Fetal structural abnormalities
	Intra-amniotic infection
	Complications of multiple pregnancies (including twin-to-twin transfusion syndrome)

approach may identify the cause in up to 80% to 90% of cases (Table 6-13).[209-212] Pathologic examination of the fetus and the placenta/fetal membranes is the single most useful means of identifying a cause for the IUFD.[210,211] Early detection and appropriate management of underlying maternal disorders (e.g., diabetes, preeclampsia) may also reduce the risk. Fetal karyotyping should be considered in all cases of fetal death to identify chromosomal abnormalities, particularly in cases with documented fetal structural abnormalities. Six to 10 percent of stillborn fetuses have an abnormal karyotype.[212] On occasion, amniocentesis may be recommended to salvage viable amniocytes for cytogenetic analysis before delivery. Fetal-maternal hemorrhage occurs in all pregnancies but is usually minimal (< 0.1 mL total volume). In rare instances, this hemorrhage may be massive, leading to fetal demise. The Kleihauer-Betke (acid elution) test allows an estimate of the volume of fetal blood in the maternal circulation, and a maternal blood sample should be drawn within 6 to 8 hours of the purported bleeding episode because of rapid clearance of fetal cells from the maternal circulation.[213] Intra-amniotic infection resulting in fetal death is usually evident on clinical examination. Placental membrane culture and autopsy examination of the fetus, placenta/fetal membranes, and umbilical cord may be useful. Fetal radiographic or MRI may sometimes be valuable if autopsy is declined.[214,215]

The inability to identify fetal heart activity or the absence of uterine growth may suggest the diagnosis. Ultrasonography is the "gold standard" for confirming IUFD by documenting the absence of fetal cardiac activity. Other ultrasonographic findings in late pregnancy include Spalding's sign (overlapping of the cranial sutures), scalp edema, and soft tissue maceration, although these usually take a few days to develop. Every effort should be made to avoid cesarean delivery in the setting of IUFD. Thus, in the absence of a contraindication, expectant management is often recommended. Latency (the period from fetal demise to delivery) varies according to the underlying cause and gestational age. In general, the earlier the gestational age, the longer the latency period. Overall, more than 90% of women go into spontaneous labor within 2 weeks of fetal death. However, many women find the prospect of carrying a dead fetus distressing and want the pregnancy terminated as soon as possible. Management options include surgical dilation and evacuation or induction of labor with cervical ripening, if indicated. Disseminated intravascular coagulation develops in 20% to 25% of women who retain a dead singleton fetus for longer than 3 weeks because of excessive consumption of clotting factors.[216,217] Therefore, delivery should be effected within this period. Induction of labor with prostaglandins or oxytocin has been shown to be safe in the setting of an IUFD.

The death of one twin in a monochorionic twin gestation poses a particular challenge. In this setting, the surviving twin is at significant risk for major morbidity, including IUFD, neurologic injury, multiorgan system failure, thromboembolic events, placental abruption, and preterm birth.[218-220] The prognosis for the surviving twin depends on the cause of death, gestational age, chorionicity, and the time between death of the first twin and delivery of the second. Dizygous twin pregnancies do not share a circulation, and death of one twin may have little impact on the surviving twin. The dead twin may be resorbed completely or may become compressed and incorporated into the membranes (*fetus papyraceus*). Disseminated intravascular coagulation in the surviving fetus and/or mother is rare.[221] On the other hand, some level of shared circulation can be demonstrated in almost all monozygous twin pregnancies, and death of one fetus in this setting raises the risk for death of its co-twin owing to profound hypotension and/or purported transfer of thromboplastic proteins from the dead fetus to the live fetus.[222] If it survives, the co-twin has a 20% risk for development of permanent neurologic injury (multicystic encephalomalacia), which may not be prevented by immediate delivery.[223,224] Therefore, management of a surviving twin depends on chorionicity and gestational age. Regular fetal surveillance (kick counts, NST, BPP) should be instituted (see Table 6-11), and delivery considered in the setting of nonreassuring fetal test results or at a favorable gestational age.

FETAL THERAPY

Continued assessment of the fetus throughout pregnancy is critical to optimizing pregnancy outcomes. In most cases, evidence of fetal compromise prompts delivery. However, in certain situations, treatment may be available to improve or even correct the underlying problem *in utero*. These interventions can be noninvasive (e.g., administration of digoxin to the mother to treat a fetal supraventricular tachycardia) or invasive (e.g., placement of a vesicoamniotic shunt) and are summarized in Tables 6-14 and 6-15, respectively.[225-260] Some of these interventions have been subjected to rigorous clinical trials and have been shown to be effective, whereas others remain investigational. The intervention that has perhaps had the greatest effect on perinatal outcome is antenatal maternal administration of corticosteroids.

TABLE 6-14 Noninvasive Treatment Options to Improve Perinatal Outcome

Clinical Condition	Treatment	Efficacy
Imminent risk for preterm birth < 34 weeks	Antenatal corticosteroids	Effective in decreasing respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis[225]
Pregestational diabetes mellitus	Strict glycemic control	Effective in decreasing rate of stillbirths and birth defects[226]
Phenylketonuria (autosomal recessive disorder due to phenylalanine hydroxylase deficiency)	Dietary manipulation (low-phenylalanine diet)	Effective in decreasing birth defects and brain damage in affected fetuses[227]
Alloimmune thrombocytopenia	Maternal intravenous immunoglobulin ± corticosteroids	Data conflicting on effect of intravenous immunoglobulin on fetal platelets; steroids probably of no benefit[228,229]
Fetal thyrotoxicosis	Maternal propylthiouracil	Effective in decreasing fetal growth restriction and subsequent neurodevelopmental defects[230,231]
Congenital adrenal hyperplasia (due usually to 21-hydroxylase deficiency)	Maternal dexamethasone	Effective in preventing virilization of female fetus if given prior to 8 to 9 weeks' gestation[232]
Fetal supraventricular tachycardia (SVT)	Maternal digoxin	Data conflicting on effect of digoxin to correct fetal SVT

TABLE 6-15 Invasive Treatment Options to Improve Perinatal Outcome

Clinical Condition	Treatment	Efficacy
Severe fetal anemia with or without hydrops fetalis	Intrauterine transfusion	Effective[233,234]
Fetal supraventricular tachycardia	Digoxin given directly to fetus by intramuscular injection	Effective
Severe obstructive uropathy	Vesicoamniotic shunt	Effective in preventing renal injury and improving survival[235]
Isolated fluid collection in the fetus (severe ascites, hydrothorax)	Fetoamniotic shunting	Effective[236]
Severe valvular stenosis	Fetal surgery (*in utero* valvuloplasty)	Investigational[237]
Fetal lung masses (congenital cystic adenomatous malformation, pulmonary sequestration)	Fetal surgery (*in utero* resection of lesion)	Investigational[238,239]
Congenital hydrocephalus	Fetal surgery (*in utero* shunting)	Investigational[240]
Congenital diaphragmatic hernia	Fetal surgery (*in utero* repair; tracheal occlusion)	Investigational[241,242]
Fetal neural tube defect	Fetal surgery (*in utero* repair)	Investigational[243-245]
Higher-order multiple pregnancy (≥ triplets)	Multifetal pregnancy reduction	Effective in improving perinatal outcomes with reduction to twins[246-249]
Twin-to-twin transfusion syndrome (TTTS)	Serial amnioreduction versus septostomy versus fetal surgery (endoscopic laser ablation, cord ligation)	Effective Laser ablation appears to give the best chance of intact survival in severe TTTS[250-255]
Preterm premature rupture of membranes	Serial amnioinfusion versus fetal surgery (laser coagulation, intra-amniotic amniopatch)	Investigational[256-258]
Ex utero intrapartum therapy (EXIT)	To facilitate oxygenation at delivery prior to ligation of the umbilical cord when the infant's airway is obstructed; may facilitate transition to extracorporeal membrane oxygenation (ECMO) in infants with severe pulmonary or cardiac malformations	Case reports of success[259,260]

Antenatal Corticosteroids

Respiratory distress syndrome (RDS) refers to respiratory compromise presenting at or shortly after delivery due to a deficiency of pulmonary surfactant, an endogenous detergent that serves to decrease the surface tension within alveoli, thereby preventing alveolar collapse. Overall, neonatal RDS affects approximately 1% of live births, but not all infants are at equal risk. The pulmonary system is among the last of the fetal organ systems to become functionally mature. Thus, RDS is primarily, although not exclusively, a disease of preterm infants, with the incidence and severity highly dependent on gestational age. For example, RDS affects more than 80% of infants younger than 28 weeks' gestation and 10% to 15% of all infants weighing less than 2500 g.[261,262] RDS

remains a major cause of perinatal morbidity and mortality in extremely preterm infants. In addition to gestational age, a number of other factors influence the risk for RDS in a given fetus. For reasons that are not clear, African-American ethnicity, female gender, preeclampsia, and intrauterine exposure to cigarette smoke are protective against the development of RDS.

In 1972, Liggins and Howie[263] demonstrated that the administration of a single course of two antenatal doses of a corticosteroid (betamethasone) reduced the incidence of RDS by 50%. This original observation has since been confirmed by a number of investigators.[225,264-267] A meta-analysis of 12 randomized controlled trials with more than 3000 participants concluded that antenatal administration of corticosteroids to women in preterm labor reduced the incidence of neonatal RDS by 40% to 60% and resulted in an improvement in overall survival.[225] In one study, a single course of antenatal corticosteroids resulted in a threefold rise in the chance of unaffected survival in neonates with a birth weight less than 1500 g.[264] Certain steroids cross the placenta and induce cellular differentiation at the expense of growth. Type II pneumocytes in the lungs differentiate and begin making pulmonary surfactant, which accounts for the decrease in risk for RDS, and endothelial cells lining the vasculature undergo cellular maturation and stabilization, which explains the concomitant drop in incidence of bleeding into the brain (intraventricular hemorrhage) or gastrointestinal tract (necrotizing enterocolitis).[265] Prednisone does not cross the placenta and therefore does not have a similar protective effect.

The National Institutes of Health and the ACOG have recommended that a single course of antenatal corticosteroids, defined as either betamethasone (12 mg intramuscularly q24 h × two doses) or dexamethasone (6 mg intramuscularly q12 h × four doses), be given after 23 to 24 weeks' gestation to any pregnant woman in whom delivery before 34 weeks' gestation is threatening.[266,267] There is as yet no proven benefit to antenatal administration of corticosteroids after 34 weeks' gestation[266,267] or between 32 to 34 weeks in the setting of preterm PROM,[268] but this situation is largely due to the absence of data in these subgroups. Although the maximum benefit of antenatal corticosteroids is achieved 24 to 48 hours after the first injection, as little as 4 hours of treatment exerts some protective effect. This protective effect lasts for 7 days, after which further benefit is unclear. Multiple (three or more) courses of antenatal corticosteroids have been associated with fetal growth restriction, smaller head circumference, and (in animals) abnormal myelination of the optic nerves; consequently, multiple courses are not routinely recommended. If a threat of preterm delivery occurs more than 2 weeks after the initial course was completed, a rescue course of corticosteroids is recommended.[269-273]

Fetal Surgery

Fetal surgery has been proposed in selected cases to prevent progressive organ damage or to restore normal anatomy and fetal development (see Chapter 7). The ideal case for fetal surgery consists of a singleton pregnancy prior to fetal viability (i.e., before 23 to 24 weeks' gestation) in which the fetus has a normal karyotype and an isolated malformation that, if untreated, will result in fetal or neonatal demise. A detailed understanding of the natural history of the malformation is essential when one is considering whether to recommend surgery. Fetal surgery should not be attempted if the natural history of the disorder is unknown or if the chances of survival without *in utero* treatment are equal to or greater than the risks of the procedure. The only two randomized controlled trials published to date in fetal surgery—one on tracheal occlusion for the management of congenital diaphragmatic hernia[274] and the other on prenatal versus postnatal repair of myelomeningocele[275]—found little significant benefit to *in utero* surgery. Repair of lesions that are not believed to be life threatening (e.g., cleft lip and palate) should be deferred until after delivery to minimize risks to the mother.

Before *in utero* surgery can be recommended, a thorough evaluation must be performed to (1) precisely characterize the defect, (2) exclude associated malformations, (3) perform a fetal karyotype analysis, and (4) eliminate the possibility that the condition can be treated using less aggressive technologies. Detailed counseling about the risks and benefits of the proposed procedure is required, and written informed consent is mandatory. Such a discussion must include a detailed review of the risks to both the fetus and the mother, including preterm PROM (28% to 100%), preterm labor and delivery (> 50%), maternal pulmonary edema (20% to 30%), placental abruption (5% to 10%), chorioamnionitis and sepsis (< 5%), and maternal death (rare).[242,244] Specific examples of fetal surgical procedures are summarized in Table 6-15.

KEY POINTS

- Accurate determination of gestational age is essential for the management of pregnancy complications and the effective use of antepartum fetal testing.
- Ultrasonography can be used to estimate gestational age, assess fetal growth, monitor amniotic fluid volume, and detect and characterize fetal anomalies.
- Appropriate fetal growth is strongly correlated with fetal health and can be assessed either clinically or with ultrasonography. Inappropriate fetal growth requires further evaluation.
- Fetal movement charts ("kick counts") can be used to confirm fetal well-being in both high- and low-risk populations. High-risk pregnancies may require additional fetal monitoring such as the nonstress test (NST), biophysical profile (BPP), or contraction stress test (CST).
- A fetal karyotype can be obtained by chorionic villus sampling, amniocentesis, or fetal blood sampling (cordocentesis).

- Doppler velocimetry has advanced our understanding of maternal-fetal physiology, but its role in confirming fetal well-being is unclear.
- Additional radiologic imaging (especially magnetic resonance imaging) may be used in selected cases to better define fetal malformations.
- A number of intrauterine therapies have been shown to improve perinatal outcome in selected cases, including antenatal corticosteroid administration, intrauterine transfusion, and fetal surgery (e.g., laser photocoagulation for twin-to-twin transfusion syndrome).
- The appropriate timing of delivery is a critical determinant of perinatal outcome. In general, delivery is indicated when the benefits of delivery to the fetus or mother outweigh the risks of continuing the pregnancy. Simply stated, delivery is indicated when the fetus is better off outside the uterus than inside. A number of variables should be considered in such a decision, the most important of which are gestational age and fetal well-being.

CHAPTER 7

Anesthesia for Fetal Surgery and Other Intrauterine Procedures

Mark D. Rollins, MD, PhD • Mark A. Rosen, MD

CHAPTER OUTLINE

Fetal therapy originated in 1963 with Sir William Liley's successful intraperitoneal blood transfusion to a fetus with erythroblastosis fetalis.[1] This was followed by many years of discouraging attempts to transfuse blood via direct cannulation of fetal vessels through a small uterine incision.[2] In 1981, after careful experimentation and practice in sheep[3,4] and rhesus monkeys,[5] the first successful human fetal surgery, a vesicostomy, was performed in a fetus with bilateral hydronephrosis due to a lower urinary tract obstruction.[6]

Advances in prenatal diagnostic technology, particularly in the resolution of imaging, contribute to increasing sophistication in diagnosis of fetal disorders, principally anatomic anomalies. Fetal therapy is largely nonsurgical (e.g., administration of medications, nutrients, blood, stem cells) (see Chapter 6). Some identified disorders are amenable to intrauterine fetal surgery, but most anatomic malformations diagnosed *in utero* remain unsuitable for antenatal intervention. Prenatal diagnosis of serious malformations (e.g., those that are uncorrectable and incompatible with normal postnatal life) allows the choice of pregnancy termination. Most correctable malformations are best managed after delivery at term gestation, but antepartum recognition allows time for the coordination of appropriate prenatal and postnatal care, including transfer of peripartum care to an appropriate medical center while the fetus is *in utero* rather than as a newly delivered, fragile neonate. Some defects, especially those that cause airway obstruction, can be treated with an intrapartum intervention, in which the fetus undergoes repair of the defect and/or the airway is secured during birth, while the uteroplacental unit remains functional.

Fetal surgery is reasonable only with informed consent and only if (1) the lesion is diagnosed accurately, (2) the lesion's severity is assessed correctly, (3) the associated anomalies that contraindicate intervention are excluded, (4) the maternal risk is acceptably low, and (5) the neonatal outcome would be better with *in utero* surgery than with surgery performed after delivery. With all fetal surgical procedures, an emphasis also must be placed on maternal welfare to guard against undue maternal risk.[7,8]

Fetal surgical interventions can be broadly categorized into three kinds of procedures, namely, open surgical procedures, minimally invasive procedures, and intrapartum procedures. **Open surgical procedures** involve both maternal laparotomy and hysterotomy with use of pharmacologic agents to maintain uterine relaxation. These procedures are typically performed near mid gestation and entail greater maternal and fetal risks compared with the minimally invasive techniques, including a significant risk for preterm premature rupture of membranes (PROM), preterm labor and delivery, uterine dehiscence, oligohydramnios, hemorrhage, pulmonary edema, and fetal mortality.[9,10] In addition, after an open surgical procedure, a cesarean delivery is required for the subsequent delivery and all future deliveries owing to the location of the hysterotomy and the associated risks for uterine dehiscence or rupture. Open fetal surgical procedures have been used to repair fetal myelomeningoceles, resect congenital pulmonary airway abnormalities, and debulk sacrococcygeal teratomas.

Minimally invasive procedures involve either endoscopic or percutaneous procedures guided by ultrasonography, typically performed at mid gestation (e.g., intrauterine blood transfusion, fetoscopic laser coagulation for twin-to-twin transfusion syndrome [TTTS]). They include a significantly lower risk for preterm labor and delivery than open procedures because they do not require a hysterotomy, yet the risk for preterm PROM remains.

The third kind of procedure involves a modification of cesarean delivery to allow intrapartum fetal therapy while the fetus remains supported by placental gas exchange. These delivery techniques are termed **EXIT procedures,** for *ex utero* intrapartum therapy.[11] EXIT procedures are most often employed (1) to secure the airway by endotracheal intubation, bronchoscopy, or tracheostomy or (2) to perform other fetal procedures while gas exchange continues in the placenta (placental bypass). The EXIT procedure enables the prevention of postnatal asphyxia in newborns with lesions such as cystic hygroma, lymphangioma, cervical teratoma, and congenital syndromes, in whom securing an airway after birth can be problematic. The procedure is also used as a bridge to extracorporeal membrane oxygenation (ECMO) for a fetus with cardiopulmonary disease at risk for postnatal cardiac failure or failure of adequate gas exchange in the lungs.

Fetal surgery is a reasonable therapeutic intervention for certain correctable fetal anomalies with predictable, life-threatening, or serious developmental consequences. If untreated, these lesions can interfere with fetal organ development or result in cardiac failure; if corrected *in utero*, irreversible organ damage and fetal demise may be prevented.

INDICATIONS AND RATIONALE FOR FETAL SURGERY

Bilateral Hydronephrosis–Obstructive Uropathy

Congenital obstructive uropathy occurs in approximately 0.1% of pregnancies.[12] Congenital bilateral hydronephrosis results from fetal urethral obstruction at the bladder outlet, most often by posterior urethral valves in male fetuses or urethral obstruction in females. Other causes of fetal obstructive uropathy include obstruction at the ureteropelvic or vesicoureteric junction and a number of complex disorders in females (e.g., cloacal plate anomalies). These uropathies are easily detected by ultrasonography, which is often performed to investigate oligohydramnios from diminished fetal urine output. Severe obstructive lesions may lead to progressive renal dysplasia and dysfunction, bladder distention, and oligohydramnios and ultimately result in devastating developmental consequences, such as limb and facial deformities and pulmonary hypoplasia (Figure 7-1).[13] Preterm delivery allows early urinary tract decompression *ex utero*, but fetal pulmonary immaturity limits the efficacy of this approach. Early intrauterine intervention with placement of a vesicoamniotic shunt allows drainage of urine from the fetal bladder into the amniotic cavity, thereby decompressing the urinary tract. In animal models, *in utero* relief of obstructive uropathy improves dysplastic renal histology, restores normal urine flow and amniotic fluid volume, and results in improved lung growth and development.[14] The applicability of these findings to human fetal obstructive uropathy remains unclear and controversial.[15]

Vesicoamniotic catheter shunts have been used for intrauterine treatment of bilateral hydronephrosis since the early 1980s.[16] These valveless, double-coiled catheters are placed percutaneously with ultrasonographic guidance, with one coil being left in the urinary bladder and the other in the amniotic space. Common problems associated with these catheters include (1) difficult placement, occlusion, and displacement; (2) fetal trauma, iatrogenic abdominal wall defects, and amnioperitoneal leaking; and (3) preterm PROM, preterm labor, and infection.[17] Neonatal survival rates after fetal vesicoamniotic shunting (performed from the 1980s to 2001) varied from 50% to 90%, with approximately half of the survivors having normal renal function.[15,18,19] Currently a multicenter, randomized controlled trial is underway comparing the perinatal mortality and renal function of fetuses with lower urinary tract obstruction treated by either vesicoamniotic shunting or conservative noninterventional care.[20]

Fetal cystoscopy is a more recent treatment option that allows direct visualization of the fetal urethra.

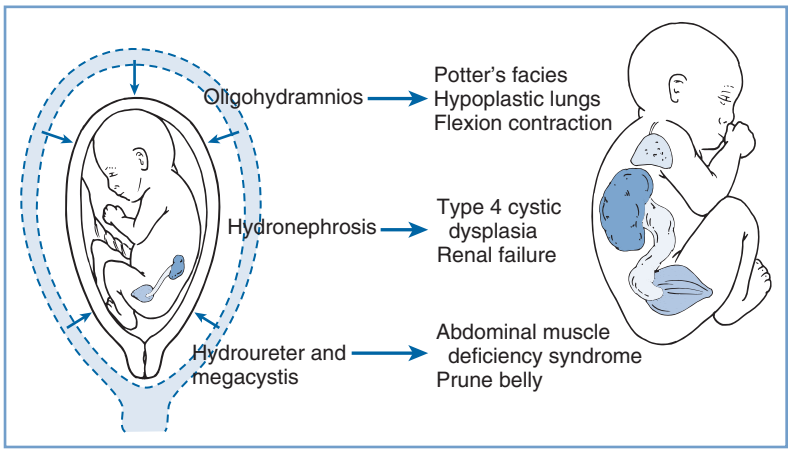

FIGURE 7-1 ■ Developmental consequences of fetal urethral obstruction. Obstructed fetal urinary flow results in hydronephrosis, hydroureter, megacystis, oligohydramnios, and pulmonary hypoplasia. (Redrawn from Harrison MR, Filly RA, Parer JT, et al. Management of the fetus with a urinary tract malformation. JAMA 1981; 246:635-9.)

Although not a viable treatment for urethral atresia, fetal cystoscopy facilitates diagnosis and treatment of lower urinary tract obstruction due to posterior urethral valves.[21] Fetal cystoscopy with ablation of posterior urethral valves appears to provide a survival advantage over conservative therapy but has not been demonstrated to improve perinatal survival over vesicoamniotic shunting.[22]

Current evidence supports fetal surgery for the correction of obstructive uropathy in selected fetuses in an effort to restore amniotic fluid volume, prevent pulmonary hypoplasia, and decrease perinatal mortality. However, the effects on long-term renal function and other morbidities remain unclear, and additional evidence is needed.

Congenital Diaphragmatic Hernia

Approximately 1 of 2500 live newborns has a congenital diaphragmatic hernia (CDH).[23] Without fetal intervention, this anomaly causes significant mortality from pulmonary hypoplasia and insufficiency. Survival rates have improved to between 60% and 85% over the past 20 years[24-27] and are closely associated with the degree of pulmonary hypertension and dysfunction.[24] Significant mortality occurs despite optimal postnatal surgical management at tertiary care medical centers (i.e., procedures involving removal of the herniated viscera from the chest, administration of surfactant, ventilation techniques that minimize lung trauma, use of ECMO, and closure of the diaphragm). Intrauterine correction of CDH has the potential to prevent the development of pulmonary hypoplasia and allow the fetal lung to develop before delivery.

The use of a fetal lamb model demonstrates that parenchymal hypoplasia and associated pulmonary vascular changes can be reversed by correction *in utero*.[3] Primary repairs of human CDH *in utero* have been undertaken only for fetuses with severe disease, with limited success but many lessons learned, including the development of minimally invasive approaches.[28,29]

Fetal lungs contribute to amniotic fluid volume by secreting more than 100 mL/kg/day of fluid that exits the trachea and mouth. Tracheal occlusion impedes the normal egress of fetal lung fluid and results in expansion of the hypoplastic lung, thereby inducing lung growth and cellular maturation in fetuses with CDH.[30,31] This occlusion technique, termed "*p*lug the *l*ung *u*ntil it *g*rows" (i.e., PLUG),[32,33] replaced primary repair *in utero* for the correction of the pulmonary hypoplasia associated with CDH. It is a less extensive, palliative fetal surgical procedure that enhances lung growth to improve postnatal survival, with postponement of the definitive repair until after birth.[30,34] Once the trachea is occluded, fetal pulmonary fluid slowly accumulates and expands the lung, pushing the viscera out of the thorax. A small detachable balloon for endoluminal tracheal occlusion is placed in the trachea via percutaneous endoscopic endotracheal intubation and is either left in place until delivery or deflated and removed earlier (Figure 7-2).[35,36]

A prospective randomized trial (1999-2001) evaluated fetal tracheal occlusion for intrauterine treatment of severe CDH.[37] Inclusion criteria included (1) a gestational age of 22 to 28 weeks, (2) left-sided herniation of the liver into the hemithorax, and (3) a low lung-to-head ratio (LHR) (i.e., < 1.4). The LHR is a ratio of the contralateral lung size compared with head circumference and is correlated with the severity of pulmonary hypoplasia and survival for a given gestational age.[38] The trial was closed early (n = 11); fetal tracheal occlusion resulted in no improvement in survival compared with control (77% versus 73%) and no reduction in morbidity at 90 days. The rates of preterm PROM and preterm delivery were higher in the fetal intervention group.[37] However, the survival rate was unexpectedly high in the control group. It is possible that the LHR criterion of less than 1.4 was not sufficiently restrictive and allowed inclusion of fetuses in the study that were likely to survive with standard postnatal tertiary medical care. Table 7-1 notes outcomes of left-sided CDH fetuses treated *in utero* or with standard postnatal care.

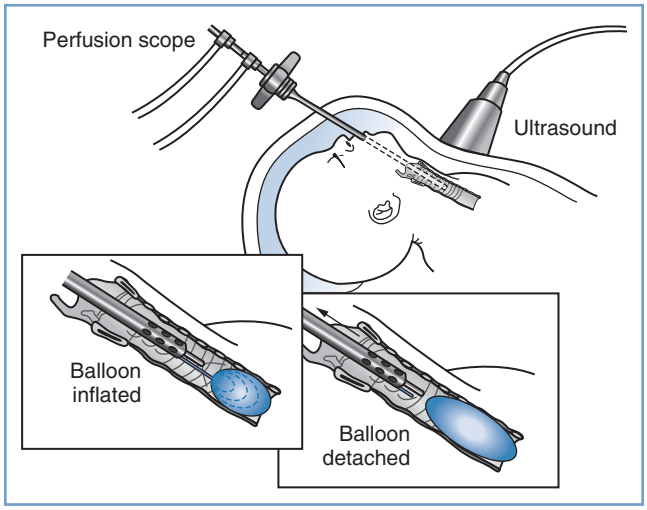

FIGURE 7-2 ■ Schematic of fetal tracheal occlusion using a balloon. (From Harrison MR, Albanese CT, Hawgood SB, et al. Fetoscopic temporary tracheal occlusion by means of detachable balloon for congenital diaphragmatic hernia. Am J Obstet Gynecol 2001; 185:730-3.)

More recently in Europe, the Fetal Endoscopic Tracheal Occlusion (FETO) Task Force began a collaboration among three medical centers for treatment of severe cases of CDH with a high risk for death.[39] FETO intervention criteria for fetuses at high risk included both LHR less than 1.0 and liver herniation into the hemithorax.[40] Use of smaller-gauge endoscopes and reversal of the tracheal occlusion before birth appear to show great promise for reduction in the risk for preterm delivery due to preterm PROM.[41,42] Owing to concern for tracheal damage by very early tracheal balloon placement,[43] the tracheal balloon is placed between 26 and 28 weeks' gestation and removed before birth by a second fetoscopic procedure near 34 weeks (if the fetus is still *in utero*).[44] This second procedure is performed to minimize the risk of preterm labor, avoid the need for the EXIT procedure, and potentially improve lung growth and minimize the reduction of type II alveolar cells associated with prolonged tracheal occlusion. Outcomes for 210 cases (through 2008) of fetuses with a mean gestational age of 27 weeks, LHR less than 1.0, and primarily left-sided

TABLE 7-1 Postnatal Survival in Fetuses with Left-Sided Congenital Diaphragmatic Hernia and Intrathoracic Liver Herniation Based on Fetal Lung-to-Head Ratio (LHR)

	Postnatal Management		*Fetoscopic Tracheal Occlusion*	
LHR (mm)*	NO. FETUSES	SURVIVAL NO. (%)	NO. FETUSES	SURVIVAL NO. (%)
0.4-0.5	2	0	6	1 (16.7)
0.6-0.7	6	0	13	8 (61.5)
0.8-0.9	19	3 (15.8)	9	7 (77.8)
1.0-1.1	23	14 (60.8)		
1.2-1.3	19	13 (68.4)		
1.4-1.5	11	8 (72.7)		
≥1.6	6	5 (83.3)		
TOTAL	86	43 (50)	28	16 (57.1)

*LHR measurements in the table were obtained at 23 to 29 weeks' gestation.

Modified from Jani JC, Nicolaides KH, Gratacos E, et al. Fetal lung-to-head ratio in the prediction of survival in severe left-sided diaphragmatic hernia treated by fetal endoscopic tracheal occlusion (FETO). Am J Obstet Gynecol 2006; 195:1646-50.

CDH (84%) were compared with those for historic postnatal treatment controls (1995-2004). Use of FETO significantly improved the survival rate (47% versus 20%), and delivery occurred at a median gestational age of 35.3 weeks.[39] However, the comparative results may represent selection bias or improvement in technique and clinical care over time. A more recent (2008-2010) randomized, controlled, single-institution trial compared cases of severe CDH (LHR < 1.0 with liver herniation) randomized to either FETO (n = 21) at 26 to 30 weeks' gestation or standard postnatal care (n = 20).[45] The overall survival rate with severe CDH was significantly greater in the FETO intervention group than in the expectant management group (52.6% versus 5.3%). In 2009, a randomized Tracheal Occlusion To Accelerate Lung growth trial (TOTAL) was started.[46] It compared postnatal management to late (30 to 32 weeks' gestation) FETO intervention for moderate lung hypoplasia and earlier FETO intervention (27 to 30 weeks' gestation) for severe lung hypoplasia. In addition, it is now understood that LHR depends on gestational age[47] and that a ratio of observed to expected LHR is a better expression of CDH severity and likelihood of survival.[48,49] This ratio is used as part of the ongoing TOTAL trial. Results of this trial will help determine if and when FETO should be offered for cases of severe CDH.

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformations (CPAM) are pulmonary tumors with cystic and solid components; these malformations were previously described as congenital cystic adenomatoid malformations (CCAM).[50] The incidence is approximately 1 in 25,000 pregnancies.[51] The classification scheme for CPAM includes five subtypes, based on cyst size, characteristics of the epithelial lining, cyst wall thickness, and the presence of mucous cells, cartilage, and skeletal muscle.[50,52] Lesions are assessed by ultrasonography and described as containing cysts larger (macrocystic) and smaller (microcystic) than 5 mm in diameter. Lesions can either regress with minimal associated morbidity or progressively enlarge, often resulting in hydrops fetalis (fetal heart failure). Small lesions detected *in utero* or in the newborn are treated after birth by surgical excision of the affected pulmonary lobe. Large lesions can cause mediastinal shift, hydrops, and pulmonary hypoplasia and can interfere with fetal or neonatal survival; fetuses with untreated lesions associated with hydrops fetalis have a survival rate of less than 5%.[53] In a retrospective single-institution review of 71 cases, the initial antenatal ultrasonographic ratio of CPAM volume to fetal head circumference (CVR) was evaluated for the formation of hydrops fetalis and postnatal outcomes.[54] Fetuses with a CVR less than 0.56 were noted to have no adverse postnatal outcomes, whereas a CVR greater than 0.56 had a positive predictive value for adverse postnatal outcome of 33%. In addition, a CVR greater than 1.6 was associated with a greater risk for hydrops fetalis.[55]

Depending on lesion size, location, and characteristics, CPAMs can be managed with either fetal intervention or postnatal resection. Macrocystic lesions have been decompressed *in utero* by placement of shunt catheters between the cysts and the amniotic cavity, resulting in sustained decompression and resolution of hydrops[56]; these procedures are followed by postnatal surgery. However, not all lesions can be decompressed successfully because the cysts are not always contiguous (i.e., in communication with each other) and can refill rapidly. In addition, these thoracoamniotic shunts have associated risks, including malfunction, displacement, fetal hemorrhage, and chorioamnionitis.[57] CPAMs inappropriate for drainage can be resected with open fetal surgery. Fetal pulmonary lobectomy for lesions associated with hydrops fetalis has resulted in a 30-day postnatal survival rate of 50%, with tumor resection allowing for compensatory lung growth and resolution of hydrops fetalis.[58] Maternal administration of betamethasone also has been noted to improve hydrops fetalis and overall outcome in selected fetuses with CPAM.[59,60] A retrospective review of 24 fetuses with predominantly microcystic CPAM and the presence of hydrops fetalis found that corticosteroid treatment resulted in better survival than resection with open fetal surgery.[61]

Intralobar and extralobar pulmonary sequestrations (bronchopulmonary sequestrations) are rarer congenital lung anomalies than CPAM and involve nonfunctional lung tissue (disconnected from the bronchial tree). As with CPAM, therapeutic options depend on fetal morbidities including hydrops fetalis and pulmonary hypoplasia. Thoracoamniotic shunts have been successfully placed to decompress massive congenital pleural effusions caused by fetal chylothorax that otherwise result in

hydrops fetalis, pulmonary compression, and fetal or neonatal death.[62]

Sacrococcygeal Teratoma

The prevalence of sacrococcygeal teratoma (SCT) is approximately 1 in 20,000 to 40,000.[63] Some fetuses with SCT undergo massive tumor enlargement, experience hydrops fetalis and placentomegaly, and die *in utero*. These tumors function as large arteriovenous fistulas, and fetal demise results from high-output cardiac failure. Management of these tumors requires close surveillance because they can grow rapidly and reach a size as large as 1000 cubic centimeters.[63] Fetuses with large lesions are at risk for intrapartum dystocia or tumor rupture and hemorrhage; these fetuses may require cesarean delivery. Fetuses with lesions diagnosed before 30 weeks' gestation have a poor prognosis but may benefit from surgical debulking *in utero;* surgical techniques have not reached the necessary level of sophistication to allow complete resection of lesions that deeply invade the pelvis. *In utero* radiofrequency ablation and thermocoagulation have been used to reduce the tumor blood supply, but the benefit remains unclear.[64] Catheterization of a fetal hand or umbilical cord vein for blood and crystalloid transfusion during tumor resection may be needed. To date, there has been no significant improvement in outcome with intervention in cases of SCT with hydropic fetalis.

Some SCT cases are accompanied by "maternal mirror syndrome" or Ballantyne syndrome, a hyperdynamic state (i.e., hypertension, peripheral and pulmonary edema) in which the maternal physiology mirrors the abnormal circulatory physiology of the hydropic fetus.[65] This syndrome is associated with a substantial increase in fetal mortality and maternal morbidity and requires aggressive management similar to that used for severe preeclampsia, a disease from which it must be distinguished. Platelet count, aspartate aminotransferase, alanine aminotransferase, and haptoglobin are typically unaffected in maternal mirror syndrome and may serve as diagnostic clues to rule out severe preeclampsia and HELLP (hemolysis, elevated liver enzymes, low platelets). Unfortunately, maternal mirror syndrome typically does not resolve quickly, even with rapid correction of the fetal pathophysiology, and severe maternal complications including pulmonary edema occur in about 20% of cases.[65]

Myelomeningocele

Although not lethal, a myelomeningocele is a protrusion of the meninges and spinal cord through a congenital defect in the vertebrae and overlying muscles and skin. It can result in lifelong morbidity and disability, including paraplegia, bowel and bladder incontinence, hydrocephalus, Arnold-Chiari II malformation, and impaired cognition.[66] Myelomeningocele has an incidence of about 1 in 2000 live births but is becoming less common owing to folate supplementation in the maternal diet. In addition, detection by ultrasonography and alpha-fetoprotein screening of maternal blood has allowed for earlier diagnosis (i.e., second trimester) and consideration of pregnancy termination.

The specific cause of myelomeningocele remains unknown. Animal models have demonstrated improved neonatal neurologic function with fetal closure of the defect *in utero*.[67,68] The results associated with defect closure support a "two-hit" disease model in which the pathology is produced by failure of the fetal neural tube to form combined with prolonged exposure to the uterine amniotic fluid.[69] Mutations of the *PAX3* gene and direct cord trauma may also play a role in the pathophysiology associated with a myelomeningocele.[70]

The 5-year mortality of myelomeningocele is approximately 8% for live births; if it is not corrected *in utero*, surgical closure must be performed within a few days after birth.[71] Ventriculoperitoneal shunting is required in 85% to 90% of uncorrected cases; however, despite successful shunting, permanent deficits such as central hypoventilation, vocal cord dysfunction, and oromotor and swallowing dysfunction can still occur from the associated Arnold-Chiari malformation.[72] The average intelligence quotient in myelomeningocele patients who require ventriculoperitoneal shunting is 80 (low normal).[73]

The purpose of fetal surgery for myelomeningocele is to improve function later in life.[69] Fetal surgery is primarily performed through an open fetal surgical technique. Preliminary results suggest that *in utero* repair successfully reverses the hindbrain herniation of the Arnold-Chiari II malformation, probably through normalization of cerebrospinal fluid flow, and decreases the need for ventriculoperitoneal shunt placement before 1 year of age.[74] More recently, a randomized, prospective, multicenter clinical trial completed between 2003 and 2010 examined the risks and benefits of open fetal surgery for myelomeningocele repair compared with standard postnatal repair in 183 patients.[75] Open fetal repair reduced the need for ventriculoperitoneal shunting and improved motor function at 30 months of age, but increased the risk for preterm birth and a partial or complete uterine dehiscence. Two perinatal deaths occurred in each group. Table 7-2 displays a subset of outcome measures that were significantly different between the prenatal and postnatal repair groups. Further data from the trial will include assessment of the long-term benefit from the prenatal intervention.

A recent study of endoscopic intrauterine myelomeningocele repair resulted in an extraordinarily high complication rate for both mothers and fetuses.[76] Of the 19 study patients, three fetuses died intraoperatively and another three procedures were stopped owing to severe hemorrhage from the procedure. Although this intervention was associated with spinal segmental neuroprotection, it resulted in significantly more complications; the authors concluded that, pending further advances, this technique is unsuitable as standard care.[76]

Twin-to-Twin Transfusion Syndrome

An abnormal connection of chorionic blood vessels in the placenta between two monochorionic twins can result in twin-to-twin transfusion syndrome (TTTS). TTTS complicates 10% to 15% of monochorionic pregnancies, usually manifests at 15 to 26 weeks' gestation, and is typically recognized at 20 to 21 weeks' gestation.[77,78]

TABLE 7-2 **Maternal and Fetal or Neonatal Complications for MOMS Trial Patients***

	Prenatal (n = 78)	Postnatal (n = 80)	*P*
Maternal Outcomes			
Chorioamniotic membrane separation	20 (26%)	0	< .001
Pulmonary edema	5 (6%)	0	.03
Oligohydramnios	16 (21%)	3 (4%)	.001
Placental abruption	5 (6%)	0	.03
Spontaneous rupture of membranes	36 (46%)	6 (8%)	< .001
Spontaneous labor	30 (38%)	11 (14%)	< .001
Blood transfusion at delivery	7 (9%)	1 (1%)	.03
Hysterotomy site thin, or partial or complete dehiscence noted at delivery	27 (36%)	N/A	
Fetal Outcomes			
Fetal bradycardia during repair	8 (10%)	0	.003
Mean gestational age at birth (weeks)	34.1 ± 3.1	37.3 ± 1.1	< .001
Mean birth weight (g)	2383 ± 688	3039 ± 469	< .001
Respiratory distress syndrome	16 (21%)	5 (6%)	.008

*The table lists maternal and fetal/neonatal complications that were significantly different ($P < .05$) between the prenatal and postnatal repair groups in the Management of Myelomeningocele Study (MOMS). Other outcomes were evaluated, but only those that were different between the two groups are included. Data for each group are shown as both an absolute number and as a percentage.

Modified from Adzick NS, Thom EA, Spong CY, et al. A randomized trial of prenatal versus postnatal repair of myelomeningocele. N Engl J Med 2011; 364:993-1004.

Intertwin transfusion is common between monochorionic twins and is usually balanced by the presence of arterioarterial (AA) and venovenous (VV) connections; the presence of AA connections is associated with a ninefold reduction in TTTS.[79] By contrast, unidirectional and imbalanced blood flow through arteriovenous (AV) chorionic vessels results in TTTS. In normal fetoplacental vasculature, the umbilical artery branches at the placenta surface and traverses and then descends into the tissue, where it further branches into capillary divisions for gas and nutrient exchange. The arterial system is "paired" with venous vasculature, which returns blood to the umbilical cord. In TTTS, the umbilical artery similarly descends into the placenta and cotyledon, but rather than connecting with a paired vein it connects with a vein that transports blood to the other twin.[80]

The twin serving as the recipient demonstrates polycythemia, polyuria, polyhydramnios, and hypertrophic cardiomyopathy; this twin is at risk for hydrops fetalis and fetal death. The twin serving as the donor is typically hypovolemic, growth restricted, and pressed against the endometrium in an oligohydramniotic sac (hence the designation "stuck" or "pump" twin) and often has a velamentous cord insertion; this twin is at risk for neonatal renal failure, tubular dysgenesis and dysfunction, and high cardiac output hydrops fetalis. Diagnosis is currently based on ultrasonographic findings that focus on differences in fetal size or amniotic sac fluid volume, presence of cardiac dysfunction in the recipient twin, umbilical cord size, and abnormal umbilical arterial flow velocity.[77,81] Twin size discordance is not always present and is no longer considered necessary to confirm the diagnosis. For unclear reasons, fetuses with TTTS are at risk for neurologic injury with white-matter lesions and long term disability; poor neurodevelopmental outcomes are associated with increased TTTS severity, delayed therapeutic interventions, and preterm delivery.[82] If TTTS is untreated, it carries a greater than 80% mortality with 15% to 50% risk for significant morbidity in surviving neonates.[83]

A variety of therapeutic management techniques have been developed, including (1) serial amnioreduction to control polyhydramnios and reduce the risk for preterm labor, (2) surgical septostomy to equalize amniotic pressures, (3) selective feticide to allow the other fetus to survive, and (4) selective fetoscopic laser photocoagulation (SFLP) of the vascular anastomoses between the two twins. Serial amnioreduction was demonstrated to improve placental perfusion and decrease the occurrence of preterm delivery.[84] In a retrospective review of 223 twin sets with TTTS, amnioreduction resulted in an overall birth survival rate of 78%, with 65% of recipient twins and 55% of donor twins alive at 1 month of age.[85] In a prospective randomized trial comparing serial amnioreduction to septostomy, there was no difference in the rate of survival between the two techniques.[86] Septostomy is rarely used for treatment because the creation of a single amniotic sac can increase the risk for umbilical cord entanglement.

The laser used for SFLP is typically inserted percutaneously through an endoscope (≤ 2.0 mm diameter) into the recipient twin's amniotic sac. Maternal anesthesia is commonly managed with either neuraxial blockade or local anesthetic infiltration from skin to myometrium. Fetoscope placement is determined by placental location and is guided by ultrasonography. Vessels that cross the dividing membrane separating the amniotic sacs are visualized, and abnormal connecting vessels are selectively coagulated with the laser.[77,80] On occasion, based on anatomic constraints created by the location of the fetuses and placenta, nonselective laser ablation is performed; however, this type of ablation is associated with higher rates of intrauterine fetal demise.[77,87] Ablation of all abnormal connecting vasculature is not needed for success of

the procedure.[88] After completion of the SFLP, amniotic fluid may be removed to reduce the degree of polyhydramnios and possibly decrease the risk for preterm labor.

A 2004 randomized multicenter trial compared laser therapy to amnioreduction for treatment of severe TTTS diagnosed between 15 and 26 weeks' gestation.[89] Rates of at least one twin survival were significantly higher in the laser treatment group at both 28 days (76% versus 56%, $P < .01$) and 6 months of life (76% versus 51%, $P < .01$). In addition, neurologic outcomes were better in the laser treatment group. A subsequent prospective study of a large subgroup of survivors from this trial observed these children for 6 years and found no additional change in survival or long-term neurologic outcome from the original 6-month data.[90] A meta-analysis of studies published between 1997 and 2007 noted that treatment of TTTS with laser ablation resulted in a higher overall rate of fetal survival than amnioreduction[91]; similar findings were demonstrated in a Cochrane review of treatment for TTTS.[92]

A more recent variation of the SFLP technique requires vascular laser ablation in a specific sequence. First, ablation occurs at the donor-to-recipient AV anastomoses, then at the recipient- to-donor AV anastomoses, then at the AA superficial anastomoses, and finally at the VV superficial anastomoses. The order of the procedure is designed to reduce the chance of hemodynamic compromise and hypotension during the procedure in the donor twin[93]; however, it is associated with longer operative times and increased case difficulty, particularly with an anterior placenta. In a single-institution study of consecutive SFLP for treatment of TTTS, twins treated with this sequence had better survival rates than twins whose SFLP procedure was performed without a specific sequence.[93] A prospective multicenter trial found a significantly improved 30-day survival of both fetuses and improved donor survival with this sequential technique when compared with a cohort control group.[94]

The most common complication of SFLP is preterm PROM with subsequent preterm labor and delivery. Other possible complications include placement of the trocar through the placenta, hemorrhage, and possible membrane perforation resulting in limb entrapment and ischemia.[77] In conclusion, trial results and meta-analyses provide evidence that SFLP results in superior outcomes than amnioreduction for the treatment of TTTS. Further research is needed to determine optimal techniques and timing of interventions for the treatment of TTTS.

Twin Reversed Arterial Perfusion Sequence

In monozygotic twins, one twin can also perfuse the other by retrograde blood flow though AA anastomoses. Twin reversed arterial perfusion (TRAP) sequence affects 1% of monozygotic twins and 1 in 30 triplets. Inadequate perfusion of the recipient twin via retrograde flow results in the development of a lethal set of anomalies that include acardia and acephalus. The normal ("pump") twin perfuses both itself and the nonviable twin and is at risk for high-output congestive heart failure, polyhydramnios, and preterm birth. If untreated, TRAP sequence is associated with a risk for intrauterine death of the pump twin exceeding 50%.[95] Diagnosis is confirmed with ultrasonographic demonstration of reverse flow to the acardiac twin via the umbilical artery. Cardiovascular failure in the pump twin is the indication for intervention, and early diagnosis is beneficial for optimal treatment.

The goal of therapy is to interrupt the vascular communication between the two twins. In contrast to the treatment of TTTS, treatment of TRAP sequence results in the death of the anomalous nonviable fetus. Percutaneous endoscopic laser or radiofrequency coagulation of the umbilical cord and/or placental vascular anastomoses is the most viable therapeutic option.[96,97] Alternative therapies include *sectio parva* (selective cesarean delivery of one of multiple fetuses), percutaneous thrombosis of the acardiac twin's umbilical cord with coils or other thrombogenic material, and alcohol-impregnated suture cord ligation. A retrospective review of 60 TRAP sequence cases from multiple European centers using endoscopic laser coagulation noted overall survival rates approaching 80% and a median gestational age of 37.4 weeks at delivery.[98] An additional study, using radiofrequency coagulation in 26 TRAP sequence cases at a single U.S. medical center, demonstrated a 92% survival rate of the viable twin with a mean gestational age of 35.6 weeks at delivery.[96] Both procedures are typically performed with infiltration of local anesthesia at the insertion site of the ablation device, although neuraxial anesthesia has also been used. The procedures are guided by ultrasonography, and absence of flow to the nonviable acardiac twin is confirmed with Doppler imaging at the end of the procedure and again 12 to 24 hours later.

Congenital Heart Defects

The most commonly performed closed fetal cardiac intervention for a congenital heart defect is an aortic valvuloplasty for mid-gestational aortic stenosis with evolving hypoplastic left heart syndrome. Technical success as high as 75% has been reported using an angioplasty balloon over a guidewire inserted percutaneously through an access cannula.[99] Approximately 40% of successful cases result in aortic regurgitation and minimal subsequent left ventricular growth; however, the physiology of the left ventricle improves and leads to improved aortic and mitral valvular growth. In about 30% of the successful cases, biventricular circulation is present at birth. Other congenital heart defects that may benefit from antepartum closed fetal cardiac intervention include (1) hypoplastic left heart syndrome with an intact or highly restrictive atrial septum and (2) evolving hypoplastic right heart syndrome with pulmonary atresia or stenosis without a ventricular septal defect.[100,101]

More complex congenital cardiac defects that might benefit from open repair have only been repaired in animal models and require fetal extracorporeal circulatory bypass; the use of fetal cardiac bypass induces a catecholamine-mediated fetal stress response that increases vascular resistance and cardiac afterload and is poorly tolerated by the immature fetal myocardium. Fetal cardiac bypass can also result in severe placental

dysfunction when the high-capacitance, low-resistance placenta is incorporated as the oxygenator, resulting in endothelial dysfunction and leukocyte and complement activation. After fetal cardiac bypass, increases in placental vascular resistance, reduced blood flow, impaired gas exchange, and fetal acidosis are frequently observed.[102,103] Correction of complex congenital cardiac defects, either open or closed, requires careful anesthetic and pharmacologic strategies for myocardial protection.

SURGICAL BENEFITS AND RISKS

The primary goal of intrauterine fetal surgery is to improve neonatal outcomes over that of surgery performed after a preterm or term delivery. The intrauterine environment supports rapid wound healing (i.e., without scarring before mid gestation),[104] and the umbilical circulation meets nutritional and respiratory needs without outside assistance. The poorly developed fetal immune surveillance system may facilitate certain invasive procedures. However, continued refinement of surgical and anesthetic techniques, reduction of maternal and fetal risk, and appropriate clinical trials for each intervention must occur before fetal surgery can be performed on a more routine basis for a given congenital anomaly.

Serious maternal complications from intrauterine fetal surgery are relatively uncommon. Maternal risks include blood loss, infection, placental abruption, and pulmonary edema secondary to tocolytic therapy and fluid overload from absorption of significant amounts of pressurized crystalloid uterine irrigation during fetoscopic techniques.[105,106] Open fetal surgery involves a hysterotomy that is not in the lower uterine segment, and therefore all future deliveries must occur via a cesarean procedure. Maternal welfare must always be emphasized.[7]

The fetal risks of intrauterine surgery remain relatively high. The most common postoperative complications are fetal central nervous system injuries, postoperative amniotic fluid leaks, membrane separation, preterm PROM, and preterm labor and delivery. Preterm delivery accounts for significant morbidity and mortality among fetuses that might otherwise have benefited from the therapeutic interventions. Chorioamniotic membrane separation can cause amniotic bands, umbilical cord strangulation, and fetal demise.[107] Improved techniques for sealing the membranes are being devised, including different surgical techniques, fibrin glue, and intra-amniotic injection of platelets and cryoprecipitate.[108,109]

ANESTHETIC MANAGEMENT

Fundamental considerations for the anesthetic management of fetal surgery are similar to those for nonobstetric surgery during pregnancy (see Chapter 17). Maternal safety is paramount. Anesthesiologists must participate in preoperative maternal assessment and exclude women when their perioperative risk is not acceptably low given the potential fetal benefit. To ensure both maternal and fetal safety, the anesthesiologist must understand the physiologic impact of pregnancy on anesthetic management (see Chapter 2) and must take an active role as a member of the multidisciplinary team. Imaging studies should be reviewed for placental location, anatomic information about the congenital lesion, and estimated fetal weight.

Unlike other surgical procedures performed during pregnancy in which the fetus is an innocent bystander (e.g., maternal appendectomy), fetal surgery involves two surgical patients. This requires the anesthesiologist to balance the anesthetic needs of both patients, as well as control uterine tone throughout the perioperative period. Complete uterine relaxation is necessary during open fetal surgical procedures.

Maternal analgesia and anesthesia can involve local infiltration, intravenous sedation, neuraxial anesthesia, general anesthesia, or a combination of these techniques, depending on the procedure, location of the placenta, and maternal co-morbidities. Fetal analgesia and anesthesia can be achieved via placental transfer of anesthetic agents given to the mother, via direct fetal intravenous or intramuscular administration of agents, or by a combination of these methods. An appropriate method of fetal monitoring and the potential requirement for fetal intravenous access or fluid resuscitation should be determined preoperatively. The operative team should be prepared for emergency situations such as maternal hemorrhage, fetal deterioration requiring aggressive intrauterine resuscitation (e.g., fetal epinephrine administration), and/or delivery and resuscitation of the viable newborn infant.[110]

Anesthesia for Minimally Invasive and Percutaneous Procedures

Local anesthetic infiltration of the abdominal wall is sufficient to reduce maternal discomfort for many percutaneous procedures (e.g., amniocentesis, cordocentesis, intrauterine blood transfusion, needle aspiration of cysts, shunt placement into the fetal bladder or thorax, SFLP for TTTS). Supplemental maternal analgesia and anxiolysis can be achieved by maternal administration of an opioid, a benzodiazepine, or a low-dose propofol infusion, which may confer some fetal immobility and analgesia via placental transfer.[111] However, when larger needles or multiple attempts are necessary for percutaneous procedures or a minilaparotomy, maternal comfort can be difficult to achieve with local infiltration, even when supplemented with sedation. In these circumstances, neuraxial anesthesia is recommended.[77,91] General anesthesia is rarely necessary for percutaneous procedures unless placental location makes the procedure significantly challenging or uterine exteriorization is needed.

Fetal movement may be hazardous for the fetus in cases of intrauterine transfusion, cord blood sampling, or thoracic shunt placement, because displacement of the needle or catheter may lead to trauma, bleeding, or compromise of the umbilical circulation. Placental transfer of maternally administered opioids and benzodiazepines can reduce fetal movement[89] but cannot ensure fetal immobility for more stimulating procedures. A randomized controlled trial of the use of a maternal remifentanil infusion (0.1 μg/kg/min) demonstrated improved fetal immobility

and operating conditions during fetoscopic surgery, when compared with maternal administration of diazepam.[112] Fetal immobility can be safely achieved with direct fetal intramuscular or umbilical venous administration of pancuronium or vecuronium (0.3 mg/kg intramuscularly or 0.1 to 0.25 mg/kg intravenously) using ultrasonographic guidance. The onset of fetal paralysis occurs in 2 to 5 minutes, with an approximate duration of 1 to 2 hours.[113] For procedures that can cause noxious stimulation to the fetus, such as shunt catheter placement or cardiac septoplasty, an opioid (e.g., fentanyl 10 to 20 µg/kg) can be administered to the fetus intramuscularly or intravenously.[114,115] When general anesthesia is employed, placental transfer of a volatile halogenated agent is usually sufficient to immobilize and anesthetize the fetus.

The fetal surgical team should be prepared for treatment of fetal compromise with immediate availability of appropriate doses of atropine and epinephrine. The obstetric team should be prepared to perform an emergency cesarean delivery if the gestational age is compatible with extrauterine viability. The anesthesiologist should be prepared to emergently provide general anesthesia if required.

Tocolysis typically is unnecessary after cordocentesis or intrauterine transfusion. For more invasive percutaneous procedures (e.g., shunt catheter placement, endoscopic techniques), some fetal surgery groups administer prophylactic tocolytic agents.

Anesthesia for Open Fetal Surgery

When corrective fetal surgery or an intrauterine procedure requires surgical access through a hysterotomy, general anesthesia is typically administered. Unique considerations for open fetal procedures include the need for profound uterine relaxation, intraoperative fetal monitoring, fetal anesthesia or analgesia, and postoperative maternal analgesia and uterine tocolysis (Table 7-3). In addition, significant maternal and fetal blood loss may occur, and the anesthesiologist must be prepared to achieve maternal and fetal resuscitation. A high concentration of a volatile halogenated agent is typically

TABLE 7-3 **Perioperative Considerations for Open Fetal Surgery**

Preoperative Considerations
- Complete maternal history and physical examination
- Fetal work-up to exclude other anomalies and imaging studies to determine fetal lesion, placental location, and estimated fetal weight
- Maternal counseling by multidisciplinary team and preoperative team meeting
- Lumbar epidural catheter placed and tested
- Prophylactic premedications for aspiration and tocolysis
- Blood products available for potential maternal and fetal transfusion
- Sequential compression devices on lower extremities for thrombosis prophylaxis

Induction and Intraoperative Considerations
- Left uterine displacement and standard monitors
- Preoxygenation for 3 minutes prior to induction
- Rapid-sequence induction and intubation
- Maintain maternal F_{IO_2} > 50% and end-tidal CO_2 28-30 mm Hg
- Ultrasonography to determine fetal and placental positioning
- Urinary catheter placed; additional large-bore IV access placed ± arterial line
- Prophylactic antibiotics administered
- Fetal resuscitation drugs and fluid transferred to scrub nurse in unit doses
- Following skin incision, high concentration of volatile anesthetic administered
- Blood pressure maintained (± 10% baseline with IV phenylephrine, ephedrine, and/or glycopyrrolate)
- Consider IV nitroglycerin if uterine relaxation not adequate
- IM administration of fetal opioid and neuromuscular blocking agent by surgeons
- Fluid restriction to < 2 L to reduce risk for maternal pulmonary edema
- IV loading dose of magnesium sulfate once uterine closure begins
- Discontinue volatile agent once magnesium sulfate load is complete
- Administer propofol, opioids, nitrous oxide as needed
- Activate epidural catheter for postoperative analgesia
- Monitor neuromuscular blockade carefully due to magnesium sulfate administration
- Extubate trachea when patient is fully awake

Early Postoperative Considerations
- Continue tocolytic therapy
- Patient-controlled epidural analgesia
- Monitor uterine activity and fetal heart rate
- Ongoing fetal evaluation

CO_2, carbon dioxide; *F_{IO_2},* fraction of inspired oxygen; *IM,* intramuscular; *IV,* intravenous.

administered to provide both maternal and fetal anesthesia as well as uterine relaxation; adequate uterine relaxation may require greater than twice the minimum alveolar concentration (MAC) of a volatile halogenated agent.[116]

Preoperatively, the mother receives agents for aspiration prophylaxis and uterine tocolysis (e.g., rectal indomethacin) and an epidural catheter is placed for postoperative analgesia. Minimal doses of preanesthetic and adjuvant anesthetic agents are given to allow significant doses of a volatile halogenated agent to be administered to achieve effective uterine relaxation; this approach may also reduce the occurrence of hypotension. The patient is placed in the supine position with left uterine displacement. After administration of 100% oxygen and denitrogenation of the lungs, a rapid-sequence induction of general anesthesia with cricoid pressure and endotracheal intubation is performed. Fetal heart rate (FHR) and umbilical cord blood flow are often monitored with ultrasonography during induction.

Initially, anesthesia is maintained with a low concentration of a volatile halogenated agent while further preparations for surgery are undertaken, including (1) obtaining additional maternal vascular access, (2) prophylactic antibiotic administration, (3) urinary bladder catheterization, and (4) ultrasonographic assessment of fetal presentation and placental location. Medications to provide fetal analgesia (e.g., fentanyl 10 to 20 μg/kg), immobility (e.g., vecuronium 0.3 mg/kg), and resuscitation (atropine 0.02 mg/kg, epinephrine 1 and 10 μg/kg, and crystalloid 10 mL/kg) are prepared in sterile labeled syringes; each syringe should contain a single weight-based unit dose. Crossmatched blood should be available for maternal transfusion. In addition, O-negative, cytomegalovirus (CMV)-negative, irradiated, leukocyte-depleted, maternally crossmatched blood should be available for fetal transfusion. For open procedures that have a high risk for significant fetal blood loss (e.g., mass resection), an intravenous catheter should be placed in the fetus to provide access for blood and fluid transfusions. An arterial catheter should be placed for maternal blood pressure monitoring if uterine tocolysis with a nitroglycerin infusion is planned. Intraoperative maternal intravenous fluids are restricted (< 2 L) to reduce the risk for postoperative pulmonary edema; some fetal surgery centers choose to limit fluids even further (< 500 mL), although no clinical trials have proven a benefit of fluid restriction in this setting.[117] The use of tocolytic agents such as magnesium sulfate and nitroglycerin has been associated with maternal pulmonary edema in patients undergoing fetal surgery.

A final discussion (i.e., surgical time-out), prophylactic antibiotic administration, and an increase in the concentration of the volatile halogenated agent should occur before skin incision. Maternal blood pressure is maintained with a mean arterial pressure within 10% of baseline values and greater than 65 mm Hg; a phenylephrine infusion provides titratable blood pressure control with minimal changes in the fetal acid-base status.[118,119] Ephedrine or glycopyrrolate boluses also can be administered to maintain maternal heart rate and improve cardiac output.[120] Maternal administration of a nondepolarizing muscle relaxant is usually not needed owing to the profound depth of anesthesia but may be used to improve operative conditions. The intrauterine location and position of the fetus is confirmed with ultrasonography just before hysterotomy to optimize the incision location.

Before uterine incision, it is important to achieve an increased end-tidal concentration of the volatile halogenated agent to provide both fetal anesthesia and uterine relaxation (typically ≥ 2 MAC). Fetal well-being can be assessed with pulse oximetry, ultrasonography for FHR monitoring, echocardiography to assess fetal ventricular contractility, and electrocardiography (ECG).

The uterus is assessed both visually and by palpation for contractions or increased tone; further tocolysis can be achieved with the administration of additional halogenated agent (≤ 3 MAC) or intravenous nitroglycerin as an infusion or in small boluses (50 to 200 μg).[121] Use of desflurane at 1.5 MAC with supplemental intravenous propofol and remifentanil has provided adequate uterine relaxation in one retrospective study.[122] For circumstances in which volatile halogenated agents or general anesthesia must be avoided (e.g., family history of malignant hyperthermia), a spinal or epidural anesthetic can be used with an intravenous infusion of nitroglycerin in doses up to 20 μg/kg/min.[121] This technique does not have a clear advantage for fetal outcome and may be associated with more morbidity. Nitroglycerin administration during open fetal surgery has been associated with maternal pulmonary edema.[117,123] Fetal intraventricular and periventricular hemorrhage and cerebral ischemia can result from changes in fetal cerebral blood flow, and concern has been raised regarding the use of tocolytic agents, which may affect vascular tone.[124]

An opioid and a muscle relaxant are administered to the fetus intramuscularly, either before uterine incision with ultrasonographic guidance or after uterine incision with direct vision. Some anesthesiologists administer atropine at this time in an effort to prevent opioid-induced fetal bradycardia; a muscle relaxant with vagolytic effects also can be chosen to minimize this type of bradycardia. Further studies are needed to determine the optimal anesthetic technique for ensuring maternal and fetal cardiovascular stability, optimal uteroplacental perfusion, and adequate fetal anesthesia to cause immobility and blockade of the fetal stress response.

A small uterine incision is created remote from the location of the placenta. A stapling device with absorbable synthetic copolymer (Lactomer) staples is used to extend the incision to seal the membranes to the endometrium and prevent excessive bleeding.[125] During surgery, the exposed fetus and uterus are bathed with warmed fluids. The intrauterine temperature is closely monitored to prevent fetal circulatory compromise associated with hypothermia.[126]

When uterine closure is initiated at the conclusion of the procedure, a loading dose of magnesium sulfate is administered (4 to 6 g intravenously over 20 minutes), followed by an intravenous infusion of 1 to 2 g per hour. As magnesium potentiates neuromuscular relaxation, close monitoring of twitch recovery is needed if a nondepolarizing muscle relaxant was administered. The volatile halogenated agent can be significantly decreased or

discontinued after the magnesium sulfate bolus has been administered. The epidural analgesia can be initiated and maternal anesthesia is maintained with additional fentanyl, nitrous oxide, and/or propofol.

Postoperative concerns include maternal and fetal pain, preterm PROM, preterm labor, infection, and a variety of potential fetal complications, including heart failure, intracranial hemorrhage, constriction of the ductus arteriosus from indomethacin, and fetal demise. Postoperative maternal analgesia can be maintained with a continuous epidural infusion of a dilute solution of local anesthetic and opioid for several days. Effective analgesia may help prevent postoperative preterm labor.[127,128] Intravenous opioids can also be used for analgesia; however, decreased FHR variability may occur.[129]

Management of postoperative preterm labor has been the "Achilles heel" of fetal surgery.[7] Tocolysis is typically provided by an infusion of magnesium sulfate for at least 24 hours; however, supplemental agents may include indomethacin, terbutaline, or nifedipine. Magnesium most likely competes with calcium at voltage-operated calcium channels, indomethacin blocks the synthesis of prostaglandins, and beta-adrenergic agonists activate adenylate cyclase in the uterine muscle, thereby reducing intracellular calcium levels. Frequently two tocolytic agents are required to create uterine quiescence. Uterine activity and FHR are monitored closely during the first 2 to 3 postoperative days. The fetus is evaluated postoperatively by ultrasonography, and if indomethacin is used, periodic fetal echocardiography is conducted to determine whether premature closure of the ductus arteriosis has occurred.

Patients recovering from open fetal surgery should remain near the fetal treatment center after being discharged. These patients are at high risk for preterm PROM, preterm labor, infection, and uterine rupture. Unless preterm labor occurs, cesarean delivery is typically planned at 37 weeks' gestation.

Anesthesia for the *Ex Utero* Intrapartum Treatment Procedure

Initially described as a method to remove the iatrogenic airway obstruction created for intrauterine treatment of CDH, the EXIT procedure has evolved into a technique useful for a number of fetal disorders that compress the airway and/or render neonatal tracheal intubation difficult or impossible. It is also useful when resuscitation and surgical intervention are required immediately before birth, while the fetus is still supported by the placentofetal circulation. Cases appropriate for an EXIT procedure include (1) thoracotomy for congenital pulmonary airway malformations and (2) tracheostomy and the removal of neck masses such as fetal teratoma. The use of an EXIT procedure may also assist the transition to ECMO for pulmonary insufficiency or the stabilization of conjoined twins prior to separation.[11,130,131] Similar to open fetal surgery procedures, sustained uterine relaxation and delay of placental separation are necessary for a successful EXIT procedure.

Anesthesia for EXIT procedures is most commonly performed with the use of general anesthesia, although neuraxial anesthesia, typically combined with intravenous nitroglycerin infusion to achieve uterine relaxation, may also be used. Multiple reviews of the surgical and obstetric considerations associated with the EXIT procedure have been published.[132-134]

The conventional anesthetic approach is a modification of the general anesthetic technique used for cesarean delivery. Preparation for fetal monitoring, airway management, fetal/neonatal resuscitation, and postdelivery care should be completed before entering the operating room. A sterile pulse oximeter probe and an end-tidal carbon dioxide indicator or gas analyzer are used for fetal monitoring during the procedure; basic ultrasonography can be added to assess the fetal heart. Unit doses of atropine, epinephrine, and calcium for intramuscular fetal injection are transferred sterilely to the scrub nurse for possible emergency intraoperative resuscitation. Supplemental fetal anesthetic agents for intramuscular injection are also prepared and transferred to the scrub nurse (see later discussion). A sterile ventilation bag with an air/oxygen source and manometer is available for the fetus, along with multiple endotracheal tube sizes and devices for fetal tracheal intubation. Catheters for intravenous access as well as crystalloid and blood (O-negative, CMV-negative, leukocyte depleted, irradiated, maternally crossmatched) should be available for fetal volume resuscitation if needed.

A maternal epidural catheter may be placed preoperatively for postoperative analgesia. Anesthetic considerations for the mother are similar to those for cesarean delivery but should also include large-bore intravenous access, availability of uterotonic agents and crossmatched blood, and the ability to quickly obtain invasive maternal monitoring if needed.

Techniques of induction and tracheal intubation do not differ from those typically used for cesarean delivery. Although techniques for maintenance of anesthesia vary between medical centers, administration of 2 to 3 MAC of a volatile halogenated agent is often needed to achieve and maintain adequate uterine relaxation. Occasionally, nitroglycerin administered intravenously as a bolus dose (50 to 200 μg) or as an infusion is required to obtain appropriate uterine relaxation. Fetal anesthesia from the halogenated agent transferred across the placenta can be supplemented by direct fetal (intramuscular) administration of an opioid (fentanyl 5 to 15 μg/kg) and a paralytic agent (rocuronium 1 to 3 mg/kg or pancuronium 0.1 to 0.3 mg/kg); some practitioners also administer intramuscular atropine (20 μg/kg) to prevent fetal bradycardia.[132,134] Intramuscular agents can be administered to the fetus either before uterine incision with ultrasonographic guidance or after incision with direct visualization. Significant variability in serum fentanyl concentrations among fetuses has been documented in umbilical cord blood during EXIT procedures,[135] and similar variability may exist with muscle relaxants and other agents.

When adequate uterine relaxation has been achieved, the placental location and edges are confirmed by intraoperative ultrasonography. Similar to open fetal procedures, the uterine incision is extended with a stapling device to minimize blood loss. The fetal head and shoulders are delivered in preparation for tracheal intubation.

For more extensive procedures, such as fetal thoracotomy, or when there is fetal bradycardia suggestive of umbilical cord compression, the fetus can be completely delivered and placed on the maternal chest and abdomen. In an effort to maintain fetoplacental circulation, warmed fluids are continuously irrigated into the uterine cavity and care is taken to avoid manipulation of the umbilical cord. The warmed irrigant maintains fetal euthermia and helps prevent decreased uterine volume, placental separation, and spasm of the cord vessels. The fetus is initially monitored with (1) a pulse oximeter probe placed on the fetal hand, (2) periodic ultrasonography, and (3) direct visualization.

The duration of the fetal procedure can range from a few minutes (e.g., bronchoscopy or intubation) to several hours (e.g., neck or thoracic mass resection, tracheostomy, or central intravascular access). Although the majority of procedures require less than an hour, the anesthetic technique should be capable of providing maternal, fetal, and uteroplacental stability over several hours.[136,137] Once surgery is completed and the trachea secured, surfactant is given if indicated. Fetal oxygen saturation is typically 40% to 60% at this time[138] but increases significantly to above 90% with ventilation of the fetal lungs. Failure to achieve a fetal saturation of at least 90% is an indication for the use of ECMO before clamping the umbilical cord and delivering the fetus.[139]

After the umbilical cord is clamped, the maternal anesthetic technique is altered to help achieve uterine tone and diminish the risk for postpartum hemorrhage.[132,140] This is accomplished by (1) substantially reducing the inspired concentration of the volatile halogenated agent; (2) adding nitrous oxide, propofol, and/or an opioid to maintain anesthesia; (3) administering oxytocin and other uterotonic agents, if needed; and (4) initiating epidural analgesia via the epidural catheter that was placed before surgery.

An alternative technique for EXIT procedures involves the use of neuraxial anesthesia.[141-143] Although this approach avoids many of the risks associated with general anesthesia, large doses of intravenous nitroglycerin (1 to 10 μg/kg/min) are often required to achieve adequate uterine relaxation. Nitroglycerin can cross the placenta; however, a significant amount is metabolized at the placental interface, resulting in minimal fetal effects.[121,143] If nitroglycerin is to be used at significant doses for a prolonged period, an arterial catheter is recommended and the patient should be observed for evidence of pulmonary edema. Fetal analgesia and immobility can be achieved with fetal administration of intramuscular drugs (see earlier discussion); maternally administered intravenous remifentanil undergoes significant transfer across the placenta and may serve as an adjuvant for fetal analgesia and immobility.[144,145] Prospective trials are necessary to delineate the advantages and disadvantages of these various anesthetic techniques for the EXIT procedure.

Fetal Response to Surgical Stimulation

The subjective phenomenon of pain has not been, and perhaps cannot be, assessed adequately in human fetuses. Pain is a multidimensional, subjective, psychological construct that can exist in the absence of physical stimuli (e.g., phantom limb pain), and it includes emotional and affective components that require higher-level cortical processing. As such, although pain is commonly associated with physical noxious stimuli, it is more than nociception or a simple reflex activity associated with a withdrawal response.[146] Attempts have been made to correlate pain with surgical stress; however, the physiologic responses are not equivalent and reductions in stress hormones should not be interpreted as an indicator of adequate analgesia.[147] The stress response is mediated primarily in the spinal cord, brainstem, and/or basal ganglia, without involvement of the cortex. This distinction acknowledged, pioneering studies of preterm neonates undergoing surgery with minimal anesthesia have revealed circulatory, sympathoadrenal, and pituitary adrenal responses characteristic of stress (e.g., increased release of catecholamines, growth hormone, glucagon, cortisol, aldosterone, and other corticosteroids; decreased secretion of insulin).[148,149] Administration of adequate anesthesia in neonates blunts this stress response,[150] and attenuation of the stress response in preterm neonates has been associated with improved outcomes.[151]

In studies of intrauterine blood transfusion in the human fetus, surgical needling of the intrahepatic vein (in contrast to the insensate umbilical cord) is associated with evidence of a stress response, including increases in plasma beta-endorphin and cortisol concentrations and decreases in the middle cerebral artery pulsatility index (determined by Doppler imaging). These responses, which may redistribute blood flow to vital organs, including the brain,[152] can be blunted by the administration of fentanyl 10 μg/kg.[114] Human fetuses elaborate pituitary-adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli as early as 18 weeks' gestation.[153-156] During late gestation, fetuses can respond to environmental stimuli such as noise, light, music, pressure, touch, and cold.[157]

Nerve terminals for the detection of touch, temperature, and vibration (not pain) are present deep within the human skin at 6 weeks' gestation and become more numerous and superficial (e.g., toward the skin surface) by 10 weeks' gestation.[158] Immature skin nociceptors likely begin to emerge at 10 weeks' gestation and are present by 17 weeks' gestation[159]; in internal organs, nociceptors develop slightly later.

Peripheral nerve fibers that control movement grow into the spinal cord at about 8 weeks' gestation. When these fibers connect with nociceptors is unknown, but the timing of these connections is delayed when compared with other sensory inputs in nonhuman, mammalian models. One human study suggested that nociceptive nerve fibers do not enter the spinal cord before about 19 weeks' gestation.[160] The cerebral cortex develops after the fetal spinal cord and brainstem. Thalamocortical axons reach the somatosensory cortex at 24 to 26 weeks' gestation.[146]

The developing cerebral cortex consists of transient fetal zones where neuronal proliferation, cell migration, apoptosis, axonal outgrowth, and synaptogenesis occur according to a highly specific timetable (see Chapter 10). Originating as a smooth layer without sulci and gyri, the

cerebral cortex, like the thalamus, has no internal cellular organization.[158] The cortical subplate is a temporary structure that serves as a waiting and organizing zone for various afferents destined for the cortex; it develops about 13 weeks' gestation and recedes after 32 to 34 weeks' gestation. The insular cortex starts developing in humans at approximately 15 weeks' gestation, with the cortical plate eventually developing into the six layers of the cerebral cortex.[161-163]

The first fibers from the thalamus reach the subplate between 12 and 18 weeks' gestation and remain until the maturation of the cortical plate. The gestational age at which thalamic pain fibers reach the human cortex only can be estimated from histologic studies of other thalamocortical circuits. Thalamic projections reach the visual subplate at 20 to 22 weeks' gestation,[162,164] the visual cortex at 23 to 27 weeks' gestation,[165] and the auditory cortical plate at 26 to 28 weeks' gestation.[166] The subplate becomes thinner in the insula and in areas of the brain where early cortical folding occurs. Extensive brain growth and maturation occur after 34 weeks' gestation, resulting in cortical sulci and gyri and an extensive network of pathways within the cortex and to the thalamus, midbrain, and spinal cord. Prior to the completion of the thalamocortical system, the midbrain reticular system is possibly responsible for pain awareness, as it is for consciousness.[162,167]

Studies of fetal electroencephalograms (EEGs) at 24 weeks' gestation demonstrate electrical activity only 2% of the time, predominantly in 20-second bursts with periods of inactivity lasting up to 8 minutes. At 30 weeks' gestation, EEGs begin showing patterns of wakefulness and sleep, but these are not concordant with fetal behavior. By 34 weeks' gestation, electrical activity is present 80% of the time, with more distinct wakefulness and sleep cycles similar to adult patterns.

Low levels of oxygenation *in utero* and endogenous neural inhibitors such as adenosine and pregnenolone may preclude optimal functioning of neural tissues and networks.[168] However, two studies using near-infrared spectroscopy in preterm infants demonstrated differences in cerebral oxygenation over the somatosensory cortex with noxious and non-noxious stimulation. This appears to indicate that noxious information is at least transmitted to the infant cortex by 25 weeks' gestation[169,170]; similarly, preterm neonates also have demonstrated cortical evoked potentials after a heel lance.[171]

Although initial fetal reactions to nociceptive stimulation are purely reflexive, and cortical processes can occur only after thalamocortical connections have been completed, nociceptive stimuli can activate a number of subcortical mechanisms; moreover, stress responses may influence the maturation of both the thalamocortical pathways and the cerebral cortex. Although the data on the consequences of fetal exposure to stressful stimuli are incomplete, recognition should be given to the possibility that noxious stimuli, which can be attenuated or blocked by anesthesia, may be associated with adverse long-term neurodevelopmental consequences.[172] For example, circumcision in nonanesthetized neonates has been associated with increased pain responses to injections performed 6 months later[173]; in addition, fetal stress has been associated with long-term adverse hormonal effects in young monkeys.[174]

The exact onset of fetal *sentience*, the capacity to feel pain, is unknown (see Chapter 5). Because of this uncertainty, it seems best to err on the side of administering adequate fetal anesthesia.[175] Altogether, clinical observations of fetal and neonatal behavior, information about the development of mechanisms of pain perception, and studies of fetal and neonatal responses to noxious stimuli provide a compelling physiologic and philosophic rationale for the provision of adequate fetal anesthesia, especially after 24 to 26 weeks' gestation. Noxious stimulation during fetal life causes a stress response, which could have both short- and long-term adverse effects on the developing central nervous system. Although the link between the stress response and pain is not always predictable, the threshold for pain relief is typically below that for stress response ablation, and the stress response to noxious stimulation is clear evidence that the fetal nervous system is reactive.[176] Administration of fetal anesthesia has been the standard practice worldwide since the inception of fetal surgery more than 30 years ago.[5,6,177,178] The importance of fetal immobility, cardiovascular homeostasis, analgesia, and perhaps amnesia have always been emphasized in fetal surgery practice.

Effects of Anesthesia on the Fetus

In fetal lambs, the concentration of halothane required to prevent movement in response to painful stimuli (1.0 MAC) is less than 40% of the concentration required in adult sheep.[179] Despite rapid placental transfer of volatile halogenated agents, experiments in sheep models have shown that fetal concentrations of these agents remain lower than maternal concentrations for significant periods after maternal administration (Figure 7-3).[180]

Experimental studies of the fetal effects of maternal administration of a volatile halogenated agent in sheep have not produced uniform results.[180-183] Maternal administration of isoflurane and halothane resulted in variable changes in fetal blood pressure, heart rate, oxygen saturation, cardiac output, and acid-base status. A retrospective analysis of cardiac imaging from both open fetal cases and EXIT procedures noted severe left ventricular systolic dysfunction in the fetus with use of high concentrations of desflurane.[122]

Maternal-fetal sheep studies, with no surgical stimulus to either the mother or fetus, show that deep maternal inhalation anesthesia (> 2.0 MAC) results in progressive fetal acidosis. By contrast, lower maternal inhalation anesthesia (1.0 MAC) also may be undesirable because it does not adequately block the fetal response to a painful stimulus, which includes increased fetal catecholamines, vasoconstriction, and redistribution of fetal blood flow.[184] However, the combined effect of adequate fetal anesthesia with a halogenated agent, intrauterine manipulation, and fetal stress on fetal cardiovascular stability and regional blood flow remains unknown. Brief fetal exposure to deep maternal inhalation anesthesia (i.e., 2.0 to 3.0 MAC) does not appear significantly detrimental to the fetus, with no fetal hypoxia, hypercarbia, or acidosis observed even after exposures of 2 hours if maternal

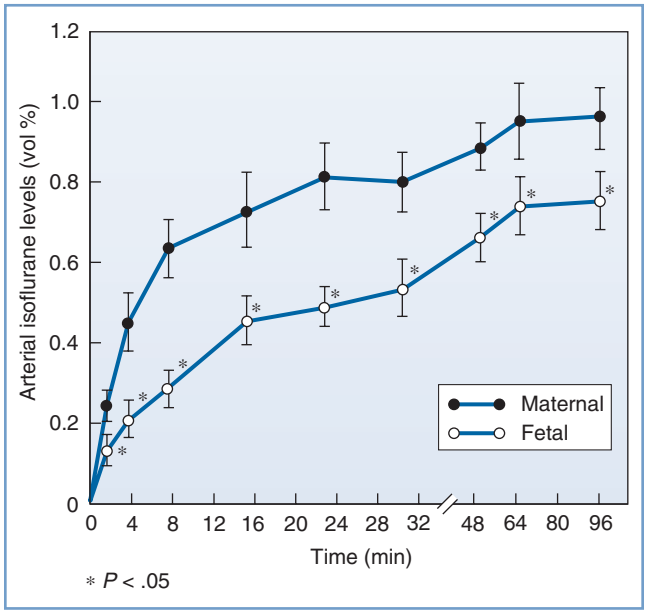

FIGURE 7-3 ■ Maternal and fetal arterial isoflurane concentrations in sheep during maternal administration of 2.0% isoflurane (mean ± SE). (From Biehl DR, Yarnell R, Wade JG, Sitar D. The uptake of isoflurane by the foetal lamb *in utero*: effect on regional blood flow. Can Anaesth Soc J 1983; 30:581-6.)

arterial pressure is maintained.[136] However, others have seen acidosis after 45 minutes of fetal exposure to anesthesia.[185]

Another concern is that anesthetic agents may result in neuronal apoptosis in the developing fetal brain (see Chapter 10). Initial evidence was found in 2003, when an anesthetic consisting of midazolam, nitrous oxide, and isoflurane was shown to alter neurons in the developing brain of 7-day-old rats and to cause long-term impairment of brain function.[186] Additional *in utero* rat studies noted that fetal exposure to isoflurane for 4 hours near mid gestation resulted in abnormal spatial memory acquisition.[187] Primate studies have demonstrated significant neurodegeneration in the neonatal period after exposure to isoflurane.[188] It is not currently known if anesthetic agents similarly affect human fetuses or newborns. Several retrospective human studies have produced inconclusive results. One retrospective cohort trial noted that a single short anesthetic exposure in children younger than age 2 years did not have long-term cognitive implications; however, exposure to multiple anesthetics was a significant risk factor for development of learning disabilities.[189] Another retrospective study examined anesthetic exposure among twins and found no causal relationship between early anesthetic exposure and learning disabilities.[190] Although there is concern for neurotoxicity in human fetuses or children exposed to anesthetic drugs, current findings remain inconclusive about the long-term effects of anesthetic agents on brain function in humans. A 2007 U.S. Food and Drug Administration advisory committee concluded that no change in clinical practice is justifiable based on current data.[191,192] The neurocognitive effect of anesthetic exposure on fetuses during fetal surgery remains unknown.

Fetal Monitoring

Maternal and fetal anesthesia, uterine incision, fetal manipulation, and surgical stress may adversely affect uteroplacental and fetoplacental circulation by several mechanisms. Maternal hypotension, increased uterine activity, and maternal hyperventilation and hypocarbia impair uteroplacental and/or umbilical blood flow. Fetal manipulation may affect fetal cardiac output, regional distribution of cardiac output, and umbilical blood flow. Direct compression of the umbilical cord, inferior vena cava, and mediastinum adversely affects fetal circulation. Current methods of intraoperative fetal monitoring include FHR monitoring, pulse oximetry, ultrasonography (including echocardiography and Doppler assessment of umbilical cord blood flow), and blood gas and acid-base analysis.

Intraoperative monitoring of the FHR during open fetal surgery was initially attempted with a standard fetal corkscrew electrode processed by a standard FHR cardiotachometer, but signal failure was frequent, secondary to low signal amplitude and movement artifact. With use of atrial pacing wires sutured to the fetus, proximal wire shielding, increased gain to allow signal amplification, and filter modification, a more reliable display of fetal ECG with visible P waves and QRS complexes was possible. Unfortunately, this technique did not eliminate motion artifact. Analysis of the fetal ECG using ST waveform analysis may prove beneficial for fetal surgery.[193] A fetal scalp electrode has been used successfully as part of an EXIT procedure to monitor FHR after the head was exposed.[194]

Plethysmography combined with pulse oximetry has proved to be very useful, particularly for the EXIT procedure. The predictive value of pulse oximetry may be superior to FHR monitoring; bradycardia has been found to be a late sign of fetal compromise in fetal lambs subjected to umbilical cord compression (Figure 7-4).[195] However, bradycardia can also precede oxyhemoglobin desaturation during human fetal surgery (Figure 7-5).[196]

Ultrasonography is a crucial intraoperative fetal monitoring device. The FHR can be determined with visualization of the heart or with Doppler assessment of umbilical cord blood flow. Fetal cardiac contractility and volume also can be assessed qualitatively by echocardiography. Unfortunately, the sterile transducer often cannot be positioned continuously because its location interferes with surgery.

New devices may allow monitoring of (1) fetal blood pressure and EEG; (2) fetal arterial blood oxygen saturation, Po_2, and Pco_2; and (3) fetal cerebral oxygenation, blood volume, and blood flow with near-infrared spectroscopy.

THE FUTURE OF FETAL THERAPY

Successful diagnosis and management of complex congenital anomalies and other fetal conditions amenable to prenatal intervention relies on a multidisciplinary team whose members communicate and work together to

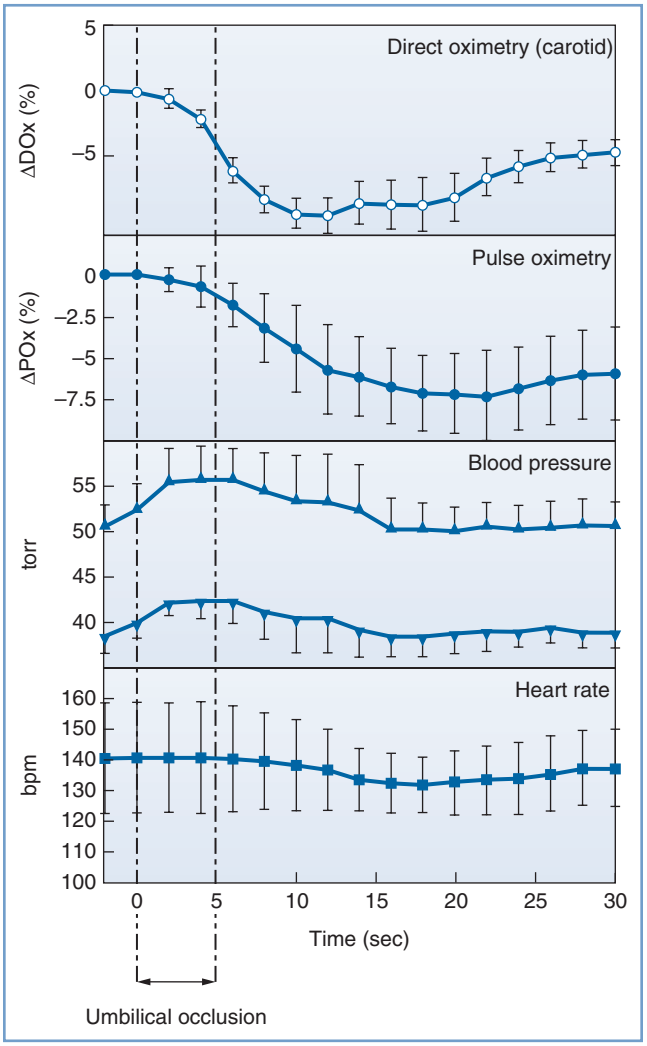

FIGURE 7-4 ■ Response to 5 seconds of umbilical cord occlusion in the fetal lamb. Direct oximetry and pulse oximetry are expressed as delta saturation ($T_x - T_0$). (From Luks FI, Johnson BD, Papadakis K, et al. Predictive value of monitoring parameters in fetal surgery. J Pediatr Surg 1998; 33:1297-1301.)

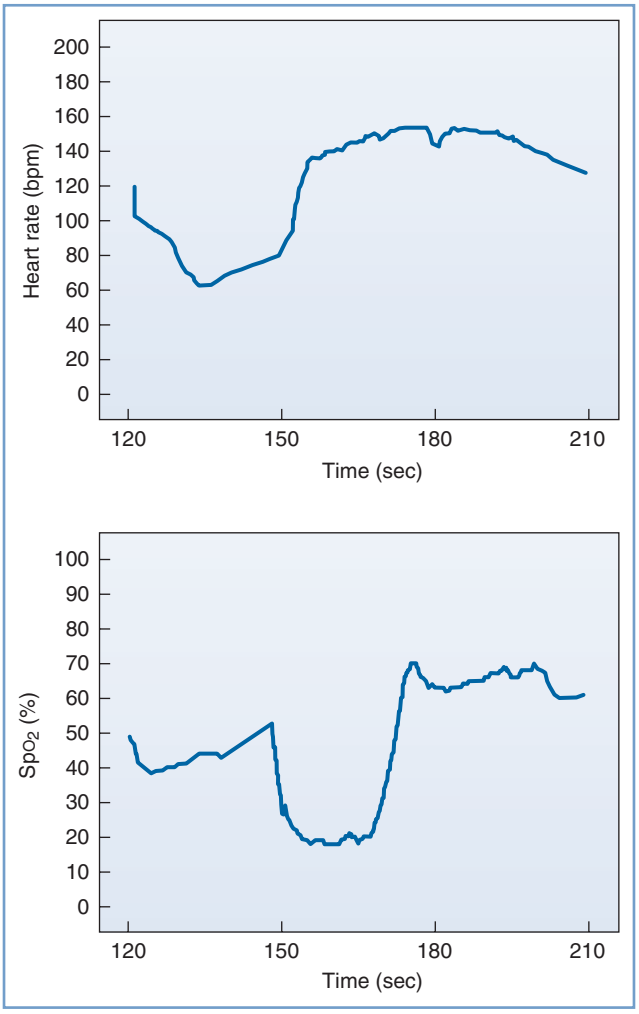

FIGURE 7-5 ■ Graphic representation of monitoring data from a fetus at 24 weeks' gestation undergoing open diaphragmatic hernia repair. Top graph shows fetal heart rate (bpm) and bottom graph shows oxygen saturation (Spo_2) detailed over a 2-minute period. The tracings demonstrate an acute decrease in fetal heart rate (FHR) with an associated decrease in fetal Spo_2. The onset of the desaturation detected in the fetal hand is delayed in relation to the onset of the bradycardia. Similarly, the recovery in FHR precedes the onset of the rapid increase in saturation. This pattern most likely represents a transport delay of the blood from the heart to the fetal hand. (From Rosen MA. Anesthesia for fetal surgery. In Hughes SC, Levinson G, Rosen MA, editors. Shnider and Levinson's Anesthesia for Obstetrics. 4th edition. Philadelphia, Lippincott Williams & Wilkins, 2002.)

improve fetal outcome without incurring substantive maternal risk. Well-organized, multidisciplinary, professional, and comprehensive fetal treatment programs at academic medical centers facilitate the sustained effort to innovate new techniques, challenge dogma, and ensure ongoing success. More collaborative clinical investigation among international research centers will benefit these efforts and guide the evolution of prenatal fetal therapy. Advances in technology will continue to drive improvement and availability of fetal intervention. For example, dynamic tracheal occlusion for CDH rather than complete occlusion, using devices that have pressure-sensitive valves to allow egress of fetal lung fluid, may improve outcome by more closely imitating normal developmental physiology and result in more normal lung function than that seen with current techniques.

With continued advances and miniaturization of invasive techniques and decreases in maternal and fetal risk, fetal intervention for a wider variety of procedures is the likely future for fetal therapy. Endoscopic repair of myelomeningocele has already been attempted. Other procedures with future potential include (1) placement of a cardiac pacemaker to restore sinus rhythm and improve survival in fetuses with complete heart block or a cardiac arrhythmia, when treatment is refractory to transplacental administration of medication; (2) repair of craniofacial anomalies, gastroschisis, and cleft lip and palate; and (3) corrections of skeletal anomalies by allogenic bone grafting. Innovations focused on tissue engineering, using stem cells and gene therapies, are exciting possibilities for future fetal therapy.

Although the rationale for prenatal fetal therapy seems straightforward, many issues remain problematic. Questions remain regarding the manner in which fetal development is modulated by intrauterine intervention. Other questions revolve around maternal and fetal rights, safety, efficacy, long-term outcomes, cost-effectiveness, and societal resource allocation. Societal expectations and the availability of therapy must be balanced against the budgetary constraints in contemporary health care. In addition, there is concern about the sensitivity, specificity, and appropriate use of diagnostic testing. Fetal therapy raises complex social, ethical, and legal issues that go beyond those customary for therapeutic intervention.[197] In some cases, distinguishing innovative therapy from experimentation is difficult. The ethical framework for the transition from innovation to clinical trials to offering fetal surgery as a standard of care must be managed thoughtfully and responsibly. A bioethics committee with representatives from both the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists has provided recommendations for medical institutions offering fetal surgery.[198]

Fetal therapy must be evaluated carefully in properly conducted trials and undertaken only with great caution and informed maternal consent. Publication in scientific journals and open communication with colleagues nationally and internationally facilitates the moral obligation of researchers to report all results to allow peer review of the merits and liabilities of fetal surgery. The principal concept of *primum non nocere* argues that it is unethical to undertake human trials until a procedure is appropriately tested in animals.[199,200]

Training programs are necessary to safely expand access and services from academic medical centers to local units. There is debate whether results of trials from tertiary academic centers such as the MOMS trial[75] are applicable to institutions that did not participate. Outcomes from new fetal centers with little experience and patients outside strict inclusion criteria may have less favorable outcomes with greater morbidity.[201] Fetuses that may benefit from invasive therapy must be carefully distinguished from those that will not. Intervention should be undertaken only when there is a reasonable probability of long-term benefit and minimal maternal risk. Despite more than 3 decades of experience, there remains much to study, a great deal to learn, and, it is hoped, a lot to achieve.

KEY POINTS

- Most malformations diagnosed *in utero* are not suitable for antenatal intervention. Fetal surgery is a reasonable option for anomalies that cause harm to the fetus before adequate development necessary for extrauterine survival (particularly lung maturity).
- Local or neuraxial anesthesia is often suitable for percutaneous or minimally invasive procedures. Open intrauterine procedures typically require administration of general anesthesia.
- Anesthetic considerations for intrauterine fetal surgery are similar to those for nonobstetric surgery in pregnant women. However, fetal surgery typically requires (1) provision of analgesia for the fetus, (2) more intensive intraoperative fetal monitoring, and (3) intraoperative uterine relaxation.
- Preterm premature rupture of membranes and preterm labor after surgery are significant barriers to optimal outcomes with fetal surgery.
- There are many medical, social, ethical, and legal questions regarding the efficacy and safety of intrauterine fetal surgery. Careful evaluation of fetal benefits and maternal risks is fundamental to the decision as to when and whether fetal intervention is appropriate.

CHAPTER 8

Intrapartum Fetal Assessment and Therapy

Elizabeth G. Livingston, MD

CHAPTER OUTLINE

The value of intrapartum obstetric interventions to assess and maintain fetal well-being has been scrutinized in recent years. Old technologies have been reassessed, and new ones have been introduced. A rising cesarean delivery rate, renewed interest in home birth, persistent cases of fetal/neonatal neurologic injury, and excessive litigation have prompted an ongoing search for methods to identify and intervene on behalf of the fetus at risk during labor and delivery.

FETAL RISK DURING LABOR

Historical epidemiologic data suggest that the fetus is at increased risk for morbidity and mortality during labor and delivery. In 1963, the British Perinatal Mortality Survey reviewed autopsy data for 1400 stillborn infants and concluded that slightly more than 30% of these losses resulted from intrapartum asphyxia.[1] Neonatal outcomes in the industrialized world have improved over the past 40 years. A Canadian database identified approximately 80 intrapartum stillbirths per 120,000 live births from 1981 to 2002, a rate of 0.67/1000; some 11 of the infants were considered viable (i.e., not severely preterm or anomalous), which indicated a preventable death rate of 0.09/1000.[2] A Scottish study indicated that perinatal deaths due to intrapartum anoxia in term, singleton, cephalic infants declined significantly from 5.7 to 3.0/10,000 births between 1988 and 2007.[3] Intrapartum stillbirths are rare in developed countries, constituting less than 10% of all stillbirths. By contrast, in some developing countries, as many as 50% of stillbirths occur intrapartum.[4] According to a World Health Organization report, intrapartum-related neonatal deaths account for almost 10% of deaths in children younger than 5 years of age.[5,6]

Experimental models lend support to the hypothesis that intrapartum events can have long-term neurologic sequelae. Fetal monkeys subjected to hypoxia *in utero* suffer neurologic injuries similar to those seen in children who presumably suffered asphyxia *in utero*.[7-9] Work with rodent models has shown similar patterns of damage.[10] Hankins et al.[11] suggested that performance of elective cesarean delivery at 39 weeks' gestation (and avoidance of a trial of labor) might result in an 83% reduction in risk for moderate or severe neonatal encephalopathy. Altogether, epidemiologic and experimental data suggest that the fetus is at significant risk during labor and delivery.

Some fetuses appear to be at greater risk for adverse intrapartum events than others. Older studies report that high-risk mothers constitute 20% of the pregnant population, but their offspring represent 50% of the cases of perinatal morbidity and mortality.[12] Various schemes to identify high-risk pregnancies have been published.[13,14] High-risk pregnancies include, but are not limited to, women with (1) **medical complications** (e.g., hypertension, preeclampsia, diabetes, autoimmune disease, hemoglobinopathy); (2) **fetal complications** (e.g., fetal growth restriction [also known as intrauterine growth restriction], nonlethal anomalies, prematurity, multiple gestation, postdatism, hydrops); and (3) **intrapartum complications** (e.g., abnormal vaginal bleeding, maternal fever, meconium-stained amniotic fluid, oxytocin augmentation of labor). Owing to inadequate sensitivity, poor positive predictive values, and the inability to modify outcomes related to risk factors, scoring systems for identifying high-risk fetuses have not been shown to improve pregnancy outcomes.[15] Lo et al.[16] indicated that more than half of infants with asphyxia had no clinical risk factors. However, for low-risk parturients who wish to avoid continuous monitoring during labor, scoring systems may demonstrate some benefit.[15] One strategy used in European centers for identifying high-risk parturients is fetal heart rate (FHR) tracing analysis at the time of admission to the labor and delivery suite; if the FHR

tracing is abnormal, patients receive more intensive monitoring.[17] A meta-analysis of this approach observed an increase in cesarean delivery rates but failed to demonstrate improvements in fetal and neonatal outcomes.[18]

The magnitude of risk for intrapartum fetal neurologic injury is a matter of some dispute. In 2003, the American College of Obstetricians and Gynecologists (ACOG) Task Force on Neonatal Encephalopathy and Cerebral Palsy concluded that 70% of these types of fetal neurologic injuries result from events that occur before the onset of labor.[19-21] Examples of antepartum events that may cause fetal neurologic injury include congenital anomalies, chemical exposure, infection, and fetal thrombosis/coagulopathy. Only 4% of cases of neonatal encephalopathy result solely from intrapartum hypoxia, an incidence of approximately 1.6/1000.[19,20,22] The Task Force identified criteria that define an acute intrapartum hypoxic event sufficient to cause cerebral palsy (Box 8-1).[19,20,23] A recent study found that fetuses that underwent a sudden and sustained deterioration of the FHR and that subsequently had a diagnosis of cerebral palsy demonstrated characteristics consistent with the criteria developed by the ACOG Task Force.[24] An additional case series of sentinel events during labor (e.g., uterine rupture, cord prolapse, placental abruption, amniotic fluid embolus) resulted in a high rate of hypoxic-ischemic encephalopathy in surviving infants.[25] Approximately 25% of fetuses may have antepartum and intrapartum risk factors for neurologic injury.

BOX 8-1 Criteria That Define an Acute Intrapartum Hypoxic Event as Sufficient to Cause Cerebral Palsy

Essential Criteria

1. Evidence of metabolic acidosis in umbilical cord arterial blood obtained at delivery (i.e., pH < 7.00, base deficit > 12 mmol/L)
2. Early onset of encephalopathy in an infant delivered at > 34 weeks' gestation
3. Cerebral palsy of the spastic quadriplegia or dyskinetic type
4. Exclusion of other identifiable causes

Criteria That Suggest Intrapartum Timing of Insult

1. Sentinel hypoxic event occurring immediately before or during labor
2. Sudden, sustained bradycardia or absence of fetal heart rate variability with persistent late or variable decelerations
3. Apgar scores of 0-3 beyond 5 minutes of life
4. Evidence of multisystem involvement within 72 hours of delivery
5. Early imaging study that shows evidence of acute, nonfocal cerebral abnormality

Modified from the American College of Obstetricians and Gynecologists Task Force on Neonatal Encephalopathy and Cerebral Palsy. Neonatal Encephalopathy and Cerebral Palsy: Defining the Pathogenesis and Pathophysiology. Washington, DC, American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, January 2003; and MacLennan A. A template for defining a causal relation between acute intrapartum events and cerebral palsy: international consensus statement. Br Med J 1999; 319:1054-9.

The ability of contemporary obstetricians to recognize and treat pregnancies at risk for hypoxia during labor is an evolving science. With the current understanding of pathophysiology and the technology in current clinical use, the extent to which obstetricians can prevent intrapartum injury is unclear.[26] It is hoped that the development of standardized, clearer definitions of intrapartum injury, and new strategies and interventions that can correct reversible pathophysiology, will lead to more precise identification and optimization of fetuses at risk.

Efforts to understand placental physiology and pathophysiology are central to the efforts to support the health of the pregnant woman and her fetus, both antepartum and intrapartum. The fetus depends on the placenta for the diffusion of nutrients and for respiratory gas exchange. Many factors affect placental transfer, including concentration gradients, villus surface area, placental permeability, and placental metabolism (see Chapter 4). Maternal hypertensive disease, congenital anomalies, and intrauterine infection are examples of conditions that may impair placental transfer.

One of the most important determinants of placental function is uterine blood flow.[27] A uterine contraction results in a transient decrease in uteroplacental blood flow. A placenta with borderline function before labor may be unable to maintain gas exchange adequate to prevent fetal asphyxia during labor. The healthy fetus may compensate for the effects of hypoxia during labor.[28,29] The compensatory response includes (1) decreased oxygen consumption, (2) vasoconstriction of nonessential vascular beds, and (3) redistribution of blood flow to the vital organs (e.g., brain, heart, adrenal glands, placenta).[30,31] Humoral responses (e.g., release of epinephrine from the adrenal medulla, release of vasopressin and endogenous opioids) may enhance fetal cardiac function during hypoxia.[27] Prolonged or severe hypoxia overwhelms these compensatory mechanisms, resulting in fetal injury or death.

INTRAPARTUM FETAL ASSESSMENT

Electronic Fetal Heart Rate Monitoring

An optimal, yet practical method for assessing fetal health during labor and delivery has not been developed. Most contemporary methods include assessment of the FHR. The FHR can be monitored intermittently with a simple DeLee stethoscope. Alternatively, either Doppler ultrasonography or a fetal electrocardiographic (ECG) electrode can be used to monitor the FHR intermittently or continuously.

Experimental models have provided insight into the regulation of the FHR. Both neuronal and humoral factors affect the intrinsic FHR. Parasympathetic outflow by means of the vagus nerve decreases the FHR, whereas sympathetic activity increases FHR and cardiac output.[27] Baroreceptors respond to increased blood pressure and chemoreceptors respond to decreased Pao_2 and increased $Paco_2$ to modulate the FHR through the autonomic

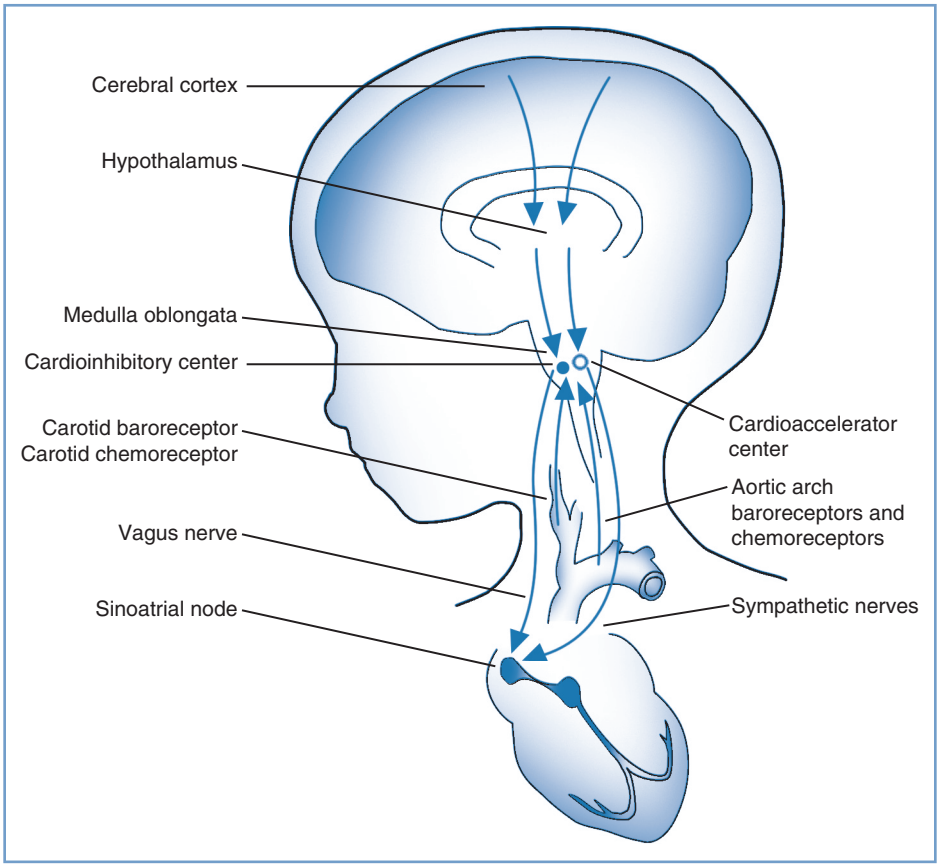

FIGURE 8-1 ■ Regulation of fetal heart rate. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

nervous system. Cerebral cortical activity and hypothalamic activity affect the FHR through their effects on integrative centers in the medulla oblongata (Figure 8-1).[27] Both animal studies and clinical observations have helped establish a correlation between FHR and perinatal outcome.

An electronic monitor simultaneously records the FHR and uterine contractions. Use of an electronic monitor allows determination of the **baseline rate** and **patterns** of the FHR and their relationship to uterine contractions. External or internal techniques can assess the FHR and uterine contractions (Figure 8-2). Doppler ultrasonography detects the changes in ventricular wall motion and blood flow in major vessels during each cardiac cycle. The monitor calculates the FHR by measuring the intervals between fetal myocardial contractions. Alternatively, an ECG lead attached to the fetal scalp enables the cardiotachometer to calculate the FHR by measuring each successive RR interval. Both external and internal methods allow continuous assessment of the FHR.

The FHR is superimposed over the uterine contraction pattern. Uterine contractions can be monitored externally with a tocodynamometer or internally with an intrauterine pressure catheter. The tocodynamometer allows determination of the approximate onset, duration, and offset of each uterine contraction. A normal pattern of uterine contractions in labor is five or less in a 10-minute period averaged over 30 minutes; tachysystole is defined as more than five uterine contractions within a 10-minute period.[32] An intrauterine pressure catheter may be used to measure the strength of uterine contractions. In some cases, an intrauterine pressure catheter is placed to determine the precise onset and offset of each uterine contraction. Such information may be used to distinguish among early, variable, and late FHR decelerations. In a nonblinded, randomized controlled trial, Bakker et al.[33] observed no significant differences in adverse neonatal outcomes with internal tocodynamometry as compared with external monitoring of uterine contractions in women in whom oxytocin was used for induction or augmentation of labor.

The following features of the FHR pattern can be assessed: (1) **baseline measurements,** (2) **variability** (the extent to which the rate changes both instantaneously and over longer periods), (3) **accelerations**, and (4) **decelerations** and their association with uterine contractions.

Baseline Fetal Heart Rate

A normal baseline FHR is defined as 110 to 160 beats per minute (bpm) and is determined by assessing the mean heart rate over a 10-minute period rounded to increments of 5 bpm.[32,34] In general, term fetuses have a lower baseline FHR than preterm fetuses because of greater parasympathetic nervous system activity. Laboratory

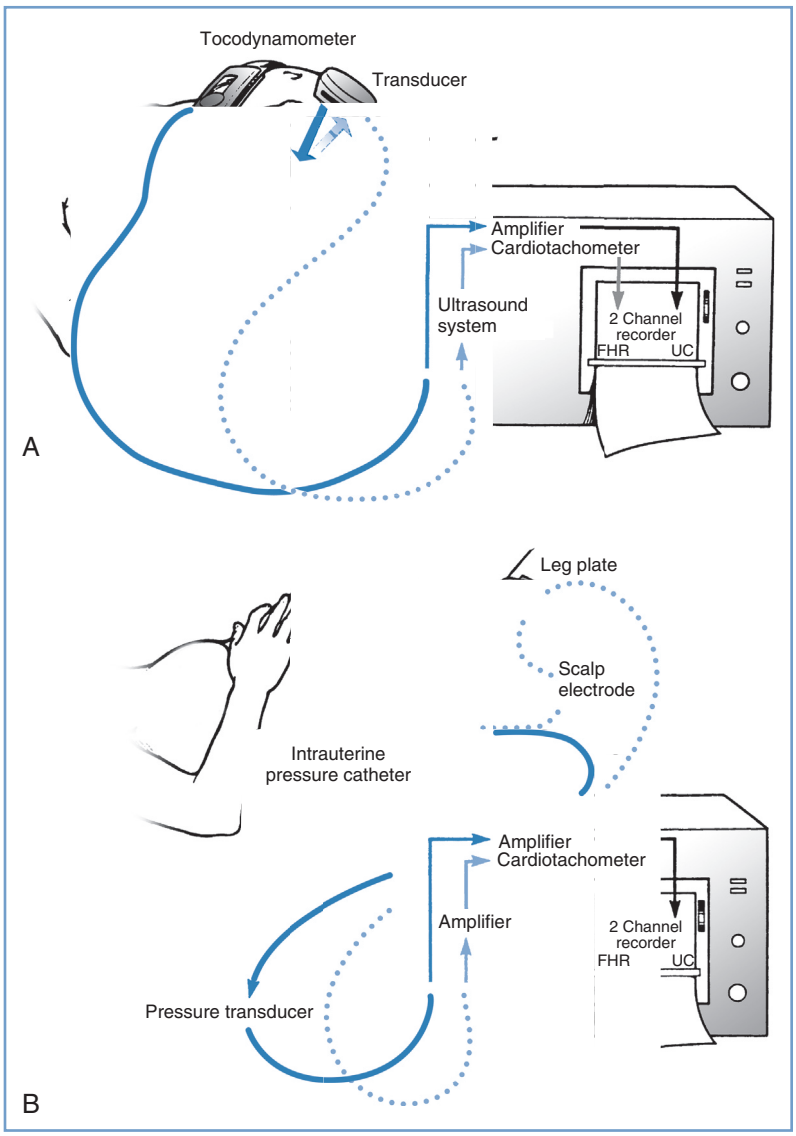

FIGURE 8-2 ■ Electronic fetal monitoring apparatus. **A,** Instrumentation for external monitoring. Contractions are detected by the pressure-sensitive tocodynamometer, amplified, and then recorded. The fetal heart rate (FHR) is monitored with the Doppler ultrasound transducer, which emits and receives the reflected ultrasound signal that is then counted and recorded. **B,** Techniques used for direct monitoring of FHR and uterine contractions (UC). Uterine contractions are assessed with an intrauterine pressure catheter connected to a pressure transducer. This signal is then amplified and recorded. The fetal electrocardiogram (ECG) is obtained by direct application of the scalp electrode, which is then attached to a leg plate on the mother's thigh. The signal is transmitted to the monitor, where it is amplified, counted by the cardiotachometer, and recorded. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

studies suggest that bradycardia (caused by increased vagal activity) is the initial fetal response to acute hypoxemia. After prolonged hypoxemia, the fetus may experience tachycardia as a result of catecholamine secretion and sympathetic nervous system activity.[28] Changes in baseline FHR may also be caused by fetal anatomic or functional heart pathology, maternal fever and/or intrauterine infections, or maternally administered medications, such as beta-adrenergic receptor agonists (e.g., terbutaline) or the anticholinergic agent atropine.

Fetal Heart Rate Variability

Fetal heart rate variability is the fluctuation in the FHR of 2 cycles or greater per minute.[32,34] Previously, FHR variability was divided into *short term* (from one beat, or R wave, to the next) and *long term* (occurring over the course of 1 minute), but this distinction is no longer made because in clinical practice variability is visually assessed as a unit (Figure 8-3). The presence of normal FHR variability reflects the presence of normal, intact pathways from—and within—the fetal cerebral cortex, midbrain, vagus nerve, and cardiac conduction system (see Figure 8-1).[27] Variability is greatly influenced by the parasympathetic tone, by means of the vagus nerve; maternal administration of atropine, which readily crosses the placenta, can eliminate some variability. In humans, the sympathetic nervous system appears to have a lesser role in influencing variability.[27] Maternal administration of the beta-adrenergic receptor antagonist propranolol has little effect on FHR variability.[27]

During hypoxemia, myocardial and cerebral blood flows increase to maintain oxygen delivery.[35,36] However, in severe hypoxemia, blood flow cannot increase sufficiently to maintain oxygen delivery and a loss of FHR variability is observed.[27] The absence of FHR variability in an anencephalic fetus indicates the influence of an intact central nervous system (CNS) in producing these patterns. In animal models, perfusion of the CNS with calcium results in depolarization of

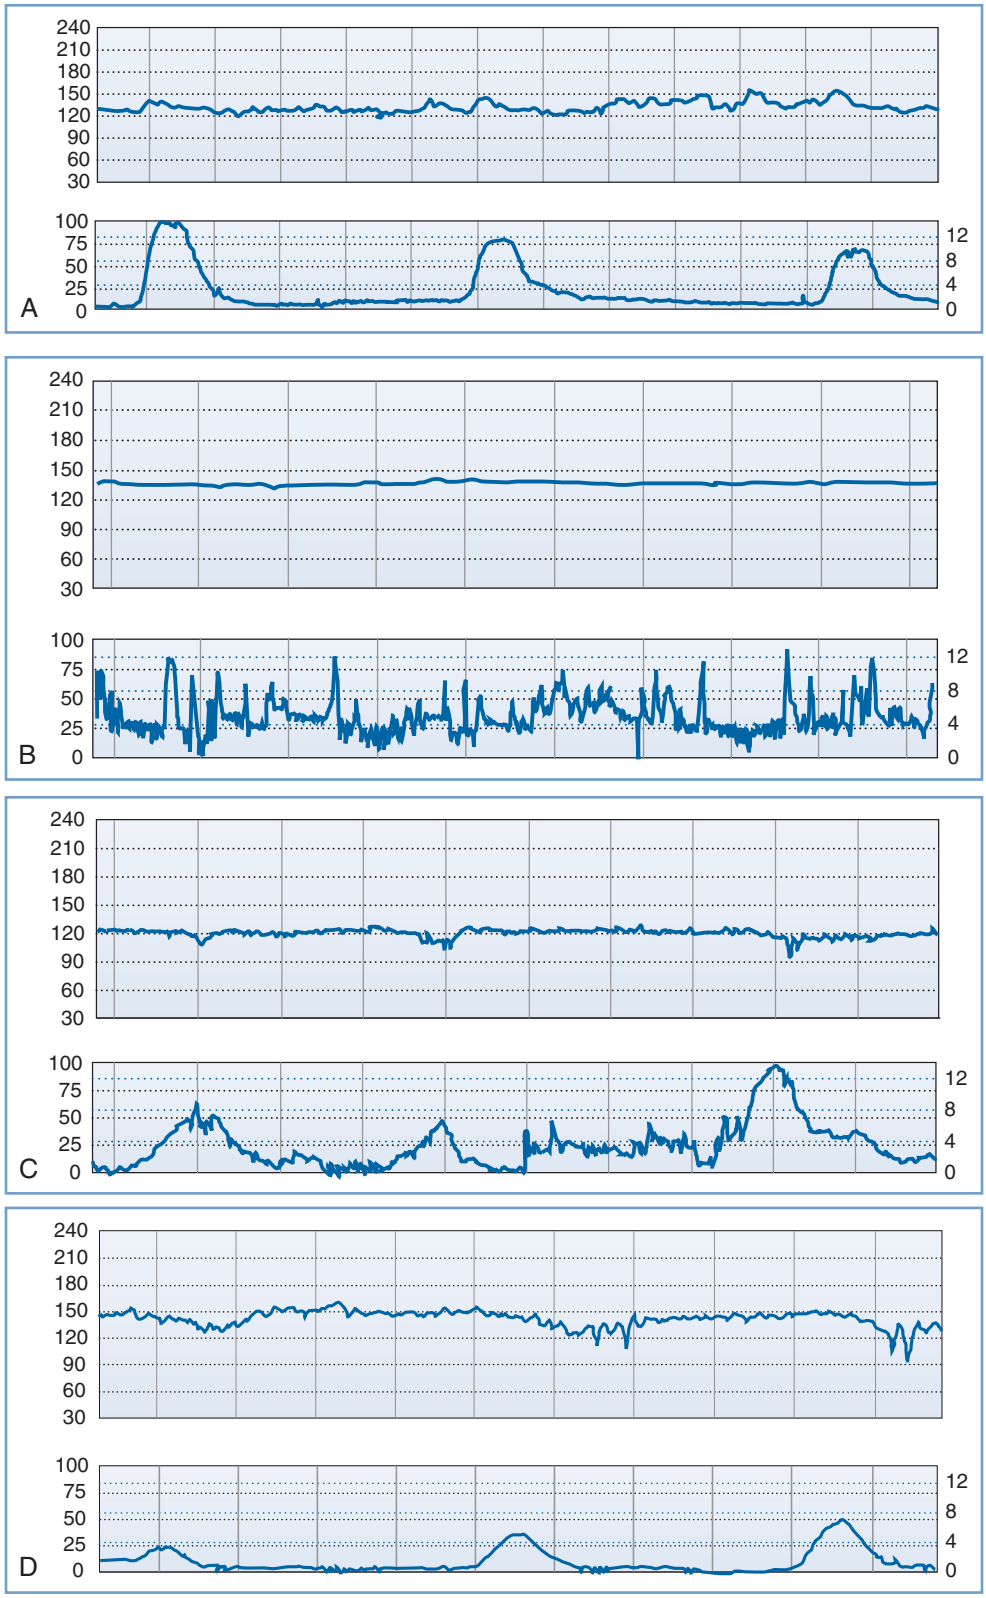

FIGURE 8-3 ■ **A,** Normal intrapartum fetal heart rate (FHR) tracing. The infant had Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. **B,** Absence of variability in a FHR tracing. Placental abruption was noted at cesarean delivery. The infant had an umbilical arterial blood pH of 6.75 and Apgar scores of 1 and 4, respectively. **C,** Early FHR decelerations. After a normal spontaneous vaginal delivery, the infant had Apgar scores of 8 and 8, respectively. **D,** Late FHR decelerations. The amniotic fluid surrounding this fetus was meconium stained. Despite the late FHR decelerations, the variability remained acceptable. The infant was delivered by cesarean delivery and had an umbilical venous blood pH of 7.30. Apgar scores were 9 and 9, respectively.

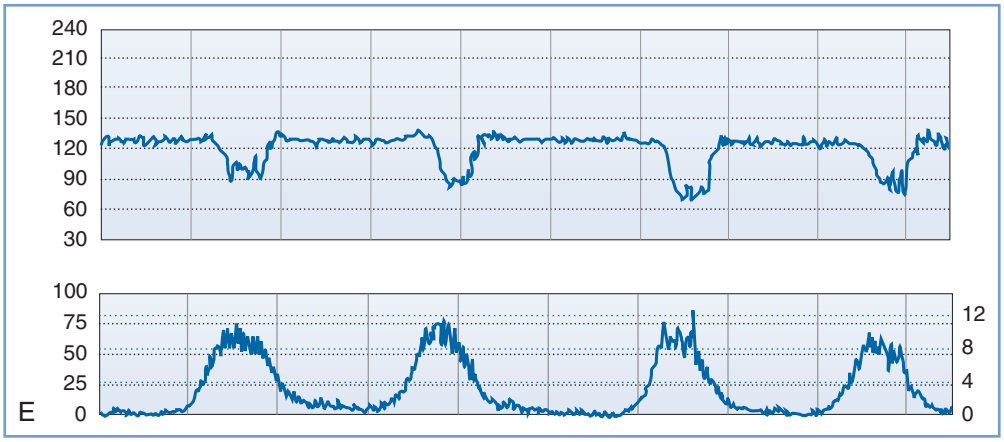

FIGURE 8-3, cont'd ■ **E,** Variable FHR decelerations. A tight nuchal cord was noted at low-forceps vaginal delivery. The infant had Apgar scores of 6 and 9, respectively. Numerical scales: *Left upper panel margin,* FHR in beats per minute; *left lower panel margin,* uterine pressure in mm Hg; *right lower panel margin,* uterine pressure in kilopascal (kPa).

electroencephalographic (EEG) activity, which abolishes FHR variability.

Clinically, the presence of normal FHR variability predicts early neonatal health, as defined by an Apgar score of greater than 7 at 5 minutes.[37,38] In a case series of monitored fetal deaths, no fetus had normal variability immediately before demise.[27] The differential diagnosis of decreased variability includes fetal hypoxia, fetal sleep state, fetal neurologic abnormality, and decreased CNS activity that results from exposure to drugs such as opioids.

Accelerations

Accelerations are abrupt changes in the FHR above the baseline. Beyond 32 weeks' gestation, an acceleration is defined by a peak of at least 15 bpm above the baseline, lasting at least 15 seconds. (Before 32 weeks' gestation, a peak of 10 bpm above the baseline, lasting at least 10 seconds, is required.[34]) A prolonged acceleration extends for at least 2 minutes; however, when greater than 10 minutes in duration, it is considered a change in baseline.[34] Antepartum FHR accelerations can occur in response to fetal movement and typically are a sign of fetal well-being; their presence indicates a reactive nonstress test. During the intrapartum period, the significance of FHR accelerations is less clear.[28,38] Although the presence of accelerations generally precludes the existence of significant fetal metabolic acidosis, in some cases intrapartum accelerations may indicate a vulnerable umbilical cord.

Decelerations

Decelerations are typically classified as early, late, or variable. **Early decelerations** occur simultaneously with uterine contractions and usually are less than 20 bpm below baseline. The onset and offset of each deceleration coincides with the onset and offset of the uterine contraction (see Figure 8-3). In animal models, head compression can precipitate early decelerations.[28] In humans, early decelerations are believed to result from reflex vagal activity secondary to mild hypoxia. Early decelerations are not ominous.

Late decelerations begin 10 to 30 seconds after the beginning of uterine contractions and end 10 to 30 seconds after the end of uterine contractions. Late decelerations are smooth and repetitive (i.e., they occur with each uterine contraction). Animal studies suggest that late decelerations represent a response to hypoxemia. The delayed onset of the deceleration reflects the time needed for the chemoreceptors to detect decreased oxygen tension and mediate the change in FHR by means of the vagus nerve.[28,39] Late decelerations may also result from decompensation of the myocardial circulation and myocardial failure. Unfortunately, clinical and animal studies suggest that late decelerations may be an oversensitive indication of fetal asphyxia.[28] However, the combination of late decelerations and decreased or absent FHR variability is an accurate, ominous signal of fetal compromise.[29,40,41]

Variable decelerations vary in depth, shape, and duration. They often are abrupt in onset and offset. Variable decelerations result from baroreceptor- or chemoreceptor-mediated vagal activity. Experimental models and clinical studies suggest that **umbilical cord occlusion,** either partial or complete, results in variable decelerations. During the second stage of labor, variable decelerations may result from compression of the fetal head. In this situation, dural stimulation leads to increased vagal discharge.[42] The healthy fetus can typically tolerate mild to moderate variable decelerations (not below 80 bpm) without decompensation. With prolonged, severe variable decelerations (< 60 bpm) or persistent fetal bradycardia, it is difficult for the fetus to maintain cardiac output and umbilical blood flow.[42]

Sinusoidal and **saltatory** patterns are two unusual FHR tracing results that may indicate fetal compromise. The sinusoidal FHR pattern is a regular, smooth, wavelike pattern that may signal fetal anemia.[27] Occasionally, maternal administration of an opioid can lead to a sinusoidal FHR pattern. The saltatory pattern consists of excessive alterations in variability (> 25 bpm) and may signal the occurrence of acute fetal hypoxia; there is a

weak association between this pattern and low Apgar scores.[27]

Limitations of Electronic Fetal Heart Rate Monitoring

Despite laboratory and clinical data suggesting that FHR monitoring accurately reflects fetal health, controversy exists regarding the ability of this assessment tool to improve fetal and neonatal outcomes. First described more than 40 years ago, the use of continuous electronic FHR monitoring increased dramatically to encompass 45% and 85% of the monitored deliveries by 1980 and 2002, respectively.[32] Retrospective reports of continuous FHR monitoring associate its use with a lower incidence of intrauterine fetal demise, neonatal seizures, and neonatal death.[43-45] By contrast, the only consistent finding from multiple case-control studies and more than a dozen prospective, randomized trials of electronic FHR monitoring (with control arms that employed intermittent FHR auscultation[46-48]) is an increased rate of operative delivery. In a meta-analysis of these trials, which included more than 50,000 women from several continents, the incidence of 1-minute Apgar scores less than 4 and neonatal seizures was decreased with the use of continuous FHR monitoring.[46-49] These results appear to suggest a correlation between abnormal FHR tracings and fetal acidemia.[41,50] An evaluation of the 2004 United States birth cohort data suggested that the use of electronic FHR monitoring was associated with a significant decrease in early neonatal and infant mortality, a decreased risk for 5-minute APGAR scores less than 4 in low-risk pregnancies, and a lower rate of neonatal seizures in high-risk pregnancies.[51]

It remains unclear why prospective studies have not confirmed greater benefit of the use of continuous electronic FHR monitoring during labor; the intensity of intrapartum assessment and care may be partially responsible. In prospective trials, women randomly assigned to receive intermittent FHR auscultation were monitored by dedicated nursing staff who provided intensive intrapartum care. By contrast, the historical cohort studies compared patients who received continuous electronic FHR monitoring and intensive intrapartum care with patients who had intermittent FHR auscultation with *nonintensive* nursing care. There are no published studies that randomly assigned a group of patients to receive no FHR monitoring; however, the continued high rate of intrapartum stillbirth in unmonitored births in the developing world suggests that FHR assessment may be beneficial.

Consistent with the findings of the prospective trials, the ACOG endorses the use of either intermittent auscultation or continuous electronic FHR monitoring during labor. In high-risk patients, the ACOG guidelines recommend that the obstetrician or nurse review the electronic FHR tracing every 15 minutes during the first stage of labor and every 5 minutes during the second stage. For low-risk patients, the intervals may be lengthened to 30 minutes for the first stage and 15 minutes for the second stage.[52] The optimal interval for intermittent FHR monitoring has not been studied, but the intervals suggested within the ACOG guidelines have some indirect support.[53] Adherence to these standards for intermittent auscultation may be difficult to achieve in the clinical setting; in one study, only 3% of parturients met these standards.[54]

Several hypotheses to account for the apparent failure of intrapartum FHR monitoring to reduce the incidence of cerebral palsy have been proposed and include (1) a large proportion of the asphyxial damage begins before the onset of labor; (2) catastrophic events (e.g., cord prolapse, placental abruption, uterine rupture) may not allow sufficient time for intervention before neurologic damage occurs; (3) a larger proportion of very low-birth-weight infants survive and thus contribute to the numbers with cerebral palsy; (4) infection is associated with abnormal FHR patterns and the subsequent development of cerebral palsy, and it is unclear that early intervention offers any benefit in such cases; and (5) the amount of asphyxia required to cause permanent neurologic damage approximates the amount that causes fetal death, leaving a narrow window for intervention.[55] The number of patients in whom cerebral palsy develops from intrapartum asphyxia is probably quite small.[55]

Limitations of FHR monitoring include a poor positive predictive value in distinguishing between abnormal FHR tracings and abnormal outcomes. Because of this imprecision, the ACOG recommended that abnormal FHR tracings be described with the term *nonreassuring fetal status* rather than *fetal distress* or *birth asphyxia*.[56] In one population-based study of California children with cerebral palsy, FHR tracings were retrospectively reviewed and compared with those of neurologically normal children (i.e., control subjects). A markedly higher incidence of tracings with late decelerations and decreased variability was found in children with cerebral palsy than in the control subjects. However, of the estimated 10,791 monitored infants weighing 2500 g or more who had these FHR abnormalities, only 21 (0.19%) had cerebral palsy, representing a false-positive rate of 99.8%.[57] Later case-control studies have yielded similar results.[16,58] A 2006 meta-analysis of 12 trials including 37,000 women suggested that electronic FHR monitoring has resulted in a decrease in the occurrence of seizures but no change in the incidence of neonatal mortality or cerebral palsy.[49] The authors suggested that electronic FHR monitoring resulted in one cesarean delivery for every 58 women monitored and that 661 women would need to be monitored to prevent one neonatal seizure.[49] Therefore, use of electronic FHR monitoring in combination with clinical and laboratory assessments has been proposed to enhance the prediction and perhaps the prevention of severe asphyxia, but with poor specificity.[16]

Further limitations of continuous FHR monitoring include (1) the poor intra-observer and inter-observer agreement despite the use of trained observers, (2) the required continual presence of a nurse or physician to assess the FHR tracing, (3) the inconvenience for the patient (e.g., confinement to bed and the application of monitor belts or a scalp electrode), and (4) the need to archive the FHR tracings as legal documents.[59-61]

Despite little evidence for its efficacy, Parer and King[62] have noted that obstetricians continue to rely heavily on

BOX 8-2 Three-Tier Fetal Heart Rate (FHR) Interpretation System

Category I tracings include all of the following:
- Baseline rate: 110-160 beats per minute (bpm)
- Baseline FHR variability: moderate
- Accelerations: present or absent
- Late or variable decelerations: absent
- Early decelerations: present or absent

Category II tracings include:
- All tracings not categorized as category I or category III
- Baseline FHR
  - Bradycardia not accompanied by absent baseline variability
  - Tachycardia
- Baseline FHR variability
  - Minimal baseline variability
  - Absent baseline variability not accompanied by recurrent decelerations
  - Marked baseline variability
- Accelerations
  - Absence of induced accelerations after fetal stimulation
- Periodic or episodic decelerations
  - Recurrent variable decelerations accompanied by minimal or moderate variability
  - Prolonged deceleration > 2 minutes but < 10 minutes
  - Recurrent late decelerations with moderate baseline variability
  - Variable decelerations with other characteristics such as slow return to baseline, overshoots, or shoulders

Category III tracings include either:
- Absent baseline FHR variability and any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
- Sinusoidal pattern

Modified from Macones GA, Hankins GDV, Spong CY, et al. The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring. Obstet Gynecol 2008; 112:661-6.

FHR monitoring for at least the following three reasons: (1) professional obstetric organizations (e.g., the ACOG) advise some form of monitoring during labor, (2) electronic FHR monitoring is logistically easier and less expensive than one-on-one nursing care during labor, and (3) individual (often anecdotal) experiences cause "many obstetricians [to] believe that in their own hands FHR monitoring is … efficacious."[62]

In 2008 the National Institute of Child Health and Human Development sponsored a workshop that resulted in the publication of updated definitions, interpretation, and research guidelines for intrapartum electronic FHR monitoring.[34] The published report proposed a three-tier system for the categorization of FHR patterns (Box 8-2).[34] The ACOG described this system in subsequent 2009 practice bulletins with suggested options for management[32,63]:

Category I (normal): Strongly predictive of *normal* fetal acid-base status at the time of observation.

Category II (indeterminate): Not predictive of *abnormal* fetal acid-base status, but without adequate evidence to classify as normal or abnormal.

Category III (abnormal): Predictive of *abnormal* fetal acid-base status at the time of observation and thus requiring prompt evaluation.

In a multicenter review of 48,444 patients, Jackson et al.[64] observed that category I, II, and III FHR tracings were present 78%, 22%, and 0.004% of the time, respectively. Only 0.2% of newborns of women whose last 2 hours of labor had exclusively category I FHR tracings had low 5-minute Apgar scores followed by admission to a neonatal intensive care unit (NICU); in contrast, when more than 75% of the last 2 hours of labor showed category II FHR tracings, the incidence of low 5-minute Apgar scores with NICU admission increased to 0.7%.

A significant difficulty with the current three-tier system is the number and heterogeneity of fetuses with category II tracings.[65] A five-tier system has been proposed.[66,67] However, Elliott et al.[68] used specialized computer software to distinguish the five tiers among 2472 FHR tracings of near-term fetuses with and without known neonatal encephalopathy and blood gas abnormalities, and they found that a lack of specificity still occurred. A correlation between the frequency and duration of FHR abnormalities with worse neonatal outcome was observed; however, the electronic FHR patterns that identified 75% of the neonatal encephalopathy group also included 29% of the normal neonates.[68]

Methods for Improving the Efficacy of Electronic Fetal Heart Rate Monitoring

Several technologies have been employed to enhance the value of electronic FHR monitoring. To facilitate continual FHR assessment, many labor-and-delivery units transmit the tracings from the bedside to the nurses' station. Presumably, this practice facilitates a rapid response to worrisome FHR tracings.

Computerized algorithms may assist in the interpretation of FHR tracings. Although some studies have suggested that computerized analysis may be more accurate than traditional methods in identifying pregnancies with a pathologic neonatal outcome, others have not confirmed this finding.[69-73] As a result, none of these computerized methods has achieved widespread use.

Continuous FHR monitoring requires the patient to wear FHR and uterine contraction monitoring devices and remain within several feet of the monitor. An alternative is the use of telemetry, which transmits the FHR from the patient to the monitor and consequently allows ambulation. The low-risk patient who wishes to ambulate probably does not require continuous electronic FHR monitoring.

Electronic archiving allows for the electronic storage and retrieval of FHR tracings and eliminates the need for long-term storage of the paper record. The FHR tracing is a medicolegal document, and if it is lost, the plaintiff's lawyer may allege that the tracing was discarded intentionally because it was detrimental to the defendant.[74]

Supplemental Methods of Fetal Assessment

Electronic FHR monitoring is more than 99% accurate in predicting a 5-minute Apgar score greater than 7. Unfortunately, this monitoring also suffers from a lack of specificity; an abnormal FHR tracing has a false-positive rate of more than 99%.[52] As a consequence, clinicians have sought additional fetal assessment tools to assist in the identification of the compromised fetus with greater specificity.

Fetal scalp blood pH determination is an older method used to confirm or exclude the presence of fetal acidosis when FHR monitoring suggests the presence of fetal compromise. Suggested indications include the presence of decreased or absent FHR variability or persistent late or variable FHR decelerations.[27] The obstetrician inserts an endoscope into the vagina, makes a small laceration in the fetal scalp (or buttock), and uses a capillary tube to collect a sample of fetal capillary blood (Figure 8-4). The technical challenges of obtaining the sample and having readily available instrumentation to conduct the test have led most U.S. centers to abandon this technique. Although early studies suggested that fetal scalp sampling may decrease the cesarean delivery rate,[75] a 1994 study reported that there was no change in the rate of cesarean delivery or perinatal asphyxia when the technique was abandoned.[76] A similar, alternative method used in Europe evaluates the fetal blood sample for the presence of lactate. When compared with pH determination, an interpretable result is obtained more frequently with lactate determination primarily owing to a smaller volume of blood required; however, no differences in fetal/neonatal/infant outcomes have been observed in trials comparing the two methods.[77]

Fetal scalp stimulation can be performed during a vaginal examination either digitally or with an Allis clamp. The heart rate of a healthy, nonacidotic fetus accelerates in response to scalp stimulation; FHR acceleration is associated with a fetal pH of at least 7.19.[78,79]

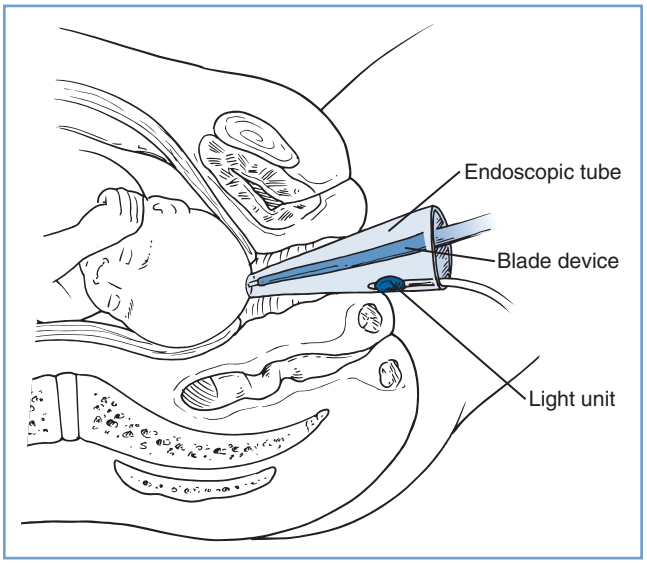

FIGURE 8-4 ■ Technique of obtaining fetal scalp blood during labor. (Redrawn from Creasy RK, Parer JT. Perinatal care and diagnosis. In Rudolph AM, editor. Pediatrics. 16th edition. New York, Appleton-Century-Crofts, 1977:121.)

Advocates of **vibroacoustic stimulation** contend that the application of an artificial larynx to the maternal abdomen results in an FHR acceleration in a healthy fetus and improves the specificity of FHR monitoring.[80] Vibroacoustic stimulation is used primarily for antepartum fetal assessment. A 2005 Cochrane review concluded that there is insufficient evidence from randomized clinical trials on which to make conclusions and recommendations regarding the use of vibroacoustic stimulation for the evaluation of fetal well-being during labor in the presence of a nonreassuring FHR tracing.[81] Nonetheless, direct fetal scalp stimulation and/or vibroacoustic stimulation have largely replaced the use of fetal scalp blood pH determination in most centers. A meta-analysis of intrapartum stimulation tests (i.e., fetal scalp blood pH determination, Allis clamp and digital fetal scalp stimulation, and vibroacoustic stimulation) found the tests to be equivalent in predicting fetal acidemia, with digital fetal scalp stimulation having the greatest ease of use.[82]

The intrapartum use of **umbilical artery velocimetry** has been used as an adjunct to FHR monitoring to assess fetal well-being, with mixed results (see Chapter 6).[83,84] The **biophysical profile (BPP),** which is composed of four ultrasonographic assessments and a nonstress test, has been observed antenatally to decrease the false-positive rate of a positive nonstress test (see Chapter 6); however, its value during intrapartum management is still under investigation.[85,86]

The presence of **meconium-stained amniotic fluid** has long been associated with an increased risk for depression at birth. Moderate to thick meconium is associated with lower Apgar scores, lower umbilical arterial blood pH, an increased incidence of neonatal seizures, and higher rates of cesarean delivery and admission to an intensive care nursery.[87-89] Although 5% to 20% of all deliveries are complicated by meconium-stained amniotic fluid, few of these infants experience neonatal depression. The odds ratio for complications is increased with meconium, but the majority of infants with neonatal complications have clear fluid.[87] Meconium-stained fluid has a poor positive predictive value and poor sensitivity in predicting adverse neonatal outcomes.[87] The physiology associated with the passage of meconium is incompletely understood. Ultrasonographic imaging suggests that the fetus regularly passes rectal contents into the amniotic fluid throughout gestation.[87] However, meconium-stained amniotic fluid is more common in pregnancies complicated by postdatism or fetal growth restriction. Putative triggers for the passage of meconium include umbilical cord compression and hypoxia. The presence of meconium combined with an abnormal FHR tracing or another risk factor (e.g., fetal growth restriction, postdatism) appears to be associated with an increased likelihood of neonatal depression.[88,89]

Among the pregnancies with meconium-stained amniotic fluid, approximately 5% develop significant neonatal respiratory compromise termed **meconium aspiration syndrome.**[90-92] Antenatal risk factors for this syndrome

include moderate or thick meconium (suggesting recent passage and lower amniotic fluid volume) and abnormal FHR tracings.[91] The lung injury likely originates from intrapartum fetal hypoxia.[91,93,94] Oropharyngeal suctioning at delivery has not proved beneficial; randomized controlled trials have suggested that vigorous newborns do not need aggressive airway cleansing with tracheal intubation (see Chapter 9).[91,95] Aggressive obstetric management of postdate pregnancies (i.e., avoidance of postdatism) has led to a substantial decrease in the incidence of meconium-stained amniotic fluid and meconium aspiration syndrome.[92]

New Technologies for Fetal Assessment

Because FHR monitoring provides only an *indirect* measure of fetal oxygenation and acid-base status, alternative technologies, such as transcutaneous Po_2, Pco_2, and pH monitors have been developed to provide a more direct assessment.[96-98] However, the use of these monitors has been limited by technical difficulties in the application of the probe(s), drift in the baseline readings, artifactual measurements, and difficulties in establishing diagnostic criteria for intervention.

ST waveform analysis of fetal electrocardiography is a technique proposed to enhance intrapartum fetal assessment. Fetal hypoxia induces changes in the ECG morphology of the ST segment and T wave. ST waveform analysis enhances the specificity of FHR tracings,[99,100] but not the sensitivity.[101] A 2006 meta-analysis of randomized controlled trials, accounting for almost 10,000 deliveries, of automatic ST waveform analysis (the STAN S21 system, Neoventa Medical, Göteborg, Sweden) demonstrated that a combination of FHR monitoring and ST waveform analysis reduced the risk for severe fetal acidosis and the incidence of neonates with encephalopathy.[102-104] No differences in the rates of cesarean delivery, 5-minute Apgar scores less than 7, or admission to the NICU were observed.[100,102,103,105,106] In a recent trial of 5600 parturients randomized to fetal observation with and without ST waveform analysis, Westerhuis et al.[107] observed a lower rate of acidosis in the ST waveform analysis group but no other differences in outcome (e.g., operative deliveries or hypoxic ischemic encephalopathy). An unmasked, randomized controlled trial of ST waveform analysis is currently being conducted to assess neonatal outcomes in 11,000 parturients within the U.S. Maternal-Fetal Medicine Network.

Reflectance pulse oximetry has been adapted for assessment of fetal oxygenation. The U.S. Food and Drug Administration (FDA) approved the Nellcor N-400 fetal pulse oximeter (Nellcor, Puritan Bennett, Pleasanton, CA) for use in the setting of a term, singleton fetus at more than 36 weeks' gestation with a vertex presentation and a nonreassuring FHR pattern after rupture of membranes.[108,109] The most commonly used probes are held in place against the fetal head or cheek with pressure from the cervix. A reliable pulse oximetry signal can be obtained in 60% to 70% of cases; however, environmental factors and physiologic events (e.g., fetal scalp congestion, thick fetal hair, vernix caseosa, uterine activity, movement artifacts) may affect the accuracy.[109] The saturation measurements are averaged every 45 seconds,[108] and the human fetus typically demonstrates an oxygen saturation of 35% to 65%. Animal and human data suggest that metabolic acidosis does not occur until the oxygen saturation has fallen below 30% for at least 10 minutes when measured with this device.[110,111] Pulse oximetry does not predict acidosis accurately in fetuses with severe variable decelerations during the second stage of labor.[112] Moreover, the accuracy of fetal pulse oximetry readings lower than 30% in human fetuses has been challenged.[108,113] Fetal pulse oximetry used in conjunction with FHR monitoring appears to reduce the rate of cesarean delivery for a nonreassuring FHR tracing; however, this reduction is offset by an increased rate of cesarean delivery for dystocia.[114-116] The absence of an effect on the overall cesarean delivery rate prompted the ACOG to withhold an endorsement of fetal pulse oximetry pending further investigation of its use.[109] A Spanish trial randomly allocated 180 women with nonreassuring intrapartum FHR tracings to receive further evaluation with either ST waveform analysis or pulse oximetry; the investigators observed a lower cesarean delivery rate in the ST waveform analysis group, with fewer low 1-minute APGAR scores and improved umbilical cord venous blood pH measurements.[117]

Proton magnetic resonance spectroscopy (^{1}H MRS) can obtain metabolic information from human and animal brains, and early investigations suggest an ability to assess fetal brain oxygenation.[118-120] ^{1}H MRS has proved useful in the evaluation of hypoxic-ischemic encephalopathy and metabolic disorders in pediatric patients. This technique can also measure levels of the metabolites lactate, *N*-acetylaspartate, creatine, choline, and inositol in fetal and neonatal neural tissue. It has been applied experimentally in a case series of fetuses with fetal growth restriction.[121] Although these measurements can be correlated with the level of tissue oxygenation, the clinical use of this technique as a means of fetal assessment remains unclear.[122]

Near-infrared spectroscopy (NIRS) has the potential to directly measure fetal tissue oxygenation.[123] Transabdominal NIRS has been used in research settings to assess placental oxygenation.[124] NIRS has gained some acceptance in assessing the effects of clinical interventions on neonatal organ oxygenation at the bedside. NIRS can detect changes in the ratio of reduced to oxygenated cytochrome-*c* oxidase in the brain and in the ratio of oxygenated to deoxygenated hemoglobin in the blood perfusing the brain; the technique can also measure the total amount of hemoglobin in the tissue, thereby allowing an estimation of tissue blood perfusion.[123] In theory, NIRS offers the opportunity to determine whether neurons are at risk for hypoxic damage; currently, the technique is being correlated with other measures of fetal well-being, such as periodic FHR changes and umbilical cord blood pH measurements at delivery. However, similar to fetal pulse oximetry, NIRS technology is limited by a frequent (approximately 20%) inability to obtain interpretable measurements and the need to correlate the measurements with long-term neurodevelopmental outcomes. As a consequence, NIRS remains a research rather than a clinical tool at this time.[123]

TABLE 8-1 Various Intrauterine Resuscitative Measures for Category II or Category III Fetal Heart Rate (FHR) Tracings or Both

Goal	Associated Fetal Heart Rate Abnormality*	Potential Intervention(s)†
Promote fetal oxygenation and improve uteroplacental blood flow	Recurrent late decelerations Prolonged decelerations or bradycardia Minimal or absent FHR variability	Initiate lateral positioning (either left or right) Administer supplemental maternal oxygen Administer intravenous fluid bolus Reduce uterine contraction frequency
Reduce uterine activity	Tachysystole with category II or III tracing	Discontinue oxytocin or cervical ripening agents Administer tocolytic medication (e.g., terbutaline)
Alleviate umbilical cord compression	Recurrent variable decelerations Prolonged decelerations or bradycardia	Initiate maternal repositioning Initiate amnioinfusion If prolapsed umbilical cord is noted, elevate the presenting fetal part while preparations are underway for operative delivery

*Evaluation for the underlying suspected cause(s) is also an important step in management of abnormal FHR tracings.
†Depending on the suspected underlying cause(s) of FHR abnormality, combining multiple interventions simultaneously may be appropriate and potentially more effective than doing individually or serially (Simpson KR, James DC. Efficacy of intrauterine resuscitation techniques in improving fetal oxygen status during labor. Obstet Gynecol 2005;105:1362-8).
From American College of Obstetricians and Gynecologists. Management of intrapartum fetal heart rate tracings. ACOG Practice Bulletin No. 116, November 2010. (Obstet Gynecol 2010; 116:1232-40.)

INTRAPARTUM FETAL THERAPY

The ACOG has suggested intrapartum management be based on the three-tier evaluation framework.[63] A category I tracing requires only periodic reevaluation, whereas a category III tracing should prompt preparation for delivery if intrauterine resuscitative measures do not result in improvement of the FHR in a timely manner (Table 8-1). Category II tracings should be evaluated for the presence of moderate variability and spontaneous or provoked accelerations, which suggest a nonacidotic fetus (see earlier discussion). The identification of potential intrapartum fetal compromise with a category II or III tracing should prompt a careful assessment of maternal, placental, and fetal factors. Clinical history, physical findings, laboratory findings, and fetal monitoring (e.g., FHR, ultrasonography) should be evaluated in an attempt to identify an etiology for poor tracings. If intrauterine resuscitative measures do not result in an improved category II tracing, or if the FHR tracing progresses to category III, then the obstetrician should consider prompt delivery.[63]

Correctable **maternal factors** that may contribute to fetal compromise include pathologic states that result in hypoxemia or decreased oxygen delivery to the placenta. **Respiratory failure** due to long-standing diseases (e.g., asthma) can be determined from the history and physical findings, whereas additional laboratory measurements may be necessary to diagnose pneumonia or pulmonary edema as an underlying cause. **Decreased oxygen delivery** to the placenta may result from acute (e.g., sepsis, hypotension) or chronic conditions. **Decreased uteroplacental perfusion** can result from reduced maternal cardiac output (e.g., cardiovascular disease) or chronic vascular disease (e.g., chronic hypertension, diabetes). Dehydration from prolonged labor is a more subtle cause of diminished uteroplacental perfusion.

Attention to the etiology of fetal hypoxemia and institution of appropriate treatments may mitigate fetal compromise. Administration of supplemental oxygen may enhance fetal oxygenation, even in the previously normoxemic mother; however, whether maternal oxygen therapy improves fetal outcome remains unclear.[125-128]

Uterine hypertonus or frequent uterine contractions (tachysystole), which may result in decreased uteroplacental perfusion, are known risks of oxytocin or prostaglandin compounds used for the induction of labor. Uterine contractions constrict the uterine spiral arteries, decreasing oxygen delivery to the placenta. A rare cause of fetal compromise is **uterine rupture,** which may result from uterine hyperstimulation, particularly in the setting of a uterine scar. **Placental abruption,** which may result in a partial or complete cessation of oxygen transfer to the fetus, can be associated with chronic or acute diseases. Long-standing vascular diseases produced by chronic hypertension or smoking, as well as acute factors such as cocaine abuse and abdominal trauma, can precipitate a placental abruption.

The treatment of uteroplacental causes of fetal compromise includes correction of uterine hypertonus or tachysystole by cessation of oxytocin infusion and the removal of cervical ripening agents (see Table 8-1). Oxytocin has a plasma half-life of 1 to 6 minutes; consequently, it may take several minutes for the hypertonus to be relieved. Alternatively, a tocolytic agent (e.g., terbutaline, nitroglycerin) may be administered. Normal maternal circulation should be maintained by avoiding aortocaval compression, expanding intravascular volume, and giving a vasopressor (e.g., phenylephrine, ephedrine) for treatment of hypotension.[129]

Fetal factors may contribute to fetal hypoxemia and acidosis. **Umbilical cord prolapse** through the cervix causes cord compression and often results in sudden fetal bradycardia. In the vast majority of circumstances, treatment of a prolapsed cord consists of manual elevation of the fetal head until emergency cesarean delivery can be accomplished. Only rarely should the umbilical cord be returned into the uterus and expectant care attempted.[130]

Reports from the developing world indicate that, in some cases, expeditious vaginal delivery may produce acceptable neonatal outcome.[131] Alternative methods to decompress a prolapsed umbilical cord include the use of the Trendelenburg position or an infusion of 500 to 700 mL of 0.9% saline into the maternal bladder until an expedited delivery can occur.[130,132,133]

Uterine contractions represent a much more common cause of **umbilical cord compression** and can manifest as variable FHR decelerations or bradycardia. **Oligohydramnios** is a risk factor for this type of cord compression, and a **change in maternal position** or the use of **saline amnioinfusion** may be therapeutic. Amnioinfusion has been observed to reduce the frequency of severe variable FHR decelerations and the incidence of cesarean delivery and to increase the umbilical cord blood pH in women with preterm premature rupture of membranes, oligohydramnios, or variable FHR decelerations during labor.[134,135] Systematic reviews have produced different conclusions as to whether *prophylactic* intrapartum amnioinfusion in patients with oligohydramnios is superior to *therapeutic* amnioinfusion in patients with both oligohydramnios and FHR abnormalities.[136,137]

Initial studies suggested that in patients with thick, meconium-stained amniotic fluid, amnioinfusion might decrease the incidence of meconium aspiration syndrome and fetal acidosis.[138-140] However, meta-analyses of studies suggest no benefit of amnioinfusion in the setting of meconium unless decelerations due to oligohydramnios are present.[141-145]

Saline amnioinfusion requires a dilated cervix, ruptured membranes, and the placement of an intrauterine catheter. Equipment that allows simultaneous saline amnioinfusion and measurement of intrauterine pressure is preferred. Either normal saline or lactated Ringer's solution may be infused as a bolus or as a continuous infusion.[146] The ideal rate of infusion has not been determined, but a commonly used regimen consists of a bolus of as much as 800 mL (infused at a rate of 10 to 15 mL/min) followed by either a continuous infusion at a rate of 3 mL/min or repeated boluses of 250 mL, as needed.[146] The necessity of either an infusion pump or a fluid warmer has not been demonstrated.[146] Alleviation of abnormal FHR patterns generally requires 20 to 30 minutes.[146]

Although most studies suggest that amnioinfusion is safe for the mother and fetus, some complications have been reported. Overdistention of the uterus and a higher rate of maternal infections and maternal respiratory distress, including cases of fatal amniotic fluid embolism, have occurred.[143,147-149] A causal relationship between amniotic fluid embolism and amnioinfusion has yet to be determined. Overdistention of the uterus may be controlled with proper documentation of fluid loss from the uterus during infusion, the provision of amnioinfusion by gravity instead of an infusion pump, and the use of ultrasonography to evaluate the fluid volume.[147]

Maternal fever may increase fetal oxygen consumption. Obstetricians should treat maternal fever with acetaminophen, a cooling blanket, and antibiotics as indicated to maintain maternal and fetal euthermia. **Hyperglycemia** also increases fetal oxygen consumption, so administration of a large bolus of a glucose-containing solution is contraindicated.

Fetal cardiac failure results in inadequate umbilical blood flow and fetal hypoxemia and acidosis. **Fetal anemia** due to maternal isoimmunization, fetal hemoglobinopathy, or fetal hemorrhage results in diminished fetal oxygen-carrying capacity. There are few options for the treatment of fetal cardiac failure or anemia during labor.

Standardization of FHR tracing interpretation and staged levels of intervention based on likely etiology will assist obstetric management. If intrapartum assessment suggests the presence of fetal compromise and fetal therapy is unsuccessful, the obstetrician should effect an expeditious, atraumatic delivery.

KEY POINTS

- A normal FHR tracing accurately predicts fetal well-being. An abnormal tracing is not very specific in the prediction of fetal compromise. Exceptions include the fetus with a prolonged bradycardia or the fetus with late FHR decelerations and absence of variability; both suggest a high likelihood of fetal compromise.
- Large, prospective, randomized studies have not confirmed that continuous electronic FHR monitoring confers substantial clinical benefit over intermittent FHR auscultation as performed by dedicated labor nurses.
- The specificity of FHR monitoring may be augmented by the use of fetal scalp stimulation, fetal vibroacoustic stimulation, and fetal scalp blood sampling. Pulse oximetry increases the specificity of FHR monitoring but does not reduce the rate of cesarean delivery.
- When possible, FHR resuscitation *in utero* is preferable to emergency delivery of an acidotic fetus.
- Saline amnioinfusion effectively prevents or relieves variable decelerations caused by umbilical cord compression and may improve perinatal outcomes in patients with oligohydramnios.

CHAPTER 9

Neonatal Assessment and Resuscitation

Susan W. Aucott, MD

CHAPTER OUTLINE

The transition from intrauterine to extrauterine life represents the most important adjustment that a neonate will make. Occurring uneventfully after most deliveries, this transition is dependent on the anatomic and physiologic condition of the infant, the ease or difficulty of the delivery, and the extrauterine environmental conditions. When the transition is unsuccessful, prompt assessment and supportive care must be initiated immediately.

At least one person skilled in neonatal resuscitation should be present at every delivery.[1] The resuscitation team may include personnel from the pediatrics, anesthesiology, obstetrics, respiratory therapy, and nursing services. The composition of the team varies among institutions, but some form of 24-hour coverage should be present within all hospitals that provide labor and delivery services.[1] A multidisciplinary team should participate in the process of ensuring that appropriate personnel and equipment are available for neonatal resuscitation.[1]

All personnel working in the delivery area should receive basic training in neonatal resuscitation to ensure prompt initiation of care before the arrival of the designated resuscitation team. The 2010 American Heart Association (AHA) Conference on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care led to the publication of updated guidelines for neonatal resuscitation.[2] Changes in these guidelines reflected a review of scientific evidence by members of the American Academy of Pediatrics (AAP), the AHA, and the International Liaison Committee on Resuscitation. These guidelines have been incorporated into the Neonatal Resuscitation Program (NRP), which is the standardized training and certification program administered by the AAP. The NRP, which was originally sponsored by the AAP and the AHA in 1987, is designed to be appropriate for all personnel who attend deliveries. To ensure the implementation of current guidelines for neonatal resuscitation, the AAP recommends that at least one NRP-certified practitioner attend every delivery.[3,4]

Both the American Society of Anesthesiologists (ASA) and the American College of Obstetricians and Gynecologists (ACOG) have published specific goals and guidelines for neonatal resuscitation (Box 9-1).[5] The ASA has emphasized that a single anesthesiologist should not be expected to assume responsibility for the concurrent care of both the mother and her child. Rather, a second anesthesia provider or a qualified individual from another service should assume responsibility for the care of the neonate, except in an unforeseen emergency.

In clinical practice, anesthesiologists often are involved in neonatal resuscitation.[6,7] Heyman et al.[7] observed that anesthesia personnel were involved in neonatal resuscitation in 99 (31%) of 320 selected Midwestern community hospitals. In 13.4% of these hospitals, the individual who administered anesthesia to the mother was also responsible for the care of the neonate; in 6.8% of these institutions, a second anesthesia provider typically assumed primary responsibility for the neonate. In a larger survey of obstetric anesthesia workforce patterns within the United States, Bucklin et al.[6] found that fewer anesthesiologists were involved in neonatal resuscitation in 2001 than in 1981, with this practice occurring in less than 5% of cesarean deliveries.

BOX 9-1 Optimal Goals for Anesthesia Care in Obstetrics:

NEONATAL RESUSCITATION

Personnel other than the surgical team should be immediately available to assume responsibility for resuscitation of the depressed neonate. The surgeon and anesthesiologist are responsible for the mother and may not be able to leave her to care for the neonate, even when a neuraxial anesthetic is functioning adequately. Individuals qualified to perform neonatal resuscitation should demonstrate:

- Proficiency in rapid and accurate evaluation of the neonate's condition, including Apgar scoring
- Knowledge of the pathogenesis of a depressed neonate (acidosis, drugs, hypovolemia, trauma, anomalies, and infection) as well as specific indications for resuscitation
- Proficiency in neonatal airway management, laryngoscopy, endotracheal intubations, suctioning of airways, artificial ventilation, cardiac massage, and maintenance of thermal stability

In larger maternity units and those functioning as high-risk centers, 24-hour in-house anesthesia, obstetric, and neonatal specialists are usually necessary.

Modified from a joint statement from the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists. Optimal goals for anesthesia case in obstetrics. Approved by the American Society of Anesthesiologists in October 2008. (See Appendix C for full document.)

Despite this relatively low incidence of primary involvement, the anesthesiologist is often asked to provide assistance in cases of difficult airway management or when members of the neonatal resuscitation team have not yet arrived. The anesthesiologist should be prepared to provide assistance, provided that such care does not compromise the care of the mother. A study of University of Pennsylvania anesthesiology residency program graduates from 1989 to 1999 revealed that, despite a desire to be certified in neonatal resuscitation, most anesthesiologists were not.[8]

In a 1991 review of the ASA Closed-Claims Database, 13% of obstetric anesthesia malpractice claims were related to neonatal resuscitation, including delayed or failed tracheal intubation and an unrecognized esophageal intubation.[9] Another review of obstetric anesthesia–related lawsuits from 1985 to 1993 demonstrated that 12 (17%) of the 69 cases involved claims of inadequate neonatal resuscitation by anesthesia personnel[7]; 10 of these 12 cases resulted in payment to the plaintiff. Written hospital policies should identify the personnel responsible for neonatal resuscitation; obstetric anesthesia providers should also maintain a high level of skill in neonatal resuscitation.

TRANSITION FROM INTRAUTERINE TO EXTRAUTERINE LIFE

Circulation

At birth, the circulatory system changes from a fetal circulation pattern (which is in parallel), through a transitional circulation, to an adult circulation pattern (which is in series) (Figure 9-1).[10] In the fetus, blood from the placenta travels through the umbilical vein and the ductus venosus to the inferior vena cava and the right side of the heart. The anatomic orientation of the inferior vena caval–right atrial junction favors the shunting (i.e., streaming) of this well-oxygenated blood through the foramen ovale to the left side of the heart. This well-oxygenated blood is pumped through the ascending aorta, where branches that perfuse the upper part of the body (e.g., heart, brain) exit proximal to the entrance of the ductus arteriosus.[11] Desaturated blood returns to the heart from the upper part of the body by means of the superior vena cava. The anatomic orientation of the superior vena caval–right atrial junction favors the streaming of blood into the right ventricle. Because fetal pulmonary vascular resistance is higher than systemic vascular resistance (SVR), approximately 90% of the right ventricular output passes through the ductus arteriosus and enters the aorta distal to the branches of the ascending aorta and aortic arch; therefore, less well-oxygenated blood perfuses the lower body, which consumes less oxygen than the heart and brain.

At the time of birth and during the resulting circulatory transition, the amount of blood that shunts through the foramen ovale and ductus arteriosus diminishes and the flow becomes bidirectional. Clamping the umbilical cord (or exposing the umbilical cord to room air) results in increased SVR. Meanwhile, expansion of the lungs and increased alveolar oxygen tension and pH result in decreased pulmonary vascular resistance and subsequently greater flow of pulmonary artery blood through the lungs.[12,13] Increased pulmonary artery blood flow results in improved oxygenation and higher left atrial pressure; the latter leads to a diminished shunt across the foramen ovale. Increased Pao_2 and SVR and decreased pulmonary vascular resistance result in a constriction of the ductus arteriosus.[14,15] Together, these changes in vascular resistance result in functional closure of the foramen ovale and the ductus arteriosus. This process does not occur instantaneously, and arterial oxygen saturation (Sao_2) remains higher in the right upper extremity (which is preductal) than in the left upper extremity and the lower extremities until blood flow through the ductus arteriosus is minimal.[16] Differences in Sao_2 are usually minimal by 10 minutes and absent by 24 hours after birth. Provided that there is no interference with the normal drop in pulmonary vascular resistance, both the foramen ovale and the ductus arteriosus close functionally, and the infant develops an adult circulation (which is in series).

Persistent fetal circulation—more correctly called **persistent pulmonary hypertension of the newborn—** can occur when the pulmonary vascular resistance remains elevated at the time of birth. Factors that may contribute to this problem include hypoxia, acidosis, hypovolemia, and hypothermia.[13,17] Maternal use of nonsteroidal anti-inflammatory drugs may also cause premature constriction of the ductus arteriosus in the fetus and thus predispose to persistent pulmonary hypertension of the newborn.[18]

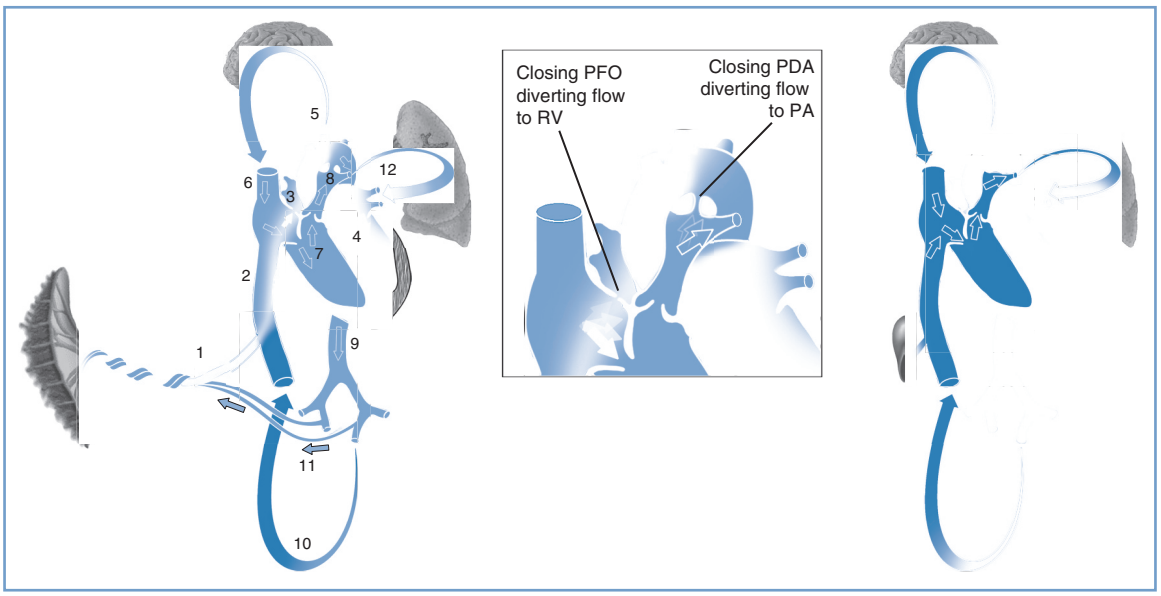

FIGURE 9-1 ■ Modification of blood flow patterns from the fetal (*left*), via the transitional (*center*), to the neonatal (*right*) circulation. In the fetal circulation, oxygenated blood (*white*) from the placenta travels through the umbilical vein (*1*) into the ductus venosus and the inferior vena cava (*2*). The majority of oxygenated blood passes through the patent foramen ovale (PFO) from the right atrium to the left atrium (*3*) and ventricle (*4*), and distributes this blood to the brain (*5*). The deoxygenated blood (*blue*) from the brain and upper extremities enters the superior vena cava, mixing with a small portion of the oxygenated blood in the right atrium, before entering the right ventricle (RV, *7*). The mostly deoxygenated blood is transported into the pulmonary artery where the majority is diverted through the patent ductus arteriosus (PDA, *8*) into the descending aorta (*9*), thereby bypassing the lungs. Some blood enters the lower body (*10*), but the majority returns to the placenta via the umbilical arteries (*11*). A small amount of blood from the pulmonary artery enters the lungs (*12*). During the transitional circulation, which occurs over a few days, the PFO closes, diverting blood from the right atrium to the right ventricle. Closure of the PDA diverts deoxygenated blood through the pulmonary arteries to the lungs. The neonatal circulation separates the oxygenated and deoxygenated blood flow pathways. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

Respiration

Fetal breathing movements have been observed *in utero* as early as 11 weeks' gestation. These movements increase with advancing gestational age but undergo a marked reduction within days of the onset of labor. They are stimulated by hypercapnia and maternal smoking and are inhibited by hypoxia and central nervous system (CNS) depressants (e.g., barbiturates). Under normal conditions, this fetal breathing activity results only in the movement of pulmonary dead space.[19]

The fetal lung contains a liquid composed of an ultrafiltrate of plasma, which is secreted by the lungs in utero[20]; the volume of this lung liquid is approximately 30 mL/kg. Partial reabsorption of this liquid occurs during labor and delivery, and approximately two thirds is expelled from the lungs of the term neonate by the time of delivery.[21] Small preterm infants and those requiring cesarean delivery may have a greater amount of residual lung liquid after delivery. These infants experience less chest compression at delivery than infants who are larger or delivered vaginally; this difference can lead to difficulty in the initiation and maintenance of a normal breathing pattern. Retained fetal lung liquid is the presumed cause of **transient tachypnea of the newborn (TTN).**[22]

The first breath occurs approximately 9 seconds after delivery. Air enters the lungs as soon as the intrathoracic pressure begins to fall. This air movement during the first breath is important, because it establishes the neonate's functional residual capacity (Figure 9-2).

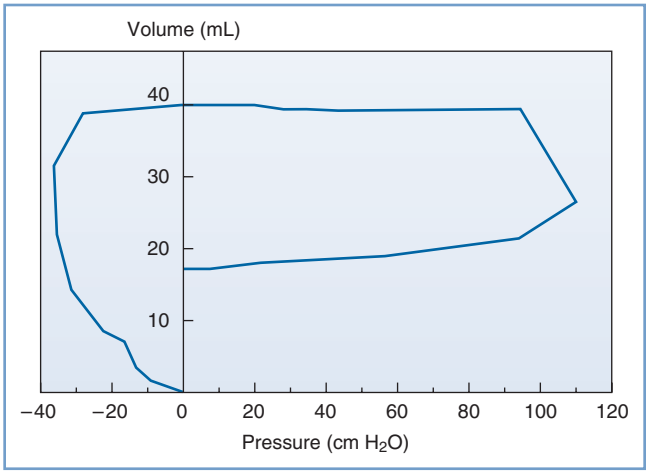

FIGURE 9-2 ■ Typical pressure-volume loop of the first breath. The intrathoracic pressure falls to −30 to −40 cm H_2O, drawing air into the lungs. The expiratory pressure is much greater than the inspiratory pressure. (Modified from Milner AD, Vyas H. Lung expansion at birth. J Pediatr 1982; 101:881.)

Lung inflation is a major physiologic stimulus for the release of lung surfactant into the alveoli.[23] Surfactant, which is necessary for normal breathing, is present within the alveolar lining cells by 20 weeks' gestation[24] and within the lumen of the airways by 28 to 32 weeks' gestation. However, significant amounts of surfactant do not appear in terminal airways until 34 to 38 weeks'

gestation unless surfactant production has been stimulated by chronic stress or maternal corticosteroid administration.[25]

Stress during labor and delivery can lead to gasping efforts by the fetus, which may result in the inhalation of amniotic fluid into the lungs.[26] This event can produce problems if the stress causes the fetus to pass meconium into the amniotic fluid before gasping.

Catecholamines

Transition to extrauterine life is associated with a catecholamine surge, which may be necessary for the process to be successful. In chronically catheterized sheep, catecholamine levels begin to rise a few hours before delivery and may be higher at the time of delivery than at any other time during life.[27] Catecholamines have an important role in the following areas: (1) the production and release of surfactant, (2) the mediation of preferential blood flow to vital organs during the period of stress that occurs during every delivery, and (3) thermoregulation of the neonate.

Thermal Regulation

Thermal stress challenges the neonate in the extrauterine environment. Neonates raise their metabolic rates and release norepinephrine in response to cold; this response facilitates the oxidation of brown fat, which contains numerous mitochondria. The oxidation results in **nonshivering thermogenesis,** the major mechanism for neonatal heat regulation.[28] This process may lead to significant oxygen consumption, especially if the neonate has not been dried off and kept in an appropriate thermoneutral environment, such as a radiant warmer. Thermal stress is an even greater problem in infants with low fat stores, such as preterm infants or infants who are small for gestational age. An alternative method to eliminate heat loss from evaporation is to provide an occlusive wrap rather than drying the infant. For infants born at less than 28 weeks' gestation, the use of polythene wraps or bags is recommended to minimize heat loss.[29,30] The maintenance of a neutral thermal environment (i.e., 34° to 35° C) is recommended. However, in the neonate with a perinatal brain injury, mild hypothermia therapy through selective head or whole body cooling is initiated in the first 6 hours of life and may be neuroprotective in the setting of hypoxia-ischemia.[31,32] Hyperthermia may worsen neurologic outcomes and should be avoided.[2,33] Hypothermia therapy, via selective head cooling or whole body hypothermia, is continued for 72 hours after initiation. Consequently, if an infant is delivered at a center where hypothermia therapy is unavailable, passive cooling can be initiated by turning the radiant warmer off while awaiting infant transfer.

Administration of epidural analgesia during labor is associated with an increase in maternal and fetal temperature.[34] Concern has been expressed that the temperature elevation associated with intrapartum epidural analgesia might result in an increase in the frequency of neonatal sepsis evaluations.[34,35] However, a number of variables (e.g., preeclampsia/hypertension, gestational age, birth weight, meconium aspiration, respiratory distress at birth, hypothermia at birth, and group B beta-hemolytic streptococcal colonization of the maternal birth canal) have been observed to be strong predictors of the performance of neonatal sepsis evaluations, whereas maternal fever and epidural analgesia have not.[36] Confounding variables may influence the findings of these types of association studies; patients who choose either to receive or not receive epidural analgesia may be inherently different. The incidence of actual neonatal sepsis is not different in term infants whose mothers either did or did not receive epidural analgesia.

ANTENATAL ASSESSMENT

Approximately 10% of neonates require some level of resuscitation.[7] The need for resuscitation can be predicted before labor and delivery with approximately 80% accuracy on the basis of a number of antepartum factors (Box 9-2).

Preterm delivery increases the likelihood that the neonate will require resuscitation. When a mother is admitted with either preterm labor or premature rupture of membranes, plans should be made for neonatal care in the event of delivery. The antenatal assessment of gestational age is based on the presumed date of the last menstrual period, the fundal height, and ultrasonographic measurements of the fetus. Unfortunately, it may be difficult to assess gestational age accurately, because menstrual dates may be unknown or incorrect, the fundal height may be affected by abnormalities of fetal growth or amniotic fluid volume, and ultrasonographic assessment of fetal age is less precise after mid pregnancy. The assessment of gestational age is most accurate in patients who receive prenatal care in early pregnancy. An accurate approximation of gestational age enables the health care team to plan for the needs of the neonate and to counsel the parents regarding neonatal morbidity and mortality. These plans and expectations must be formulated with caution and flexibility, because the antenatal assessment may not accurately predict neonatal size, maturity, and/or condition at delivery.

A variety of **intrauterine insults** can impair the fetal transition to extrauterine life. For example, neonatal depression at birth can result from acute or chronic uteroplacental insufficiency or acute umbilical cord compression. Chronic uteroplacental insufficiency, regardless of its etiology, may result in fetal growth restriction. Fetal hemorrhage, viral or bacterial infection, meconium aspiration, and exposure to opioids or other CNS depressants also can result in neonatal depression. Although randomized trials have not confirmed that fetal heart rate (FHR) monitoring improves neonatal outcome, a nonreassuring FHR tracing is considered a predictor of the need for neonatal resuscitation.[37]

Studies have evaluated the use of fetal pulse oximetry for the evaluation of fetal well-being during labor. This technique involves the transcervical insertion of a flexible fetal oxygen sensor until it rests against the fetal cheek. A randomized trial found that use of the fetal pulse oximeter in conjunction with FHR monitoring led to a

BOX 9-2 Risk Factors Suggesting a Greater Need for Neonatal Resuscitation

Antepartum Risk Factors

- Maternal diabetes
- Hypertensive disorder of pregnancy
- Chronic hypertension
- Fetal anemia or isoimmunization
- Previous fetal or neonatal death
- Bleeding in second or third trimester
- Maternal infection
- Maternal cardiac, pulmonary, renal, thyroid, or neurologic disease
- Polyhydramnios
- Oligohydramnios
- Premature rupture of membranes
- Fetal hydrops
- Post-term gestation
- Multiple gestation
- Discrepancy between fetal size and dates (i.e., last menstrual period)
- Drug therapy (e.g., lithium carbonate, magnesium, adrenergic-blocking drugs)
- Maternal substance abuse
- Fetal malformation
- Diminished fetal activity
- No prenatal care
- Maternal age > 35 years

Intrapartum Risk Factors

- Emergency cesarean delivery
- Forceps or vacuum-assisted delivery
- Breech or other abnormal presentation
- Preterm labor
- Precipitous labor
- Chorioamnionitis
- Prolonged rupture of membranes (> 18 hours before delivery)
- Prolonged labor (> 24 hours)
- Macrosomia
- Category II or III fetal heart rate patterns
- Use of general anesthesia
- Uterine tachysystole with fetal heart rate changes
- Maternal administration of opioids within 4 hours of delivery
- Meconium-stained amniotic fluid
- Prolapsed umbilical cord
- Placental abruption
- Placenta previa
- Significant intrapartum bleeding

Modified from Textbook of Neonatal Resuscitation. 6th edition. Elk Grove Village, IL, American Academy of Pediatrics and American Heart Association, 2011:216.

reduction in the number of cesarean deliveries performed due to a nonreassuring FHR tracing.[38] However, this decrease was offset by an increased number of cesarean deliveries performed due to dystocia, raising the concern that the presence of the probe might predispose to dystocia. As a consequence, the ACOG has recommended further study before fetal pulse oximetry is used routinely in clinical practice.[39] A meta-analysis of five trials concluded that there was some benefit to fetal pulse oximetry in the presence of a nonreassuring FHR tracing, but the use of fetal pulse oximetry did not lead to an overall reduction in the cesarean delivery rate.[40]

Infants with **congenital anomalies** (e.g., tracheoesophageal fistula, diaphragmatic hernia, CNS and cardiac malformations) may need resuscitation and cardiorespiratory support. Improved ultrasonography allows for the antenatal diagnosis of many congenital anomalies and other fetal abnormalities (e.g., nonimmune hydrops). Obstetricians should communicate knowledge or suspicions regarding these entities to those who will provide care for the neonate in the delivery room to allow the resuscitation team to make specific resuscitation plans.

In the past, infants born by either elective or emergency cesarean delivery were considered more likely to require resuscitation than infants delivered vaginally. Evidence suggests that repeat cesarean deliveries and those performed for dystocia—in patients without FHR abnormalities—result in the delivery of infants at low risk for neonatal resuscitation, especially when the cesarean deliveries are performed with neuraxial anesthesia.[3,4,41] Of interest, infants born by elective repeat cesarean delivery are at higher risk for subsequent respiratory problems (e.g., transient tachypnea of the newborn) than similar infants born vaginally. In addition, infants born by cesarean delivery after a failed trial of labor are at a higher risk for neonatal sepsis than similar infants born vaginally.[42] Emergency cesarean delivery is considered a risk factor for the need for neonatal resuscitation.

NEONATAL ASSESSMENT

Apgar Score

Resuscitative efforts typically precede the performance of a thorough physical examination of the neonate. Because NRP instructions require simultaneous assessment and treatment, it is important that the neonatal assessment be both simple and sensitive. In 1953, Dr. Virginia Apgar, an anesthesiologist, described a simple method for neonatal assessment that could be performed while care was being delivered.[43] She suggested that this standardized and relatively objective scoring system would differentiate between infants who require resuscitation and those who need only routine care.[44]

The Apgar score is based on five parameters that are assessed at 1 and 5 minutes after birth. Further scoring at 5- or 10-minute intervals may be done if initial scores are low. The parameters are heart rate, respiratory effort, muscle tone, reflex irritability, and color. A score of 0, 1, or 2 is assigned for each of these five entities (Table 9-1). A total score of 8 to 10 is normal; a score of 4 to 7 indicates moderate impairment; and a score of 0 to 3 signals the need for immediate resuscitation. Dr. Apgar emphasized that this system does not replace a complete physical examination and serial observations of the neonate for several hours after birth.[45]

The Apgar score is widely used to assess neonates, although its value has been questioned. The scoring system may help predict mortality and neurologic morbidity in *populations* of infants, but Dr. Apgar cautioned against the use of the Apgar score to make these

TABLE 9-1 **Apgar Scoring System**

Parameter	Score		
	0	1	2
Heart rate (bpm)	Absent	< 100	> 100
Respiratory effort	Absent	Irregular, slow, shallow, or gasping respirations	Robust, crying
Muscle tone	Absent, limp	Some flexion of extremities	Active movement
Reflex irritability (nasal catheter, oropharyngeal suctioning)	No response	Grimace	Active coughing and sneezing
Color	Cyanotic	Acrocyanotic (trunk pink, extremities blue)	Pink

bpm, beats per minute.
Modified from Tabata BK. Neonatal resuscitation. In Rogers MC, editor. Current Practice in Anesthesiology. 2nd edition. St. Louis, Mosby, 1990:368.

predictions in an *individual* infant. She noted that the risk for neonatal mortality was inversely proportional to the 1-minute score.[45] In addition, the 1-minute Apgar score was a better predictor of mortality within the first 2 days of life than within 2 to 28 days of life.

Several studies have challenged the notion that a low Apgar score signals perinatal asphyxia. In a prospective study of 1210 deliveries, Sykes et al.[46] noted a poor correlation between the Apgar score and the umbilical cord blood pH. Other studies, including those of low-birthweight infants, have found that a low Apgar score is a poor predictor of neonatal acidosis, although a high score is reasonably specific for excluding the presence of severe acidosis.[47-53] By contrast, the fetal biophysical profile has a good correlation with the acid-base status of the fetus and the neonate (see Chapter 6).[54] The biophysical profile includes performance of a nonstress test and ultrasonographic assessment of fetal tone, fetal movement, fetal breathing movements, and amniotic fluid volume.[54]

Additional studies have suggested that Apgar scores are poor predictors of long-term neurologic impairment.[55,56] The Apgar score is more likely to predict a poor neurologic outcome when the score remains 3 or less at 10, 15, and 20 minutes. However, when a child has cerebral palsy, low Apgar scores alone are not adequate evidence that perinatal hypoxia was responsible for the neurologic injury.

The ACOG Task Force on Neonatal Encephalopathy and Cerebral Palsy published criteria for defining an intrapartum event sufficient to cause cerebral palsy.[57] An Apgar score of 0 to 3 beyond 5 minutes of age is not included in the list of "essential criteria"; rather, it is one of five criteria that "collectively suggest an intrapartum timing (within close proximity to labor and delivery…) but are nonspecific to asphyxial insults."[57-62]

In a retrospective analysis of 151,891 singleton infants born at 26 weeks' gestation or later between 1988 and 1998, Casey et al.[63] examined the relationship between Apgar scores and neonatal death rates during the first 28 days of life. The highest relative risk for neonatal death was observed in infants with an Apgar score of 3 or less at 5 minutes of age. The 5-minute Apgar score was a better predictor of neonatal death than the umbilical arterial blood pH. In term infants, the relative risk for neonatal death was eight times higher in infants with a 5-minute Apgar score of 3 or less than in those with an umbilical arterial blood pH of 7.0 or less.[63,64] In preterm infants, lower 5-minute Apgar scores were associated with younger gestational ages (i.e., mean score 6.6 ± 2.1 for infants born at 26 to 27 weeks' and 8.7 ± 0.8 for infants born at 34 to 36 weeks' gestation).[63,64] Similarly, earlier studies found that preterm infants were more likely than term infants to have low 1- and 5-minute Apgar scores, independent of neonatal oxygenation and acid-base status. Respiratory effort, muscle tone, and reflex irritability are the components of the score that are most influenced by gestational age.[65]

The earlier the gestational age, the greater the likelihood of a low Apgar score, even in the presence of a normal umbilical cord blood pH. Preterm infants often require active resuscitation efforts immediately after delivery, and these manipulations may affect the components of the Apgar score. For example, pharyngeal and tracheal stimulation may cause a reflex bradycardia, which affects the heart rate score.[49] In addition, it is difficult to judge respiratory effort during suctioning or endotracheal intubation.

During cases of active neonatal resuscitation, the Apgar scores often are not assigned at the appropriate times; rather, these scores may be assigned retrospectively. In these situations, the individual must rely on recall of the infant's condition at earlier times, introducing inaccuracy. Even if the scores are assigned at the appropriate times, there may be disagreement among the several individuals who are providing care for the infant. To avoid bias, Dr. Apgar recommended that someone not involved in the care of the mother assign the score.

Although there is some appeal to the use of objective measurements (i.e., Sao_2, heart rate) rather than subjective observations, it should not be inferred that the subjective components of the Apgar score (e.g., muscle tone) are less important. There are some practical limitations that may make objective measurements difficult to obtain (e.g., movement artifact with pulse oximetry).[16] However, newer-generation pulse oximeters provide more accurate estimations of Sao_2 (see later discussion).[66]

In summary, the usefulness of the Apgar score is still being debated more than 50 years after its inception.[63,64]

The Apgar scoring system is used throughout the world, but its limitations must be kept in mind. Low Apgar scores alone do not provide sufficient evidence of perinatal asphyxia; rather, Apgar scores can be low for a variety of reasons. Preterm delivery, congenital anomalies, neuromuscular diseases, antenatal drug exposure, manipulation at delivery, and subjectivity and error may influence the Apgar score.

Umbilical Cord Blood Gas and pH Analysis

Umbilical cord blood gas and pH measurements reflect the fetal condition immediately before delivery and can be obtained routinely after delivery or measured only in cases of neonatal depression. These measurements may be a more objective indication of a neonate's condition than the Apgar score. However, there is a delay between obtaining the samples and completing the analysis; during this interval, decisions must be made on the basis of clinical assessment. The ACOG[67] has recommended that cord blood gas measurements be obtained in circumstances of cesarean delivery for fetal compromise, low 5-minute Apgar score, severe growth restriction, abnormal FHR tracing, maternal thyroid disease, intrapartum fever, and/or multiple gestations.

The fetus produces carbonic acid (from oxidative metabolism) and lactic and beta-hydroxybutyric acids (primarily from anaerobic metabolism). Carbonic acid, which is often called *respiratory acid*, is cleared rapidly by the placenta as carbon dioxide when placental blood flow is normal. However, metabolic clearance of lactic and beta-hydroxybutyric acids requires hours; thus, these acids are called *metabolic* or *fixed acids*. In the fetus, metabolic acidemia is more ominous than respiratory acidemia because the former reflects a significant amount of anaerobic metabolism.

The measured components of umbilical cord blood gas analysis are pH, Pco_2, Po_2, and HCO_3^-. Bicarbonate (HCO_3^-) is a major buffer in fetal blood. The measure of change in the buffering capacity of umbilical cord blood is reflected in the delta base, which is also known as the base excess or deficit; this value can be calculated from the pH, Pco_2, and HCO_3^-. Ideally, blood samples from both the umbilical artery and vein are collected. Umbilical artery blood gas measurements represent the fetal condition, whereas umbilical vein measurements reflect the maternal condition and uteroplacental gas exchange. Unfortunately, it may be difficult to obtain blood from the umbilical artery, especially when it is small, as it is in very low-birth-weight (VLBW) infants. Caution should be used in the interpretation of an isolated umbilical venous blood pH measurement, which can be normal despite the presence of arterial acidemia.

Proper blood sampling and handling are necessary. The measurements should be accurate, provided that (1) the umbilical cord is double clamped immediately after delivery[68-70]; (2) the samples are drawn, within 15 minutes of delivery,[71] into a syringe containing the proper amount of heparin[72]; and (3) the samples are analyzed within 30 to 60 minutes.[71,73] The Po_2 measurement is more accurate if residual air bubbles are removed from the syringe.

Historically, a normal umbilical cord blood pH measurement was believed to be 7.2 or higher.[74] However, investigators have challenged the validity of this number, given its lack of distinction between umbilical arterial and venous blood despite clear differences in their normal measurements.[75] One study noted that the median umbilical arterial blood pH in vigorous infants (those with 5-minute Apgar scores of 7 or higher) was 7.26, with a measurement of 7.10 representing the 2.5th percentile.[76] Published studies suggest that the lower limit of normal umbilical arterial blood pH measurements may range from 7.02 to 7.18 (Table 9-2).[46,77-86] A number of factors may also influence the umbilical arterial blood pH measurement. A fetus subjected to the stress of labor has lower pH measurements than one born by cesarean delivery without labor.[83] Offspring of nulliparous women tend to have a lower pH than offspring of parous women, a difference that is likely related to a difference in the duration of labor.[87]

Some studies have suggested that preterm infants have a higher incidence of acidemia; however, later studies have observed that term and preterm infants have similar umbilical cord blood gas and pH measurements.[78,79,87] Preterm infants often receive low Apgar scores despite the presence of normal umbilical cord blood gas and pH measurements; therefore, the assessment of umbilical cord blood may be especially helpful in the evaluation of preterm neonates.

Physicians should use strict definitions when interpreting umbilical cord blood gas and pH measurements. Terms such as *birth asphyxia* should be avoided in most cases.[57] *Acidemia* refers to an increase in the hydrogen ion concentration in the blood. *Acidosis* occurs when there is an increased hydrogen ion concentration in tissue. *Asphyxia* is a clinical situation that involves hypoxia (i.e., a decreased level of oxygen in tissue), damaging acidemia, and metabolic acidosis.

When acidemia is present, the type—respiratory, metabolic, or mixed—must be identified (Table 9-3). Metabolic acidemia is more likely to be associated with acidosis than respiratory acidemia and is clinically more significant. Similarly, mixed acidemia with a high Pco_2, an extremely low HCO_3^-, and a high base deficit is more ominous than a mixed acidemia with a high Pco_2 but only a slightly reduced HCO_3^- and a low base deficit. Mixed or metabolic acidemia (but not respiratory acidemia) is associated with an increased incidence of neonatal complications and death.[87] In their study of 3506 term neonates, Goldaber et al.[88] noted that an umbilical arterial blood pH measurement less than 7.00 was associated with a significantly higher incidence of neonatal death. All neonatal seizures in their study occurred in infants with an umbilical arterial blood pH less than 7.05. By contrast, a short-term outcome study failed to show a good correlation between arterial blood pH and the subsequent health of an infant.[53] In the previously discussed large study reported by Casey et al.,[63] an umbilical arterial blood pH of 7.0 or less was a poorer predictor of the relative risk for neonatal death during the first 28 days of life than a 5-minute Apgar score of 3 or less.

TABLE 9-2 Studies Reporting Umbilical Cord Arterial Blood Gas Measurements*

Study	Sample Size	pH	P_{CO_2}	Bicarbonate	Base Deficit	P_{O_2}

TABLE 9-3 Criteria Used to Define Types of Acidemia in Neonates with an Umbilical Arterial pH Measurement Less Than 7.20

Classification	P_{CO_2} (mm Hg)	HCO_3^- (mEq/L)	Base Deficit (mEq/L)*
Respiratory	High (> 65)	Normal (≥ 22)	Normal (–6.4 ± 1.9)
Metabolic	Normal (< 65)	Low (≤ 17)	High (–15.9 ± 2.8)
Mixed	High (≥ 65)	Low (≤ 17)	High (–9.6 ± 2.5)

*Means ± SD given in parentheses.
From the American College of Obstetricians and Gynecologists. Assessment of fetal and newborn acid-base status. ACOG Technical Bulletin No. 127. Washington, DC, April 1989.

However, 6264 infants were excluded from their study because umbilical arterial blood gas measurements could not be obtained, and these infants had a higher incidence of neonatal death than those for whom blood gas measurements were available (4.5 per 1000 versus 1.2 per 1000, respectively). In a separate review of 51,519 term deliveries, Yeh et al.[89] found an increased risk for adverse outcomes in infants with a pH less than 7.10, with the lowest risk in infants with a pH between 7.26 and 7.30; however, 75% of infants with neurologic morbidity had a normal pH. Thus, it is important to remember that neonates may suffer multiorgan system damage, including neurologic injury, even in the absence of low pH and Apgar scores.

According to the ACOG Task Force, an umbilical arterial blood pH less than 7.0 and a base deficit greater than or equal to 12 mmol/L at delivery are considered one part of the definition of an acute intrapartum hypoxic event sufficient to cause cerebral palsy.[57] The base deficit and bicarbonate (the metabolic component) values are the most significant factors associated with morbidity in neonates with an umbilical arterial blood pH less than 7.0. Ten percent of infants with an umbilical arterial base deficit of 12 to 16 mmol/L have moderate to severe complications, which increases to 40% when the deficit is greater than 16 mmol/L.[67]

Abnormal FHR patterns and umbilical cord blood gas measurements are not consistently correlated with poor neonatal outcomes.[37] In a longitudinal study that evaluated outcomes at 6.5 years of age, Hafstrom et al.[90] found that infants with an umbilical arterial blood pH less than 7.05 but a normal examination at birth had outcomes that did not differ from those for matched infants with a normal umbilical arterial blood pH.

As Dr. Apgar emphasized in 1962, the most important components of neonatal assessment are a careful physical examination and continued observation for several hours.[45] Additional information can be gained from the antenatal history, Apgar scores, and umbilical cord blood gas and pH measurements, provided that clinicians are aware of the proper methods of interpretation as well as the limitations of these methods of assessment.

Respiration and Circulation

There are some similarities between the initial assessment of the neonate and the initial assessment of an adult who requires resuscitation. In both situations, the physician should give immediate attention to the ABCs of resuscitation (i.e., airway, breathing, circulation).

The normal neonatal respiratory rate is between 30 and 60 breaths per minute. Breathing should begin by 30 seconds and be regular by 90 seconds of age. Failure of the neonate to breathe by 90 seconds of age represents either primary or secondary apnea, based on the neonatal rhesus monkey asphyxia model.[91] In this model, gasping motions were observed for approximately 1 minute immediately after delivery; this was followed by a 1-minute period of apnea (primary apnea), then 5 minutes of gasping motions, and a final period of apnea (secondary or "terminal" apnea). During *primary apnea*, but not secondary apnea, tactile stimulation of the newborn monkey initiated breathing efforts. In addition, although heart rate was low with both periods of apnea, a reduction in blood pressure was observed only during secondary apnea. With the onset of secondary apnea (approximately 8 minutes after birth), the pH was 6.8 and the Pao_2 and $Paco_2$ measurements were less than 2 and 150 mm Hg, respectively.

This experimental model illustrates two important points. First, distinguishing primary from secondary apnea is not possible unless blood pressure and/or blood gases and pH are measured. Second, by the time secondary apnea has begun, blood gas measurements have deteriorated significantly. Therefore, during evaluation of the apneic neonate, aggressive resuscitation must be initiated promptly if tactile stimulation does not result in the initiation of spontaneous breathing.

Assessment of the adequacy of respiratory function requires comprehensive observation for signs of neonatal respiratory distress. These signs include cyanosis, grunting, flaring of the nares, retracting chest motions, and unequal breath sounds. The adequacy of respiratory function can also be assessed by the estimation of Sao_2. The reliability of pulse oximetry for the assessment of neonatal Sao_2 was questioned initially because of concerns about the accuracy of spectrophotometric assessments of fetal hemoglobin and the difficult signal detection caused by the rapidity of the neonate's heart rate.[92,93] The newer generation of pulse oximetry monitors, which employ signal extraction and averaging techniques, are able to provide more reliable measurements, especially in the presence of poor perfusion, patient movement, and ambient light artifacts.[66,94]

Pulse oximetry provides accurate estimates of Sao_2 during periods of stability but may overestimate values during rapid desaturation.[95] In addition, the Sao_2 (Spo_2) measurements may fluctuate in the delivery room as a result of the ongoing transition from the fetal to the neonatal circulation, and it may take more than 10 minutes to achieve a preductal Sao_2 greater than 95% in a healthy term infant. Overall, the newer-generation pulse oximeters reliably provide continuous noninvasive Sao_2 measurements and are useful for neonatal monitoring.[96-98]

The pulse oximeter sensor should be applied to the neonate's right upper extremity, which receives preductal blood flow (see earlier discussion); because CNS blood flow is also preductal, right upper extremity Sao_2 measurements provide a more accurate assessment of CNS oxygenation.[16] Sensor placement can be difficult on skin that is wet and covered with vernix caseosa; therefore, it may be easier to place the sensor over the right radial artery, especially in preterm infants.[94]

Neonatal arterial blood sampling is technically difficult and thus rarely obtained in the delivery room. Cannulation of the umbilical artery is useful in infants who will require frequent blood sampling. This procedure often requires the use of microinstruments (especially in preterm and VLBW infants) and the ability to monitor the infant when obscured from view by surgical drapes; therefore, this procedure is usually performed in the neonatal intensive care unit (NICU).

The normal neonatal heart rate may be greater than 160 beats per minute (bpm) in the very early preterm neonate, but it should be within the range of 120 to 160 bpm by 28 weeks' gestational age. The heart rate can be determined in several ways. The clinician can lightly grasp the base of the umbilical cord and feel the arterial pulsations. (This method cannot be used in situations in which the pulsations become difficult to feel, such as in an infant with a low cardiac output.) Alternatively, the clinician can listen to the apical heartbeat. When either of these two methods is used, the evaluator should tap a hand with each heartbeat so that other members of the resuscitation team are aware of the rate. By contrast, the use of a pulse oximeter provides an audible heart rate, the additional benefit of Sao_2 monitoring, and the ability to eliminate the need for an additional team member.

Measurement of arterial blood pressure is not a priority during the initial assessment and resuscitation of the neonate.[2] However, observation for signs of abnormal circulatory function is considered essential. These signs include cyanosis, pallor, mottled coloring, prolonged capillary refill time, and weakness or absence of pulses in the extremities. One of the causes of abnormal circulatory function is hypovolemia, which should be anticipated in cases of bleeding from the umbilical cord or the fetal side of the placenta or whenever a neonate does not respond appropriately to resuscitation. The hypovolemic neonate may exhibit not only signs of abnormal circulatory function but also tachycardia and tachypnea. (Neonatal hypovolemia usually does not accompany placental abruption, which may cause maternal bleeding or other conditions associated with fetal asphyxia.)

Neurologic Status

The initial neonatal neurologic assessment requires only simple observation. The neonate should demonstrate evidence of vigorous activity, including crying and active flexion of the extremities. Signs of possible neurologic abnormalities include apnea, seizures, hypotonia, and unresponsiveness. Neonates should be assessed for physical signs of hypoxic-ischemic encephalopathy (Table 9-4). The stages of hypoxic-ischemic encephalopathy are associated with different outcomes: stage I, good; stage II,

TABLE 9-4 **Stages of Neonatal Hypoxic-Ischemic Encephalopathy**

Stage I	Stage II	Stage III
Irritable	Lethargic/obtunded	Coma
Normal respirations	Depressed respirations	Apnea
Hypertonic	Hypotonic	Flaccid
Increased reflexes	Decreased reflexes	Absence of reflexes
No seizures	Occasional seizures	Status epilepticus or nearly isoelectric electroencephalogram
Good outcome	Moderate outcome	Poor outcome

Modified from Eicher DJ, Wagner C. Update on neonatal resuscitation. J S C Med Assoc 2002; 98:115.

moderate; and stage III, poor.[99] Although detailed neurologic assessment is performed after the neonate is transferred to the NICU, assessment of tone, baseline heart rate, respirations, and reflex activity is part of both the Apgar scoring system and the assessment for hypoxic-ischemic encephalopathy and is made initially in the delivery room.

Gestational Age

When assessing a very small neonate whose gestational age appears to be lower than that of viability, the evaluator must consider whether it is appropriate to initiate and maintain resuscitation efforts. The neonatal gestational age is often assessed with the use of the scoring systems described initially by Dubowitz et al.[100] and subsequently modified by Ballard et al.[101] The **Dubowitz system** makes use of an external score based on physical characteristics, described previously by Farr et al.,[102,103] and a neurologic score. The **Ballard system** uses simplified scoring criteria to assess gestational age. Ballard et al.[101] eliminated certain physical criteria such as edema and skin color because of the unreliability of these criteria in some clinical conditions. In addition, they abbreviated the neurologic criteria on the basis of observations by Amiel-Tison.[104]

The Dubowitz and Ballard scores are most accurate when used to estimate gestational age at 30 to 42 hours, rather than during the first several minutes, after birth. These scoring systems are also less accurate in very small preterm infants. In one study of 100 preterm infants with birth weights less than 1500 g, agreement among antenatal measures of gestational age (e.g., last menstrual period, ultrasonography determination) and postnatal measures (e.g., Dubowitz and Ballard scores) was poor.[105] Both scoring systems overestimated gestational age in this subset of VLBW infants. Ballard et al.[106] refined their scoring system to provide a more accurate estimate of gestational age in preterm infants (Figure 9-3). The new Ballard score assesses **physical criteria,** such as eyelid fusion, breast tissue, lanugo hair, and genitalia, and **neurologic criteria,** such as wrist "square window." (The square window assessment is performed by flexing the infant's wrist on the forearm and noting the angle between the hypothenar eminence and the ventral aspect of the forearm.) Although the new Ballard score may be more accurate than the older score for the assessment of preterm infants, inconsistencies occur with all of these methods. Of particular interest is the observation that fetuses of different racial origin appear to mature at different rates (i.e., black fetuses mature faster than white fetuses).[107]

Another commonly used criterion for the estimation of gestational age is birth weight. Normal values for birth weight are published and readily available.[108] Although birth weight may help physicians estimate the gestational age of an otherwise healthy preterm infant, physicians cannot rely on birth weight to provide an accurate estimate of gestational age in an infant who suffered from intrauterine growth restriction or who is large for gestational age.

Because of the potential for inaccurate gestational age estimation in the delivery room, it is best not to use these scoring systems to guide decisions regarding the initiation or continuation of neonatal resuscitation immediately after delivery. In most circumstances, the neonate's response to resuscitative efforts is the best indicator as to whether further intervention is warranted.

NEONATAL RESUSCITATION

The equipment and medications needed for neonatal resuscitation are listed in Box 9-3. Equipment, supplies, and medications should be checked regularly to ensure that all components are available and functional.

Although previously published guidelines recommended suctioning of the mouth and nose after delivery of the head, the guidelines published in 2010 do *not* recommend routine intrapartum oropharyngeal and nasopharyngeal suctioning for infants born with either clear or meconium-stained amniotic fluid.[2]

Timing of cord clamping may vary by the gestational age and vigor of the infant. Current evidence suggests that a delay in cord clamping for 1 minute after the delivery of vigorous term infants improves iron stores throughout early infancy.[109] In vigorous preterm infants, a brief delay in cord clamping (30 seconds to 3 minutes) is associated with improved blood pressure and a lower incidence of intraventricular hemorrhage[110]; no alterations in Apgar scores or need for delivery room resuscitation have been observed with this practice.[111] In nonvigorous infants, regardless of gestational age, the benefits of delayed cord clamping may be outweighed by the need to promptly initiate resuscitation.

After delivery is complete, the neonate is transferred to the resuscitation area. The availability of sterile blankets allows the individual performing the delivery to

Neuromuscular maturity

FIGURE 9-3 ■ Modified Ballard scoring system for clinical assessment of maturation in neonates. This scoring system was expanded to include extremely preterm infants, and it was refined to improve the accuracy of assessment of more mature infants. (Modified from Ballard JL, Khoury JC, Wedig K, et al. New Ballard score, expanded to include extremely premature infants. J Pediatr 1991; 119:418.)

remain sterile while transferring the infant; this issue is especially important during cesarean deliveries. The timing of delivery should be noted, assessment and appropriate resuscitative measures should be continued, and Apgar scores should be assigned at the appropriate intervals (Figure 9-4).

The physician or nurse should place the infant beneath an overhead radiant warmer and promptly dry the skin of infants delivered at greater than 28 weeks' gestation. The infant who is delivered preterm at less than 28 weeks' gestation should be placed in a polythene bag or wrapping to prevent heat loss.[29,30] Hypothermia can result in increased oxygen consumption and metabolic acidosis[112] and leads to a significantly higher mortality rate among preterm infants.[113]

Selective cerebral hypothermia[114] or whole-body hypothermia[31,32] may protect against brain injury in the asphyxiated infant. The use of intentional hypothermia

BOX 9-3 Equipment and Drugs Needed for Neonatal Resuscitation

Suction Equipment

- Bulb syringe
- Mechanical suction and tubing
- Suction catheters: 5F or 6F, 8F, and 10F or 12F
- 8F feeding tube and 20-mL syringe
- Meconium aspiration device

Bag-and-Mask Equipment

- Neonatal resuscitation bag with a pressure-release valve or pressure manometer and valve to deliver positive end-expiratory pressure (the bag must be capable of delivering 90% to 100% oxygen) or a pressure limiting T-piece resuscitator
- Face masks, term and preterm newborn sizes (masks with cushioned rim preferred)
- Air source with tubing
- Oxygen with flowmeter (flow rate up to 10 L/min) and tubing (including portable oxygen cylinders)
- Blender to mix air and oxygen to adjust oxygen delivery

Intubation Equipment

- Laryngoscope with straight blades: No. 0 (preterm) and No. 1 (term)
- Extra bulbs and batteries for laryngoscope
- Tracheal tubes: 2.5, 3.0, 3.5, and 4.0 mm ID
- Stylet (optional)
- Scissors
- Tape or securing device for tracheal tube
- Alcohol sponges
- CO_2 detector (optional)
- Laryngeal mask airway (optional)

Medications

- Epinephrine 1:10,000 (0.1 mg/mL), 3- or 10-mL ampules
- Isotonic crystalloid (normal saline or lactated Ringer's solution) for volume expansion, 100 or 250 mL
- Sodium bicarbonate 4.2% (5 mEq/10 mL), 10-mL ampules
- Normal saline, 30 mL
- Dextrose 10%, 250 mL
- Normal saline "fish" or "bullet" (optional)
- Feeding tube: 5F (optional)
- Umbilical vessel catheterization supplies:
  - Sterile gloves
  - Scalpel or scissors
  - Povidone-iodine solution
  - Umbilical tape
  - Umbilical catheters: 3.5F, 5F
  - Three-way stopcock
- Syringes: 1, 3, 5, 10, 20, and 50 mL
- Needles: 25, 21, and 18 gauge, or puncture device for needleless system

Miscellaneous

- Gloves and appropriate personal protection
- Radiant warmer or other heat source
- Firm, padded resuscitation surface
- Clock (timer optional)
- Warmed linens
- Stethoscope
- Tape: ½ or ¾ inch
- Cardiac monitor and electrodes and/or pulse oximeter with probe (optional for delivery room)
- Oropharyngeal airways
- Polythene wrap or bags (for infants < 28 weeks' gestation)

ID, internal diameter.

Modified from Textbook of Neonatal Resuscitation. 6th edition. Elk Grove Village, IL, American Academy of Pediatrics and American Heart Association, 2011:216.

therapy requires an NICU with defined protocols and multidisciplinary support. When assessing an infant for hypothermia therapy, the radiant warmer can be turned off to allow passive cooling. With further assessment, if the criteria for hypothermia therapy are not met, the infant can be warmed. Hyperthermia should be avoided in all infants.[2]

The neonate should be positioned in a way that allows the airway to remain open, with the head in the "sniffing" position (the neck flexed on the chest and the head extended on the neck, thereby aligning the oropharynx, pharynx, and hypopharynx). Suctioning of the mouth and nose with a bulb syringe may be necessary if secretions accumulate.

The neonate with a normal respiratory pattern, heart rate, and color requires no further intervention. Often the neonate has a normal respiratory pattern and heart rate but may not be pink. Acrocyanosis often persists for several minutes after delivery and does not require intervention. However, an evaluation for choanal atresia can be performed at this time with the gentle insertion of a small suction catheter through each nostril into the nasopharynx. Vigorous nasal suctioning should be avoided because it can cause trauma to the nasal mucosa and result in progressive edema and airway obstruction. The neonate is an obligate nasal breather; thus, choanal atresia is a potentially lethal anomaly that requires immediate attention. If this anomaly is present (as evidenced by failure of nasal passage of the catheter), the neonate should have an oral airway or endotracheal tube inserted and an evaluation performed for repair of the obstruction. The classic clinical presentation for choanal atresia is an infant with cyanosis and respiratory distress at rest who becomes pink when crying.

Tactile stimulation should be used if the neonate does not breathe immediately; this consists of gently rubbing the back and flicking the soles of the feet. Tactile stimulation does not trigger respiratory efforts during secondary apnea in the neonate. Therefore, if the neonate does not begin to breathe spontaneously after tactile stimulation, the evaluator should begin positive-pressure mask ventilation. If the neonate has an abnormally slow heart rate (i.e., less than 100 bpm), positive-pressure ventilation should be performed until the heart rate rises to the

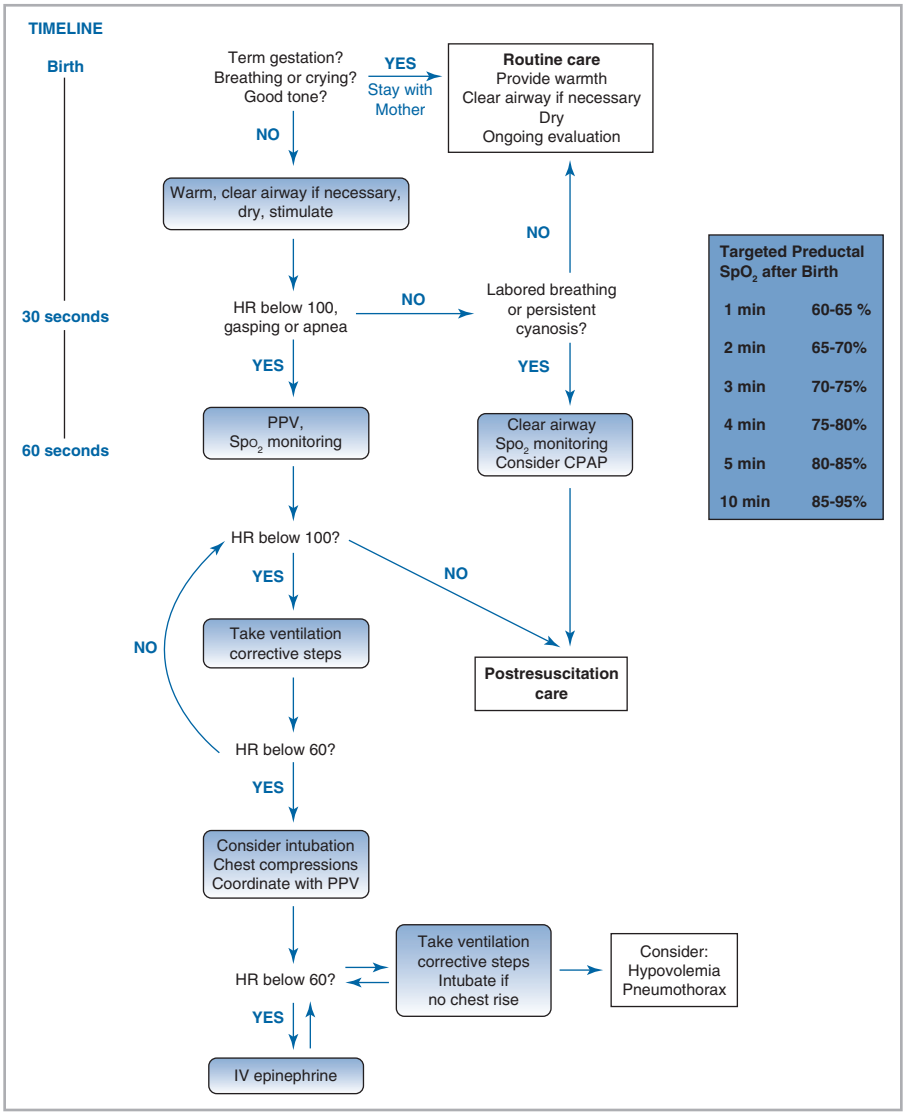

FIGURE 9-4 ■ Algorithm for resuscitation of the newly born infant. *HR,* heart rate; *PPV,* positive-pressure ventilation; *Spo_2,* oxygen saturation. (Modified from Textbook of Neonatal Resuscitation. 6th edition. Elk Grove Village, IL, American Academy of Pediatrics and American Heart Association, 2011:216. Figure by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

normal range. Overzealous tactile stimulation (e.g., slapping the back) is not useful; it provides no advantage over the more moderate methods and can cause traumatic injury. Infants with labored or persistent cyanosis may benefit from continuous positive airway pressure.

High concentrations of oxygen (as opposed to ambient air) can raise production of oxygen free radicals, which have been linked to hypoxia-reoxygenation injury.[115] Additionally, an association between neonatal oxygen supplementation and childhood cancer has been noted with supplemental oxygen exposure for 3 minutes or longer.[116] In two studies, term or near-term infants were randomly assigned to receive neonatal resuscitation with either room air or 100% oxygen; no major outcome differences were observed.[117,118] Subsequently a pooled meta-analysis of five trials, consisting of 1032 term or near-term infants, showed a significantly lower mortality rate with no evidence of harm when resuscitation was performed initially with room air rather than 100% oxygen.[119] The current guidelines for neonatal resuscitation for term infants recommend the use of room air for assisted ventilation. In preterm infants, assisted ventilation should be initiated with an inspired oxygen concentration (Fio_2) of 30% to 90% and should be guided by the response to resuscitation and the use of pulse oximetry to assess oxygenation. The Fio_2 should be lowered as soon as possible to minimize the risk for retinopathy of prematurity and pulmonary toxicity. Sao_2 measurements of 85% to 92% are thought to be adequate and appropriate for neonates of less than 34 weeks' gestation.[117,118,120,121] A meta-analysis detected no significant differences in neurodevelopmental outcomes at 12 to 24 months of age between infants resuscitated with either room air or 100% oxygen.[122]

Positive-pressure ventilation must be performed correctly to ensure that it is effective and does not cause

barotrauma. A ventilation bag with a volume of 250 to 500 mL may be used. The circuit must contain a safety pop-off pressure valve (e.g., at 35 cm H_2O), a visible pressure gauge, or both. An oxygen flow rate of 5 to 10 L/min is adequate. Alternatively, a T-piece, which is a valved mechanical device, may be used; it allows more consistent delivery of target inflation pressures and long inspiratory times. The mask must be of appropriate size and shape to ensure a good seal around the nose and mouth. A variety of masks should be available to accommodate infants of all sizes and gestational ages. For the infant with excessive occipital scalp edema (e.g., caput succedaneum), placing a small roll under the shoulders to alleviate hyperflexion of the neck may be helpful.

During the first assisted breath, positive pressure at 30 cm H_2O in term infants should be maintained for 4 to 5 seconds at the end of inspiration to overcome the surface tension of the lungs and open the alveoli.[123] The neonatal response to a large, rapid inflation of the lungs is a sharp inspiration of its own (Head's paradoxical reflex).[124] Subsequent breaths should be delivered at a rate of 40 to 60 breaths per minute, with intermittent inspiratory pauses to prevent the development of atelectasis. The maximum pressure generated should range between 20 and 30 cm H_2O, with an inspiration-to-expiration ratio of approximately 1 : 1. In preterm infants, whose lungs may be more easily injured, initial inflation pressures of 20 to 25 cm H_2O may be adequate. If mask ventilation is needed for longer than 2 to 3 minutes, the stomach should be emptied with an orogastric catheter. Distention of the stomach with air can compromise respiratory function in the neonate. This maneuver should be performed with care, because pharyngeal stimulation can result in arrhythmias and apnea.[125]

The adequacy of respiratory resuscitation can be monitored from observation of its effect on heart rate; an increase in heart rate is the first consistently reliable sign of effective oxygenation. By contrast, changes in color occur slowly, are difficult to assess, and are a relatively poor index of successful resuscitation.

When the neonate's heart rate is higher than 100 bpm, positive-pressure ventilation can be stopped, and the infant can be reevaluated for spontaneous respiratory effort. If the neonate does not begin to breathe and if an opioid effect is the suspected etiology, administration of **naloxone** is *not* recommended. Naloxone can worsen the neurologic damage caused by asphyxia[126,127] and can precipitate acute neonatal opioid withdrawal, including seizure activity in cases of maternal opioid abuse. Assisted ventilation should be continued until resolution of the opioid effect rather than attempting to reverse it with naloxone.

If positive-pressure mask ventilation does not improve oxygenation (as reflected by an increase in heart rate), prompt tracheal intubation is indicated. Tracheal intubation must be performed gently to avoid damage to the delicate neonatal neck and airway. The size of the neonate's head is large relative to that of its body; therefore, the neonate is in the optimal position when it lies supine. In most cases, it is not necessary to elevate or hyperextend the neonate's head during laryngoscopy. The neonatal larynx is more anterior than that of the adult, and visualization often is easier when cricoid pressure is applied. The practitioner should hold the laryngoscope and apply cricoid pressure with the same hand. The thumb and first two fingers hold the base of the laryngoscope, the third finger rests on the mandible, and the fourth finger applies cricoid pressure. This technique promotes gentleness during airway manipulation. The distance from the gums to the larynx often is surprisingly short. A common mistake is to advance the laryngoscope blade too deeply—past the larynx and into the esophagus. When this error occurs, the larynx falls into view if the laryngoscope blade is withdrawn slowly to allow a second attempt.

The diameter of the endotracheal tube should be large enough to allow adequate ventilation and insertion of a suction catheter (if needed) but small enough to avoid causing trauma and subsequent subglottic stenosis. The ratio of internal diameter to gestational age should be less than 0.1 (e.g., 3.0 mm tube/35 weeks' gestation = 0.09).[128,129]

After tracheal intubation, positive-pressure ventilation should be resumed by means of an appropriate circuit, as described earlier for mask ventilation. Assessment of proper tube placement is accomplished by listening for breath sounds in both axillae. Exhaled CO_2 detection is the recommended method for confirming placement of the tube in the trachea.[2] False-negative results can occur in situations in which the infant is correctly intubated, with the tube in the trachea, but pulmonary blood flow is poor or absent. This may lead to unnecessary extubation in critically ill infants. As noted previously, the F_{IO_2} should be reduced as soon as possible, especially in the preterm neonate. The addition of a pulse oximeter and an oxygen blender allows more targeted delivery of supplemental oxygen to the preterm infant immediately after birth. If the neonate is to remain intubated, a chest radiograph should be obtained to confirm the exact position of the endotracheal tube. The skill and experience required for correct tracheal intubation and effective bag-and-mask ventilation may be lacking in providers who are inexperienced with neonatal resuscitation; as a consequence, the laryngeal mask airway (LMA) has been evaluated as a potential alternative airway device for neonatal resuscitation.[130-132] The LMA is blindly inserted into the pharynx, and a cuff is inflated to provide a low-pressure seal around the larynx. When evaluated in term infants requiring resuscitation at delivery, use of the LMA was found to be highly successful and without complications.[130,131] The revised neonatal resuscitation guidelines state that the LMA is an acceptable alternative means of establishing an airway in infants born at 34 weeks' gestation and greater and weighing over 2000 g; it can be used by appropriately trained providers when bag-and-mask ventilation is ineffective or attempts at tracheal intubation have been unsuccessful.[2]

One cause of unequal breath sounds and eventual circulatory collapse is a tension pneumothorax. Some physicians have recommended that providers of neonatal resuscitation be skilled in needle aspiration of a tension pneumothorax.[1] This maneuver is accomplished by placement of a 22- or 25-gauge needle in the second intercostal space in the midclavicular line (on the side where no

breath or heart sounds are heard). Air will rush out of the needle hub, thereby reducing the tension pneumothorax.

In the vast majority of resuscitations, the neonate responds to ventilatory support. Chest compressions are needed in only 0.03% of deliveries.[133] Chest compressions are indicated when the heart rate is less than 60 bpm despite adequate ventilation with supplemental oxygen for 30 seconds.[2]

The preferred method for providing chest compressions is with the thumbs of both hands and the hands encircling the chest.[2,134] Pressure is applied over the sternum just below an imaginary line drawn between the nipples; pressure applied over the lower part of the sternum or xiphoid can injure the abdomen. The sternum should be compressed to approximately one third the anteroposterior dimension of the chest, and the compression depth must be adequate to produce a palpable pulse.[2,135-137] The compression time should be slightly shorter than the release time, particularly to improve blood flow in the very young infant.[138] Ventilation is compromised if the chest is compressed simultaneously with the administration of positive-pressure ventilation. The recommended ratio of compressions to breaths is 3:1.[139,140] This pattern is given at a rate of 120 events per minute, with 90 chest compressions and 30 breaths administered each minute. Respirations, heart rate, and color should be rechecked every 30 seconds. Compressions should be resumed until the heart rate is 60 bpm or higher. Positive-pressure ventilation with supplemental oxygen titrated to Sao_2 should be continued until the heart rate is higher than 100 bpm.

Medications are rarely required during neonatal resuscitation because most neonates who require resuscitative measures respond well to satisfactory oxygenation and ventilation alone.[141] However, a variety of pharmacologic agents should be available in the delivery room (see Box 9-3). **Epinephrine** (0.01 to 0.03 mg/kg or 0.1 to 0.3 mL/kg of a 1:10,000 solution) should be administered if the heart rate remains lower than 60 bpm after 30 seconds of adequate ventilation and chest compressions.[2] Intravenous administration is the preferred route (via an umbilical venous line). While intravenous access is being established, intratracheal administration through an endotracheal tube may be considered; however, a larger dose of epinephrine (0.05 to 0.1 mg/kg) may be required. Administration of epinephrine is especially important if the heart rate is zero. Epinephrine raises the heart rate (the major determinant of neonatal cardiac output) and restores coronary and cerebral blood flow.[142]

Sodium bicarbonate is used infrequently during resuscitation. Because of its high osmolarity, this agent can cause hepatic injury at any gestational age and cerebral hemorrhage in the preterm infant[143,144]; it may also compromise myocardial and cerebral function.[145,146] It should be given only during prolonged resuscitation and when adequate ventilation and circulation have been established. Arterial blood gas measurements and serum chemistry determinations should guide the use of sodium bicarbonate. The current recommended dose is 1 to 2 mEq/kg of a 0.5 mEq/mL solution given over at least 2 minutes by slow intravenous push.

Atropine is not recommended for use during neonatal resuscitation. Epinephrine is considered the drug of choice for the treatment of bradycardia.

Calcium administration is not recommended for neonatal resuscitation, unless it is given specifically to reverse the effect of magnesium (which may have crossed the placenta from the mother to the fetus). Evidence suggests that calcium administration causes cerebral calcification and decreases survival in stressed neonates.[147]

Volume expanders must be given strictly according to recommended dosage. A continuous infusion is dangerous in the neonate, because it can easily result in the administration of an excessive fluid volume. Fluid overload can cause hepatic capsular rupture, brain swelling in the asphyxiated infant, or intracranial hemorrhage in the preterm infant. Fluids and medications can be administered either intravenously (most commonly through the umbilical vein) or, if necessary, intraosseously.

The cannulation of the umbilical vein involves insertion of a soft catheter into the cut end of the vein (Figure 9-5). The catheter is advanced until blood return is noted, but no more than 2 cm past the abdominal surface. If ongoing vascular access is required during the neonate's hospital course, the soft umbilical catheter can be advanced through the ductus venosus into the inferior vena cava. Care must be taken to avoid leaving the tip in an intermediate location because of possible hepatic damage if a high-osmolarity substance (e.g., improperly diluted sodium bicarbonate) were injected. Other complications of umbilical venous catheterization are hemorrhage and sepsis. The prolonged absence of vascular access in critically ill neonates can lead to hypoglycemia, which in association with hypoxia, can increase the risk for adverse neonatal outcomes.[148]

Intraosseous access is accomplished by insertion of a 20-gauge needle into the proximal tibia approximately 1 cm below the tibial tuberosity.[149] This technique may be easier to perform for practitioners who have little experience with intravenous or umbilical neonatal catheterization. Absorption from the neonatal bone marrow into the general circulation occurs almost immediately.[150,151] This rapid absorption results from the preponderance of red bone marrow over yellow bone marrow; yellow bone marrow is less vascular and is the dominant form of marrow after 5 years of age. Complications related to this technique are rare and include tibial fracture (which occurs more often in older children)[152] and osteomyelitis. The risk for infection is proportional to the duration of intraosseous infusion[153-155]; therefore, the needle should be removed after 1 to 2 hours and, if necessary, a more conventional route of access should be established. Current guidelines state that intraosseous access should be used for medication administration or volume expansion when venous access is difficult to achieve.[2]

Volume expanders should be considered when the infant demonstrates signs of shock, such as pale skin, poor perfusion, and weak pulse, or has not shown adequate response to other resuscitative measures. **Normal saline** and **lactated Ringer's solution** are the preferred volume expanders, given initially at 10 mL/kg over 5 to 10 minutes, with doses repeated as necessary after reassessment for ongoing hypovolemia. Intravascular volume

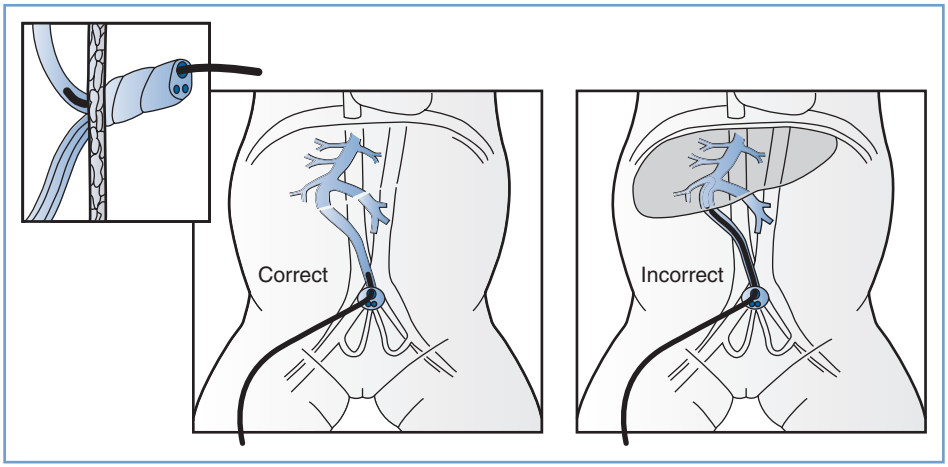

FIGURE 9-5 ■ Cannulation of the umbilical vein. A 3.5F or 5F umbilical catheter with a single end-hole and a radiopaque marker should be used. For emergency use, the catheter should be inserted into the vein of the umbilical stump until the tip of the catheter is just below the skin level but free flow of blood is present. If the catheter is inserted farther, there is a risk for infusing solutions into the liver and possibly causing damage. (Adapted from Textbook of Neonatal Resuscitation. 6th edition. Elk Grove Village, IL, American Academy of Pediatrics and American Heart Association, 2011:216.)

should be assessed through evaluation of heart rate, capillary refill time, and color. If heavy blood loss is suspected, O-negative packed red blood cells may be used according to the same dosage regimen.[2] Red blood cells replete the oxygen-carrying capacity as well as the intravascular volume. O-negative blood should be available at all times for emergency use during neonatal resuscitation. Placental blood has been used for neonatal volume expansion,[156] but this practice is discouraged in most institutions because of the risks of infection or transfusion of clotted blood. Albumin administration is no longer recommended, because it carries a risk for infectious disease and has been associated with higher mortality.[157]

SPECIAL RESUSCITATION CIRCUMSTANCES

Meconium Aspiration

There has been significant interest in the management of the neonate whose airway has been exposed to meconium-containing amniotic fluid. Meconium is present in the intestinal tract of the fetus after approximately 31 weeks' gestation. Meconium-stained amniotic fluid is present in 10% to 15% of all pregnancies; the incidence is higher in post-term pregnancies. Intrapartum passage of meconium may be associated with fetal stress and hypoxia.[158,159]

Meconium aspiration syndrome (MAS) is defined as respiratory distress in a neonate whose airway was exposed to meconium and whose chest radiographic study exhibits characteristic findings, including pulmonary consolidation and atelectasis.[160] Treatment of MAS often involves the use of positive-pressure ventilation and is associated with a 5% to 20% incidence of pneumothorax from pulmonary air leaks.[161] In one study of 176,790 infants born between 1973 and 1987, the annual death rate from MAS was as high as 6 per 10,000 live infants.[162] Extracorporeal membrane oxygenation (ECMO) and inhaled nitric oxide have been used for the treatment of pulmonary hypertension associated with MAS and have been observed to reduce mortality rates.[163-165]

Neonatologists have attempted to determine whether peripartum suctioning of the neonate's airway reduces the risk for developing MAS. Gregory et al.[162] published the original study of 80 meconium-exposed neonates who were born either vaginally or by cesarean delivery. All infants underwent tracheal intubation and suctioning after delivery. In 34 infants, no meconium was observed below the vocal cords; none of these infants demonstrated MAS. Meconium was noted below the cords in the remaining 46 infants, and MAS developed in a total of 16 (35%) of these infants. These investigators concluded that "all infants born through thick, particulate, or 'pea soup' meconium should have the trachea aspirated immediately after birth."[162] Subsequent studies documented similar findings for all infants born through meconium-stained fluid,[166] with a suggestion that earlier suctioning could decrease the incidence of MAS.[167] However, additional investigators documented that airway suctioning at birth does not prevent MAS and its associated mortality[168,169]; these studies indicated that MAS was primarily a result of intrauterine events such as asphyxia or sepsis. Hypoxia induces pathologic changes in the pulmonary vasculature, which results in pulmonary hypertension and respiratory distress after birth. The pulmonary damage is independent of meconium aspiration; therefore, it is not prevented by the suctioning of meconium.

Murphy et al.[170] examined the lungs of 11 neonates who had MAS and died within 4 days of birth. Ten of these neonates also had a diagnosis of persistent pulmonary hypertension, and all had evidence of excessive muscularization of the intra-acinar arteries, which is an abnormal finding in the fetus or neonate.[171,172] Meyrick and Reid[173] demonstrated that chronic hypoxia (i.e., at least 4 weeks' duration), but not acute hypoxia, results in pulmonary vascular muscularization in an animal model.

Murphy et al.[170] concluded that the pathologic findings in the 1- to 4-day-old human lung could not be explained by the postdelivery effects of meconium aspiration; a more likely origin was the intrauterine maldevelopment of the pulmonary vasculature. They suggested a potential link between greater intestinal motility, passage of meconium, and precocious muscularization of the intra-acinar arteries.

A prospective study designed to assess the efficacy of routine tracheal suctioning of meconium to prevent MAS indicated little or no benefit to this practice.[174] Among the infants who underwent tracheal suctioning, four experienced MAS and two had laryngeal stridor. By contrast, none of the infants who did not undergo suctioning had complications, suggesting that vigorous neonates who have begun breathing before transfer to the resuscitation table may derive little or no benefit from tracheal suctioning and, in fact, may suffer some harm.

A subsequent review of studies published between 1980 and 1999 found that most cases of severe MAS were not causally related to meconium aspiration but rather resulted from intrauterine stress.[175] The authors concluded that severe MAS is a misnomer because, in most cases, much more than meconium aspiration has contributed to the lung damage. The implication is that when severe MAS occurs, inadequate suctioning at delivery or during resuscitation should not be considered the cause; therefore, other causes of intrauterine lung damage should be investigated.

Amnioinfusion—the instillation of saline into the amniotic cavity—has been used successfully for reduction of cord compression in the presence of oligohydramnios during labor. It has also been proposed as a potential treatment to reduce the incidence of MAS in infants born to women with thick meconium staining of the amniotic fluid. Potential benefits include (1) the reduction of cord compression, thus alleviating fetal compromise and acidemia that contribute to MAS, and (2) the dilution or washing out of the meconium in the amniotic fluid. A large multicenter randomized trial found no difference in rates of MAS or other neonatal disorders with the use of amnioinfusion.[176,177] Thus, the routine practice of amnioinfusion for meconium-stained fluid alone is not recommended.[178]

Current guidelines do not recommend routine intrapartum oropharyngeal and nasopharyngeal suctioning before delivery of the infant's head,[2,179] given that a large multicenter randomized trial showed no benefit to this practice in term-gestation infants.[180] After stabilization of the infant, meconium may be gently cleared from the mouth and nose by means of a bulb syringe or a large suction catheter (e.g., 12F to 14F).

Preterm Infant

The preterm neonate, especially the VLBW infant, is at higher risk for problems with multiple organ systems simply because of immaturity. During resuscitation, the physician should give special attention to the effect of prematurity on the lungs and the brain. Before the addition of surfactant and high-frequency ventilation to the therapeutic armamentarium of the neonatologist, pulmonary hyaline membrane disease (also known as neonatal respiratory distress syndrome) was the overwhelming obstacle to the attempted salvage of the very preterm infant.

Between 1970 and 2005, the proportion of infants weighing less than 1500 g at delivery rose from 1.17% to 1.5%; in 2009, the proportion stabilized at 1.45%.[181] The survival rate of these 500- to 1500-g infants has increased to approximately 85%.[181] Of these, 5% to 10% have what is characterized as cerebral palsy and 25% to 50% exhibit behavioral and cognitive deficits that lead to important school problems (see Chapter 10).[182,183] These VLBW infants constitute a tiny proportion of the birth population, but they are at the highest risk for development of cerebral palsy; infants weighing less than 1500 g at birth account for 25% of cases of this disorder.[58]

Markers for brain injury affecting preterm infants are germinal matrix intraventricular hemorrhage (IVH) and periventricular leukomalacia. The brain injury may occur either as a consequence of the IVH and its sequelae or as an associated finding. The incidence of germinal matrix IVH in preterm infants declined from 35% to 50% in the late 1970s and early 1980s to approximately 15% in the mid 1990s.[184] Despite the decreased incidence of germinal matrix IVH, which is directly related to prematurity,[183] the overall burden of disability has sharply increased in recent years due to the proportion of very preterm infants who are surviving.[184] Periventricular leukomalacia, which is the classic neuropathology associated with hypoxic-ischemic cerebral white matter injury in the preterm infant, commonly accompanies IVH.[185]

The fragility of the immature subependymal germinal matrix predisposes the preterm infant to the development of IVH. The hemorrhage originates from the endothelial cell–lined vessels that course through the germinal matrix in free communication with the venous circulation (i.e., the capillary–venule junction). The mechanism of damage to these endothelial cells and to the integrity of these capillaries has been investigated in animal models[186] and in human neonates by means of Doppler velocimetry.[187]

Volpe,[188,189] who has reviewed the theories of the pathogenesis of germinal matrix IVH, has concluded that the pathogenesis is multifactorial; different combinations of factors are relevant in different patients. The three major categories in the pathogenesis of IVH are intravascular, vascular, and extravascular. **Intravascular factors** include fluctuating cerebral blood flow (CBF), which can result from respiratory disturbances in the ventilated preterm infant with neonatal respiratory distress syndrome[187,190]; increases in CBF[186,191]; increases in cerebral venous pressure[192]; decreases in CBF followed by reperfusion; and platelet and coagulation disturbances.[193] **Vascular factors** include the tenuousness of the capillary integrity of the germinal matrix and the vulnerability of the matrix capillaries to hypoxic-ischemic injury.[194] **Extravascular factors** include deficient vascular support, excessive fibrinolytic activity, and a possible postnatal decrease in extravascular tissue pressure.[195]

Of special interest in the discussion of antepartum and intrapartum care and neonatal resuscitation are the possible interventions that may prevent or lessen the severity

of IVH. The best way to prevent germinal matrix IVH is to prevent preterm birth. Infection and inflammation are the most common identified causes of preterm birth at the lowest relevant gestational age.[196] Antenatal *treatment* of infections has not been proved to prevent preterm labor or premature rupture of membranes[58]; however, *prevention* of infection, if possible, may be an important way to reduce the risk for IVH. Another intervention that lowers the incidence of IVH is the transportation of the preterm mother while the fetus is still *in utero* to a center that specializes in the care of high-risk neonates.[1]

Various antenatal pharmacologic interventions have been evaluated for the prevention of IVH. Clinical trials of antenatal maternal administration of phenobarbital[197,198] and vitamin K[199,200] have yielded conflicting results, and their routine use is not currently recommended.[58]

Corticosteroids are currently the most beneficial antenatal pharmacologic intervention for the prevention of IVH. This effect was first noticed when obstetricians began giving betamethasone and dexamethasone to pregnant women to help accelerate fetal lung maturity. The mechanism behind this protection is thought to be improved neonatal cardiovascular stability, which results in less hypotension and less need for blood pressure treatment in these infants.[201] Antenatal betamethasone administration leads to lower placental vascular resistance and higher placental blood flow.[202] This improvement in placental blood flow may decrease impairment of the preterm infant's cerebral autoregulation. In addition, corticosteroids may stimulate the maturation of the germinal matrix. There is consensus regarding the efficacy of a single course of corticosteroids in patients at risk for preterm delivery, but the risks and benefits of multiple courses of corticosteroids for women who remain undelivered 7 days after the initial dose are still controversial. Obstetricians must balance the possible benefits of these agents against their potentially deleterious effects on neuronal and organ growth (see Chapter 34).

Multiple studies have demonstrated a lower incidence of cerebral palsy in infants of mothers given magnesium sulfate for the treatment of preeclampsia or for tocolysis[203,204]; subsequent studies have observed a similar benefit when magnesium has been given specifically for fetal neuroprotection.[205-207] An ACOG committee opinion[208] now recommends the administration of magnesium sulfate to mothers in preterm labor. Maternal magnesium sulfate administration does not result in a decreased incidence of IVH, although the incidence of high-grade (grade III or IV) lesions may be reduced.[209] Although some investigators have suggested that antenatal exposure to magnesium sulfate results in a higher risk for adverse neonatal outcomes,[210] others have observed no association between umbilical cord blood magnesium concentration and the need for delivery room resuscitation when magnesium was administered for neuroprotection in anticipation of a preterm birth.[211]

Postnatal interventions that may prevent IVH include the avoidance of overly rapid infusion of volume expanders or hypertonic solutions such as sodium bicarbonate.[143,212] The establishment of adequate ventilation is the most beneficial immediate intervention that helps preserve cerebrovascular autoregulation in the preterm infant. The prevention of hypoxemia and hypercarbia is essential, because they are both linked to pressure-passive cerebral circulation, which in turn leads to the development of IVH.[212]

Among infants who exhibit fluctuating CBF velocity, Pearlman et al.[213] found that treatment with pancuronium bromide, which corrects this fluctuation, reduced both the incidence and severity of IVH.[213] Other clinical trials have evaluated the efficacy of other pharmacologic agents for the correction of fluctuating hemodynamic disturbances. Studies of meperidine[214] and fentanyl[215] have shown some benefit, but the side effects and need for prolonged ventilation associated with these agents must be weighed against any potential benefits.

If the use of antepartum and intrapartum pharmacologic prophylaxis against IVH becomes part of preterm delivery management, the practice of obstetric anesthesia for preterm patients will be directly affected. For example, the conventional wisdom is that preterm infants are more sensitive than term infants to the effects of maternally administered agents such as analgesics[216] and that this effect is inherently deleterious. However, if this effect is found to protect the preterm infant brain from factors that may lead to IVH (e.g., hemodynamic instability), perhaps obstetric anesthesia providers will no longer attempt to avoid the placental transfer of pharmacologic agents but will deliberately administer these agents to the mother with the intent that they reach the fetus.

Congenital Anomalies

Occasionally, neonatal resuscitation is complicated by congenital anomalies of the airway or diaphragm. These anomalies may manifest as respiratory distress, which resolves only when appropriate resuscitation techniques are used. For example, neonates are obligatory nose breathers. The diagnosis and management of choanal stenosis and atresia include placement of an oral airway or endotracheal tube until a definitive surgical procedure can be performed.

Other congenital anomalies that cause upper airway obstruction include (1) micrognathia, as in Pierre Robin sequence; (2) macroglossia, as in Beckwith-Wiedemann syndrome or glycogen storage disease type II; (3) laryngeal webs; (4) laryngeal atresia; (5) stenosis or paralysis at the level of the vocal cords; (6) subglottic stenosis; (7) subglottic webs; (8) tracheal agenesis; and (9) tracheal rings. Obstruction also can occur as a result of tumors such as subglottic hemangiomas. The presence of a cleft palate may lead to difficulty with manual ventilation. In an infant with micrognathia or macroglossia, airway patency may be maintained if the neonate is kept in the prone position, which reduces posterior movement of the tongue into the pharynx. If macroglossia is extreme, use of an oral airway or a small nasogastric or orogastric suction catheter may be necessary to prevent complete obstruction of the pharynx by the tongue.

When respiratory distress and difficulty with bag-and-mask ventilation are encountered, laryngoscopy should be performed. The cause of the obstruction may be evident if it is supraglottic in location. Some supraglottic entities

(e.g., laryngeal webs) may be treated successfully by passing an endotracheal tube through the obstruction and into the trachea. Subglottic lesions may require tracheostomy. The help of an otolaryngologist may be invaluable during resuscitation of a neonate with congenital airway obstruction. If there is antepartum evidence of such a condition (e.g., laryngeal stenosis), it is best to have an otolaryngologist present at the time of delivery.[217] If obstruction is discovered after delivery, the resuscitator should not hesitate to call for surgical assistance.

Fetal neck masses such as cervical teratoma and lymphangioma can lead to extrinsic airway compression. The resulting distortion of the airway can result in airway obstruction, and it may be difficult—if not impossible—to secure an airway in a timely fashion at delivery. These masses often are diagnosed before delivery because of the associated occurrence of polyhydramnios resulting from esophageal compression. In these rare cases, a multidisciplinary team should be assembled before delivery to assist in securing the airway. Leichty et al.[218] described a way of providing the time necessary to secure an airway, known as the **ex utero intrapartum treatment (EXIT) procedure** (see Chapter 7). An EXIT procedure delivers the fetal head and shoulders, but keeps the lower torso and umbilical cord intact within the uterus, thereby maintaining placental perfusion and oxygenation. The fetus can be given additional agents intramuscularly (fentanyl, vecuronium, and atropine) to provide fetal analgesia and to prevent movement and breathing. The FHR and Sao_2 are monitored continuously via a pulse oximeter probe attached to the fetal hand. The pediatric surgeon can then perform direct laryngoscopy, rigid bronchoscopy, or tracheostomy if necessary. After establishment of the airway, the delivery of the infant is completed.

The EXIT procedure has been considered an option for fetuses with a number of congenital anomalies.[219,220] A common indication for the EXIT procedure is an intrinsic airway obstruction. Intrinsic airway obstruction of the larynx or upper trachea (e.g., laryngeal web, subglottic cyst, tracheal atresia) can lead to retention of bronchial secretions and subsequent pulmonary distention; this constellation of findings is often classified as **congenital high airway obstruction syndrome (CHAOS).**[219] Use of the EXIT procedure resulted in the first long-term survival of a child with this syndrome.[221]

The EXIT procedure also may be useful in conditions such as severe congenital heart disease, in which the need for emergency ECMO at birth is anticipated. The EXIT procedure allows for the placement of arterial and venous cannulas before umbilical cord clamping, thereby avoiding an unstable period between the termination of placental perfusion and the institution of ECMO. [219] Other possible indications for the EXIT procedure include the resection of congenital cystic adenomatoid malformations and as a first step in separation procedures for conjoined twins with cardiovascular involvement.

Noah et al.[222] compared the short-term maternal outcomes of 34 patients who underwent the EXIT procedure between 1994 and 1999 with those in a control group who underwent nonemergency primary cesarean delivery. The EXIT procedure group had a higher estimated blood loss, but there was no difference in the postoperative hematocrit or duration of hospital stay. The EXIT procedure group also had a higher rate of superficial wound infection (15% versus 2%), but the incidence of endometritis was not different. A review of fetal and maternal outcomes after performance of an EXIT procedure in 12 infants with a giant neck mass found that 11 infants survived and 10 had normal development. All of the six mothers who desired future pregnancies subsequently had uncomplicated deliveries.[223]

Anesthetic considerations for the mother during an EXIT procedure include those relevant to general anesthesia for the mother undergoing cesarean delivery or other surgical procedures during pregnancy (see Chapters 7, 17, and 26). Several volatile halogenated agents have been used for the EXIT procedure, including isoflurane, desflurane, and sevoflurane.[219] The anesthetic management for an EXIT procedure differs from that for a routine cesarean delivery in the following ways: (1) general anesthesia is used much more often than neuraxial anesthesia, (2) a greater depth of anesthesia is achieved and maintained, (3) maximum uterine relaxation is desirable, (4) warm fluid is occasionally instilled into the uterus, and (5) a second anesthesiologist provides care for the fetus.[220]

George et al.[224] described an alternative approach for the EXIT procedure with the use of combined spinal-epidural anesthesia (1.5 mL of bupivacaine 0.75%, fentanyl 15 μg, and morphine 0.15 mg, administered intrathecally, followed by placement of a multiorifice epidural catheter). Supplemental oxygen was provided through a face mask at 6 L/min. Immediately before uterine incision, the patients were given intravenous nitroglycerin 50 to 100 μg, followed by an infusion of nitroglycerin (0.5 to 1.5 μg/kg/min), allowing adequate uterine relaxation for partial delivery of the infant's head. Maternal hypotension occurred in two of the three women and required vasopressor administration. After the infant's airway was secured and the infant's delivery was completed, the nitroglycerin was discontinued at the time of umbilical cord clamping.

Esophageal atresia and **tracheoesophageal fistula** occur in 1 of every 3000 births.[225] There are many variations of these anomalies, the most common being esophageal atresia with a distal tracheoesophageal fistula (80% to 90% of cases). Neonates with a tracheoesophageal fistula are at increased risk for the pulmonary aspiration of gastric contents through the fistula into the lung. When the presence of a tracheoesophageal fistula is not known antepartum, it should be suspected if bubbling secretions are observed during spontaneous or bag-and-mask ventilation. Once a tracheoesophageal fistula is suspected, bag-and-mask ventilation should be discontinued, because its use may contribute to overdistention of the gastrointestinal tract with air, possibly leading to difficulty in ventilation from impingement of the enlarged stomach on the diaphragm. A suction catheter should be placed in the esophageal pouch to facilitate the removal of oral secretions. If mechanical ventilation is necessary, an endotracheal tube should be inserted with the tip distal to the entrance of the fistula. This positioning can be accomplished by performing an intentional right mainstem bronchial intubation followed by slowly

TABLE 9-5 Guidelines for Withholding or Discontinuing Resuscitation

Conditions with high survival, acceptable risk for morbidity	≥ 25 weeks' gestational age Most congenital malformations	Resuscitation nearly always indicated
Conditions with poor prognosis, high risk for morbidity	23 to 25 weeks' gestational age	Parental desires about initiating/continuing resuscitation should be supported
Conditions with almost certain death or unacceptably high morbidity	< 23 weeks' gestational age Birth weight < 400 g Anencephaly Chromosomal abnormalities incompatible with life (e.g., trisomy 13)	Resuscitation not indicated

Modified from Neonatal Resuscitation: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Pediatrics 2010; 126:e1400-1413.

withdrawing the tube until breath sounds are auscultated on the left; a lack of breath sounds over the stomach should then be confirmed. Percutaneous gastrostomy placement may be necessary during resuscitation to facilitate decompression of the gastrointestinal tract.

Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in 3000 live births.[226] The mortality rate from CDH is 30% to 60%. In 80% to 90% of cases the CDH occurs on the left side and is the result of herniation of the gut through the posterolateral defect of Bochdalek. During formation of the lung, herniation of the gut into the thoracic cavity results in hypoplasia of the lung tissue and pulmonary vasculature. This hypoplasia may be unilateral, but often it is bilateral because of the shift in mediastinal structures to the other side. CDH should be suspected when a neonate has respiratory difficulty and a scaphoid abdomen; this abnormal abdominal shape results from the presence of abdominal contents in the thorax.

During resuscitation of the neonate with CDH, bag-and-mask ventilation is contraindicated because it allows further distention of the gut, which would further impinge on the lung. Tracheal intubation is recommended, followed by the placement of a nasogastric or orogastric tube to ensure decompression of the gastrointestinal tract. Ventilation should consist of low-positive-pressure breaths to decrease the risk for causing a pneumothorax on the side contralateral to the CDH. If a pneumothorax does occur, it must be evacuated promptly. In the neonate, evacuation is accomplished initially by placement of a 22-gauge needle into the second intercostal space in the midclavicular line and aspiration of air with an attached stopcock and syringe. Severe pulmonary hypertension often accompanies CDH. Maintenance of euthermia, normoxia, and adequate systemic blood pressure promotes pulmonary artery blood flow.

Whenever congenital anomalies of the respiratory tract are noted, the presence of other anomalies should be suspected. It is important to evaluate the neonate promptly for cardiac malformations, especially if appropriate resuscitative efforts are not successful. Echocardiography is used to evaluate cardiac structures and function.

ETHICAL CONSIDERATIONS

The current neonatal resuscitation guidelines address the ethical considerations of non-initiation or discontinuation of resuscitation in the delivery room.[2] Extremes of prematurity (< 23 weeks' confirmed gestation) and severe congenital anomalies (e.g., anencephaly, confirmed trisomy 13 or 18) are examples of circumstances when non-initiation of resuscitation is considered appropriate. Because intrapartum confirmation of pertinent information may not be possible, it is recognized that initiation of resuscitation may occur and that its discontinuation may then be appropriate after further information has been obtained and discussion with family has occurred. In some cases, a trial of therapy may be appropriate, which does not always mandate continued support. In situations or conditions in which there is a high rate of survival and acceptable morbidity (i.e., ≥ 25 weeks' gestation and most congenital malformations), resuscitation is generally indicated. For those situations with a poor prognosis, including unlikely survival and potentially high morbidity (i.e., 23 to 25 weeks' gestation), the parents' desires as to initiation of resuscitation should be supported (Table 9-5).[227]

Discontinuation of resuscitation of an infant with cardiopulmonary arrest may be appropriate if spontaneous circulation has not occurred in 15 minutes. After 10 minutes of asystole, survival itself and survival without severe disabilities are very unlikely.[227-232]

NEUROBEHAVIORAL TESTING

It is difficult to detect subtle neurobehavioral differences among neonates during the assignment of Apgar scores or the performance of the initial neurologic examination; therefore, investigators have developed and studied methods of documenting neonatal neurobehavioral status (Table 9-6). In the past, the neonate was considered incapable of exhibiting higher cortical function. However, investigators have noted that the term neonate is able to sense and respond to a variety of stimuli in a well-organized fashion.[233-235]

In 1973, Brazelton[236] described the Neonatal Behavioral Assessment Scale (NBAS) with the following four variables as key determinants of neonatal neurobehavior: (1) various prenatal influences (e.g., infection); (2) the maturity of the infant, especially its CNS; (3) the effects of analgesics and anesthetics administered to the mother before and during delivery; and (4) the effects of difficulties encountered during delivery (e.g., trauma). The NBAS was developed as a tool to detect neurobehavioral

TABLE 9-6 **Neurobehavioral Tests for Neonates**

Neurobehavioral Test	Items Tested	Focus	Uses
Brazelton (Neonatal Behavioral Assessment Scale)	45 individual tests taking 45 minutes	Early cortical function	Evaluates prenatal influences, effects of maturity, maternal medications, effects of difficult delivery
Scanlon (Early Neonatal Behavior Scale)	26 observations taking 6-10 minutes	Early cortical function	Evaluates effects of maternal medications
Amiel-Tison (Neurologic and Adaptive Capacity Score)	20 criteria taking 3-4 minutes	Motor tone	Differentiates drug-induced depression from depression related to asphyxia, trauma, or neurologic disease

abnormalities that resulted from any of these four variables.

This scale consists of 47 individual tests with 27 evaluating behavior and 20 evaluating elicited or provoked responses. The 47 tests can be completed in approximately 45 minutes. The NBAS evaluates the ability of the neonate to perform complex motor behaviors, to alter the state of arousal, and to suppress meaningless stimuli. The goal is to provide an extensive evaluation of neonatal cortical function and to detect subtle differences among groups of infants. Habituation (i.e., the ability to suppress the response to meaningless, repetitive stimuli) is considered an excellent indicator of normal early cortical function.[233]

In 1974, Scanlon et al.[237] described the Early Neonatal Behavioral Scale (ENNS), which consisted of tests that were easy to perform and score quantitatively during the neonatal period. The ENNS was developed primarily for the evaluation of the effects of maternal medications (e.g., analgesic and anesthetic agents) on neonatal neurobehavior. The ENNS consists of (1) 15 observations of muscle tone and power, reflexes (e.g., rooting, sucking, Moro), and response to stimuli (e.g., light, sound, pinprick); (2) 11 observations of the infant's state of wakefulness; (3) an assessment of the ability of the neonate to habituate to repetitive stimuli; and (4) an overall general assessment of neurobehavioral status. This test can be performed in 6 to 10 minutes.

In 1982, Amiel-Tison et al.[238] described the Neurologic and Adaptive Capacity Score (NACS) to differentiate neonatal depression secondary to maternally administered drugs from depression due to asphyxia, birth trauma, or neurologic disease. Whereas the ENNS concentrates on the infant's habituation ability, the NACS emphasizes motor tone as a key indicator of drug-induced abnormal neurobehavior. The basis for this emphasis on neonatal motor tone is explained as follows: unilateral or upper body hypotonus may occur as a result of either birth trauma or anoxia, but global motor depression is more likely a result of anesthetic- or analgesic-induced depression. A total of 20 criteria are tested in the areas of adaptive capacity, passive tone (e.g., scarf sign), active tone (e.g., assessment of the flexor and extensor muscles of the neck), primary reflexes (e.g., Moro), and alertness. The total possible score is 40, and a score of 35 to 40 is considered normal. The NACS can be performed in 3 to 4 minutes.

Amiel-Tison et al.[238] examined inter-observer reliability and assessed the correlation of results between the NACS and ENNS. The inter-observer reliability was 93% for the NACS and 88% for the ENNS. Approximately 92% of infants with high scores on the ENNS scored equally well on the NACS. However, the reliability of NACS has been questioned[239,240]; Halpern et al.[241] examined 200 healthy term infants with the NACS and found poor inter-observer reliability. In contrast, in 2002 Amiel-Tison[242] reported her later experience with the NACS and documented good inter-observer reliability.

Anesthesiologists have used neurobehavioral testing to document the effects of analgesic and anesthetic agents and techniques on neonatal neurobehavior (see Table 9-6); the American Academy of Pediatrics[243] and the U.S. Food and Drug Administration[244,245] have recommended that these investigations be performed. A number of studies have demonstrated transient, serum concentration–dependent depression of neonatal neurobehavior with the maternal administration of systemic agents (e.g., meperidine, diazepam).[246-248] However, in a NBAS examination that controlled for patient and labor and delivery characteristics, only decreased habituation was observed in neonates born to mothers who had received intravenous meperidine.[249] Similarly, maternal administration of intravenous fentanyl appears to minimally affect neonatal NACS examinations.[250]

As is the case with many studies of systemic agents, studies of epidural anesthesia are often confounded by variables that are difficult to control, such as different patient populations, varied durations of labor, and multiple drug administrations. Scanlon et al.[237] introduced the ENNS in a study of the effect of maternal epidural anesthesia on neonatal neurobehavior. The researchers concluded that epidural anesthesia was associated with lower ENNS scores because of decreased muscle strength and tone. In this study, all patients who had received epidural anesthesia were considered part of one group, although 9 patients had received lidocaine and 19 had received mepivacaine. Further investigation showed that epidural lidocaine, even when administered in larger doses for cesarean delivery, does not affect ENNS scores.[251] The difference in ENNS scores between the epidural and nonepidural groups noted in the earlier study[237] was most likely related to the use of mepivacaine rather than lidocaine.[252] As was observed with lidocaine, epidurally administered bupivacaine, 2-chloroprocaine,

and etidocaine—when given for cesarean delivery—do not affect ENNS scores.[251,253] Kuhnert et al.[254] assessed NBAS scores in a group of infants exposed to either epidural lidocaine or 2-chloroprocaine. Although the investigators observed subtle changes in neurobehavior in the group of infants whose mothers had received lidocaine, they concluded that other variables (e.g., mode of delivery) are more likely to affect performance on neurobehavioral testing.

Sepkoski et al.[255] compared NBAS scores between two groups of vaginally delivered infants. In one group, the mothers had received epidural bupivacaine, and in the other group, the mothers had received no anesthesia or analgesia. The infants in the epidural group showed less alertness, less orientation ability, and less motor function maturity than the infants in the control group. However, variables such as duration of labor, incidence of oxytocin administration, and incidence of instrumental delivery were not similar in the two groups. Earlier, Abboud et al.[256] performed ENNS examinations on vaginally delivered infants whose mothers had received epidural bupivacaine. In this study, epidural administration of bupivacaine did not affect the ENNS scores. The maternal doses of epidural bupivacaine and the maternal venous and umbilical cord blood bupivacaine concentrations were similar to those noted by Sepkoski et al.[255] Abboud et al.[256] also noted normal ENNS scores for infants whose mothers had received epidural lidocaine or 2-chloroprocaine.

Critics of the ENNS and NACS claim that the evaluations are unable to demonstrate subtle differences in neurobehavior that would be detected by the more comprehensive NBAS.[257] However, although some differences have been observed in NBAS performance among groups of infants exposed or not exposed to local anesthetics, confounding variables have prevented clear conclusions as to cause and effect.

Hodgkinson et al.[258] observed that the subarachnoid administration of tetracaine for cesarean delivery did not adversely affect ENNS performance. Other studies have indicated that NACS performance is not significantly affected by the maternal epidural administration of opioids[259-264] or epinephrine (in combination with a local anesthetic).[265-268]

The effects of general anesthetic agents on neonatal neurobehavior have been evaluated by the ENNS and NACS. In a prospective, randomized study, Abboud et al.[269] assessed NACS performance at 15 minutes, 2 hours, and 24 hours of age in infants whose mothers received general, epidural, or spinal anesthesia for cesarean delivery. Women who underwent general anesthesia received thiopental 4 mg/kg followed by enflurane 0.5% with nitrous oxide 50% in oxygen. Although the NACS was lower at both 15 minutes and 2 hours of age in the infants in the general anesthesia group than in the infants in the neuraxial anesthesia groups, no difference in NACS results was noted at 24 hours of age.

Hodgkinson et al.[258] used the ENNS to evaluate outcomes among three groups of infants, all of whom were delivered by elective cesarean delivery. One group of women received general anesthesia with thiopental 4 mg/kg followed by 50% nitrous oxide. A second group received general anesthesia with ketamine 1 mg/kg followed by 50% nitrous oxide. A third group received spinal anesthesia with tetracaine 6 to 8 mg. The ENNS evaluations were conducted at 4 to 8 hours of age and again at 24 hours. During the 4- to 8-hour examination, infants in the spinal anesthesia group scored significantly higher on multiple components of the ENNS than did infants in either of the general anesthesia groups. At 24 hours, infants in the spinal anesthesia group scored significantly higher than those in the thiopental group in alertness, total decrement score, and overall assessment. Similarly, infants in the spinal anesthesia group scored higher than those in the ketamine group in alertness and overall assessment. No significant differences existed between the scores of the thiopental group infants and the ketamine group infants.[258] Palahniuk et al.[270] observed similar results in a study that compared groups of infants whose mothers received either epidural anesthesia or general anesthesia for elective cesarean delivery. Infants whose mothers had received thiopental and nitrous oxide scored significantly lower in the alertness component of the ENNS than infants whose mothers had received epidural lidocaine with epinephrine.

Stefani et al.[271] observed that subanesthetic maternal doses of enflurane or nitrous oxide did not affect neonatal neurobehavior (as assessed by ENNS and NACS) at 15 minutes, 2 hours, and 24 hours of age. Abboud et al.[272] obtained similar results from NACS examinations of infants whose mothers had received subanesthetic doses of isoflurane.

The long-term effects of perinatal exposure to either general or neuraxial anesthesia at the time of cesarean delivery compared with vaginal delivery appear limited. In a population-based birth cohort, Sprung et al.[273] found that children exposed to either general or regional anesthesia during cesarean delivery were not more likely to develop learning disabilities than children who were delivered vaginally.

In summary, subtle changes in neonatal neurobehavior may result from factors such as antepartum maternal drug exposure. Parent-infant bonding and the ability of the infant to breast-feed may be adversely affected by these neurobehavioral changes.[233] These transient effects may seem trivial to some observers but important to others. With regard to the long-term neurologic outcome of individual infants, performance during neurobehavioral assessment may aid the observer in the formulation of a prognosis. However, as demonstrated with Apgar scores, the prognostic value of an isolated test score is likely to be lower than the prognostic value of multiple factors considered together during the overall assessment of an individual infant.

KEY POINTS

- The anesthesia provider attending the mother should not be responsible for resuscitation of the neonate. However, all anesthesia providers should be prepared to provide assistance during neonatal resuscitation when it is needed.

- Adverse conditions at birth (e.g., hypoxia, acidosis, profound hypovolemia, hypothermia) may impair the transition from intrauterine to extrauterine life. Impaired transition may manifest as persistent pulmonary hypertension of the newborn.
- The Apgar scoring system gives the practitioner a standard guide for assessing the need for neonatal resuscitation.
- No single factor should be considered prognostic of poor neurologic outcome. A combination of factors, including severe metabolic acidemia and Apgar scores of 3 or less beyond 5 minutes, are included among the criteria that suggest the occurrence of intrapartum hypoxia of sufficient severity to cause long-term neurologic impairment. However, not all infants who fulfill these criteria suffer permanent neurologic injury.
- Severe mixed or metabolic acidemia—but not respiratory acidemia alone—is associated with a higher incidence of neonatal complications and death.
- During evaluation of the apneic neonate, assisted ventilation should be initiated promptly if tactile stimulation does not result in the initiation of spontaneous breathing.
- Air rather than 100% oxygen should be used for initial neonatal resuscitation. If necessary, the administration and titration of supplemental oxygen should be guided by pulse oximetry.
- Meconium-exposed neonates no longer require nasopharyngeal and oropharyngeal suctioning before delivery of the thorax or endotracheal tube suctioning after delivery. Meconium-stained fluid may represent evidence of fetal compromise; thus, the infant may be more likely to require neonatal resuscitation.
- In most circumstances, decisions about the initiation or continuation of resuscitation in the delivery room should be based on the neonate's response to resuscitative efforts rather than an estimation of gestational age. Parental desires should be considered when the prognosis for infant survival is poor.

CHAPTER 10

Fetal and Neonatal Neurologic Injury

Tania F. Esakoff, MD • Sarah J. Kilpatrick, MD, PhD • Arvind Palanisamy, MBBS, MD, FRCA

CHAPTER OUTLINE

The detection and diagnosis of fetal and neonatal brain injury have been advanced by improvements in functional imaging and the identification of potential biochemical markers. Evidence indicates that inflammatory mediators play an important role in the pathophysiology of fetal brain injury. Evidence also suggests that maternal administration of magnesium sulfate before anticipated early preterm birth reduces the risk for cerebral palsy in surviving infants. New data suggest that induced hypothermia is beneficial for the treatment of neonatal hypoxic ischemic encephalopathy. Of specific concern to anesthesia providers is rodent and nonhuman primate data that suggest that fetal exposure to anesthetic agents may have harmful effects on neurogenesis and synapse formation in the developing brain. Overall, however, little progress has been made in reducing the incidence of neonatal brain injury and cerebral palsy.

FETAL BRAIN DEVELOPMENT

Generation of the various cell types that populate the developing brain, and the subsequent layering and organization, is a precisely regulated process encoded by genetic programs and modified by epigenetic influences.[1-4] Contrary to previous dogma, it is now well established that the brain continuously evolves during ontogeny and that these processes are susceptible to subtle changes in the internal and external milieu. Although such neurodevelopmental processes occur throughout the human lifespan, the process is most robust and dynamic during the perinatal period.[5] Much of our understanding of the processes that drive fetal brain development comes from studies in rodents and nonhuman primates.[6] With recent advances in neuroimaging, it is now possible to study brain anatomy and assess neurobehavioral changes in the human fetus.[7]

When pathways leading to orderly brain development are deconstructed, three major events appear critical to the establishment of functional synapses. **Neuronal proliferation, migration,** and **cellular differentiation** occur in a preordained fashion to establish early neural circuitry. These processes often overlap and occur at different rates in different brain regions. **Neurogenesis**, a term that encompasses both neuronal proliferation and subsequent survival, begins with neural stem/progenitor cells in neurogenic niches such as the subventricular zone and the subgranular zone of the dentate gyrus. These neural progenitor cells undergo mitosis to generate immature neurons that migrate in a radial fashion and laminate the cortex in an "inside-out" fashion.[8] Interneurons, which comprise 10% to 15% of the total neuronal cells in the brain, originate from the ganglionic eminences in the developing brain.[9] These newly generated interneurons, which play an indispensable role in circuit inhibition, migrate in a tangential manner to populate

distinct brain areas. Both forms of migration are guided by cell-intrinsic mechanisms as well as by structural scaffolds and humoral mediators such as **gamma-aminobutyric acid (GABA)** and **glutamate**.[10,11]

In humans, neurogenesis starts and peaks at 5 and 25 weeks' gestation, respectively, while neuronal migration is completed between 30 and 36 weeks' gestation.[12] Between 20 and 40 weeks' gestation, these processes are followed by the generation of an array of supporting glial cells, such as astrocytes and oligodendrocytes.[12] Concurrently, synapse formation begins as early as the 10th week of gestation and continues to increase gradually at a rate of approximately 4% per week until the end of the second trimester. After this phase, a robust and exponential increase in synapse formation (almost 40,000 synapses/min) occurs between 28 weeks' and term gestation.[13] These processes, in conjunction with the onset of myelination, result in a fivefold increase in brain volume and the appearance of morphologic features of the mature brain such as sulci and gyri. By 24 weeks' gestation the fetus has all the neural machinery necessary to perceive pain.[14] Many clinicians recommend that appropriate measures should be taken to provide fetal analgesia during fetal surgical procedures from this point onward.[15]

Although the ontogeny of neurotransmitter systems is less well studied, a wealth of animal and human data indicates that these systems appear very early in life, before the phase of active synaptogenesis.[12] The presence of these neuromodulatory substances before synapse formation lends credence to the view that they serve a trophic role during early brain development, a role that is distinct from their predominant role of facilitating synaptic neurotransmission in the mature brain. Among these neurotransmitters, GABA remains the most widely studied (Figure 10-1).[16] Although GABA has an inhibitory action in the mature brain, GABA serves an excitatory role during fetal brain development. The major mechanism for this role reversal is the differential expression of chloride ion transporters NKCC1 and KCC2; these transporters increase the intracellular concentration of chloride in developing neurons.[17] On stimulation of **GABA receptors** that are expressed in neural progenitor cells and immature neurons, chloride ions are actively extruded, causing membrane depolarization rather than the hyperpolarization seen in mature neurons. This depolarizing effect of GABA decreases DNA synthesis and inhibits proliferation of neural progenitor cells,[18] causes concentration- and time-dependent effects on neuronal migration,[11] and plays a major role in activity-dependent synapse formation.[19]

The ***N*-methyl-D-aspartate (NMDA)-subtype glutamate receptors** originate later than the GABA receptors and remain functionally silent because of magnesium ion–induced channel blockade; thus, they play a limited role during early brain development. Dopaminergic, cholinergic, and serotonergic systems develop concomitantly and appear fully functional by the second trimester.[12] Pharmacologic interventions (e.g., ethanol, antiepileptic drugs) that act directly or indirectly on these powerful neuromodulator systems induce long-lasting impairment of fetal brain development, mainly owing to impaired neurogenesis and/or altered neuronal migration.[20-22] Alteration of this excitation-inhibition balance is purported to be responsible for an array of childhood neurodevelopmental disorders.

Experimental studies reveal that the fetal blood-brain barrier is morphologically well developed and functionally competent at term.[23] Convincing evidence confirms that the endothelial tight junctions of the blood-brain barrier are as effective in the term fetus as in the adult, although the exact time that blood-brain barrier competency is established in the human fetus is unknown. In rodents, data suggest that the fetal blood-brain barrier is established between embryonic days 11 and 17 (term gestation is 22 days), a time period that corresponds to approximately the late second and early third trimesters in humans.[24]

CEREBRAL PALSY

History, Definitions, and Significance

In 1861, John Little, an orthopedic surgeon, first described cerebral palsy in a report to the Obstetrical Society of London. Described as a neonatal neurologic disorder associated with difficult labor or birth trauma, the disorder was known as Little's disease until William Osler coined the term *cerebral palsy* in 1888.[25] A precise definition and classification of cerebral palsy has proved elusive. In the forward to the "Report on the Definition and Classification of Cerebral Palsy," published in 2007 in *Developmental Medicine and Child Neurology*, Peter Baxter[25] wrote, "This [supplement] illustrates the difficulties inherent in trying to agree what we mean by the terms we use and that a classification that suits one purpose, such as a diagnostic approach, may not always be ideal for others, such as therapy issues. Defining and classifying cerebral palsy is far from easy. We do need a consensus that can be used in all aspects of day-to-day care and for future research on cerebral palsy."

Today, **cerebral palsy** is defined as a nonprogressive disorder of the central nervous system (CNS) present since birth that includes some impairment of motor function or posture.[25] *Intellectual disability* (formerly known as *mental retardation*) may be present but is not an essential diagnostic criterion. Various forms of cerebral palsy exist, with differences in pathology, pathophysiology, and potential relationships with intrapartum events. The literature on cerebral palsy is difficult to review and understand. Data from individual studies are difficult to compare because of variations in the duration of follow-up, birth weight classifications, inclusion criteria for congenital abnormalities, and exclusion criteria for various causes of death. Terms such as *hypoxic-ischemic encephalopathy of the newborn*, *newborn asphyxia*, *birth asphyxia*, and *asphyxia neonatorum* are difficult to distinguish. Some authorities, including the American College of Obstetricians and Gynecologists (ACOG), have argued that the term *birth asphyxia* should be abandoned.[26]

Intrapartum events continue to receive the blame for some cases of cerebral palsy. It is a widely believed theory that an intrapartum reduction in fetal oxygen delivery may cause cerebral palsy, and early reports in primates

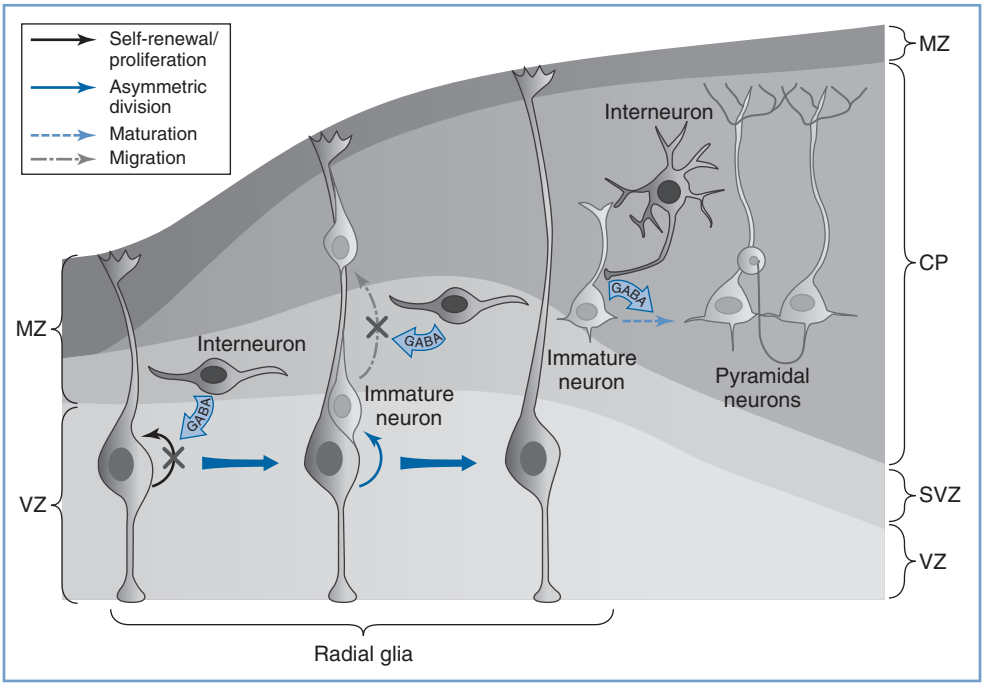

FIGURE 10-1 ■ Gamma–aminobutyric acid's (GABA) role in regulating embryonic cortical development. During corticogenesis, interneurons migrating in the subventricular zone (SVZ) can release GABA and activate GABAergic receptors on the radial glia, depolarizing these progenitors and decreasing their proliferation. Radial glia generate immature pyramidal neurons through asymmetric division, and the migration of these immature neurons along the radial fibers is decreased by GABA signaling. As young neurons assume their position in the cortex and begin to mature, GABA-mediated depolarization by the interneurons is required for the development of dendritic arbors and excitatory synaptic inputs from other pyramidal neurons. *MZ,* marginal zone; *VZ,* ventricular zone; *SVZ,* subventricular zone; *CP,* cortical plate. (From Wang DD, Kriegstein AR. Defining the role of GABA in cortical development. J Physiol 2009; 587:1873-9.)

demonstrated that perinatal asphyxia could cause brain injury.[27] Continuous electronic fetal heart rate (FHR) monitoring, which has largely replaced intermittent FHR auscultation during labor, is believed to prompt the delivery of at-risk fetuses and thus reduce asphyxial events. However, despite a higher incidence of cesarean delivery, no reduction in the incidence of cerebral palsy has been observed since the widespread implementation of continuous electronic FHR monitoring during labor.[28,29] Further, among patients with new-onset late FHR decelerations, an estimated 99% of tracings would be false positive "if used as an indicator for subsequent development of cerebral palsy."[30] This information is probably surprising to the lay public and trial lawyers as well as to obstetricians; a survey of maternal-fetal medicine fellows showed that they, too, have greatly overestimated the diagnostic accuracy of FHR monitoring.[30]

Large randomized trials have not demonstrated better fetal and neonatal outcomes with continuous electronic FHR monitoring than with intermittent FHR auscultation.[31,32] In an editorial citing observations made by Schifrin and Dame,[33] Friedman[34] opined, "The absence of either suggestive or overtly ominous fetal heart rate patterns is reliably reassuring." Unfortunately, there is little objective evidence that reassuring FHR tracings exclude the subsequent occurrence of cerebral palsy. In a 1993 review of published FHR monitoring studies, Rosen and Dickinson[35] could not identify FHR patterns that were consistently associated with neurologic injuries. Moreover, no consistent FHR pattern was observed in a subset of 55 brain-damaged infants. These investigators concluded, "We do not advocate the abandonment of the use of electronic fetal monitoring, but we do believe that it is yet to be proved to be of value in predicting or preventing neurologic morbidity." A more focused application of FHR monitoring may ultimately be found useful. For example, fetal inflammatory changes, which can be associated with neurologic injury, may be associated with characteristic FHR findings.[36] Thus, electronic FHR monitoring provides incomplete data that should be evaluated in the clinical context in which is it used.

Despite significant limitations in the use of intrapartum electronic FHR monitoring, there is no doubt that it will continue to be used for the foreseeable future. In a review of medicolegal issues in FHR monitoring, Schifrin and Cohen[37] noted that despite its limitations, "Monitoring deserves credit for reducing intrapartum death, one of the original rationales for its development."

A 2008 workshop (sponsored by the Eunice Kennedy Shriver National Institute of Child Health and Human Development, the ACOG, and the Society for Maternal-Fetal Medicine [SMFM]) updated the definitions of various types of FHR tracings to simplify interpretation for providers.[38] As a result, a three-category system was developed. Category I FHR tracings provide the most reassuring evidence of fetal well-being and strongly predict *normal* fetal acid-base status at the time of observation. Category III tracings are the most ominous; these tracings predict *abnormal* fetal acid-base status at the time

of observation and require prompt evaluation. Most FHR tracings are category II (indeterminate). Category II tracings are *not* predictive of *abnormal* fetal acid-base status, but they do not provide sufficient evidence to be classified as either normal or abnormal; these tracings require continued surveillance and reevaluation (see Chapter 8).

Intrapartum events are responsible for some cases of cerebral palsy[39]; however, these cases are few. After exclusion of infants with significant congenital anomalies, intrapartum events—including asphyxial insults—likely account for only 5% to 8% of all cases of cerebral palsy at all gestational ages.[40,41] In 1999, the International Task Force on Cerebral Palsy published a consensus statement summarizing criteria that are necessary and suggestive of an intrapartum etiology for neurologic abnormalities (Box 10-1).[42] In 2010, a proposed evidence-based neonatal workup to confirm or refute allegations of intrapartum asphyxia was published.[43]

BOX 10-1 Criteria to Define an Acute Intrapartum Hypoxic Event as Sufficient to Cause Cerebral Palsy

Essential Criteria (all four must be met)

1. Evidence of metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH < 7 and base deficit ≥ 12 mmol/L)*
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks' gestation
3. Cerebral palsy of the spastic quadriplegic or dyskinetic type†
4. Exclusion of other identifiable etiologies, such as trauma, coagulation disorders, infectious conditions, and genetic disorders

Criteria That Collectively Suggest an Intrapartum Event—within Close Proximity to Labor and Delivery (e.g., 0 to 48 hours)—but Are Nonspecific to Asphyxial Insults

1. A sentinel (signal) hypoxic event occurring immediately before or during labor
2. A sudden and sustained fetal bradycardia or the absence of fetal heart rate variability in the presence of persistent, late, or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal
3. Apgar scores of 0 to 3 beyond 5 minutes
4. Onset of multisystem involvement within 72 hours of birth
5. Early imaging study showing evidence of acute nonfocal cerebral abnormality

*Buffer base is defined as the amount of buffer in blood available to combine with nonvolatile acids. A buffer base of 34 mmol/L is equivalent to a whole blood base deficit of 12 mmol/L.

†Spastic quadriplegia and, less commonly, dyskinetic cerebral palsy are the only types of cerebral palsy associated with acute hypoxic intrapartum events. Spastic quadriplegia is not specific to intrapartum hypoxia. Hemiparetic cerebral palsy, hemiplegic cerebral palsy, spastic diplegia, and ataxia are unlikely to result from acute intrapartum hypoxia.

From Nelson KB, Grether JK. Potentially asphyxiating conditions and spastic cerebral palsy in infants of normal birth weight. Am J Obstet Gynecol 1998; 179:507-13.

Epidemiology and Etiology

The causes of cerebral palsy are not known, but the varying forms suggest a multifactorial etiology. The Collaborative Perinatal Project still represents one of the largest studies of the antecedent factors associated with cerebral palsy. The investigators in this study evaluated the outcomes of 54,000 pregnancies among patients who delivered at 12 university hospitals between 1959 and 1966. They evaluated more than 400 variables in a univariate analysis,[44] which identified potential risk factors that were then subjected to a more rigorous multivariate analysis.[45] Maternal age, parity, socioeconomic status, smoking history, maternal diabetes, duration of labor, or use of anesthesia was not associated with cerebral palsy in the univariate analysis. The factors most strongly associated with cerebral palsy in the multivariate analysis were (1) maternal mental retardation, (2) birth weight of 2000 g or less, and (3) fetal malformations. Other factors associated with cerebral palsy included (1) breech presentation (but not vaginal breech delivery), (2) severe proteinuria (more than 5 g/24 h) during the second half of pregnancy, (3) third-trimester bleeding, and (4) a gestational age of 32 weeks or less. There was a slight association between cerebral palsy and fetal bradycardia, chorioamnionitis, and low placental weight. However, only 37% of the cases of cerebral palsy occurred in patients with one or more of these identified risk factors.

Rosen and Dickinson[46] reviewed studies from Europe, Australia, and the United States that were published between 1985 and 1990 and included data from 1959 to 1982. The incidence of cerebral palsy ranged from 1.8 to 4.9 (composite rate of 2.7) cases per 1000 live births. The incidence of certain conditions in infants with cerebral palsy was as follows: birth weight less than 2500 g, 26%; diplegia, 34%; hemiplegia, 30%; quadriplegia, 20%; and extrapyramidal forms, 16%.

Two more recent studies from Australia reexamined the risk factors for cerebral palsy. A large epidemiologic study from 1998 noted an incidence of neonatal encephalopathy of 3.8 per 1000 term births.[47] The investigators identified preconception and antepartum factors that were associated with neonatal encephalopathy (Box 10-2). In the second study from 2011, the greatest risks for cerebral palsy included (1) preterm birth, (2) fetal growth restriction (also known as intrauterine growth restriction), (3) perinatal infection, and (4) multiple gestation.[48] Upper respiratory tract and gastrointestinal infections during pregnancy and instrumental (forceps or vacuum) vaginal delivery were not associated with cerebral palsy.[48] Evidence suggests that intrapartum factors alone are associated with neonatal encephalopathy in less than 5% of cases.[47,49] These data, along with the recognition that most patients with identified risk factors do not have children with cerebral palsy, have led the majority of investigators to agree that most cases of cerebral palsy cannot be predicted and that the identification of pregnancy-related conditions contributes minimally to the identification of patients at risk for having a child with cerebral palsy.

In 2000, the ACOG and the American Academy of Pediatrics (AAP) convened the Neonatal Encephalopathy

BOX 10-2 Risk Factors for Neonatal Encephalopathy

Preconception Factors*

- Increasing maternal age
- Mother unemployed, unskilled laborer, or stay-at-home
- No private health insurance
- Family history of seizures
- Family history of neurologic disorders
- Infertility treatment

Antepartum Factors*

- Maternal thyroid disease
- Severe preeclampsia
- Bleeding in pregnancy
- Viral illness in pregnancy
- Postdates pregnancy
- Fetal growth restriction
- Placental abnormalities

*Significantly and independently associated with neonatal encephalopathy in multiple logistic regression analysis.

Philadelphia, Mosby, 2009. Information compiled from Badawi N, Kurinczuk JJ, Keogh JM, et al. Antepartum risk factors for neonatal encephalopathy: the Western Australia case-control study. BMJ 1998; 317:1549-53.

and Cerebral Palsy Task Force. The resulting landmark report,[49] which was released in 2003, was reviewed and endorsed by such groups as the U.S. Department of Health, the National Institutes of Health, the SMFM, the Child Neurology Society, the March of Dimes Birth Defects Foundation, the Society of Obstetricians and Gynaecologists of Canada, and the Royal Australian and New Zealand College of Obstetricians and Gynaecologists. The Task Force extended the earlier international consensus statement regarding the requirements for establishing a causal relationship between intrapartum events and cerebral palsy (see Box 10-1).[42] The consensus statement led to several medicolegal conclusions[42,49]:

1. The only types of cerebral palsy associated with intrapartum hypoxia are spastic quadriplegia and, less commonly, dyskinesia.
2. Intellectual disability, learning disorders, and epilepsy should not be ascribed to birth asphyxia unless accompanied by spastic quadriplegia.
3. No statements about severity should be made before an affected child is 3 to 4 years of age, because mild cases may improve and dyskinesia may not be evident until then.
4. Intrapartum hypoxia sufficient to cause cerebral palsy is always accompanied by neonatal encephalopathy and seizures.

Phelan et al.[50] subsequently confirmed that fetuses that experienced a sudden and sustained deterioration of the FHR, and that subsequently were found to have cerebral palsy, demonstrated characteristics consistent with the ACOG/AAP Task Force criteria[50] for intrapartum asphyxial injury.

Peripartum Asphyxia and Cerebral Palsy

Asphyxia may be defined as insufficient exchange of respiratory gases.[51] Although accurate, this definition does not include an index of severity or have any predictive value. Unfortunately, most studies have not used a uniform definition of *birth asphyxia*.[52-54]

In 1953, Dr. Virginia Apgar, an anesthesiologist, introduced her scoring system to identify newborn infants in need of resuscitation and to assess the adequacy of subsequent resuscitation efforts.[55] Although the Apgar score has also been used to identify infants at risk for cerebral palsy, only a weak association has been found.[56,57] In the Collaborative Perinatal Project, only 1.7% of children with a 1-minute Apgar score of 3 or less developed cerebral palsy.[58] Among infants who weighed more than 2500 g at delivery, the incidence of cerebral palsy was 4.7% if the 5-minute Apgar score was 0 to 3 and 0.2% if the 5-minute Apgar score was at least 7. Among infants who weighed less than 2500 g with the same 5-minute Apgar scores, the incidence of cerebral palsy was 6.7% and 0.8%, respectively. Among all infants, a higher incidence of cerebral palsy was observed if the Apgar score remained 3 or less for longer than 5 minutes. The incidence of early neonatal death increased among those infants with prolonged neonatal depression.

Most infants who subsequently manifest evidence of cerebral palsy have a normal 5-minute Apgar score. In the Collaborative Perinatal Project, only 15% of the infants in whom cerebral palsy later developed had a 5-minute Apgar score of 3 or less, approximately 12% had a score of 4 to 6, and the remaining 73% had a score of at least 7.[58] It must also be noted that preterm delivery is independently associated with a low Apgar score.

Although most cases of cerebral palsy are not attributed to intrapartum insults, intrapartum asphyxia does occur and can have serious consequences. However, the degree of asphyxia necessary to produce irreversible CNS injury is unclear. In some cases, an intrapartum insult that might have otherwise been innocuous might be superimposed on subclinical chronic fetal compromise and result in permanent injury.

Umbilical cord blood gas measurements are often used to diagnose suspected asphyxia. However, the definition of *normal* umbilical cord blood gas and pH measurements remains unclear.[51] In one study of 15,073 *vigorous* neonates (arbitrarily defined as having a 5-minute Apgar score of 7 or more) conducted between 1977 and 1993, the median umbilical arterial blood gas measurements (with the 2.5th percentile in parentheses) were as follows: pH 7.26 (7.10), Po_2 17 (6) mm Hg, Pco_2 52 (74) mm Hg, and base excess –4 (–11) mEq/L.[51] Only small differences in median pH and other measurements were present when infants were grouped according to gestational age. These data suggest that umbilical arterial blood pH in vigorous neonates can be as low as 7.10 and base excess may be as low as –11 mEq/L.

Although intrapartum events are most likely associated with a minority of cerebral palsy cases, clinical studies have attempted to define the associated extent and duration of perinatal asphyxia. Fee et al.[59] defined asphyxia as an umbilical arterial blood pH of less than

7.05 with a base deficit greater than 10 mEq/L; they concluded that this threshold was a poor predictor of adverse neurologic outcomes. Goodwin et al.[60] defined asphyxia as an umbilical arterial blood pH of less than 7.00; with the use of this definition, hypoxic ischemic encephalopathy and abnormal neurologic outcome were associated with acidemia. Goldaber et al.[61] also observed greater neonatal morbidity and mortality among term infants (birth weight > 2500 g) with an umbilical arterial blood pH of less than 7.00.

Low et al.[62,63] also studied complications of intrapartum asphyxia in term and preterm infants. They developed a complication score that expressed the magnitude of neonatal complications. Among term infants, the frequency and severity of newborn complications increased with the severity and duration of metabolic acidosis at birth. Importantly, respiratory acidosis at birth did not predict complications in newborns. Similar results were noted for preterm infants delivered between 32 and 36 weeks' gestation. In contrast, in infants delivered before 32 weeks' gestation, complications were similar in the control and asphyxia (defined as umbilical arterial blood buffer base < 30 mmol/L) groups. When this scoring system was used in term infants, the threshold for moderate or severe newborn complications was an umbilical arterial blood base deficit of 12 mmol/L.[63]

Relatively few studies have followed neurodevelopmental examinations for a sufficient duration to make meaningful conclusions about peripartum predictors of neurologic injury. Nagel et al.[64] performed such examinations in 30 children in whom umbilical arterial blood pH was less than 7.00 at delivery, 28 of whom survived the neonatal period. Evaluation at 1 to 3 years of age detected 3 children who had experienced an episode of hypertonia. The majority of children exhibited no major problems, with only 1 child displaying mild motor developmental delay. Another study examined neonatal complications (neonatal death, grade 3 or 4 intraventricular hemorrhage, gastrointestinal dysfunction, and neonatal seizures) in 35 newborns with an umbilical arterial blood pH of less than 7.00 at delivery, 3 of whom died during the neonatal period.[65] An umbilical arterial blood base deficit greater than or equal to 16 mmol/L and a 5-minute Apgar score less than 7 had a sensitivity and specificity for predicting adverse neonatal outcomes of 79% and 81%, respectively. These investigators did not perform any follow-up neurologic examinations after the neonatal period.[65]

Because metabolic acidosis may be a predictor of complications in newborns, the severity of intrapartum acidosis could be an important variable. Gull et al.[66] studied a small cohort of 27 patients with terminal bradycardia who were delivered vaginally. Not surprisingly, the umbilical arterial blood base deficit was greater in infants with end-stage bradycardia than in controls. The loss of short-term FHR variability for more than 4 minutes during terminal bradycardia correlated with the development of metabolic acidosis.

The relationship between umbilical arterial blood base excess values and the timing of hypoxic injury has been estimated in human and animal studies.[67] In addition, in a 2010 systematic review and meta-analysis, an umbilical cord arterial blood pH less than 7.00 was significantly associated with important, biologically plausible, adverse neonatal outcomes (i.e., neonatal mortality, hypoxic ischemic encephalopathy, intraventricular hemorrhage, periventricular leukomalacia, cerebral palsy).[68] Unfortunately, this relationship does not consider the role of previous or repetitive hypoxic episodes before the episode in question and therefore cannot accurately pinpoint the time of injury. Fortunately, the human fetus is quite robust, and episodes of intrauterine asphyxia usually yield a normal neonate. A much smaller number of fetuses experiencing such episodes die *in utero*. Blumenthal[69] concluded that there is a fine threshold between normality and death from asphyxia.

The increased presence of nucleated red blood cells in the umbilical circulation at delivery has been proposed as a marker of the occurrence and timing of intrauterine asphyxia.[50,70,71] However, data from these investigations demonstrated considerable variability and were influenced by birth weight and gestational age.[72] Furthermore, the timing of the injury may be difficult to determine with confidence, because multiple episodes of asphyxia may have occurred. In such cases, the nucleated red blood cell count may reflect and implicate only the most recent, but possibly least important, event. Both nucleated red blood cell and lymphocyte counts appear to undergo more sustained elevations in cases of antepartum asphyxia than in cases of intrapartum asphyxia.[49]

Chorioamnionitis, Fever, and Cerebral Palsy

An association between cerebral palsy and chorioamnionitis has been demonstrated in preterm infants and term infants of normal birth weight.[73,74] An elevated maternal temperature is one sign of chorioamnionitis, but alone it is insufficient for the diagnosis. Other signs include, but are not limited to, maternal and fetal tachycardia, foul-smelling amniotic fluid, uterine tenderness, and maternal leukocytosis. The diagnosis remains unproven until confirmed by placental culture or histologic examination.

The mechanism by which chorioamnionitis is associated with cerebral palsy is unclear; however, inflammatory cytokines may play a role (see later discussion).[75-77] A landmark meta-analysis published in 2000 reported that both clinical and histologic chorioamnionitis were strongly associated with an increased risk for cerebral palsy and periventricular leukomalacia in both preterm and term infants.[78] In a 2010 meta-analysis, both histologic (pooled odds ratio [OR], 1.83; 95% confidence interval [CI], 1.17 to 2.89) and clinical chorioamnionitis (OR, 2.42; 95% CI, 1.52 to 3.84) were again found to be significantly associated with cerebral palsy.[79]

Several studies have demonstrated a tendency for maternal temperature to rise after administration of epidural analgesia during labor (see Chapter 37).[80] Although the mechanism of epidural analgesia–associated maternal pyrexia remains unclear, fever due to epidural analgesia alone is not associated with cerebral palsy.[81] Epidural analgesia has been blamed for the common obstetric practice of antibiotic administration to mothers with fever but no other evidence of chorioamnionitis. This

practice may lead to unnecessary neonatal sepsis evaluations and antibiotic exposure.[82] Rather than treat all women with pyrexia for presumed chorioamnionitis, Mayer et al.[83] correctly noted that physicians should make an effort to differentiate true chorioamnionitis from incidental maternal fever. These investigators found that additional signs of chorioamnionitis were present in all cases in which the diagnosis was later confirmed by culture or pathologic examination. Neuraxial anesthesia is not a risk factor for cerebral palsy.[44]

The mode of delivery has been examined as an independent risk factor for **periventricular leukomalacia**, the most common form of ischemic brain injury in surviving preterm infants in whom cerebral palsy later develops. In 99 women with chorioamnionitis who delivered between 25 and 32 weeks' gestation, vaginal delivery had a significant association with periventricular leukomalacia.[84] Because the cesarean delivery group likely included a substantial number of infants with nonreassuring FHR tracings, the better outcomes in these infants is striking. Prospective trials are needed to confirm these retrospective observations.

PATHOPHYSIOLOGY OF FETAL ASPHYXIA

Intrauterine Hypoxemia and the Fetal Brain

The fetus is exclusively dependent on the placenta for oxygen and nutrients; thus, acute and chronic conditions that affect the placenta or the umbilical cord can deprive the fetus of one or more of these vital resources. Recent evidence from experimental animal models and humans suggest that both hypoxemic and inflammatory pathways interact and augment fetal brain damage.

The spectrum of neurologic injury in neonates depends on the duration and gestational age at hypoxemic-ischemic insult. *Acute* hypoxemia during the early- to mid-gestational period in sheep affects the predominant neurodevelopmental events such as neurogenesis and neuronal migration. Such hypoxemia causes the death of cerebellar Purkinje cells and hippocampal pyramidal neurons, as well as impaired neuronal migration.[85] In contrast, acute hypoxemia in late gestation appears to spare the hippocampus and cerebellum but causes neuronal death in the cerebral cortex and striatum.[86] Furthermore, acute perinatal anoxia causes long-term changes in dendritic arborization and synaptic connectivity.[87,88]

Experimental models of *chronic* hypoxemia, based on restriction of placental mass or blood flow, demonstrate an array of completely different effects on the fetal brain. Chronic placental insufficiency relatively spares the fetal brain compared with other organ systems, although it results in reduced fetal brain weight. Overall, neurons appear to survive chronic and mild hypoxemia; even minor behavioral changes appear to resolve fully by adulthood in animal models. It is not known whether these effects are mediated by hypoxemia *per se*, or by other accompanying conditions such as chronic reduction of fetal nutrient supply or altered maternal-fetal endocrine status.

Dysregulation of neuronal calcium transport appears to be the initial pathway by which cerebral hypoxemia causes perinatal neuronal injury.[89] Hypoxia-induced changes in the NMDA receptor increases cellular permeability to calcium; such increases in intracellular calcium trigger a variety of downstream effects, ultimately resulting in generation of free radicals, peroxidation of lipid membranes, and nuclear fragmentation. It has long been recognized that developing oligodendroglia are highly vulnerable to excitotoxic injury in preterm infants.[90] Altered maturation or premature oligodendrocyte death can occur in areas of severe hypoxia-ischemia as a result of up-regulation of inflammatory cytokines by activated microglia, elevated glutamate levels, or depleted levels of the antioxidant glutathione. It is highly likely that a combination of these mechanisms, modified by the nature and duration of insults and gestational age, determine the ultimate neurobehavioral phenotype.

Maternal Inflammation and Fetal Brain Injury

Although the development of the fetal brain is encoded by genetic programming, such programs remain highly susceptible to environmentally induced epigenetic modifications and appear closely intertwined with maternal immune and endocrine systems. Recent experimental and epidemiologic studies reveal that maternal infection and inflammation early in pregnancy can cause an array of neurodevelopmental abnormalities in the offspring such as schizophrenia and autism.[91-94] Among maternal infections, chorioamnionitis is the best characterized and thoroughly investigated model of perinatal neuroinflammation. Although the exact contribution of maternal inflammation to perinatal brain injury is obscured because of the association of chorioamnionitis with preterm delivery and hypoxic-ischemic encephalopathy, inflammatory experimental models have revealed much information on cytokine induction, their transport across the placenta and amniotic fluid, and subsequent activation of the fetal immune system.

The exact mechanism by which maternal inflammation triggers a fetal immune response is likely multifactorial (Figure 10-2). Despite the presence of circulating immune cells as early as 7 weeks' gestation in humans, antigen presentation is suboptimal because of reduced expression of the major histocompatibility complex class II on antigen-presenting cells. Furthermore, the T cells are relatively immature. Therefore, maternally derived humoral mediators seem credible candidates to initiate and perpetuate an inflammatory cascade across the placenta. This idea has gained traction with the identification of maternal interleukin-6 (IL-6) in the fetal circulation as early as the second trimester, suggesting the possibility of transplacental transfer of proinflammatory cytokines.[95] Proinflammatory mediators such as IL-6 cause significant impairment of placental blood flow and fetal hypoxemia in animal models, dysregulate the barrier function of both the placenta and the immature fetal blood-brain barrier, trigger production of acute-phase

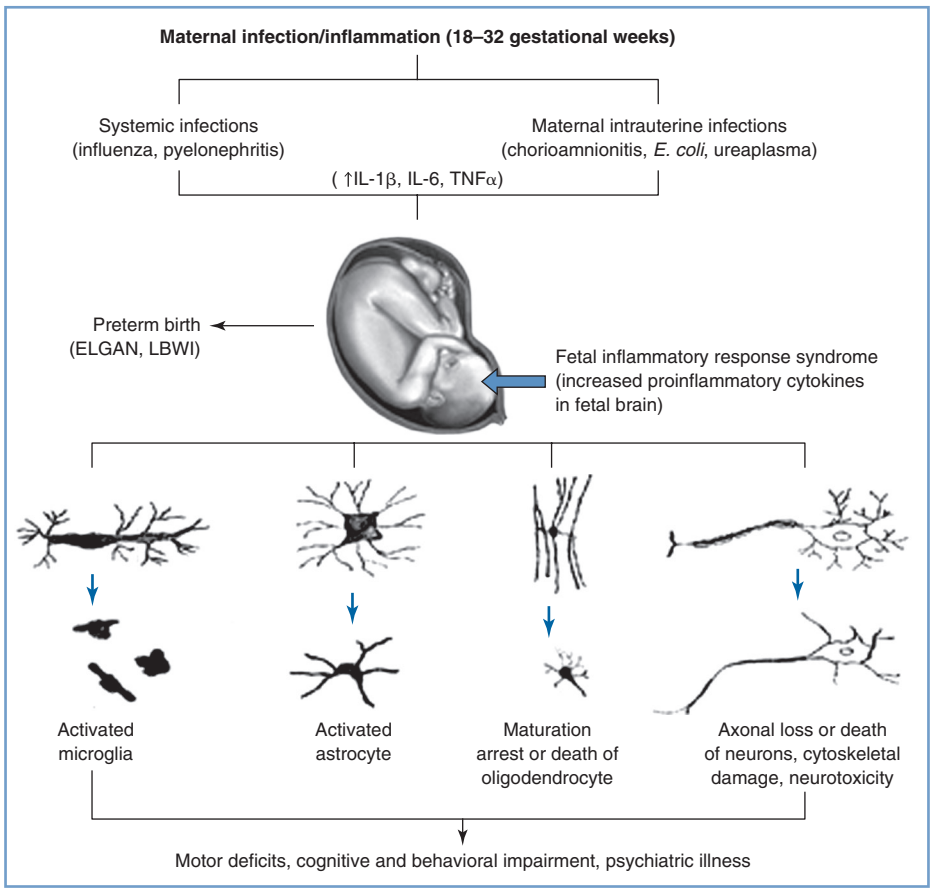

FIGURE 10-2 ■ Probable mechanisms of fetal brain injury with *in utero* exposure to maternal inflammation. *IL,* interleukin; *TNF,* tissue necrosis factor; *LBWI,* low birth weight infant; *ELGAN,* extremely low gestational age neonate. proteins from the fetal liver, promote T-cell entry into the immature brain parenchyma, and disrupt the orderly patterning of the fetal cerebral cortex.[91,93,96-99] The role of inflammatory mediators in this phenomenon is reinforced by the direct correlation that exists between plasma levels of IL-6 and the severity of functional deficits in offspring.[100,101] In addition to IL-6, cytokines such as IL-1β, IL-7, and IL-13 are up-regulated in the fetal brain after a prenatal immune insult, a phenomenon that suggests collective activation of the innate fetal immune response.[102]

Both microglia (the major resident macrophages in the developing brain) and the complement system have been implicated as amplifiers of this immune response. During normal fetal development, microglia invade and colonize the fetal brain during the first and second trimesters[103] and are readily activated by proinflammatory mediators such as IL-1β. Activated microglial cells either cause a direct cytotoxic effect on oligodendrocytes and impair myelination or produce long-lasting alterations in neuronal-glial crosstalk, resulting in impaired synaptic function and subsequent neurodevelopmental disorders.[3,91,104]

At the cellular level, numerous mechanisms are involved in propagating the prenatal immune response. Collectively, robust experimental evidence suggests that prenatal inflammation alters fetal brain development at the molecular, cellular, and circuit levels. Epidemiologic studies have shown a strong correlation between maternal infection/inflammation and neurodevelopmental disorders such as schizophrenia and autism.[92,105,106]

Animal Models of Fetal Asphyxia

Much of our knowledge of the fetal response to insufficient exchange of respiratory gases has been gained through the use of animal models. However, the limitations of these models must be acknowledged. Raju[107] reviewed the various animal models of fetal brain injury. At birth, sheep and guinea pig brains are much closer to maturity than the human brain. In this regard, rat pup and human brains are more similar to each other because they both undergo significant extrauterine development (Figure 10-3).[108] Nonetheless, the importance of this distinction has been challenged. Previously, investigators relied mainly on morphologic milestones (e.g., the brain growth spurt) to compare species at different stages of development. A computerized method attempted to more accurately compare observations among 10 species (including humans) by evaluating the mathematical relationships of more than 100 developmental events and factors (e.g., evolutionary, genetic, neurochemical,

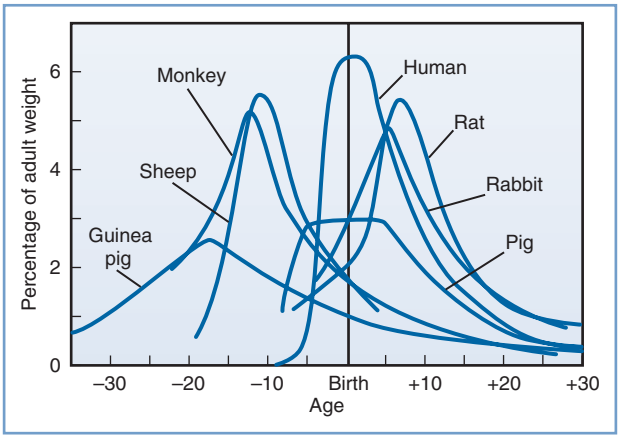

FIGURE 10-3 ■ Brain growth spurts of seven mammalian species expressed as first-order velocity curves of the increase in weight with age. The units of time for each species are as follows: guinea pig (days); rhesus monkey (4 days); sheep (5 days); pig (weeks); human (months); rabbit (2 days); rat (days). Rates are expressed as a percentage of adult weight for each unit of time. (From Penning DH. Fetal and neonatal neurologic injury. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia: Principles and Practice. 4th edition. Philadelphia, Mosby, 2009; modified from Dobbing J, Sands S. Comparative aspects of the brain growth spurt. Early Hum Dev 1979; 3:79-83.)

neuroanatomic).[109] Although all events have not been catalogued for any one species, the iterative process allows information to be added to improve the theoretic model and is freely available online.* This method is not completely understood or accepted but may explain some of the variability observed among various models of developmental brain injury.

One advantage of the chronically instrumented fetal lamb is that it is similar in size to the human fetus, thus facilitating the placement of electrodes and vascular catheters in both the fetus and the mother. Investigators may obtain measurements while the mother (and fetus) remains anesthetized or from awake animals that have recovered from surgery. Studies of animals with continuous instrumentation allow the assessment of fetal breathing movements, gross body movements, brain electrical activity (electroencephalogram), and blood gas and pH measurements. Blood concentrations of glucose, lactate, and various hormones can also be determined. Microdialysis techniques have been used to evaluate neurotransmitter release within the fetal brain *in vivo* in acute, exteriorized, and chronic preparations.[110-112] Other studies have measured fetal cerebral blood flow *in vivo* during episodes of hypoxemia[113] and during maternal infusion of ethanol.[114] Together, these studies have enhanced the understanding of the fetal brain response to pathophysiologic insults *in utero*. Ultimately, these insights may lead to improved diagnoses, treatment, and prevention of fetal brain injury.

Studies have used a variety of methods to produce fetal hypoxemia and acidemia in fetal lambs. Each method attempts to mimic one or more clinically relevant situation(s), including (1) decreased concentration of maternal inspired oxygen for several hours[115] or days[116]; (2) decreased uterine blood flow, which may be accomplished by placement of an adjustable clamp on the common iliac artery[117]; (3) decreased umbilical blood flow, either by total obstruction[118] or by means of a slow, progressive obstruction[119]; (4) selective uteroplacental embolization[120]; (5) maternal hemorrhage[121]; and (6) a combination of two insults, such as hypoxemia plus hypotension.[122]

Care must be exercised in the application of knowledge gained from hypoxia-ischemia studies conducted on nonfetal models (e.g., rat pups) to the problem of insufficient intrauterine gas exchange. The fetus and the fetal brain exist in a relatively hypoxemic environment. Despite preferential streaming of the most highly oxygenated blood to the brain and heart, the average Po_2 measured in the carotid artery of fetal lambs at term is approximately 22 mm Hg.[123] Further, unlike adult conditions in which global anoxia (i.e., cardiac arrest) or focal ischemia (i.e., stroke) is the clinical correlate, fetal asphyxia typically involves diminution, but not absence, of delivery of oxygen, with variable degrees of respiratory or metabolic acidosis. A complete loss of cerebral blood flow rarely occurs, except as a terminal event. Of course, prolonged hypoxemia and decreased oxygen delivery can lead to acidemia and myocardial failure, followed by ischemia and rapid fetal demise. Fetal hypoxemia may result from the compromise of any or all of the steps involved in maternal-fetal oxygen transport (Box 10-3).[124] The impact of repeated hypoxic-ischemic insults should not be underestimated, and numerous clinical scenarios can be envisioned whereby this might occur (e.g., repetitive umbilical cord occlusion, chronic abruption). Moreover, brief insults that may be harmless could cause damage if repeated, as has been demonstrated in adult rats[125] and in fetal lambs.[126]

The neuropathology of intrauterine asphyxia depends, to some extent, on gestational age. In fetal lambs exposed to sustained hypoxemia with developing acidemia, immature fetuses demonstrated a predominantly periventricular injury, whereas mature fetuses had a primarily cortical injury, although there was some overlap (Figure 10-4).[127] This finding is consistent with injury patterns in humans. It is not surprising that the biophysical and biochemical responses to hypoxemia vary between preterm and term fetuses. Matsuda et al.[115] observed that the development of metabolic acidemia, reduced fetal breathing and body movements, and an altered sleep state were much less pronounced in mid-gestational fetal lambs subjected to hypoxemia than in fetal lambs at term.

Neuropathology of Fetal Asphyxia

The mechanism and timing of an asphyxial insult can affect the resulting fetal or neonatal pathology. Acute, complete asphyxia must be distinguished from incomplete, brief, or intermittent asphyxia or chronic hypoxemia. *Complete asphyxia* may occur in the setting of a total placental abruption or umbilical cord occlusion (as may occur with a uterine rupture or umbilical cord prolapse), which if unrecognized and not treated rapidly leads to

fetal demise. *Incomplete asphyxia* may occur in any setting in which oxygen delivery to the fetus is inadequate to meet all of its needs (e.g., brief and/or repeated episodes of partial umbilical cord occlusion, placental embolization, or incomplete placental abruption). This latter category of asphyxia presumably contributes to the largest proportion of cases of cerebral palsy attributed to antepartum events. In these cases, the insult is not severe enough to lead to immediate fetal death but can profoundly affect fetal brain growth and development. Ongoing studies are attempting to determine whether there is a period of time *in utero* when the fetus is especially vulnerable to neurologic injury.

Using a primate model to perform seminal research on the subject of perinatal brain injury, Myers[27] identified two patterns of injury based on whether the fetus suffered complete or partial asphyxia. True complete asphyxia was demonstrated in fetal monkeys at term subjected to varying durations (0 to 25 minutes) of complete asphyxia. These fetuses were resuscitated when possible, a procedure that often required the use of cardiac massage and epinephrine, and postmortem examinations revealed extensive pathology in brainstem areas. In humans, such a severe intrauterine insult would most likely be incompatible with extrauterine survival. If survival did occur, the infant would show obvious encephalopathy and multiorgan system dysfunction at birth. The second pattern (i.e., partial asphyxia) is more relevant to the discussion of human cerebral palsy. In studies of fetal monkeys subjected to partial asphyxia,[128] some animals demonstrated cortical necrosis, subcortical white matter damage, and

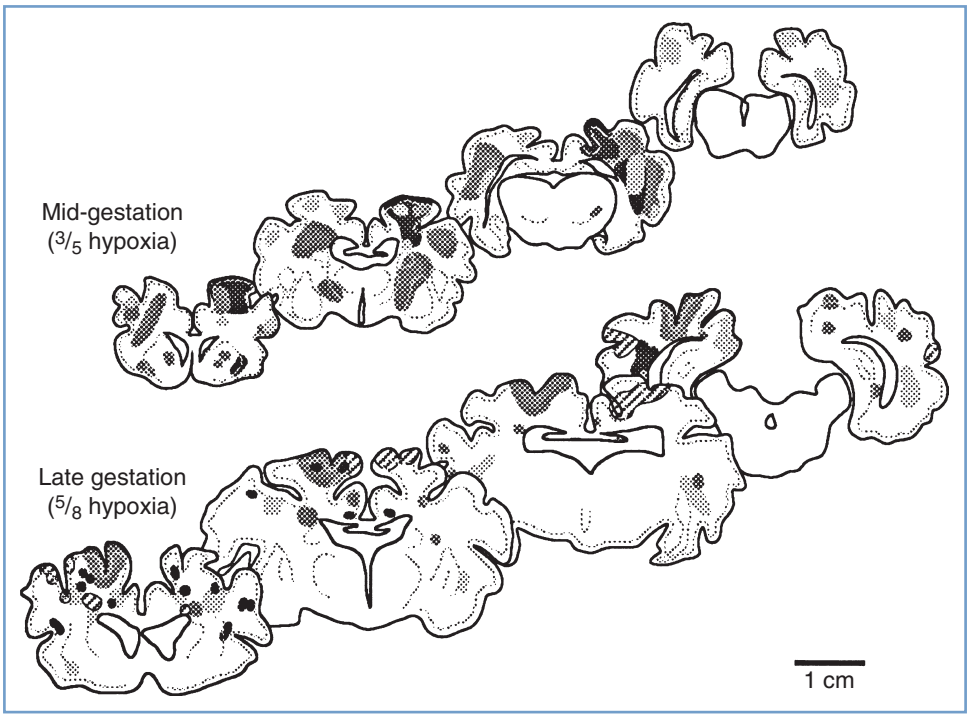

FIGURE 10-4 ■ Composite diagram showing distribution of hypoxic injury in mid-gestational (*top*) and near-term (*bottom*) fetal lambs at 3 days after 8 hours of arterial hypoxemia. Hypoxemia was produced by placing the pregnant ewe in a chamber with reduced ambient oxygen. Each shading pattern represents an individual animal. The severity of injury is not indicated in this diagram. (From Penning DH, Grafe MR, Hammond R, et al. Neuropathology of the near-term and midgestation ovine fetal brain after sustained in utero hypoxemia. Am J Obstet Gynecol 1994; 170:1425-32.)

basal ganglia damage. Although these two studies form the core of our knowledge of perinatal brain injury in primates, there were relatively few animals in each experimental group, and considerable variation in response occurred. Some animals suffered no injury, whereas others could not be resuscitated.

Several investigators have attempted to summarize the neuropathology of fetal and neonatal asphyxia.[128-130] Volpe[131] emphasized that the variation in neuropathology after intrauterine asphyxia depends on the fetal gestational age. Volpe also proposed a framework for these variations. The principal sites of injury in preterm fetuses are the white matter (especially periventricular white matter) and the basal ganglia, whereas older fetuses demonstrate injury primarily in the gray matter of the cortex and cerebellum.

Periventricular leukomalacia is the most common pathologic finding in preterm infants with brain injury.[131] This lesion is characterized by coagulative necrosis of the white matter adjacent to the lateral ventricles and around the foramen of Monro, especially at the external angle of the lateral ventricles and the optic radiation.[132] With long-term survival, the lesion may progress to a widening of the ventricles and hydrocephalus *ex vacuo*. Clinically, periventricular leukomalacia may not be apparent at birth.[129] Developing hydrocephalus may be detected on computed tomography or ultrasonographic examination. In more subtle cases, magnetic resonance imaging (MRI) may show decreased myelination (see later discussion).[133]

The pathophysiology of periventricular leukomalacia is unclear. Conventional wisdom has held that periventricular leukomalacia is an ischemic lesion unique to preterm infants.[134] The insult is thought to occur in an arterial border zone perfused by end-arterial branches of the middle and posterior cerebral arteries. This border zone has been identified by DeReuck,[134] who demonstrated periventricular arborizations between vessels penetrating to the ventricles (i.e., ventriculopedal vessels) and between vessels arising from the ventriculochoroidal arteries (i.e., ventriculofugal vessels). Others have challenged DeReuck's anatomic findings and have questioned whether periventricular leukomalacia is a purely ischemic lesion.[135,136]

White matter in the immature fetal brain may be at increased risk for hypoxic-ischemic injury because of a limited ability of its vessels to vasodilate.[131] If this were true, autoregulation would be precluded in situations of hypotension. However, at least one study has shown that blood flow to white matter actually may increase (relative to gray matter) during fetal asphyxia.[137] Fetal white matter may be more metabolically active than gray matter because of large numbers of actively myelinating cells.[131] In situations of marginal oxygen supply, glia are subsequently at greater risk for injury. One study has suggested that immature astrocytes are more susceptible to ischemic death than mature astrocytes.[138] Studies in fetal lambs have successfully produced pathologic changes similar to those present in infants with periventricular leukomalacia.[127] These models may help clarify the mechanism of this common pathologic correlate of cerebral palsy in the preterm infant.

BOX 10-4 Fetal Cerebral Responses to Asphyxia

Fetal Cerebral Metabolism

- Increased oxygen extraction
- Use of alternative energy sources
- Decreased growth
- Altered behavioral state

Fetal Cerebral O_2 Transport

- Redistribution of cerebral blood flow

From Penning DH. Fetal and neonatal neurologic injury. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia: Principles and Practice. 4th edition. Philadelphia, Mosby, 2009. Modified from Richardson B. The fetal brain: metabolic and circulatory responses to insufficient exchange of respiratory gases. Clin Invest Med 1993; 16:103-14.

Fetal Adaptive Responses

The fetus takes advantage of several adaptive responses for survival and growth in the relatively hypoxemic intrauterine environment; these adaptive changes to intrauterine hypoxemia vary between immature and mature fetuses. Fetal responses to asphyxia may be categorized as an alteration of fetal metabolism or maximization of fetal oxygen transport (Box 10-4).[124] Richardson[139] defined the *oxygen margin of safety* as the extent to which fractional oxygen extraction can increase and fetal arterial Po_2 can decrease before tissue oxygen supplies are inadequate. Regardless of the etiology of decreased oxygen delivery to the fetus, fetal oxygen consumption is maintained by increasing oxygen extraction until oxygen delivery is approximately 50% of normal.[140] Lower levels of tissue oxygen tension result in progressive metabolic acidemia and a terminal decrease in oxygen consumption.[139]

Alterations in substrate use may affect the fetal response to insufficient exchange of respiratory gases. Unlike the adult brain, the fetal brain can use ketone bodies and lactate as alternative energy sources.[141] In gravid ewes, a reduction in uterine blood flow results in reduced fetal glucose consumption.[141] Current opinion holds that hyperglycemia should be avoided in adult humans at risk for ischemia.[142] Hyperglycemia may exacerbate metabolic acidosis by providing substrate for anaerobic metabolism, which increases lactic acid production. However, Vannucci and Mujsce,[143] citing experiments in neonatal rat pups, suggested that the immature brain may respond differently and that glucose administration may actually reduce hypoxic-ischemic brain injury. These investigators did not consider earlier work by Blomstrand et al.,[144] who studied the effects of hypoxia in the anesthetized, exteriorized fetal lamb. In that study, hyperglycemia accelerated the loss of somatosensory evoked potentials, the onset of metabolic acidosis, and the reduction of cerebral oxygen consumption. Until these different observations are reconciled, the maintenance of normoglycemia *in utero* appears prudent.

During chronic hypoxemia, the fetus may also restrict the use of energy derived from oxidative metabolism to maintain essential cellular processes. This may lead to

decreased somatic growth and fetal growth restriction. Using an ovine model of asphyxia, Hooper[145] detected decreased incorporation of tritiated [^{3}H]-thymidine (which reflects decreased DNA turnover and, presumably, decreased cell division) in fetal tissue. The decrease in incorporation of tritiated [^{3}H]-thymidine was not uniform in all tissues. The rates of DNA synthesis were maintained in most fetal tissues (including the fetal brain) but were greatly reduced in the lung, the skeletal muscle, and the thymus gland.

The fetus can conserve additional energy by decreasing breathing and gross body movements. Rurak and Gruber[146] demonstrated a 17% reduction in oxygen consumption in fetal lambs that were paralyzed by a neuromuscular blocking agent. Perceptible fetal movements represent an index of fetal health. Many obstetricians instruct their patients to count episodes of fetal activity for specified periods and to consult them if fetal movements are decreased or absent (see Chapter 6). Fetal hypoxemia results in decreases in both activity and rapid eye movement (REM) sleep in fetal lambs. REM sleep states are associated with an increased cerebral metabolic rate for oxygen ($CMRo_2$).[113] Thus, during periods of fetal stress, reductions in fetal body movements or REM sleep lead to a significant decline in fetal energy expenditure.

Oxygen deprivation typically results in a change in and/or redistribution of fetal cardiac output.[147] The magnitude of these changes depends on the mechanism and severity of oxygen deprivation. Sheldon et al.[148] demonstrated that experimental fetal hypoxemia (produced by the administration of a decreased maternal-inspired concentration of oxygen) resulted in greater blood flow to the brain, myocardium, and adrenal glands. In fetal lambs, a brief (4-minute) complete arrest of uterine and ovarian blood flow resulted in a decrease in blood flow to all organs except the myocardium and adrenal glands.[149]

FETAL AND NEONATAL ASSESSMENT

Fetal Neurobehavioral Assessment

With recent advances in the understanding of prenatal brain development and imaging technology, there is considerable interest in monitoring and codifying fetal neurologic development and behavior to predict postnatal neurodevelopment.[150] The driving principle is that fetal behavioral patterns reflect complex interactions between the maternal environment and primitive neuronal network generators in the developing brain. There is an overwhelming convergence of opinion that most neurodevelopmental disorders have an intrauterine origin and that there is extensive neurobehavioral continuity from the fetal to the neonatal period.[151]

Although the assessment of high-risk pregnancies has included an analysis of certain aspects of fetal behavior, until recently there have been no unified scales for assessment of fetal neurobehavior. Current fetal neurobehavioral scales assess a variety of behaviors that can be categorized into the four main domains described by DiPietro[150]: (1) heart rate, (2) motor activity, (3) existing behavioral state, and (4) responsiveness to external stimuli. The Fetal Neurobehavioral Coding System (FENS) incorporates most elements of fetal behavior and is a direct extension of the NICU Network Neurobehavioral Scale (NNNS) used for neonatal assessment.[152] Using ultrasonography, FENS analysis can identify specific behaviors in fetuses with growth restriction; compared with normally developing fetuses, fetuses with growth restriction demonstrate a delayed appearance of behavioral states, longer behavioral state transitions, and disorganized behavioral patterns. These tests have been validated in other paradigms, including pregnancies that were complicated by maternal diabetes, substance abuse, and cigarette smoking.

A recently developed, more comprehensive scale is the Kurjak Antenatal Neurodevelopmental Test (KANET), which includes an assessment of eight fetal parameters related to fetal behavior, general movements, and other physical signs (e.g., head circumference, presence or absence of overlapping cranial sutures, finger movements).[153] However, these fetal assessment studies are time-consuming and require specific training to codify behaviors. In addition, because the brain structures driving such behaviors have not been clearly identified, it is difficult to understand the significance of differences in behavior, if any.

Fetal Neuroimaging Assessment

In vivo MRI provides details of the architecture of the developing brain beginning in the eighteenth gestational week and can quantify brain growth and structural abnormalities.[154] The use of more sophisticated techniques such as MR tractography and functional fetal MRI is likely to enhance our understanding of normal brain development and thus facilitate identification of abnormal development. Until controlled trials demonstrate adequate sensitivity, specificity, and positive predictive power for these tests, their clinical potential is limited. These potential advantages will need to be balanced against the potential detrimental effects of ultrasonography and MRI on fetal neuronal development and migration.[155]

Neonatal Radiologic Diagnosis of Cerebral Injury

MRI is a useful tool in the diagnosis of neonatal brain injury.[156,157] MRI can assist in the diagnosis of hypoxic ischemic encephalopathy in newborn infants,[158] provide three-dimensional evaluations to determine the volume of gray matter and the extent of white matter myelination (thus providing valuable insights into normal and abnormal brain development),[159] and estimate the timing of the brain injury in patients with cerebral palsy.[160] The presence of cerebral edema confirms recent-onset brain injury; edema develops 6 to 12 hours after injury and resolves within 4 days.[161] Unfortunately, the changes are subtle and the time frame of interest may extend before or after the intrapartum period. Nonetheless, the information can be quite helpful, and early imaging should be performed in cases of suspected brain injury. There is a

strong correlation between anatomic brain lesions detected on MRI and specific types of cerebral palsy.[161] MRI is particularly sensitive in the detection of periventricular leukomalacia, although many children with this MRI abnormality have clinically normal neurologic development.[162]

New imaging techniques, such as diffusion tensor imaging and magnetic resonance spectroscopy, may offer advantages over conventional MRI when performed early (i.e., hours) after a hypoxic-ischemic insult. Diffusion tensor imaging detects the microscopic movement of water particles in brain tissue. Magnetic resonance spectroscopy analyzes the signal of protons attached to molecules such as glutamate, glutamine, and lactate, among others.[163] These methods, developed in rabbit[164] and sheep[165] models of intrauterine hypoxia, detect acute chemical changes in brain tissue and may accurately predict motor outcome in preterm infants.[166] Injury patterns detected with these methods are present for several days and resolve over the next week, at which point the chronic injury becomes visible with conventional MRI. Identification of injuries shortly after birth with these newer techniques can support the hypothesis that an injury occurred within days of delivery.[163] Thus, magnetic resonance spectroscopy and diffusion tensor imaging are powerful new tools for timing the occurrence and understanding the pathophysiology of perinatal brain injury.[163] Cerebral ultrasonography remains a useful technique in the early neurologic neonatal assessment,[167] especially for the critically ill infant who might not be a candidate for transfer to an MRI facility.

ANESTHESIA AND BRAIN INJURY

Anesthetic agents have profound effects on brain metabolism and synaptic transmission. These effects may be direct or indirect and protective or harmful.

Labor Analgesia and the Fetal Brain

Labor analgesia usually entails administration of *lower concentrations* of analgesic/anesthetic agents for a *longer duration* than occurs during administration of anesthesia for surgical procedures. Despite widespread use of analgesic and sedative drugs during labor, little attention has been paid to the neurodevelopmental consequences of antepartum and intrapartum fetal exposure to these drugs. Because neurodevelopmental events at term are quite different from those that occur during the second trimester, there is a need to design experimental studies to investigate the effects of analgesic techniques and drugs administered during the third trimester of pregnancy.

Parenteral Opioids

Among systemic opioids used for labor analgesia, meperidine remains the most widely studied. Although it is well recognized that opioids cross the placenta and enter the fetal circulation,[168] the long-term effects of peripartum opioid exposure on the infant's neurodevelopmental trajectory are unclear. Only a few preclinical studies have addressed this question.[169,170] Endogenous opioid systems are active in the fetal brain, and the presence of their cognate receptors at critical sites during this period suggests that these systems are intricately linked to early neurodevelopment.[171-174] Preclinical evidence suggests that opioid mechanisms play an important role in both early and adult neurogenesis by modulating neuronal progenitor proliferation and differentiation.[175-177] Of concern, fetal rat exposure to morphine during the entire second trimester alters offspring hippocampal development.[178] However, animal studies of opioid abuse in pregnancy should not be extrapolated to peripartum opioid use in humans because of differences in the gestational age as well as differences in drug dose and duration of administration. Only focused studies will reveal the true consequences of intravenous opioid administration for labor analgesia at term gestation.

Neuraxial Techniques

Studies of neuraxial analgesia in labor usually focus on analgesic quality and obstetric and short-term neonatal outcomes. To date, no randomized trials have evaluated the long-term effects of neuraxial analgesia on brain development in offspring. Epidurally administered local anesthetics cross the placenta and enter the fetal circulation. Golub[179] randomized nonlaboring pregnant rhesus monkeys at term to receive epidural bupivacaine (total dose of 1.2 mg/kg) or saline.[179] No differences in specific cognitive deficits were identified between groups; however, exposed offspring demonstrated a prolonged increase in motor disturbance behaviors at 10 to 12 months of age, suggesting that perinatal interventions can alter postnatal behavioral ontogeny. In the only human evidence to date, investigators examined the association between the use of neuraxial labor analgesia and the incidence of childhood learning disabilities in a population-based birth cohort of children from Olmsted County, Minnesota.[180] The incidence of childhood learning disabilities was not associated with the use of neuraxial labor analgesia (adjusted hazard ratio, 1.05).[180]

Inhalational Agents

The use of inhalational anesthetic agents during labor and delivery became popular after the successful use of chloroform by John Snow during Queen Victoria's delivery of Prince Leopold in 1853. Other inhalational agents were subsequently introduced, including nitrous oxide, trichloroethylene, cyclopropane, and methoxyflurane. Although the use of halogenated agents has been supplanted by widespread adoption of neuraxial techniques for labor analgesia, nitrous oxide is still widely used in many countries. Typically it is administered as 50% nitrous oxide in oxygen using a blender device (e.g., Nitronox in the United States) or premixed in a single cylinder (e.g., Entonox in the United Kingdom) (see Chapter 22).

Scientific studies of the fetal and neonatal effects of inhalational analgesics are generally of limited quality.[181,182] Available evidence suggests that inhalational anesthetic

agents, including nitrous oxide, have minimal or no effect on Apgar and neurobehavioral adaptation scores immediately after delivery.[183,184] However, none of these studies has evaluated long-term neurodevelopmental outcomes. This knowledge gap is critical, because robust evidence suggests that early-life neural reprogramming, following pharmacologic and inflammatory insults, affects behavioral development later in life. Of concern is compelling animal evidence that anesthetic agents, when administered during a critical period of brain development, cause widespread neurodegeneration with subsequent learning, memory, and behavioral problems (see later discussion).[185,186] Nitrous oxide, in particular, is now known to be a potent developmental neurotoxin in animal models, yet its effects (if any) on human neurodevelopment are unclear.

Epidemiologic evidence from young children receiving anesthetic agents appears to support the possibility that anesthesia and surgery are associated with learning disabilities and attention deficit disorders later in life.[187] Thus, although the pattern of nitrous oxide administration during labor is unlike its administration for surgical anesthesia, the administration of nitrous oxide for labor analgesia merits closer scientific scrutiny.

Maternal Anesthesia and the Fetal Brain

Despite the popularity of neuraxial techniques in obstetric anesthesia, many pregnant women continue to require general anesthesia for either pregnancy-related or nonobstetric surgical procedures. The commonly used anesthetic agents freely cross the placenta and reach the fetal brain, causing fetal sleep or sedation. Obstetric anesthesia research has focused primarily on the teratogenic effects of anesthetic agents administered during the first trimester (see Chapter 17) and the effects of anesthetic agents on neonatal behavior when administered during cesarean delivery. Historically, the second trimester has been assumed to be a safe period for surgery and anesthesia, primarily because of a lack of targeted studies. However, during the past decade, extensive animal research has shown that anesthetic agents, when administered during the phase of synaptogenesis, can induce a profound neurodegenerative response in the developing brain and cause functional impairment in offspring.[185,188]

Human epidemiologic studies appear to support an association between early childhood exposure to anesthetic agents and subsequent functional impairment. However, it is unclear whether these adverse outcomes result from the underlying disease, surgery, or anesthesia or a combination of these factors.[187,189] A recent study found evidence that repeated anesthesia exposures or a cumulative anesthesia exposure time greater than 2 hours during early childhood was associated with a nearly twofold increase in the incidence of learning disabilities and attention deficit hyperactivity disorder.[189] Because human synaptogenesis appears to begin during the third trimester, there is now serious concern that intrauterine fetal exposure to these anesthetic agents may result in similar functional impairment. Because there is no precise way to monitor human fetal brain development *in utero*, the potential long-term effects of maternal anesthesia on the fetal brain must be investigated in animal models. However, given the considerable differences in neural maturation among species (Figure 10-5; see also Figure 10-3), and the duration of anesthesia exposure in relation to the lifespan of the organism, these results should be interpreted with caution.[190,191]

The exact mechanisms by which anesthetic agents impair early brain development are still under active investigation.[192] Anesthetic agent interactions with GABA and the NMDA-subtype of glutamate receptors decrease activity-dependent synapse formation and cause apoptotic neurodegeneration in multiple areas of the developing brain. These histopathologic changes have been well investigated, especially in the hippocampal formation, which is an area that is crucial for memory. Early exposure to anesthetic agents affects long-term potentiation in the hippocampus and affects spatial working memory in animal models.[185] These changes do not appear to be caused by direct cytotoxicity[193] but rather by a combination of effects on both neuronal and nonneuronal cells in the developing brain (Box 10-5).

Of specific concern are the effects of anesthetic agents on neurogenesis and synapse formation in the fetal brain. Human neural ontogeny suggests that the second trimester is a period of active fetal brain development, with neuroblast proliferation peaking between the 5th and 25th postmenstrual weeks. Because GABA and glutamate play a crucial role in these processes, there is concern that prolonged and nonphysiologic modulation of the fetal GABA and glutamatergic systems, as might occur during second-trimester maternal anesthesia, might affect neurogenesis, neuronal migration, and/or synapse formation.

In one of the first animal studies to simulate a clinically relevant scenario,[194] a single exposure to 1.4% isoflurane (1 MAC [minimum anesthetic concentration]) for 4 hours during the second trimester caused long-lasting impairment of spatial working memory in rodent offspring. Although the exact mechanisms behind these behavioral disturbances are unclear, other studies suggest that midgestational exposure to isoflurane up-regulates the proapoptotic protein caspase-12, decreases overall synapse numbers in the fetal hippocampus, and down-regulates the plasticity-associated protein GAP-43.[195,196] Similar results have been reported in pregnant guinea pigs and macaques, suggesting that the fetal brain remains highly susceptible to maternal mid-trimester anesthesia.[197,198] Furthermore, isoflurane suppresses neurogenesis in rodents both *in vitro* as well as *in vivo*,[199-201] causing a depletion of the neural stem cell pool. At least *in vitro*, this phenomenon appears to be dose dependent.[201] At the present time, the impact of reduced neurogenesis on behavioral deficits and the effect of anesthetic agents on neuronal migration remain unknown.

When these studies are extended to the third trimester, the results are mixed. In one rodent study, maternal administration of 1.3% isoflurane for 6 hours during the third trimester had no effect on offspring neurodevelopment.[202] However, these investigators performed another dose-response study in term rodents and found that maternal administration of 3% isoflurane, but not 1.3%

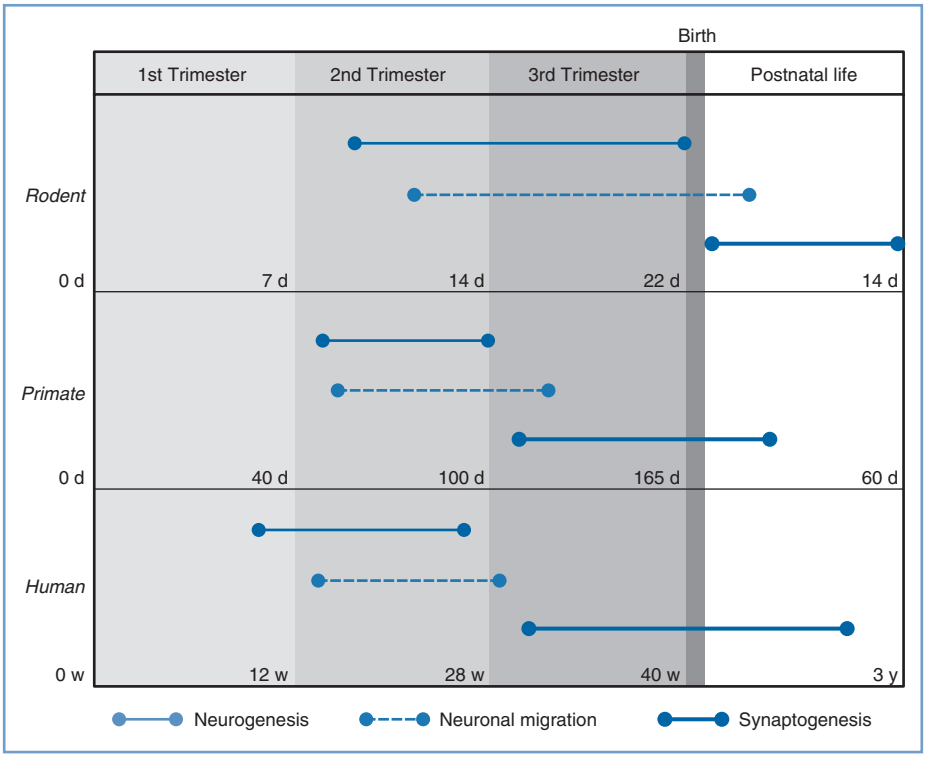

FIGURE 10-5 ■ Time lines of major neurodevelopmental events *in utero* in rodents, nonhuman primates, and humans. Events are as marked in the figure legend (*d,* days; *w,* weeks; *y,* years). Synaptogenesis is predominantly a postnatal event in rodents, unlike that in primates and humans. (From Palanisamy A. Maternal anesthesia and fetal neurodevelopment. Int J Obstet Anesth 2012; 21:152-62.)

BOX 10-5 Salient Features of Developmental Anesthetic Neurotoxicity

- Apoptotic neuronal death during synaptogenesis
- Suppression of neurogenesis
- Morphologically abnormal synapse formation
- Altered dendritic spinogenesis
- Impairment of hippocampal long-term potentiation
- Deformation of neuronal and astroglial cytoskeletal protein
- Aberrant cell cycle reentry during neuronal mitosis
- Neuronal mitochondrial dysfunction
- Abnormal intraneuronal calcium homeostasis

From Palanisamy A. Maternal anesthesia and fetal neurodevelopment. Int J Obstet Anesth 2012; 21:152-62.

isoflurane, for 1 hour caused fetal brain hippocampal neurodegeneration.[203] No neurodegenerative changes were observed after third-trimester exposure in guinea pigs.[197] Thus, collectively, it appears that the fetal brain is less vulnerable to the adverse effects of anesthetic agents during the third trimester. This phenomenon could be due to the stage of neurodevelopment, or more likely, to an increase in the levels of neuroprotective hormones such as estrogen, progesterone, neurosteroids, and oxytocin during the third trimester.

The relative fetal/neonatal safety of third-trimester maternal anesthesia was supported by a robust, population-based birth cohort study (in Olmsted County, Minnesota) that sought to determine the incidence of learning disabilities in children after maternal administration of general or neuraxial anesthesia during cesarean or vaginal delivery.[204] Children exposed to general anesthesia during cesarean delivery were not more likely to develop learning disabilities compared with those born vaginally with no exposure to general anesthesia. Although the study was retrospective and used data from 1976 to 1982, it is reassuring that even the children whose mothers required emergency general anesthesia (presumably secondary to presumed fetal compromise) did not have a higher incidence of learning disability. Further epidemiologic work is required to ascertain the effects of maternal anesthesia during nonobstetric surgery in the second trimester and that of nitrous oxide analgesia during labor.

Meanwhile, the potential for anesthesia-related neurotoxicity will undoubtedly undergo continued scrutiny. In a comprehensive editorial,[205] McGowan and Davis made the following conclusions: Additional animal studies are needed to define molecular mechanisms, risks, and potential treatments for anesthetic-related neurotoxicity in the developing brain; future studies should be relevant to human development and clinical practice; human studies of adequate statistical power are needed to identify any evidence of injury from intrauterine exposure to anesthetic agents; future studies should take advantage of advances in genomics and proteomics and should target the identification of sensitive and specific biomarkers for neurocognitive injury; some forms of developmental brain injury might be prevented or ameliorated by periprocedural therapy (e.g., anti-apoptotic agents such as melatonin).[205,206]

McGowan and Davis[205] affirmed the U.S. Food and Drug Administration's (FDA) conclusion[207] that currently, "there [is] no scientific basis to recommend changes in clinical [anesthesia] practice." They noted that the "real enemy" includes "known and understood causes of brain injury and death," such as hypoxia and cardiovascular collapse. They cautioned, "[W]e must not let our enthusiasm for understanding the possible neurocognitive risks of anesthetics … obscure our awareness of this enemy or prevent us from alleviating pain."[205] The FDA's position was reaffirmed in March 2011.[208]

Fetal Neuroprotection

Throughout gestation, the fetus remains concealed, protected, and nourished by a combination of maternal anatomic and physiologic factors. For example, the amniotic fluid cushions the fetus against trauma, and the placenta serves as a conduit to ensure a continuous supply of maternal nutrients to the developing fetus. Despite these inbuilt protective mechanisms, the fetus remains vulnerable to maternal insults such as infection and fever, drugs, and acute changes in placental physiology. Among all organ systems, the developing central nervous system appears to be most susceptible to such insults. Understanding the developmental aspects of neuroprotective mechanisms will therefore enable generation of targeted neuroprotective therapies.

Role of the Placenta

One of the fundamental neuroprotective mechanisms is the barrier function of the placenta. The placenta serves as a conduit for chemical communication between the mother and the developing fetus; endocrine signals, growth factors, and cytokines freely traverse the placenta, which dynamically adapts to chronic changes in the maternal-fetal environment to preserve fetal growth and viability.[209,210] However, this function also allows transplacental transfer of an array of pharmacologically active molecules either by passive diffusion or active transport.[211] By virtue of its enzymatic machinery, the placenta is capable of detoxification of some of these potentially harmful chemicals, making it the first line of defense against potentially harmful environmental agents.

Although passive diffusion along a concentration gradient is the most widely studied placental transport mechanism, recent studies have elucidated the roles of two important active transport molecules in the syncytiotrophoblast, which actively extrudes xenobiotics: phospho-glycoprotein (P-gp) and breast cancer resistance protein (BRCP).[212] The activity of these transporters varies with gestational age and certain pathophysiologic conditions (e.g., preeclampsia, intrauterine infection) and is influenced by the steroid hormones of pregnancy. Thus, it is possible that placental permeability to certain drugs could depend on a complex interplay of several factors. In addition to this barrier function, the human placenta secretes estrogen and progesterone in very high concentrations; these hormones, as well as others, eventually enter the fetal circulation, where they serve as substrates for *de novo* neurosteroid synthesis in the fetal brain.[213] In particular, allopregnanolone has been shown to exert neuroprotective effects in the fetal brain (see later discussion).[214]

Humoral Mechanisms

Published studies have extensively investigated the intricate and symbiotic relationship between the fetus and maternal hormones throughout pregnancy. Much of our understanding comes from elaborate murine and primate research models in which changes in maternal levels of hormones closely parallel changes in the fetal plasma and/or brain. Throughout pregnancy, there is a gradual rise in the levels of many maternal hormones such as progesterone, estradiol, and oxytocin.[215-217] At term or during labor the levels of these hormones are 40- to 100-fold higher than in the nonpregnant state.

Many of these hormones freely cross the placenta and are transported to the fetal brain, where they profoundly influence neurodevelopment. For example, estradiol and progesterone influence neural stem cell proliferation, modulate apoptosis and synaptogenesis in a region-specific manner, alter subcellular signaling mechanisms, and promote dendritic growth and spinogenesis through specific receptor mechanisms.[215,216] Estradiol, in particular, prevents cell death in both neuronal and non-neuronal cell lines.

Maternal plasma oxytocin levels gradually increase during pregnancy and reach a peak during the second stage of labor. Oxytocin is of particular importance because it has significant effects on GABAergic signaling in fetal neurons. In a series of elegant experiments, investigators showed that oxytocin transiently switched the action of GABA on immature rodent fetal neurons from *depolarizing* to *hyperpolarizing* at term gestation.[218] This finding raises the possibility that oxytocin protects the fetal brain during the stressful process of labor and delivery.[219]

NEUROPROTECTIVE THERAPIES

Magnesium Sulfate and Cerebral Palsy

Until recently there was considerable controversy regarding the role of magnesium sulfate in preventing or possibly exacerbating fetal brain injury. Although some controversy remains, the publication of several large randomized studies of the effect of antenatal maternal magnesium sulfate administration on offspring outcome has dramatically altered practice guidelines and clinical practice.[220-222] Although none of these studies demonstrated significant improvement in the primary outcome, all showed reduced cognitive morbidity and none showed any increase in pediatric morbidity or mortality associated with magnesium sulfate use for neuroprotection.

In a placebo-controlled trial of women who were thought likely to deliver within 24 hours and before 30 weeks' gestation in New Zealand and Australia, Crowther et al.[220] reported a lower incidence of substantial gross motor dysfunction (3.4% versus 6.6%; relative risk [RR], 0.51; 95% CI, 0.29 to 0.91) and combined death or substantial gross motor dysfunction (17% versus 22.7%; RR,

0.75; 95% CI, 0.59 to 0.96) in children whose mothers were randomized to receive antenatal magnesium sulfate treatment. In another large trial from France, which included women in preterm labor before 33 weeks' gestation, a significant reduction in death and/or gross motor dysfunction was again identified in the children whose mothers received magnesium sulfate (25.6% versus 30.8%; OR, 0.62; 95% CI, 0.41 to 0.99).[221] A reduction in death and/or motor or cognitive dysfunction (34.9% versus 40.5%; OR, 0.68; 95% CI, 0.47 to 0.99) was observed in the magnesium-exposed offspring at 2 years of age.[221] Finally, a randomized, controlled multicenter trial in the United States found that fetal exposure to magnesium sulfate within 24 hours of preterm delivery (between 24 and 32 completed weeks' gestational age) did not reduce the combined risk for moderate or severe cerebral palsy or death. However, fetal exposure to magnesium sulfate reduced the risk for moderate or severe cerebral palsy among survivors (1.9% versus 3.5%; RR, 0.55; 95% CI, 0.32 to 0.95) and was associated with a decreased overall rate of cerebral palsy (4.2% versus 7.3%; $P = .004$).[222]

Although the results are optimistic, it is difficult to compare these trials owing to differences in inclusion criteria, study interventions/dosages, and outcomes. Nonetheless, after the publications of these trials, it has been concluded from meta-analyses that fetal exposure to magnesium sulfate may reduce the risk for cerebral palsy without increasing the risk for neonatal death.[223,224]

In 2010, the ACOG and the SMFM released a joint committee opinion that supported antenatal maternal magnesium sulfate administration for fetal neuroprotection, stating that the available evidence suggests that magnesium sulfate administered before anticipated early preterm birth reduces the risk for cerebral palsy in surviving infants.[225] Physicians electing to use magnesium sulfate for fetal neuroprotection should develop specific guidelines regarding inclusion criteria, treatment regimens, concurrent tocolysis, and monitoring. The ACOG and the SMFM have concluded that it is reasonable to use a protocol based on one of the large randomized trials[220-222]; magnesium sulfate should be offered to women at high risk for anticipated preterm delivery (< 28 to 32 weeks' gestational age) within 24 hours.[220-222] A loading dose of magnesium sulfate 4 to 6 g should be administered, followed by a maintenance infusion of 1 to 2 g/h for 12 to 24 hours, at which point the risk for impending preterm delivery should be reassessed. If there is no longer a concern for impending delivery, the magnesium sulfate should be discontinued and restarted with active labor or when delivery is again thought to be imminent.

Hypothermia

Some investigators have described improved outcomes after the use of hypothermia in neonates at risk for hypoxic ischemic encephalopathy. One group of investigators has described an experimental model of severe intrauterine hypoxia in preterm fetal sheep, in which asphyxia was produced by 25 minutes of complete umbilical cord occlusion.[226] Cerebral hypothermia (fetal extradural temperature reduced from 39° to 29° C) decreased the loss of striatal neurons and oligodendroglia. This finding was associated with improved basal ganglia function after ischemia.

These and other experimental results prompted a randomized clinical trial of whole-body hypothermia for neonates with hypoxic ischemic encephalopathy.[227] Eligible neonates were older than 36 weeks' gestational age, had moderate or severe encephalopathy, and were admitted to the neonatal intensive care unit within 6 hours of birth. Body temperature was lowered to 33.5° C for 72 hours in neonates randomized to hypothermia treatment. Death or moderate to severe disability at 18 to 22 months of age occurred in 44% of 102 infants in the hypothermia group, compared with 62% of 106 infants in the control group (risk ratio, 0.72; 95% CI, 0.54 to 0.95; $P = .01$). Although encouraging, these results are at odds with those from another large multicenter randomized trial.[228] In an editorial attempting to reconcile these opposing results, several possible explanations were suggested.[229] Importantly, in the study that demonstrated no benefit, cooling began later and more time was required to achieve complete cooling, because head (not total body) cooling was employed.[228] Moreover, the study that showed no benefit with hypothermia may have included infants who were so severely affected that no therapy would have been beneficial.[228] This possibility highlights the importance of patient selection in these clinical trials.

In 2012, the whole-body hypothermia investigators published the results of follow-up evaluations of the original study subjects at 6 to 7 years of age. There was no difference in the combined primary outcome of death or an IQ score less than 70 (47% versus 62%, $P = .06$) between the hypothermia group and the control group.[230] The hypothermia group had a lower incidence of death or severe disability (41% versus 60%, $P = .03$), but there was no difference in moderate or severe disability (35% versus 38%, $P = .87$). Attention-executive dysfunction occurred in 4% of the hypothermia group versus 13% of the usual care group ($P = .19$), and visuospatial dysfunction occurred in 4% of the hypothermia group versus 3% of the usual care group ($P = .80$).[230] Thus, although there was no significant difference in the primary outcome, whole-body hypothermia decreased the incidence of death and did not increase the rate of a low IQ score or severe disability among survivors.

A 2013 meta-analysis of 11 randomized controlled trials of hypothermia therapy, which included 1505 term and late preterm infants, concluded that the benefits of cooling on survival and neurodevelopment outweigh the short-term adverse effects.[231] The authors advised that hypothermia should be instituted in term and late preterm infants with moderate-to-severe hypoxic ischemic encephalopathy if identified before 6 hours of age. Further trials are necessary to identify appropriate cooling techniques and to refine patient selection.

Experimental Neuroprotection

Perlman[232] has reviewed various strategies for treating hypoxic-ischemic neonatal injuries, including administration of inflammatory mediator modulators, excitatory amino acid receptor agonists and antagonists, free radical

scavengers, and platelet-activating factor antagonists. These emerging therapeutic strategies stem from basic neuroscience research on brain development and the pathophysiology of ischemic injury.

The role of white matter in the attenuation of hypoxic-ischemic brain damage (e.g., through uptake of excitatory amino acids or sequestration of potassium and hydrogen ions) is underappreciated,[233-235] and drugs that inhibit the release of excitatory amino acids or antagonize their receptors may be of benefit.[236] Multiple strategies may be necessary to inhibit the deleterious pathways initiated by brain ischemia and hypoxia.[237] The combination of oxygen free-radical scavengers and calcium entry–blocking agents appears to have some efficacy in limiting postasphyxial injury in neonatal sheep.[238] A "brain cocktail," consisting of free radical scavengers, modifiers of nitric oxide activity, metabolic inhibitors, calcium and iron chelators, and drugs that affect the excitatory amino acid systems, may someday be administered to fetuses and neonates at risk for brain injury. Additional compounds that may inhibit CNS necrosis or apoptosis, either *in utero* or in the neonatal period, include agents that interrupt the inflammatory cascade, progesterone, and other steroids.

Among the pharmacologic candidates for neuroprotection, **erythropoietin** (EPO) appears promising[239]; EPO is known to have wide-ranging actions, including anti-apoptotic and neurotrophic effects. In a preterm fetal sheep model, EPO was shown to reduce axonal damage and decrease the astrocytic and microglial response to maternally administered lipopolysaccharide (which leads to fetal brain damage).[239] In addition, EPO was also shown to confer protection against placental and fetal liver damage, suggesting that EPO could potentially buttress the placental barrier and prevent fetal injury. In the first human clinical study, EPO administration in full-term neonates was associated with an almost 50% reduction in death and disability at 18 months when the hypoxic-ischemic injury was moderate but not severe.[240] Although neonatal EPO therapy does not appear to increase the risk for thrombotic effects, the safety and efficacy of EPO administration to pregnant mothers, and its role in fetal neuroprotection, remains to be investigated.[240]

Another agent with potential for fetal neuroprotection is **melatonin**, a highly effective antioxidant with reliable transplacental transfer and a wide therapeutic index. Administration of melatonin to fetal sheep compromised by experimental umbilical cord occlusion prevents oxidative stress, reduces lipid peroxidation, modulates microglial activation, and decreases the extent of brain damage.[241] The translational potential of other agents such as *N*-acetylcysteine (NAC), allopurinol, neurosteroids such as allopregnanolone, anesthetic agents such as xenon, and creatine appears limited.

The ability to accurately predict which fetuses are at risk for neurologic injury, and when, is still rudimentary, because the most vulnerable periods of fetal development are still unknown, and noninvasive fetal surveillance techniques are not very advanced. The ability to identify these "at risk" infants *in utero* is a necessary step in designing effective therapeutic regimens that interfere minimally with the normal trophic activities of the developing brain.

KEY POINTS

- Cerebral palsy is a nonprogressive disorder of the central nervous system that is present (but rarely obvious) at birth and involves some impairment of motor function or posture. Intellectual disability may or may not be present.
- The term *birth asphyxia* should be used sparingly, if at all, in medical records. More descriptive terms that describe the neonate's tone, color, respiratory effort, and metabolic status should be used when possible.
- The incidence of cerebral palsy is approximately 2 per 1000 live births and has not decreased despite the widespread use of intrapartum fetal heart rate monitoring and a higher cesarean delivery rate.
- The Apgar score is a poor predictor of cerebral palsy.
- Preterm delivery is a risk factor for cerebral palsy
- Spastic quadriplegia and, less commonly, dyskinesia are the only types of cerebral palsy associated with acute intrapartum hypoxic events.
- Intrapartum hypoxia sufficient to cause cerebral palsy is always accompanied by neonatal encephalopathy and seizures.
- Fetal compensatory responses to hypoxemia *in utero* include (1) a redistribution of fetal cardiac output, with increased blood flow to the brain, myocardium, and adrenal glands; (2) decreased fetal energy consumption as a result of decreased fetal breathing and body movements; and (3) maintenance of essential cellular processes at the expense of intrauterine fetal growth.
- Chorioamnionitis is associated with an increased risk for cerebral palsy. Epidural analgesia during labor is associated with an elevated maternal temperature (but not chorioamnionitis). More accurate diagnosis of chorioamnionitis may prevent unnecessary evaluations for sepsis in neonates of mothers with a small rise in temperature during labor.
- No published data suggest that a given anesthetic drug or technique is more likely to protect fetal neurologic function (provided that the anesthetic technique is administered according to the recommended guidelines for good anesthesia practice).
- Better knowledge of the process and regulation of apoptosis (programmed neuronal cell death) may lead to the development of strategies to prevent irreversible fetal neurologic injury.

PART IV

FOUNDATIONS IN OBSTETRIC ANESTHESIA

Donald Caton, M.D.

As Simpson predicted, physicians used obstetric anesthesia sparingly until patients forced the issue. A major impetus came from early feminists. Suffragettes recognized that they could not participate fully in the economic and political life of the country unless they were healthy. For this reason they made obstetric care, including anesthesia, part of their campaign for political parity.

Early feminists had good reason to be concerned about obstetric care. Despite many improvements in medicine, maternal morbidity and mortality hardly changed between 1830 and 1930. Women were debilitated by the sequelae of poorly managed deliveries and exhausted by frequent pregnancies and management of large families. Accordingly, feminists sought care by obstetricians rather than by midwives, deliveries in hospitals rather than at home, and adequate time for recuperation before returning to their normal responsibilities. Other initiatives were construction of special maternity units, better instruction in obstetrics in medical schools, and training of more obstetricians.

They also campaigned for obstetric anesthesia. Feminists and physicians alike believed that the pain of childbirth, in and of itself, contributed to the disability of women later in life. To improve the quality and availability of anesthesia, feminists founded two organizations: The National Twilight Sleep Association began in the United States just before the beginning of World War I, and the National Birthday Trust Fund started in Great Britain in 1928.

Both organizations influenced the practice of obstetric anesthesia. Physicians explored new ways to manage the pain of childbirth, including the use of rectal ether and intravenous opioids. They also performed many important studies on the use of regional anesthesia.

For obstetricians, regional anesthesia had several advantages. First, it appeared to be safe and easy to administer, a feature that was especially important because qualified anesthesiologists were in short supply. Second, regional anesthesia allowed obstetricians to make more liberal use of operative techniques for vaginal delivery (e.g., episiotomy, use of forceps), which were just coming into vogue. No less important, regional anesthesia appeared to satisfy the desires of women who wanted more comfortable deliveries. These motives prompted the use of various regional blocks, including presacral, paravertebral, spinal, lumbar epidural, and caudal epidural anesthesia. In conjunction with this clinical work, scientists studied the anatomy and physiology of uterine function and childbirth pain, including the neurologic pathways involved in the perception of childbirth pain. Our current practices of obstetric anesthesia, particularly the emphasis on regional anesthesia, are a direct outgrowth of scientific studies and clinical trials that began during this period.[1-4]

CHAPTER 11

Patient Safety and Team Training

David J. Birnbach, MD, MPH • Eduardo Salas, PhD

CHAPTER OUTLINE

In 2000, the publication of the Institute of Medicine (IOM) report *To Err is Human: Building a Safer Health Care System* was a seminal event for the health care system in the United States.[1] Prior to the publication of this report, many physicians and hospital administrators refused to acknowledge the frequent occurrence of preventable morbidity and the reality that our health care system was not adequately addressing the issue of patient safety. Subsequently, we have learned that tens of thousands of patients die each year as a result of medical errors. In the past decade, numerous changes have been advocated, including mandating minimum nurse-to-patient ratios,[2] reducing working hours of resident physicians,[3] and advancing the science of simulation training and teamwork, particularly in the medical environment.[4,5] Data from high-risk organizations suggest that health care errors do not usually occur because of ill-trained medical personnel but rather are due to systems that "set up" both the patient and the health care provider. As Pratt[6] eloquently stated in a 2012 review of simulation in obstetric anesthesia, "Historically, medicine was simple, largely ineffective, and mostly safe (excluding perhaps trephination and bloodletting). Modern medicine is complex, highly effective, but dangerous." The field of patient safety attempts to reduce that danger, which is very real in the fields of obstetrics and obstetric anesthesiology. Each year in the United States, approximately 600 women die of pregnancy-related causes; 68,000 experience severe obstetric morbidity; and 1.7 million experience delivery-related complications.[7] In this chapter, medical errors are reviewed and several modalities that can be used by labor and delivery unit personnel to reduce both the incidence and sequelae of these errors are highlighted.

PATIENT SAFETY AND MEDICAL ERRORS

Traditional assessments of medical error often blamed individuals and have failed to address the broader systems issues that allowed the error to occur. Newer approaches are based on an understanding that humans will make errors and therefore encourage creation of robust systems to prevent these errors from occurring or to minimize their impact on patients if they occur. This paradigm change has borrowed heavily from other high-risk arenas, such as the aviation and the nuclear industries.

The Swiss Cheese Model

Patients are typically not injured by a single event resulting from a single act of a careless individual. More often an underlying systems problem made the error possible, and numerous individual actions "fall through the cracks" of a system that does not catch them, resulting in error and harm. James Reason described the "Swiss cheese" model of error (Figure 11-1), in which he explained how numerous contributing factors are responsible for the ultimate harm.[8] Reason developed this model to illustrate how analyses of major accidents and catastrophic systems failures tend to reveal multiple, smaller failures that led up to the actual adverse event. In the model, each slice of cheese represents a safety barrier or precaution relevant to a particular hazard. For example, if the hazard were wrong-site surgery, slices of the cheese might include processes for identifying the right or left side on radiology tests, a protocol for signing the correct site when the surgeon and patient first meet, and a second

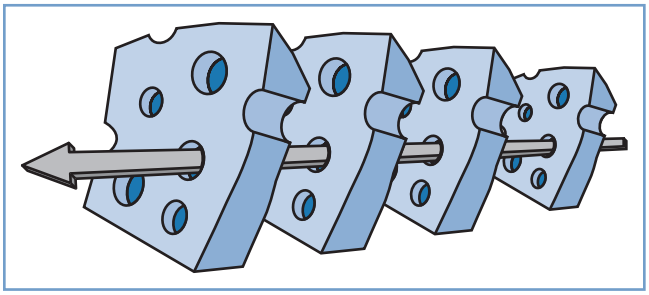

FIGURE 11-1 ■ Swiss cheese model of organizational accidents. (From Reason JT. Human Error. Cambridge, UK, Cambridge University Press, 1990.)

protocol for reviewing the medical record and checking the previously marked site in the operating room. Each barrier has "holes"; hence, the term *Swiss cheese*. For some serious events (e.g., operating on the wrong person) the holes will rarely align; however, even rare cases of harm are unacceptable. Reason's model highlights the need to think of safety as a system—a set of organizational and cultural layers that influence and shape one another. Reason has eloquently summarized the process, stating "rather than being the main instigators of an accident, operators tend to be the inheritors of system defects created by poor design, incorrect installation, faulty maintenance, and bad management decisions. Their part is usually that of adding the final garnish to a lethal brew whose ingredients have already been long in the cooking."[9]

Figure 11-2 illustrates the use of the Swiss cheese model to evaluate a real near-miss case involving the misidentification of an obstetric patient who nearly underwent the wrong procedure (an unwanted tubal ligation). It describes how the combination of numerous system errors came very close to allowing the wrong procedure to be performed. The events unfolded as follows:

1. A nulliparous woman in active labor at term arrived on the labor and delivery unit in severe pain. She spoke a foreign language and was poorly understood by the labor and delivery staff. No translator was called because her husband was helping with the translation.
2. Because the patient was in such severe pain, she rushed to answer all the questions and answered several incorrectly. As per hospital policy (due to HIPAA [Health Insurance Portability and Accountability Act of 1996] regulations), the husband was asked to leave the room while the history was being taken and was therefore not present to assist in the translation.
3. There was another patient on the labor and delivery unit with the same last name and a similar sounding first name. The hospital protocol for this occurrence was not followed. Patient initials, not last names, were listed on the labor and delivery "board," so that other staff were unaware of the identical patient names.
4. The patient developed a nonreassuring fetal heart rate (FHR) tracing and was scheduled for urgent cesarean delivery. The obstetric resident physician informed the anesthesiologist of this decision and, mistaking the two patients with identical names, booked the case for a cesarean delivery *plus* bilateral tubal ligation. Unlike the other patient with the same name, the patient going to the operating room did not want or expect a tubal ligation.
5. The case was delayed because of a shift change, and the obstetricians urged the nurses to hurry. This caused friction between the nurses and obstetricians, and they did not work as a team. There were no "board rounds," and communication between labor and delivery staff and operating room staff was suboptimal.
6. The patient arrived in the operating room and was very anxious and crying. The anesthesiologist administered fentanyl 50 μg to calm the patient and she became very sedated.
7. A "time-out" was performed, but it was not taken seriously. The patient was asleep and did not participate. The attending obstetrician was not present. Conversations continued during the time-out.
8. Following the flawed time-out, it was agreed that this patient was to undergo a primary cesarean delivery and tubal ligation. Her husband was not present during the time-out but was brought to the room immediately after this activity. The surgical procedure began.
9. The attending obstetrician arrived after the start of the procedure and questioned the planned tubal ligation, not because he knew about the second patient but because he was informed that this patient was nulliparous. Immediate investigation revealed that the patient was not supposed to receive a tubal ligation. A major error was narrowly averted.

As in many such situations, a conglomeration of many missteps resulted in the potential for patient harm.

Medical Errors

Today there is widespread interest in changing the health care culture to build safer systems, including ensuring the appropriate physical work environment, developing redundancies in safety procedures, allowing health care workers to report their mistakes (including near misses) without fear of punishment, and providing mechanisms to learn from the experiences. None of these systems will achieve the ultimate goal of patient safety without the support of physicians as well as hospital administrators. In addition, although vital to improving the current condition, these steps do not obviate the need for well-trained and well-rested physicians and nurses. The American College of Obstetricians and Gynecologists (ACOG) Committee Opinion on Patient Safety in the Surgical Environment summarizes this well when it states: "Common sense dictates that the surgeon and the surgical team should be alert and well rested when initiating major surgical procedures."[10] The opinion also suggests that "adequate backup personnel should be available to relieve individuals who detect diminished performance in themselves or others due to fatigue, so that the risk for error is not increased."[10] Although the Accreditation Council on Graduate Medical Education has enacted restrictions on resident physician work hours to prevent

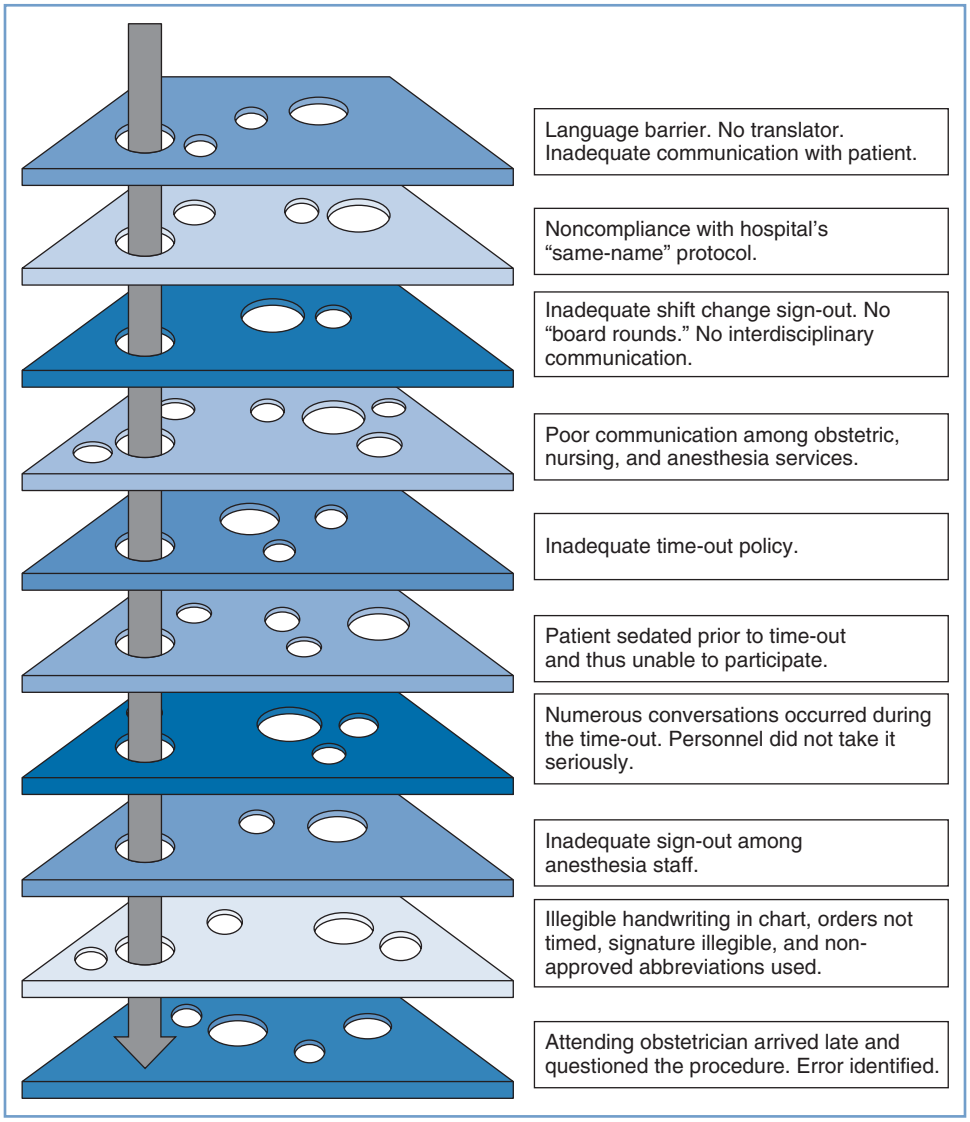

FIGURE 11-2 ■ "Swiss cheese" diagram of near-miss event illustrating how numerous layers/barriers to harm were breached and how these events almost resulted in permanent harm (permanent sterility) to the patient. See text for explanation.

sleep deprivation, there are no such limits on attending physician work hours. Rothschild et al.[11] found that the risk for surgical complications was increased if attending physicians had slept less than 6 hours the night before the procedure.

Another ACOG committee opinion[12] stated that promoting safety requires that all those in the health care environment recognize that the potential for errors exists and that women's health care should be delivered in an environment that encourages disclosure and exchange of information in the event of errors, near misses, and adverse outcomes. The ACOG[12] has recommended the following seven safety objectives:

1. Develop a commitment to encourage a culture of patient safety.
2. Implement recommended safe medication practices.
3. Reduce the likelihood of surgical errors.
4. Improve communication with health care providers.
5. Improve communication with patients.
6. Establish a partnership with patients to improve safety.
7. Make safety a priority in every aspect of practice.

The IOM has defined **medical error** as a "failure of a planned action to be completed as intended, or the use of a wrong plan to achieve an aim." Communication problems are consistently identified as a leading cause of medical errors in obstetrics,[13] and the Joint Commission has found that although the majority of these events have multiple root causes, lack of effective communication along with leadership and human factors are often the primary causes of sentinel events.[14] Several of the 2012 Joint Commission National Patient Safety Goals relate to error reduction on the labor and delivery unit (Box 11-1).[15] Departments of anesthesiology and obstetrics and gynecology should regularly review the national patient safety goals established by the Joint Commission. Hospitals are regularly surveyed to verify their compliance with these goals.

BOX 11-1 Key Joint Commission National Patient Safety Goals: 2012

- Identify patients correctly (NPSG.01.01.01).
  - Use at least two patient identifiers when providing care.
- Improve staff communication. Report critical results of tests and diagnostic procedures on a timely basis (NPSG.02.03.01).
  - Get important test results to the right staff person on time.
- Label all medications, medication containers, and other solutions on and off the sterile field in perioperative and other procedural settings (NPSG.03.04.01).
  - Before a procedure, label all medications.
- Maintain and communicate accurate patient medication information (NPSG.03.06.01).
  - Obtain information on the medications the patient is currently taking when he or she is admitted.
  - Compare the medication information the patient brought to the hospital with the medications ordered for the patient by the hospital to identify and resolve discrepancies.
- Implement evidence-based practices for preventing surgical site infections (NPSG 07.01.01).
  - Use hand cleaning guidelines from the Centers for Disease Control and Prevention or the World Health Organization. Set goals for improving hand cleaning. Use the goals to improve hand cleaning.
- Prevent mistakes in surgery (UP.01.01).
  - Make sure that the correct surgery is done on the correct patient and at the correct place on the patient's body.
  - Pause before the surgery to make sure that a mistake is not being made.

NPSG, National Patient Safety Goal; *UP*, Universal Protocol.
Summarized from the Joint Commission 2012 National Patient Safety Goals. Available at http://www.jointcommission.org/standards_information/npsgs.aspx. Accessed November 2012.

Although those working in health care have made great efforts to reduce preventable patient harm,[16] the progress has not been as dramatic as necessary. Leape and Berwick, two "fathers" of the field of patient safety, suggested that the lack of progress following the release of the initial IOM report is due to the "culture of medicine."[17] They believe that this culture is deeply rooted, both by custom and training, in autonomous individual performance. It remains possible that systematic and appropriate use of medical simulation, along with other important changes to our systems, will facilitate the necessary cultural changes and lead to improved patient safety. Labor and delivery units are no different than other medical care environments, and most still have many opportunities to change culture and practice to optimize patient safety. Nabhan and Ahmed-Tawfik[18] suggested that the concept of patient safety in obstetrics is "not as strong as desirable for the provision of reliable health care." In many units a punitive culture still exists and results in suppression of error reporting, lack of proper communication, and failure of appropriate feedback.[18] Obviously, this culture needs to change before we can significantly improve patient safety. Pronovost and Freishlag[19] eloquently described the operating room environment when they stated that "operating rooms are among the most complex political, social, and cultural structures that exist, full of ritual, drama, hierarchy, and too often conflict." These authors concluded that poor teamwork contributes prominently to most adverse events, including those in the operating room.[19]

TEAMS AND TEAMWORK

Health care should be considered a team activity. Teams take care of patients. Furthermore, health care teams operate in an environment characterized by acute stress, heavy workload, and high stakes for decision and action errors.[20] Individuals have limited capabilities; when their limitations are combined with organizational and environmental complexity, human error is virtually inevitable.[21] The labor and delivery unit is an exceedingly complex environment. In fact, the labor and delivery unit requires intense, error-free vigilance with effective communication and teamwork among various clinical disciplines who, although working together, have probably never trained together. This group includes obstetricians, midwives, nurses, anesthesiologists and nurse anesthetists, and pediatricians. The addition of trainees at all levels and in all disciplines enhances the potential for communication error. Siassakos et al.[22] suggested that one of the most important components of effective training in obstetrics includes multiprofessional training and integration of teamwork training with clinical teaching.

A **team** consists of two or more individuals who have specific roles, perform independent tasks, are adaptable, and share common goals. Salas et al.[23] have defined **teamwork** as a complex yet elegant phenomenon. It can be defined as a "set of interrelated behaviors, actions, cognitions, and attitudes that facilitate the required task work that must be completed."[23] Lack of teamwork has been identified as a leading cause of adverse events in medicine. Team behavior and coordination, particularly communication or team information sharing, are critical for optimizing team performance.[24] Baker et al.[25] stated that to work together effectively, team members must possess specific knowledge, skills, and attitudes (KSAs), including skill in monitoring each other's performance, knowledge of their own and their teammates' task responsibilities, and a positive disposition toward working in a team. These authors have described characteristics of effective teams, which include team leadership, mutual performance monitoring, backup behavior, adaptability, shared mental models, communication, team/collective orientation, and mutual trust. Moreover, effective team performance in complex environments requires that team members hold a shared understanding of the task, their equipment, and their teammates (Table 11-1).[26,27]

Teamwork is essential for safe patient care. The IOM suggested that team training and implementation of team behaviors may improve patient safety.[28] The Joint Commission has recommended a risk-reduction strategy for decreasing perinatal death or injury. This strategy includes the implementation of team training and mock

TABLE 11-1 **Characteristics of Effective Teams**

Knowledge/Skills/ Attitudes	Characteristics of the Team
Leadership	Roles are clear but not overly rigid. Team members believe leaders care about them.
Backup behavior	Members compensate for each other. Members provide feedback to each other.
Mutual performance monitoring	Members understand each other's roles.
Communication adaptability	Members communicate often and anticipate each other.
Mutual trust	Members trust each other's intentions.

emergency drills for shoulder dystocia, emergency cesarean delivery, and maternal hemorrhage.[29]

Team training promotes the acquisition of adaptive behaviors, shared cognitions, and relevant attitudes. It is an instructional strategy that ideally combines practice-based delivery methods with realistic events, guided by medical teamwork competencies (i.e., behaviors, cognitions, and/or attitudes). Murray and Enarson[30] stated that "when a crisis complicates patient care, teamwork among health care professionals is frequently strained, resulting in more frequent as well as more serious failures in managing critical events." This scenario occurs all too often on the labor and delivery unit.

After many years of uncertainty, there is now encouraging evidence that team training improves safety of clinical outcomes, especially in the operating room[31,32] and labor and delivery suite. Neily et al.[32] reported that surgical mortality decreased by 18% at 74 United States Veterans Health Administration hospitals that implemented a team training program, compared with a 7% mortality reduction in 34 control hospitals that did not implement such a program. Nielson et al.[33] reported that team training effectively reduced the decision-to-delivery time for emergency cesarean delivery. Similarly, after mandatory interdisciplinary team training for all labor and delivery staff in a unit in the United Kingdom, the median decision-to-delivery interval for a prolapsed umbilical cord decreased from 25 to 15 minutes. After initiation of team training in a community hospital, Shea-Lewis et al.[34] reported a reduction in the adverse outcome index (AOI: a composite maternal and neonatal adverse outcome index[35]) from 7% to 4%.

Team Leadership

There is a clear difference between the *leadership of individuals* and *team leadership*. One who is leading independent individuals will diagnose a problem, generate possible solutions, and implement the most appropriate solution. In contrast, team leadership does not involve handing down solutions to team members but rather consists of defining team goals, setting expectations, coordinating activities, organizing team resources, and guiding the team toward its goals.[36]

Team leaders can improve team performance in many ways (e.g., by promoting coordination and cooperation). These individuals not only must be technically competent but also must be competent in leadership skills.[20] Anesthesia providers and other physicians do not routinely train to be competent team leaders. Many of the tasks necessary can and must be learned during team training. Simulation may play a key role in this education. Team leadership training has been developed to successfully train specific team leader behaviors, and the implementation of these programs has been shown to improve team performance.[23] Hackman[37] described successful team performance as consisting of three primary elements:

1. Successful accomplishment of the team's goals
2. Satisfaction of team members with the team and commitment to the team's goals
3. The ability of the team to improve different facets of team effectiveness over time

High-Reliability Organizations and Teams

Despite the inevitability of human error, some organizations that operate in complex environments are able to maintain an exceptionally safe workplace. These organizations, including the aviation and nuclear power industries, have been termed *high-reliability organizations* (HROs). These organizations can also be hospitals and other health care organizations. Sundar et al.[38] defined HROs as institutions where individuals, working together in high-acuity situations facing great potential for error and disastrous consequences, consistently deliver care with positive results and minimal errors. Teams that exhibit behaviors that facilitate the characteristics and values held by the HRO may be defined as *high-reliability teams* (HRTs). Wilson et al.[21] have defined five guidelines for HRTs. These teams must:

1. Use closed-loop communication and other forms of information exchange to promote shared situational awareness regarding factors internal and external to the team.
2. Develop shared mental models that allow team members to monitor other members' performance and offer backup assistance when needed.
3. Demonstrate a collective organization that allows members to be assertive, to take advantage of functional expertise, and to seek and value input from other team members.
4. Seek to recognize complexities of their task environment and accordingly develop plans that are adequate and promote flexibility.
5. Use semi-structured feedback mechanisms such as team self-correction to manage, and quickly learn from, errors.

Hunt et al.[39] defined characteristics associated with high-performing teams, including situational awareness,

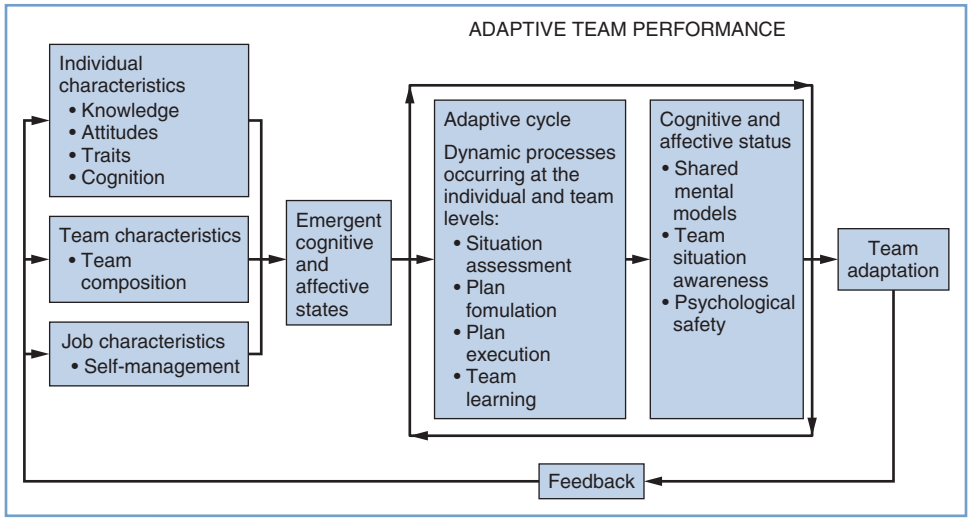

FIGURE 11-3 ■ **Adaptive team performance.** (Modified from Salas E, Rosen MA, Burke CS, et al. The making of a dream team: when expert teams do best. In Ericsson KA, Charness N, Hoffman RR, Feltovich RJ, editors. The Cambridge Handbook of Expertise and Expert Performance. Cambridge, UK, Cambridge University Press 2006:439-456.)

leadership, followership, closed-loop communication, critical language, standardized practice, assertive communication, adaptive behaviors, and workload management. An adaptive team performance framework that illustrates the relationship between variables, emergent states, and the multiple phases of the team adaptation cycle has been described by Salas et al.[40] (Figure 11-3).

Cultural factors may play a large role in team performance. According to Salas et al.,[27] these factors include attitudes (especially as they relate to previous experiences with teams) and motivation. Although it has been suggested that an individual team member's personality may be counterbalanced by others, Janis[41] suggested that openness, conscientiousness, and neuroticism are essential for individuals to succeed in command positions.

Thomas et al.[42] conducted a qualitative assessment of teamwork and suggested that factors that influence the ability to work together could be divided into three categories: provider characteristics (personal attributes, reputation, expertise), workplace factors (staffing, work organization, work environment), and group influences (communication, relationships, and teamwork). These categories can be addressed, at least in part, by working together in teams in a simulated environment and evaluating teamwork and human performance. Lyndon[43] suggested that the application of human performance-based theory has demonstrated that "communication patterns, team function, workload, and coping mechanisms affect both individual and group ability to identify evolving problems and make appropriate management decisions in complex decision-making situations."[43]

Team Training

Patient safety is "predicated on trust, open communication, and effective interdisciplinary teamwork."[44] It is often the *interactions* among health care workers that determine whether a specific plan of care is effective or ineffective.[45] However, in the current environment medical students, residents, attending physicians, nursing students, nurses, and midwives rarely learn or train to work as teams.

The Liaison Committee on Medical Education (LCME), which is jointly composed of members of the American Medical Association and the Association of American Medical Colleges, has affirmed the importance of teaching communications skills and teamwork. For example, LCME standard ED19 states that "there must be specific instruction in communication skills as they relate to professional responsibilities, including communication with patients, families, colleagues, and other health professionals."[46] Teamwork needs to be not only taught but also monitored. Box 11-2 summarizes best practices in team performance measurement for simulation-based training.

Why is teamwork training important for labor and delivery unit personnel? As previously noted, communication problems are consistently identified as a leading cause of medical error, and these problems can be addressed during team training. The 2000-2002 Confidential Enquiries into Maternal Deaths in the United Kingdom emphasized that "emergency drills for maternal resuscitation should be regularly practiced in clinical areas in all maternity units."[47] That report listed six direct maternal deaths plus one late maternal death due to anesthesia. Esophageal intubation was the cause of three maternal deaths. Each of these cases involved a trainee without immediate senior backup; and in two cases, capnography was not used, which was in direct violation of mandatory monitoring requirements. In an accompanying editorial, Ngan Kee[48] stated, "This should give pause for thought to all involved with *training* in obstetric anesthesia" [italics added].[48] These reports remind us not only of the need for appropriate supervision of trainees but also of the need to use simulation-based training for learning and practicing both crisis management and important techniques and procedures that are not frequently encountered in clinical practice. Emergency

BOX 11-2 Summary of Best Practices in Team Performance Measurement

- Ground measures in theory:
  - Use theory to determine what variables to measure.
  - Capture aspects of Input → Process → Output models of team performance.
- Design measures to meet specific learning outcomes.
- Clearly articulate the purpose of measurement.
- Design the measurement system to capture information necessary for making decisions about the learning outcomes.
- Capture competencies.
- Measure multiple levels of performance.
- Link measures to scenario events.
- Focus on observable behaviors.
- Incorporate multiple measures from different sources.
- Capture performance processes in addition to outcomes:
  - Obtain information not only about the end result but also about how the team reached that performance outcome.
- Train observers and structure observation protocols.
- Facilitate post-training debriefing and training remediation.

administration of general anesthesia for the parturient is such an event.

Simulation-Based Training in Obstetrics

Traditional medical and nursing education has relied on the treatment of real patients in actual clinical settings. Many educators now believe that the current availability of medical simulations and the knowledge gained from the science of team training may improve patient outcomes. Most medical and nursing schools have purchased simulators and are using them in undergraduate and graduate education.

Obstetricians have identified the importance of preparing for clinical emergencies and have reiterated that conducting emergency drills may reduce or prevent the severity of medical emergencies.[49] In addition, simulation may impact patient safety because it offers opportunities to discover latent conditions and performance gaps that could adversely affect patient care.[50,51] During 46 *in situ* simulations of obstetric emergencies, Riley et al.[52] identified 965 breaches of defensive barriers (a system element that serves to prevent system errors from causing injury), of which 47.8% were classified as latent conditions (existing conditions that may interact with ongoing activities to precipitate error). The authors suggested that simulation helps providers recognize and remedy both active failures and latent conditions before they combine to cause bad outcomes.[52]

Research in simulation-based team training has shown that when trainees have an opportunity to practice relevant competencies in a structured scenario and receive diagnostic feedback on their individual and collective performance, simulation performance improves. This clearly indicates the importance of guided practice (by scenario events) and measurement.

Many authors have suggested that drills are useful on the labor and delivery unit.[53-56] Sorenson[54] stated that "mock emergency training is an opportunity for staff to learn to identify risk factors and prepare for interventions in the event of an obstetric emergency." Gardner and Raemer[55] suggested that simulation is a practical and safe approach to the acquisition and maintenance of task-oriented and behavioral skills across the spectrum of medical specialties. In the realm of obstetric anesthesia practice, investigators have demonstrated that simulation may be a useful tool for assessment of performance in a simulated emergency situation (e.g., failed intubation in an obstetric patient) when combined with practice and formal teaching.[56]

Training in perinatal emergencies with high-fidelity simulation improved the speed with which anesthesia providers responded to these emergencies and improved the quality of their care.[57] Lipman et al.[58] demonstrated, in a dramatic fashion, the use of simulation-based assessment to evaluate optimal performance of cardiopulmonary resuscitation during simulated maternal cardiac arrest. The authors demonstrated numerous deficiencies in the performance of key advanced cardiac life support (ACLS) tasks that are critical to resuscitation of a pregnant woman. These tasks included the ability to correctly deliver chest compressions (56% correct), ensure left uterine displacement (44% correct), switching chest compressors every 2 minutes (33% correct), and appropriate defibrillation (6% correct).[58] Box 11-3 outlines the advantages of simulation for research, training, and performance assessment.

When an adverse perinatal outcome associated with an error occurs, it is likely that more than one individual will be involved and blamed.[59] Similarly, when an unexpected injury occurs to a mother or infant, several providers are typically involved, and often there is a problem with the "system" that allowed the error to occur. Obstetricians, anesthesia providers, pediatricians, labor nurses, midwives, and operating room staff all work together as part of this system. Therefore, optimal simulation exercises involve all these key players and evaluate not only their behaviors and communication skills but also problems within the system in which they work. Simulation of reality-based scenarios in the labor and delivery unit or operating room allows anesthesia providers, obstetricians, midwives, nurses, and pediatricians to practice their roles and communication skills. Hunt et al.[39] suggested that medical teams require practiced interaction and communication to be effective and efficient.

Simulation of perinatal events range from high-fidelity human simulators (typically located off site) to low-technology simulations and drills that can be performed on the labor and delivery unit.[31] Simulated scenarios (guided by desired learning outcomes) can be designed to train nurses, obstetric and anesthesia resident physicians, and midwives individually or as teams. However, simulation should not be reserved for individuals in training; attending physicians may also benefit from participation. Simulated events commonly include maternal

BOX 11-3 Advantages of Simulation for Research, Training, and Performance Assessment

- No risk to patients.
- Many scenarios can be presented, including uncommon but critical situations in which a rapid response is needed.
- Participants can see the results of their decisions and actions; errors can be allowed to occur and reach their conclusion (in real life a more capable clinician would be obligated to intervene).
- Identical scenarios can be presented to different clinicians or teams.
- The underlying causes of the situation are known.
- With mannequin-based simulators, clinicians can use actual medical equipment, exposing limitations in the human–machine interface.
- With full re-creations of actual clinical environments, complete interpersonal interactions with other clinical staff can be explored and teamwork, leadership, and communication training can be provided.
- Intensive and intrusive recording of the simulation session is feasible, including audiotaping, videotaping, and even physiologic monitoring of participants. There are no issues of patient confidentiality; the recordings can be preserved for research, performance assessment, or accreditation.

Modified from Gaba DM. Anesthesiology as a model for patient safety in health care. BMJ 2000; 320:785-8.

hemorrhage (antepartum as well as postpartum), failed intubation, failed neuraxial blockade, seizures, cardiac arrest, anaphylaxis, umbilical cord prolapse, and shoulder dystocia. Thomson et al.[60] reported that drills to practice management of eclampsia were successful in the identification of deficiencies in team preparation. They concluded[60]:

> *Repetition of drills in our unit has improved the care of simulated patients with eclampsia. In subsequent drills patient management has followed evidence-based practice, with an enhanced level of efficiency. Staff [are] summoned faster, the resuscitation process is better organized, and drugs are prepared and administered more quickly.*

Similarly, another group reported significant improvement in participants' knowledge after multidisciplinary obstetric training.[61]

Maslovitz et al.[51] used simulation to identify five recurrent obstetric management mistakes:

1. Delay in transporting a bleeding patient to the operating room
2. Unfamiliarity with prostaglandin administration to treat uterine atony
3. Poor cardiopulmonary resuscitation techniques
4. Inadequate documentation of shoulder dystocia (important for the legal defense of these cases)
5. Delayed administration of blood products to reverse disseminated intravascular coagulation

BOX 11-4 Drills Advocated for Use by Labor and Delivery Staff Undergoing Team Training*

- Profound fetal bradycardia
- Magnesium sulfate overdose
- Shoulder dystocia
- Maternal hemorrhage
- Failed tracheal intubation
- Anaphylaxis
- Amniotic fluid embolism
- Severe preeclampsia/eclampsia/HELLP syndrome

**Used at the University of Miami Miller School of Medicine/Jackson Memorial Hospital Center for Patient Safety.*
HELLP, hemolysis, elevated liver enzymes, low platelet count.

The drills advocated for use by labor and delivery staff at the University of Miami Miller School of Medicine/Jackson Memorial Hospital are outlined in Box 11-4.

Simulation-based training must be implemented appropriately if it is to be effective. Salas et al.[5] suggested the following guidelines for appropriate implementation:

1. Understand the training needs and requirements.
2. Embed instructional features (e.g., performance measurement and feedback) within the simulation.
3. Craft the scenarios based on expected/desired learning outcomes.
4. Create opportunities for assessing and diagnosing individual and/or team performance within the simulation.
5. Guide learning.
6. Focus on cognitive/psychological simulation fidelity.
7. Form a mutual partnership between subject matter experts and learning experts.
8. Ensure the effectiveness of the training program.

Simulation exercises may also impact outcome by teaching improved communication to individuals and teams during transfer of patients' care from one set of caregivers to another, (i.e., so-called handovers or hand-offs). A recent survey from the United Kingdom found that handovers were rarely documented in writing and that 4% of units reported critical incidents after inadequate handovers in the preceding 12-month period.[62] This interesting study describes the use of the SBAR technique (situation–background–assessment–recommendation) and the potential to practice sign-offs and handovers during practice drills.

Team Training in Obstetrics

As noted, teamwork is critical for the delivery of quality health care, especially in complex environments such as the labor and delivery unit. Awad et al.[63] reported that medical team training improved communication in the operating room as assessed by team members using a validated scoring system. Why initiate team training on

the obstetric service? The following case report by Sachs[64] illustrates the need:

A healthy 38-year-old woman needed emergency cesarean delivery after a failed instrumental delivery. At surgery, the uterus was found to be ruptured and the fetus was stillborn. After unsuccessful attempts to repair the uterus, the patient underwent a cesarean hysterectomy and required massive transfusion and a 3-week hospital stay.

Was anyone at fault? According to the root cause analysis, lack of teamwork on many levels played a significant role in this patient's hospital course. In particular, Sachs[64] reported that communication was poor and there was a lack of mutual performance cross-monitoring, inadequate conflict resolution, suboptimal situational awareness, and work overload.

Crew Resource Management

Although relatively new to obstetrics, team drills have been successfully used in other areas of medicine, including anesthesia, intensive care, and emergency medicine, often using lessons learned from crew resource management (CRM) training. The human error aspects of many air crashes are thought to include failure of communication, decision making, and leadership.[65] In the airline industry, CRM began as a program to train pilots to reduce error by making better use of human resources in the cockpit.[66] CRM training has led to safety and performance improvements beyond those produced by improvements in equipment and technology.[5,65]

Airlines use many tools to reduce human error; CRM training is just one. Other tools include use of checklists, standardized maintenance, ability to report errors without disciplinary repercussions, and simulator training. Not all of these, however, are easily adaptable to medicine. That said, Helmreich[67] identified several lessons learned from CRM that can be applied to the practice of medicine. He believes that errors in competence require technical training and that errors in decisions or communication require team training. Furthermore, Helmreich[67] suggested that adaptation of CRM to health care similarly requires the development of nonpunitive methods to collect information on errors so that this information can be used to evaluate team performance. It has been suggested that elements of CRM that are useful in medical settings include briefings, conflict resolution procedures, and performance reviews.[23] There is evidence that operator attitudes about teamwork, hierarchy, errors, and stress affect performance among aviators working together in teams.[68] Evidence also suggests that these attitudes are relevant in the health care environment.[69]

Salas et al.[70] suggested that CRM training will not be effective or achieve its desired outcomes in health care without the following 12 prerequisites:

1. The physicians must be "on board."
2. The concept of teamwork becomes part of the "DNA" of the health care professional.
3. CRM is supplemented by other teamwork-focused training strategies.
4. The design, development, and delivery of CRM are scientifically rooted.
5. CRM training is designed systematically.
6. CRM is part of a learning organization's strategy to promote patient safety and quality care.
7. Teamwork is rewarded and reinforced by the health care provider.
8. CRM training is evaluated at multiple levels for specific outcomes.
9. CRM is supported by simulation or practice-based approaches.
10. The health care provider is "ready" to receive training.
11. The patient is part of the team.
12. The team training is recurrent.

Some health care providers will benefit more than others from CRM training and learning. For example, one study noted that physicians with poorer performance at the beginning of CRM training showed greater improvements after training.[71]

Disruptive Behavior

Whereas miscommunication is common on the labor and delivery unit, some events are not caused by difficulties with communication but rather result from disruptive behavior by a team member. It is estimated that 3% to 5% of physicians exhibit disruptive behavior.[72] Disruptive and intimidating behavior occurs frequently on labor and delivery units and is observed in personnel of diverse disciplines, including obstetricians, anesthesia providers, family practitioners, pediatricians, nurses, midwives, and administrators. In one survey, disruptive behavior was reported on more than 60% of labor and delivery units from personnel who responded to a questionnaire.[73]

Disruptive behavior includes angry outbursts, rudeness or verbal attacks, physical threats, intimidation, noncompliance with policies, and sexual harassment. Disruptive behavior contributes to the nursing shortage, near misses, and adverse occurrences. This behavior does not always involve physicians. Termed *horizontal hostility*, it occurs among nurses as well, and includes rudeness, verbal abuse, humiliating statements, unjustly critical statements, withholding information, and gossip.[74] Disruptive behavior is not always effectively managed by the organization[73] and should be considered when using simulation to improve team behaviors.

Options for Simulator Training in Obstetrics

Both high-technology and low-technology approaches to simulation have been used for training labor and delivery staff.[54] Simulation centers often use high-fidelity simulation with interactive computerized mannequins in a realistic working environment (e.g., labor room or operating room) that includes a full complement of working equipment and staff.[75] The mannequin is quite realistic; it has a pulse, heart and breath sounds, ventilatory movements, and electrocardiographic and pulse oximetry tracings. All vital signs can be adjusted via computer control, as can the ability to intubate or ventilate.[75]

Not all simulation exercises and drills for obstetrics need to be performed in high-fidelity simulators. Some authors[76] have argued that classroom training is a better

option, particularly given the high cost[77] and resources necessary for high-fidelity simulation. The inability to arrange for staff of several disciplines to be absent from the labor and delivery unit simultaneously often precludes the use of high-technology simulation and may make on-site exercises more practical.[54]

On the other hand, Gaba[78] has countered that high-fidelity simulation need not be cost-prohibitive and that it provides the required "real-life" experience necessary for training in the management of complex real-life scenarios. Morgan et al.[79] reported an obstetric simulation model that included the participation of real surgeons (rather than actors playing the role of surgeons). This was the first published report of high-fidelity simulation of obstetric team performance with anesthesia providers, nurses, and obstetricians involved in the hands-on management of obstetric crises.

Several options are available for teaching teamwork and crisis intervention in obstetrics. Multidisciplinary obstetric simulated emergency scenarios (MOSES) was developed by the St. Bartholomew Hospital Group in the United Kingdom[80] and involves participation of obstetricians, anesthesia providers, and midwives in team training on a high-fidelity simulator. MedTeams was developed by the U.S. Armed Forces and Dynamics Research Corporation. Originally employed in emergency departments,[65,81,82] it has now been used for labor and delivery teams.[33] The course consists of "train the trainer" sessions that focus on seven dimensions that are essential to teamwork. Behaviorally anchored rating scales (BARS) are used to assess various key behaviors. Additionally, in a 2006 review, Harris et al.[83] discussed the challenges of implementation of team training in an obstetric care environment.

Other evidence-based programs have emerged. TeamSTEPPS was developed by the U.S. Department of Defense and Agency for Healthcare Research and Quality (AHRQ) as a team training and implementation toolkit.[84] The program is adaptable, medically relevant, and based on findings from the science of team performance, and it is applicable to training on labor and delivery units.

What is the evidence that team training and simulation reduce errors and improve outcomes? Morey et al.[65] reported that the MedTeams program reduced errors in the emergency department, and they observed a statistically significant improvement in team behaviors. The clinical error rate in providers who received MedTeams training decreased from 31% to 4%. Grunebaum et al.[85] implemented team training as well as other comprehensive patient safety changes to their obstetric practice and found that their interventions resulted in decreased compensation payments and sentinel events. Clark et al.[86] described implementation of a comprehensive redesign of patient safety processes that was associated with improved patient outcomes and a decline in litigation rates. The authors of the report stressed that "every member of the obstetric team should be not only empowered but also required to intervene and halt any process that is deemed to be dangerous." This behavior can be achieved as part of a team training program.

Accumulating evidence suggests that medical simulation and team training improve teamwork and communication and allow recognition of potential areas of weakness in obstetric care. We, as well as others,[25,38,87] believe that these are viable strategies to mitigate medical errors. We also agree with Pearlman et al.,[88] who stated that "we have the moral imperative as a specialty to fully engage in the identification of our own best practices, to advance safety research in obstetrics and gynecology, and to implement broadly those practices which are best."

In addition to better communication, team training, and simulation-based education, several other changes to our cultures and systems need to occur in order to significantly improve patient safety on the labor and delivery unit. These changes include:

- Learning from our mistakes
- Changing the culture on the labor and delivery floor to one of a "just culture"[89]
- Having buy-in and support from hospital leadership to implement the necessary changes
- Improving the care of the high-risk parturient so that every member of the team is more prepared and working as a team member[90]
- Improving and automating the collection of quality metrics, collecting appropriate data on outcomes, and sharing the data with practitioners on a regular basis[91]
- Developing and implementing systems to reduce drug administration errors[92,93]
- Tearing down the silos so that we learn from each other's mistakes and improvement processes, whether from department to department, hospital to hospital, or country to country[93]

The challenge for the next decade will be to implement these changes and test their effectiveness in improving patient safety.

KEY POINTS

- Medical errors harm tens of thousands of patients each year.
- To err is human; therefore, systems should be developed to prevent or "catch" errors before the patient is harmed.
- Poor communication among health care workers is the primary cause of sentinel events.
- Teamwork is essential to safe patient care, and team training may improve patient safety.
- Simulation-based training is an educational tool that may improve responses to obstetric emergencies.
- Adaptation of some elements of aviation crew resource management training may improve team performance in health care.
- Disruptive behavior interferes with safe patient care and is observed in physicians as well as other members of the health care team.

CHAPTER 12

Spinal, Epidural, and Caudal Anesthesia: Anatomy, Physiology, and Technique

Naveen Nathan, MD • Cynthia A. Wong, MD

CHAPTER OUTLINE

The art and science of neuraxial anesthesia requires a thorough appreciation of neuroanatomy and the physiologic effects imposed by medications commonly administered via the spinal and/or epidural route. The focus of this chapter is to characterize the anatomic and technical considerations for neuraxial anesthesia. The reader is referred to Chapter 23 for a corresponding discussion of the physiologic and untoward effects of neuraxial analgesia in laboring women and to Chapter 26 for a discussion of neuraxial anesthesia for cesarean delivery. Successful administration and management of neuraxial anesthesia requires well-developed technique moderated by sound clinical judgment.

ANATOMY

Neuraxial Anatomy

The Spinal Cord, Spinal Canal, and Meninges

The cephalad aspect of the spinal cord is continuous with the brainstem through the foramen magnum. The spinal cord most often terminates as the conus medullaris at the level of the lower border of the first lumbar vertebral body. The conus medullaris is attached to the coccyx by means of a neural-fibrous band called the filum terminale, which is surrounded by the nerves of the lower lumbar and sacral roots, known as the cauda equina. Within the bony vertebral column are three membranes: the pia mater, the arachnoid mater, and the dura mater. The pia mater is a highly vascular membrane that closely invests the spinal cord. The arachnoid mater is a delicate, nonvascular membrane closely adherent to the third and outermost layer, the dura. The subarachnoid space, located between the pia mater and arachnoid mater, contains (1) cerebrospinal fluid (CSF), (2) spinal nerves, (3) a trabecular network between the two membranes, (4) blood vessels that supply the spinal cord, and (5) lateral extensions of the pia mater—the dentate ligaments. The dura mater is a membrane composed of collagen that encapsulates the spinal cord, the deeper meningeal layers, and the subarachnoid space. This layer forms a connective tissue sheath along the vertical axis of the central nervous system (CNS) that is contiguous with connective tissue covering the lateral extension of spinal nerve roots as they exit the intervertebral foramina. The interface between the dural and arachnoid layers has been described as a potential space capable of expansion

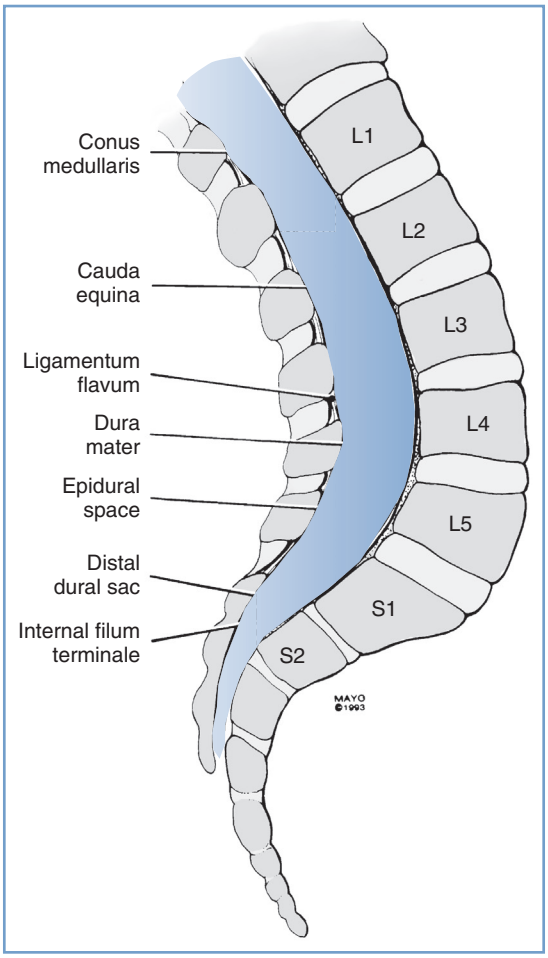

FIGURE 12-1 ■ Distal neuraxial anatomy. In pregnant women, the spinal cord usually ends at the lower border of the first lumbar vertebral body. The subarachnoid space continues to the second sacral vertebral level.

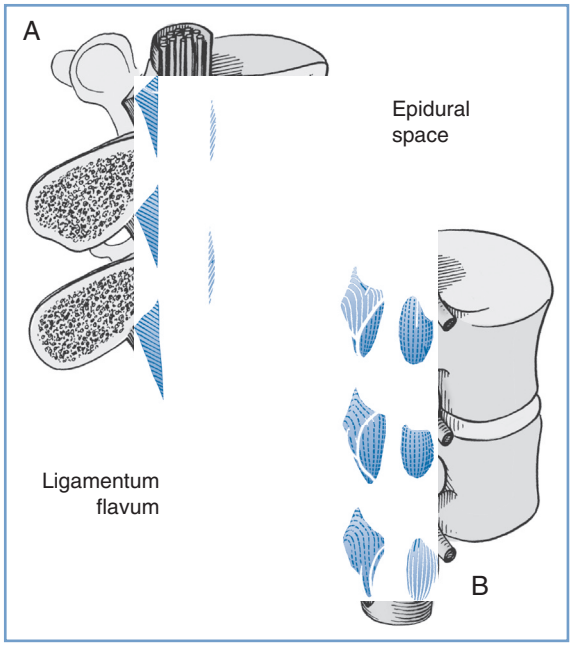

FIGURE 12-2 ■ **A,** Sagittal section of the epidural space demonstrates that the contents of the epidural space depend on the level of the section. **B,** Three-dimensional drawing of the epidural space shows the discontinuity of the epidural contents. However, this potential space can be dilated by the injection of fluid into the epidural space. (Redrawn from Stevens RA. Neuraxial blocks. In Brown DL, editor. Regional Anesthesia and Analgesia. Philadelphia, WB Saunders, 1976:323).

subsequent to mechanical trauma. Unintentional injection of local anesthetic into this *subdural space* may explain some cases of failed spinal anesthesia. It may also explain the rare, slow-to-develop cases of high spinal anesthesia after the inadvertent subdural injection of larger volumes of local anesthetic intended for epidural administration.[1] Although the spinal cord ends at the level of the bodies of L1 and L2 in most patients, the subarachnoid space and cauda equina continue to the S2 level (Figure 12-1).

The Epidural Space

The epidural space is located external to the sac of the dura mater and contains loose connective tissue, adipose tissue, lymphatics, spinal nerve roots, and the internal vertebral venous plexus (Batson's plexus) (Figure 12-2). This space is bound by the posterior longitudinal ligament anteriorly, the ligamentum flavum and the periosteum of the lamina posteriorly, the pedicles of the vertebrae, and the intervertebral foramina with their contents laterally. The epidural space is closed at the foramen magnum where the spinal dura attaches to the dura of the cranium and at the sacral hiatus by the sacrococcygeal ligament. Frequently, anatomic references will illustrate neuraxial anatomy by way of sagittal and/or transverse cross section. This may result in the erroneous impression that the epidural space is a continuous columnar entity that envelops the dural sac at all points about its perimeter. Investigations using cryomicrotome sections and three-dimensional reconstruction of radiologic data verify that the epidural space is in fact discontinuous along the vertical and lateral axes of the spinal canal. It varies in anteroposterior thickness according to dermatomal distribution, being widest at the level of lumbar vertebrae and thinnest in the cervical region.[2,3] Epiduroscopy and epidurography suggest the presence of a dorsal median connective tissue band in some individuals.[4] Anatomic dissection and computed tomographic epidurography have also suggested the presence of epidural space septa. This band (or these septa) may provide an explanation for unilateral or incomplete epidural anesthesia.[5] However, some investigators have suggested that the dorsal median band is an artifact of epidural space distention or an anatomic manifestation of the previously unappreciated epidural space segmentation.[3]

The Vertebral Column and Ligaments

The ligamentum flavum lies posterior to the epidural space (Figure 12-3). The lamina, the spinous processes of the vertebral bodies, and the interspinous ligaments lie posterior to the ligamentum flavum. Posterior to these structures are the supraspinous ligament (which extends

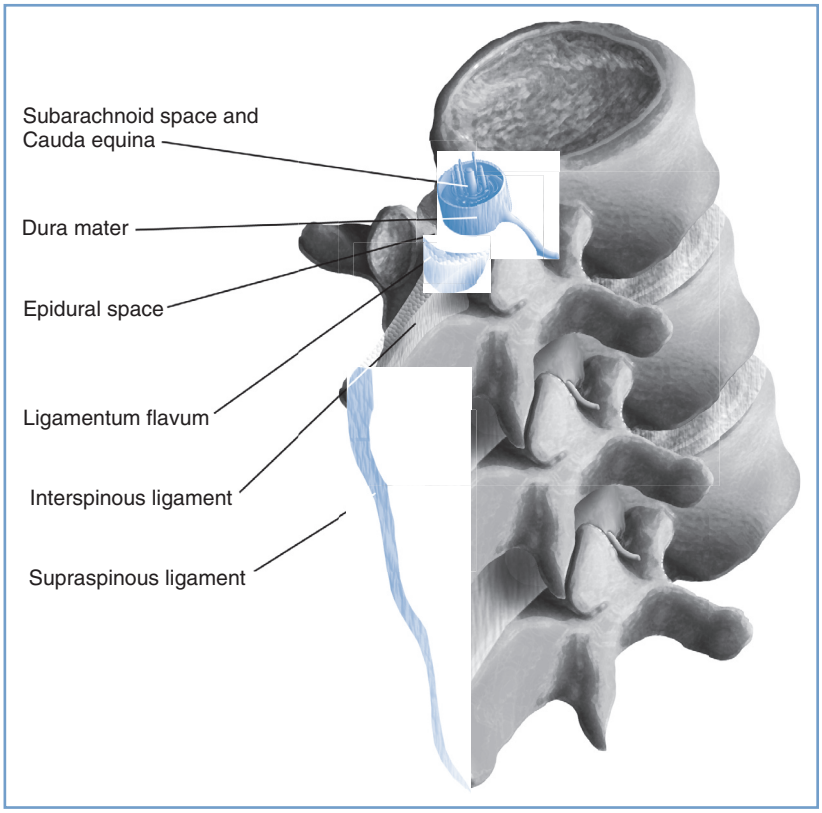

FIGURE 12-3 ■ Central neuraxial anatomy. Note the variable thickness of the ligamentum flavum, which is greatest in the midline and decreases as it fans out laterally. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

from the external occipital protuberance to the coccyx), subcutaneous tissue, and skin. Historically, some have described the ligamentum flavum as a single ligament. In actuality, however, it is composed of two curvilinear ligaments that join in the middle and form an acute angle with a ventral opening.[3,6] Much like the epidural space, the ligamentum flavum is not uniform from skull to sacrum; indeed, it is not uniform even within a single intervertebral space. The thickness of the ligamentum flavum varies with vertebral level, body mass index, and age, as does the distance between the skin and the epidural space (Table 12-1).[7,8]

Anatomic Changes of Pregnancy

The normal anatomic changes of pregnancy affect the use of neuraxial anesthesia techniques. Uterine enlargement and vena caval compression result in engorgement of the epidural veins. Unintentional intravascular epidural catheter cannulation and injection of local anesthetic are more common in pregnant patients than in nonpregnant patients. In addition, the vertebral foraminal veins, which are contiguous with the epidural veins, are enlarged and obstruct one of the pathways for anesthetic egress from the epidural space during administration of epidural anesthesia. The enlarged epidural veins also may displace CSF from the thoracolumbar region of the subarachnoid space, as does the greater intra-abdominal pressure of pregnancy; this displacement partly explains the lowered dose requirement for spinal anesthesia in pregnant women.[9] Subarachnoid dose requirements are also affected by the lower specific gravity of CSF in pregnant patients than in nonpregnant patients.[10]

The hormonal changes of pregnancy affect the perivertebral ligamentous structures, including the ligamentum flavum. The ligamentum flavum may feel less dense and "softer" in pregnant women than in nonpregnant patients; thus, sensing the passage of the epidural needle through the ligamentum flavum may be more difficult. It may also be more difficult for a pregnant woman to achieve flexion of the lumbar spine. Progressive accentuation of lumbar lordosis alters the relationship of surface anatomy to the vertebral column. At least three changes may occur. First, a pregnant woman's pelvis rotates on the long axis of the spinal column; thus, the line joining the iliac crests (Tuffier's line) assumes a more cephalad relationship to the vertebral column (e.g., this imaginary line might cross the vertebral column at the L3 to L4 interspace rather than the L4 to L5 interspace).

TABLE 12-1 **Distance from the Skin to the Epidural Space in 1000 Parturients**

Lumbar Interspace	Distance (cm)		
	MEDIAN	5TH PERCENTILE	95TH PERCENTILE
L1-2	4.23	3.12	6.33
L2-3	4.86	3.29	7.32
L3-4	4.93	3.57	7.44
L4-5	4.78	3.25	6.75

From Harrison GR, Clowes NWB. The depth of the lumbar epidural space from the skin. Anaesthesia 1985; 40:685-7.

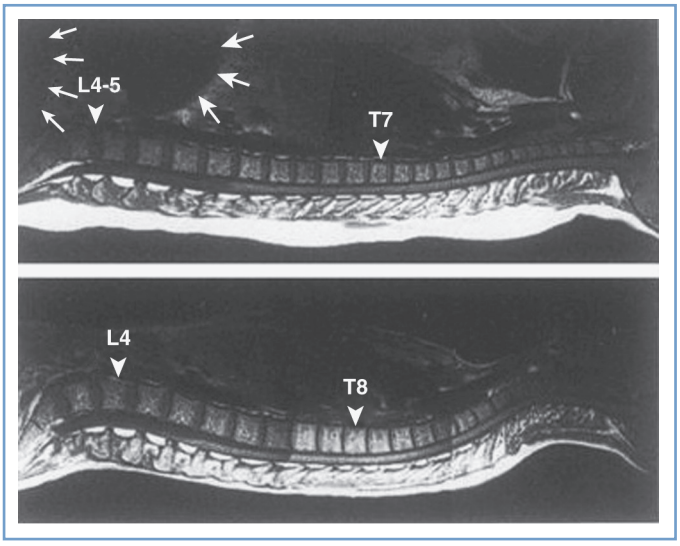

FIGURE 12-4 ■ The curvature of the spinal column in the pregnant female (*top*) and nonpregnant female (*bottom*). The large and small white arrows indicate the uterus and fetal head, respectively. The apex of the lumbar lordosis moves caudad (*triangular arrow*), and the thoracic kyphosis is reduced and moves cephalad *(triangular arrow*) in the pregnant woman. (Reprinted with permission from Hirabayashi Y, Shimizu R, Fukuha H. Anatomical configuration of the spinal column in the supine position. II. Comparison of pregnant and non-pregnant women. Br J Anaesth 1995; 75:6-8.)

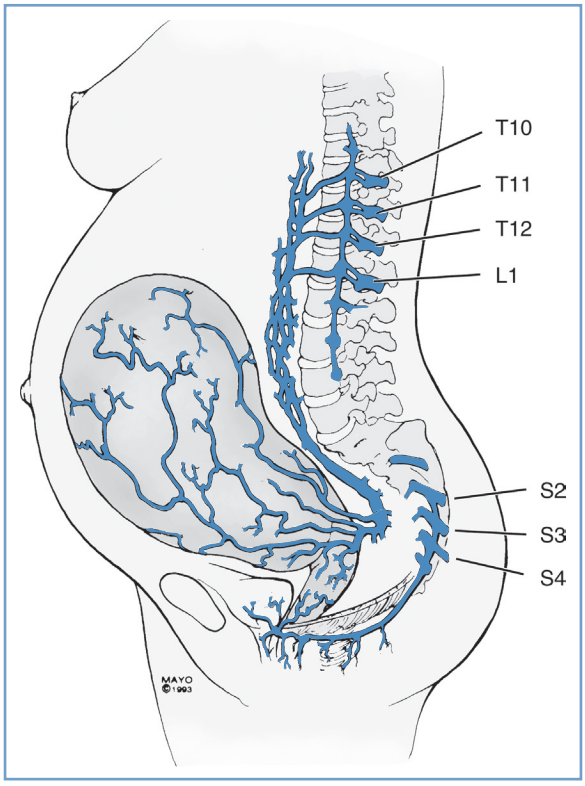

FIGURE 12-5 ■ Pain pathways during labor and delivery. The afferent pain pathways from the cervix and uterus involve nerves that accompany sympathetic fibers and enter the neuraxis at T10 to L1. The pain pathways for the pelvic floor and perineum include the pudendal nerve fibers, which enter the neuraxis at S2 to S4.

Second, there is less space between adjacent lumbar spinous processes during pregnancy. It may be more difficult to use the midline approach to identify the epidural or subarachnoid space in pregnant women. (Thus the often-heard comment, "She has a narrow interspace.") Third, magnetic resonance imaging has shown that the apex of the lumbar lordosis is shifted caudad during pregnancy, and the typical thoracic kyphosis in women is reduced during pregnancy.[11] These changes may influence the spread of subarachnoid anesthetic solutions in supine patients, leading to a higher sensory level in the pregnant patient (Figure 12-4).[12] Finally, labor pain makes it more difficult for some women to assume and maintain an ideal position while the anesthesia provider performs neuraxial anesthesia.

PHYSIOLOGY

Obstetric Pain Pathways

Pain during the first stage of labor results primarily from changes in the lower uterine segment and cervix. Pain is transmitted by visceral afferent nerve fibers that accompany the sympathetic nerves and enter the spinal cord at the T10 to L1 segments. During the late first stage and second stage of labor, pain results from distention of the pelvic floor, vagina, and perineum. Pelvic pain is transmitted by somatic nerve fibers, which enter the spinal cord at the S2 to S4 segments (Figure 12-5).

During cesarean delivery, additional nociceptive pathways are involved in the transmission of pain, and a T4 level of anesthesia is required to provide adequate anesthesia. Most cesarean deliveries are performed with a horizontal (e.g., Pfannenstiel) skin incision, which involves the infraumbilical T11 to T12 dermatomes. During surgery, stretching of the skin may involve dermatomes two to four levels higher. Intraperitoneal manipulation and dissection involve poorly localized visceral pain pathways. Visceral pain may be transmitted by pathways as high as the celiac plexus. Additional somatic pain impulses may occur as a result of diaphragmatic stimulation because the intercostal nerves innervate a portion of the peripheral diaphragm.

Physiology of Neural Blockade

Hormonal changes, anatomic changes, and decreases in CSF specific gravity likely are responsible for the lower local anesthetic dose requirements for spinal anesthesia in pregnant women.[10,13] Local anesthetics produce conduction blockade primarily by blocking sodium channels in nerve membranes, thereby preventing the propagation of neural impulses. Differential blockade is manifested as differences in the extent of cephalad blockade of temperature discrimination and vasomotor tone, sensory loss to pinprick, sensory loss to touch, and motor function. Temperature discrimination and vasomotor tone are blocked to the greatest extent (i.e., most cephalad level)

and motor function to the least extent. During spinal anesthesia, local anesthetics act directly on neural tissue in the subarachnoid space. Regression of anesthesia can be explained by the simple vascular uptake of local anesthetic from the subarachnoid space and spinal cord.[14] Epidural anesthesia has a much smaller zone of differential motor–sensory–sympathetic blockade; this difference suggests that the mechanism of epidural anesthesia must involve more than simple diffusion across the dura. For many years, nerve fiber size was presumed to be the primary determinant of susceptibility to local anesthetic blockade (i.e., smaller fibers are blocked more readily than larger fibers). However, later studies have shown that the length of nerve fiber exposed to local anesthetic is as important as the size of the nerve fiber. Fink[15] hypothesized that the length of nerve fiber exposed to local anesthetic affects the extent of the differential zone of motor and sensory blockade. With spinal anesthesia, the local anesthetic concentration required to block sufficient sodium channels to affect motor, sensory, and sympathetic function is less than that needed for the better-protected nerves found in the epidural space; thus, a wider band of differential blockade occurs during spinal anesthesia than during epidural anesthesia.

The understanding of the mechanisms of spinal and epidural anesthesia likely remains oversimplified. Nonetheless, it seems clear that spinal anesthesia results primarily from the effects of local anesthetic on the spinal cord, whereas epidural anesthesia results from the effects of local anesthetic on nerve tissue within both the epidural and subarachnoid spaces.

BOX 12-1 Suggested Resuscitation Equipment and Drugs That Should Be Available During Administration of Neuraxial Analgesia/Anesthesia

Drugs

- Hypnotic-amnestic agents (propofol, ketamine, midazolam)
- Succinylcholine
- Ephedrine
- Epinephrine
- Phenylephrine
- Atropine
- Calcium chloride
- Sodium bicarbonate
- Naloxone

Equipment

- Oxygen source
- Suction source with tubing and catheters
- Self-inflating bag and mask for positive-pressure ventilation
- Face masks
- Oral airways
- Laryngoscope and assorted blades
- Endotracheal tubes with stylet
- Eschmann stylet (bougie)
- Qualitative carbon dioxide detector

TECHNIQUE

Pre-procedural Considerations

Monitoring

The American Society of Anesthesiologists (ASA) has published guidelines for administration of neuraxial anesthesia in obstetric patients (see Appendix A). Among other things these recommendations address (1) the required presence of qualified anesthesia and obstetric care providers, (2) immediate availability of resuscitation medication and equipment (Box 12-1), (3) mandatory pre-procedural intravenous access, and (4) employment and documentation of maternal vital signs and fetal heart rate (FHR) monitoring.

During the initiation of neuraxial analgesia for labor, all patients are monitored with an automatic blood pressure cuff and a pulse oximeter to facilitate continuous assessment of the maternal heart rate and oxygenation. Maternal blood pressure is measured every 1 to 2 minutes after the administration of the test and therapeutic doses of local anesthetic for approximately 15 to 20 minutes, or until the mother is hemodynamically stable. Subsequently (during maintenance of neuraxial analgesia), maternal blood pressure is measured every 15 to 30 minutes or more frequently if hypotension ensues. Continuous pulse oximetry during maintenance analgesia is used in selected patients (e.g., patients with obstructive sleep apnea or cardiovascular disease). Rarely, invasive hemodynamic monitoring is necessary. The sensory level of analgesia and the intensity of motor block are assessed after the administration of the test and therapeutic doses of local anesthetic. Subsequently, sensory level and motor block are assessed at regular intervals.

Neither the ASA nor the American College of Obstetricians and Gynecologists (ACOG) provides a specific recommendation as to whether continuous FHR monitoring is necessary during performance of neuraxial anesthesia procedures. The ASA Task Force on Obstetric Anesthesia[16] has stated:

> *The fetal heart rate should be monitored by a qualified individual before and after administration of neuraxial analgesia for labor. The Task Force recognizes that continuous electronic recording of the fetal heart rate may not be necessary in every clinical setting and may not be possible during initiation of neuraxial anesthesia.*

The anesthesia provider cannot predict when hypotension will occur during the administration of neuraxial anesthesia. In addition, there is concern that intrathecal administration of an opioid is associated with a higher incidence of nonreassuring FHR patterns than other neuraxial techniques (see Chapter 23).[17] Thus, we believe that continuous electronic FHR monitoring should be performed both during (if possible) and after the administration of neuraxial analgesia in all laboring women. In some cases, the mother's position or maternal obesity precludes the use of an external Doppler device to monitor the FHR. In such cases (especially when there is

concern regarding fetal well-being), it is helpful for the obstetric provider to place a fetal scalp electrode to monitor the FHR.

Informed Consent, Patient-Procedure Verification, and Partner's Presence

Prior to initiation of neuraxial anesthesia, a pre-procedural verification process (i.e., "time-out") is instituted as part of compliance with national patient safety recommendations from hospital accreditation organizations.[18] The participation of the patient, the anesthesia care provider, and a third party such as a member of the nursing staff may lead to the discovery of concerns that should be addressed before the initiation of neuraxial anesthesia. The risk of neuraxial procedures relates to (1) the physical instrumentation of the spinal axis and (2) physiologic changes associated with medication administration via this anatomic route. Contraindications to needle or catheter placement include patient refusal or inability to cooperate, ongoing bleeding diathesis, infection either at the site of intended intervention or untreated systemic blood-borne illness, and increased intracranial pressure predisposing to cerebral herniation. Contraindications to injecting local anesthetics via the epidural or spinal route include severe hypovolemia and allergy to local anesthetics. It would be axiomatic that patient refusal presents an absolute contraindication to an elective procedure. A thorough preoperative assessment of current fetal well-being, maternal volume status, intrapartum systemic opioid use, antibiotic administration for ongoing chorioamnionitis or other infectious process, and a brief reiteration of known maternal disease states, including allergies, will readily identify most of the major concerns that would render neuraxial anesthesia potentially hazardous. The anesthesia provider should weigh the risks and benefits of neuraxial anesthesia for each patient.

Informed consent should include a frank discussion about anesthetic procedures and risks. Surveys of postpartum women have demonstrated that most parturients want to know the possible complications of epidural analgesia, even those that are rare.[19,20] It is best to relay this information before the onset of labor (e.g., during antenatal classes),[21] or early in the intrapartum period, although doing so is not always feasible. Some anesthesia providers fear that distressed, desperate, or sedated parturients may not understand the discussion of anesthetic procedures. However, adequacy of consent can be demonstrated not only by documentation of information provided to the patient but also by the lack of patient objection to a procedure and the cooperation provided by the patient during the procedure.[22] In a survey of North American anesthesiologists, Brull et al.[23] found that a majority of clinicians did not disclose the most severe risks of central neuraxial anesthesia to their patients. Additionally, most anesthesiologists cited inaccurate incidences of these complications. We do not find it difficult to explain the procedure and the risks of neuraxial analgesia to a laboring woman. The preanesthetic evaluation allows the physician to communicate a sense of concern and to demonstrate a commitment to the patient's care. Most laboring women understand the need for informed consent, and they appreciate the opportunity to participate in decisions about their care.

Management of the pregnant patient occurs in a unique clinical care environment in which the presence of the patient's spouse or family member must be addressed. Most often, the dictates of local institutions will establish whether a partner's presence during neuraxial labor analgesia is acceptable. However, hospital policy may be vague enough that the discretion lies in the hands of the anesthesia provider. Intuition may suggest that a partner who remains present during the conduct of neuraxial analgesia may help alleviate the patient's ongoing anxiety regarding the procedure. Conversely, the partner may be so apprehensive or disruptive that the partner's presence becomes counterproductive to the care of the patient. Orbach-Zinger et al.[24] randomized 84 nulliparous women to either presence or absence of their partner during labor epidural catheter placement. Interestingly, patient and partner anxiety, as measured by a validated anxiety questionnaire, were reduced when partners were absent during the procedure.

Patient Positioning

Pregnant women have an exaggerated lumbar lordosis, and it is more difficult for them to flex the lumbar spine. However, most pregnant women are young, and youth usually allows sufficient flexibility to facilitate the insertion of a needle into the epidural or subarachnoid space. Whether the block is initiated in the lateral or sitting position is a matter of provider and patient preference. Notable advantages of the lateral position include (1) orthostatic hypotension is less likely and (2) the position often facilitates continuous FHR monitoring during placement of the epidural catheter. Vincent and Chestnut[25] performed a study in which they observed that neither the sitting nor the lateral position was consistently superior with regard to patient comfort. However, pregnant women who preferred the left lateral decubitus position weighed less and had lower body mass indices than women who preferred the sitting position. The sitting position is likely associated with a higher incidence of orthostatic hypotension and syncope. However, the sitting position is preferred—and may be required—in obese parturients, in whom identification of the midline is usually significantly easier in the sitting position. Further, morbidly obese women may experience hypoxemia when placed in the lateral decubitus position.

One study demonstrated a greater reduction in maternal cardiac output with maximal lumbar flexion in the lateral decubitus position than in the sitting position during identification of the epidural space in laboring women.[26] The researchers speculated that maximal lumbar flexion in the lateral decubitus position results in concealed aortocaval compression. In contrast, they suggested that the uterus falls forward (and thus does not cause aortocaval compression) when the patient assumes the sitting flexed position. They recommended that "the tight fetal curl position be avoided," especially when the patient assumes the lateral decubitus position for identification of the epidural or intrathecal space.

Aortocaval compression must be avoided at all times. The gravid uterus can occlude the inferior vena cava and aorta when the parturient assumes the supine position.[27-29] This position may cause maternal hypotension[30,31] and reduce uteroplacental perfusion,[32] even in the absence of anesthesia. Increased venous tone in the lower extremities helps overcome partial occlusion of the inferior vena cava in unanesthetized pregnant women. If maternal hydration is inadequate and if aortocaval compression is not avoided, the onset of anesthesia-induced sympathetic blockade may result in decreased venous return, cardiac output, and uteroplacental perfusion.[29]

Maternal position during placement of the epidural catheter does not seem to affect the incidence of unintentional dural puncture. However, adoption of the lateral recumbent head-down position for epidural catheter placement may reduce the incidence of epidural venous puncture.[33]

When spinal or epidural anesthesia is performed with the patient in a lateral position, the patient's back should lie at, and parallel to, the edge of the bed, for at least two reasons. First, the edge is the most firm section of the mattress. If the patient lies away from the edge of the bed, the patient's weight will depress the mattress, and the anesthesia provider must work in a "downhill" direction. Second, this position allows anesthesia providers to keep their elbows flexed, facilitating control of fine hand and wrist muscle movements. The plane of the entire back should be perpendicular to the mattress. When asked to flex the lower back, patients typically roll the top shoulder forward, an action that rotates the spine (which is undesirable) but does not flex the lower back.

Similarly, patients positioned sitting should have their feet supported by a stool with the backs of their knees against the edge of the bed, a maneuver that helps position the patient's back closer to the anesthesia provider. The shoulders should be relaxed symmetrically over the hips and buttocks. Beds in obstetric units often break at the foot, and the split in the mattress encourages the patient's seat to slope downhill if she is straddling the mattress split; this position will cause spine rotation and may make the procedure more difficult.

When spinal anesthesia is performed, the patient's posture relative to the baricity of the anesthetic solution should be considered, because it influences the extent of blockade, the latency of blockade, and the incidence of hypotension. The incidence, timing, and extent of hypotension in the period immediately after initiation of the block depend on the type of block (e.g., spinal, epidural, or combined spinal-epidural [CSE]), drug characteristics (e.g., baricity, concentration), patient position during the procedure, and patient position in the period following the procedure. For example, when spinal anesthesia is initiated with a hyperbaric solution for instrumental vaginal delivery, it often makes sense for the patient to be sitting to ensure the rapid onset of sacral anesthesia. Conversely, spinal anesthesia for cervical cerclage can be initiated with the patient in the steep lateral Trendelenburg position with a hypobaric anesthetic solution.

Posture has less influence on the spread of epidural anesthesia.[34-36] During epidural anesthesia, a unilateral block more likely results from the malposition of the catheter (or perhaps an anatomic barrier within the epidural space) than from patient position, particularly after a bolus injection. Norris and Dewan[34] observed that gravity did not augment the spread of anesthesia in patients receiving epidural anesthesia for cesarean delivery, and they concluded that posture does not need to be manipulated to ensure adequate bilateral epidural anesthesia. In at least two studies it was noted that the use of the sitting position is not necessary for the development of good sacral anesthesia when large volumes of epidural local anesthetic are given for cesarean delivery.[34,36] However, Reid and Thorburn[36] observed that use of the sitting position appeared to delay the spread of anesthesia to the midthoracic dermatomes. In comparison with the bolus administration of epidural local anesthetic, the extent of blockade may be more gravity dependent when the anesthetic is administered as a continuous infusion over a prolonged period.

Some anesthesiologists contend that maternal position after epidural catheter placement affects the efficacy of epidural analgesia, although this is a matter of some dispute. Beilin et al.[37] observed that the placement of the laboring woman in the supine position with a 30-degree leftward tilt was associated with better epidural analgesia than maintenance of the left lateral decubitus position. In contrast, Preston et al.[38] observed no difference in analgesia and a significantly higher incidence of fetal bradycardia with the supine wedged position than with the full lateral position.

Caudal anesthesia is used infrequently in modern obstetric anesthesia practice. However, there remain some circumstances in which a caudal technique is useful and/or advantageous. It is a good choice for the second stage of labor in selected patients in whom the lumbar epidural approach is hazardous or contraindicated (e.g., fusion or instrumentation of the lumbar spine). In most cases, caudal anesthesia can be successfully performed with the patient in a lateral decubitus position.

Aseptic Technique

There appears to be a great degree of practice variation among anesthesia providers with respect to aseptic technique during administration of neuraxial anesthesia.[39-41] This lack of consensus may result from an underappreciation of the gravity of infectious complications related to neuraxial anesthesia.[42-44] Indeed the incidence of epidural abscess and spinal meningitis is generally so low that many of the available recommendations are based on evidence from other domains of infection control (e.g., surgical wound site and central venous catheter–related infection).[45-47] Nonetheless, neurologic compromise resulting from neuraxial infection can be a devastating complication.

Infection of the epidural space tends to result in the formation of an abscess, most commonly formed by *Staphylococcus aureus* found in the epidermis of either the patient or the anesthesia provider. In contrast, meningitis associated with neuraxial procedures is most commonly caused by *Streptococcus viridans.* Viridans species of streptococcus may reside in the oronasopharyngeal tract of providers or patients or in the vagina. Potential routes

of infection include the (1) epidural catheter track, (2) bloodstream, (3) equipment, and (4) injectate. A more in-depth discussion of neuraxial infection is found in Chapter 32.

Guidelines describing aseptic technique for regional and neuraxial anesthetic procedures have been published by professional anesthesiology organizations, including the ASA, the Association of Anaesthetists of Great Britain and Ireland, and the American Society of Regional Anesthesia and Pain Medicine.[47-49] The following recommendations deserve emphasis:

1. Given that the oropharyngeal and skin flora of the anesthesia provider are implicated in many cases of neuraxial infection, the provider should don a surgical facemask and hat before initiation of spinal/epidural anesthesia. Microbial sampling in laminar-flow operating theaters has shown a 22-fold increase in bacterial counts when a facemask and hat are not worn.[50]
2. Washing hands with an alcohol-based antiseptic solution is recommended because this has been shown to be superior to antimicrobial soap.[51] Jewelry (e.g., rings, watches) should be removed before and sterile gloves worn after hand cleansing.
3. The patient's skin should be decontaminated, preferably with a chlorhexidine-in-alcohol solution.[47] An abundance of evidence affirms the superior bacteriocidal and bacteriostatic efficacy of chlorhexidine compared with povidone-iodine.[46,52] If chlorhexidine is not available, then povidone-iodine with alcohol, rather than povidone-iodine alone, is preferred.[47,53] Of importance, the anesthesia provider is encouraged to exercise patience in allowing the antiseptic to dry, because a major mechanism of antisepsis is the desiccating action of alcohol.

Equipment and Placement of Needle/Catheter

Spinal Anesthesia

The first equipment decision involves determining whether to perform a single-shot or continuous technique. Continuous spinal anesthesia is not a new technique; indeed, some physicians performed continuous spinal anesthesia more than 50 years ago. Currently, a large-bore epidural needle and catheter must be used for continuous spinal anesthesia, because the U.S. Food and Drug Administration rescinded approval for the use of small-bore microcatheters in 1992.[54] Therefore, the risk for post–dural puncture headache is significant. This technique is useful after *unintentional* dural puncture with an epidural needle. In the morbidly obese patient, it may be easier to manipulate and advance a rigid epidural needle than a more flexible spinal needle; thus the technique is useful for establishing continuous analgesia or anesthesia in this patient population, particularly when the need for anesthesia is urgent. However, for most obstetric patients, a single-shot technique is preferred for spinal anesthesia.

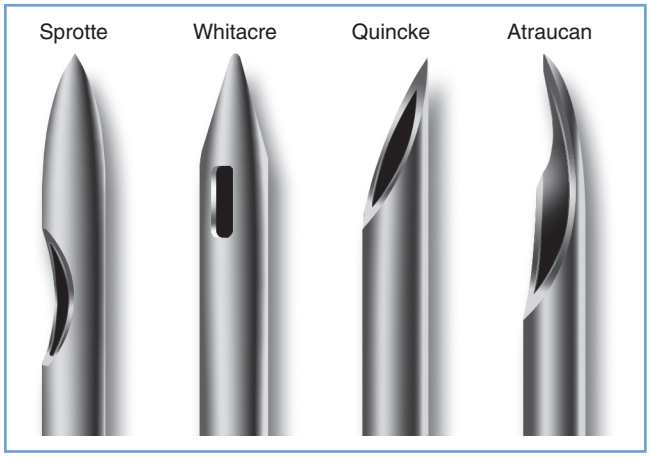

FIGURE 12-6 ■ Spinal needle assortment often used in parturients. Each needle is shown in an open-bevel view and an oblique orientation. The Whitacre and Sprotte needles have cone-shaped bevels, whereas the Quincke has a cutting bevel. (Other sizes are available in some of these needle designs.)

The primary equipment choice for spinal anesthesia concerns the type and size of the spinal needle. Cutting-bevel needles (e.g., Quincke) are rarely used in contemporary obstetric anesthesia practice because of the unacceptably high incidence of post–dural puncture headache associated with their use.[55] Instead, non-cutting needles (e.g., Whitacre, Sprotte, Gertie Marx) are used almost exclusively (Figure 12-6). Some anesthesia providers refer to the non-cutting needles as "pencil-point needles." It is now believed that the pencil-point needles cause more trauma to the dura, which then results in a more intense inflammatory response than occurs with cutting-bevel needles. Presumably, the inflammation results in more rapid closure of the dural defect.[56]

Needle size must also be determined. Larger needles offer a greater fidelity of tactile feedback as the anesthesia provider traverses tissue planes of variable impedance when performing spinal anesthesia. Furthermore, larger needles are more likely to withstand the high resistance encountered when contacting bone without bending or shearing. In general, the "ease-of-use" advantages associated with larger needles must be balanced against a lower incidence of post–dural puncture headache with smaller needles. Most anesthesia providers use 25- or 27-gauge non-cutting needles for routine spinal anesthesia in obstetric patients. However, anesthesia providers should make individual decisions based on their own skills, practice setting, and the patient. The urgency of the procedure may also influence the choice of needle size. For example, a 27-gauge needle might be chosen for spinal anesthesia for an elective procedure, and a larger (e.g., 22-gauge) needle might be chosen when the subarachnoid space must be entered quickly because of severe fetal compromise.

With a small-gauge needle (i.e., 24-gauge or smaller), use of an introducer needle is preferable. The introducer needle engages the interspinous ligament and more accurately guides the trajectory of the smaller spinal needle than is possible with use of a small-gauge spinal needle

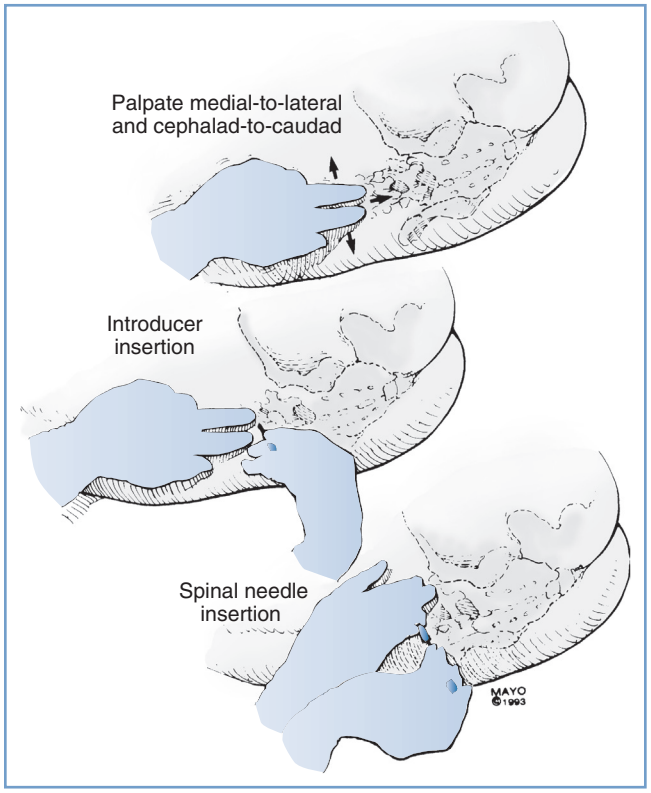

FIGURE 12-7 ■ The midline approach for spinal needle insertion requires accurate identification of a lumbar interspinous space. The palpating fingers are rolled in a medial-to-lateral and cephalad-to-caudad direction; an introducer is then inserted through the interspinous space almost perpendicular to the lumbar spinous process. Once the introducer is seated in the interspinous ligament, the spinal needle is inserted; the needle is stabilized in a tripod fashion during insertion (much like a dart being thrown).

alone. The introducer needle also aids with skin puncture; it is often difficult to puncture the skin with noncutting needles.

Either the midline or the paramedian approach can be used to enter the subarachnoid space. The midline approach requires the patient to reduce her lumbar lordosis to allow access to the subarachnoid space between adjacent spinous processes (usually L3 to L4, sometimes L4 to L5 or L2 to L3). The interspinous space may be identified with one (usually the thumb or index finger) or two fingers (usually the index and middle fingers) of the anesthesia provider's nondominant hand. The single finger "slides" along the skin in the midline from cephalad to caudad until it "settles" into an interspinous space. The two fingers identify the interspinous space by palpating the caudad border of the more cephalad spine. The fingers identify the midline by rolling in a medial-to-lateral direction (Figure 12-7).

Next, the anesthesia provider injects local anesthetic intradermally and subcutaneously. The introducer needle is inserted into the substance of the interspinous ligament. It is helpful if the introducer needle is embedded in the interspinous ligament; therefore, obese patients may require a longer introducer needle. The introducer needle should lie in the sagittal midline plane. It is then grasped and steadied with the fingers of the nondominant hand while the dominant hand holds the spinal needle like a dart. The fifth finger may be used as a tripod against the patient's back to prevent patient movement from causing unintentional needle insertion to a level deeper than intended, and to "brake" the needle. As the needle passes through the ligamentum flavum and the dura, characteristic changes in resistance are noted. A "pop" is often perceived as the needle tip traverses the ligamentum flavum. A subsequent and more pronounced pop is perceived as the needle tip exits the dura-arachnoid. The stylet is removed, and CSF should appear in the needle hub. If CSF does not appear, the stylet is replaced, and the needle is advanced a few millimeters and again checked for CSF flow. This process continues until either bone is encountered or CSF returns through the needle. If neither occurs, the needle and introducer are withdrawn and the process is repeated.

Although with time and practice the tactile feedback produced by advancing a needle through tissues of variable resistance will become utterly familiar to the anesthesia provider, the novice may be unsure of the anatomic position of the needle tip, especially if unexpected resistance (i.e., contact with bone) or an unexpected and premature "pop sensation" is encountered during needle advancement. A stepwise problem-solving approach is reasonable. First, the anesthesia provider should reconfirm that (1) the patient has normal anatomy (i.e., not scoliotic), (2) she is acceptably positioned at an appropriate height for the anesthesia provider, and (3) the chosen point of needle insertion is the true midline plane. If these assertions are true, and the needle tip encounters bone, it is highly likely that the osseous structure is either the inferior or superior spinous process. One of two maneuvers may overcome this barrier. After slight withdrawal of the needle, simple angulation in a cephalad or caudad direction may redirect the needle trajectory sufficiently to achieve access to the central neuraxial canal. One must appreciate the "toughness" of the interspinous ligament. Even a 17-gauge epidural needle can be bent if the angle is changed without some prior retraction of the needle. Furthermore, if a spinal needle/introducer complex is used, care must be exercised that angulation of the spinal needle does not occur without first withdrawing it into the lumen of the introducer. Thereafter, the entire spinal needle/introducer complex is angulated before the spinal needle is re-advanced. Angulation of the spinal needle without first withdrawing it into the introducer creates a fulcrum at the junction of the introducer tip where the spinal needle emerges and can potentially damage or even shear the delicate spinal needle (Figure 12-8).[57]

Alternatively, the needle may be withdrawn fully into subcutaneous tissue and either raised or lowered (cephalad or caudad) while still maintaining an angulation that is parallel to the original trajectory. Which approach is more effective may depend on the reason for the initial bone contact. If the patient has very narrow interspaces, then careful raising or lowering of the needle while maintaining a trajectory parallel to the floor may be appropriate. However, if the patient is overly flexed forward, it is possible that her lumbar spinous processes are projecting

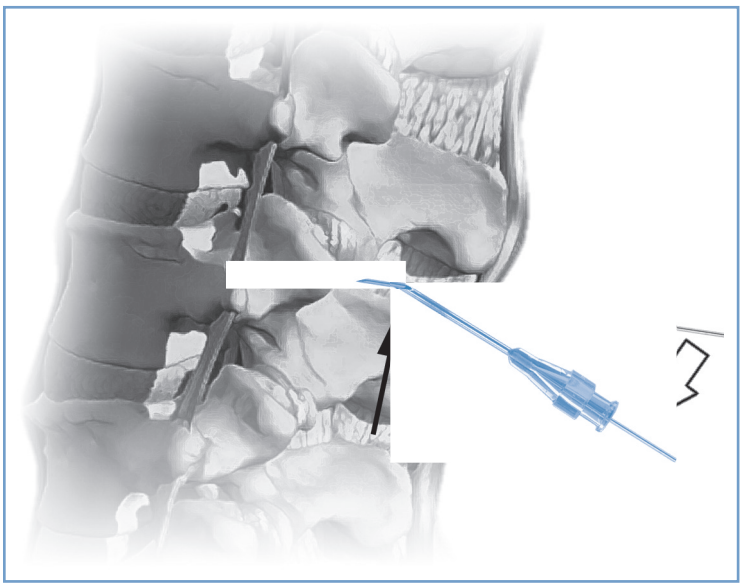

FIGURE 12-8 ■ Change of needle trajectory during spinal anesthesia. Note that if both the spinal needle and its introducer needle are manipulated without prior retraction of the spinal needle into the lumen of the introducer (*open arrow*), a fulcrum is created (*dark arrow*) where the risk for bending or shearing the delicate spinal needle may occur. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

in a slightly upward angulation (relative to the perpendicular transverse plane). This may require that the needle be re-angulated accordingly. If bone is still encountered despite all these considerations, it is likely that the needle tip is in fact *not* in the midline plane and is contacting the vertebral lamina. This may occur if the initial skin puncture is not in the midline, the needle tip deviates from the midline as it is advanced, or the patient's spine is rotated (either from poor positioning or scoliosis). Clues that the needle tip is not midline include (1) the patient complaining of lateralizing pain, (2) lack of CSF flow despite appropriate needle depth, and (3) the perception of "soft" or "mushy" tissue during needle advancement (paraspinous tissue) rather than the more "rigid" ligamentous tissue, or even a false "pop" as the needle tip exits the interspinous ligament laterally into paraspinous tissue. Much like the progressive modifications described earlier for correct alignment in the superoinferior plane, so too can these approaches be employed for redirecting in the lateral plane (Figure 12-9). The novice is advised to make systematic changes in a stepwise fashion, rather than indiscriminately changing needle direction without first considering the anatomic problem.

Once CSF is freely dripping from the needle hub, the dorsum of the provider's nondominant hand steadies the spinal needle against the patient's back while the syringe with local anesthetic is attached to the needle. After aspirating to ensure the free flow of CSF, the anesthesia provider injects the local anesthetic at a rate of approximately 0.2 mL per second. After completion of the injection, some anesthesia providers again aspirate approximately 0.2 mL of CSF and reinject it into the subarachnoid space. This last step reconfirms the needle location and clears the needle of the remaining local anesthetic. The patient is then repositioned as appropriate.

For most patients, the midline approach is faster and less painful than the paramedian approach. The midline approach is also easier to teach than the paramedian approach, because it requires mental projection of the anatomy in only two planes, whereas the paramedian approach requires appreciation of a third plane and estimation of the depth of the subarachnoid space from the skin (Figure 12-10).

Nevertheless, the paramedian approach is a useful technique that allows for the successful identification of the subarachnoid or epidural space in difficult cases. The paramedian approach does not require that the patient fully reduce her lumbar lordosis. This approach exploits the larger target that is available when the needle is inserted slightly off the midline.

A common error that is made with the paramedian approach is the insertion of the needle too far off the midline; the vertebral lamina then becomes a barrier to needle insertion. With the paramedian approach, the palpating fingers should again identify the caudad edge of the more cephalad spinous process. A skin wheal is raised 1 cm lateral and 1 cm caudad to this point; a longer needle is then used to infiltrate the deeper tissues in a cephalomedial plane. This step contrasts to the midline approach, in which the local anesthetic is not injected beyond the subcutaneous tissue. The spinal introducer is then inserted 10 to 15 degrees off the sagittal plane in a cephalomedial direction, and the spinal needle is advanced through the introducer needle toward the subarachnoid space. Another common error is to use an excessive cephalad angle with initial needle insertion. When the needle is inserted correctly and contacts bone, it is redirected slightly cephalad. If bone is again encountered, but at a deeper level, the slight stepwise increase in cephalad angulation is continued, and the needle is "walked" up and off the lamina. As with the midline approach, the characteristic feel of the ligamentum flavum and dura can be appreciated. The aim of the paramedian approach is to puncture the dura in the midline, even though the needle is inserted off the midline. Use of the paramedian approach requires insertion of a greater length of needle.

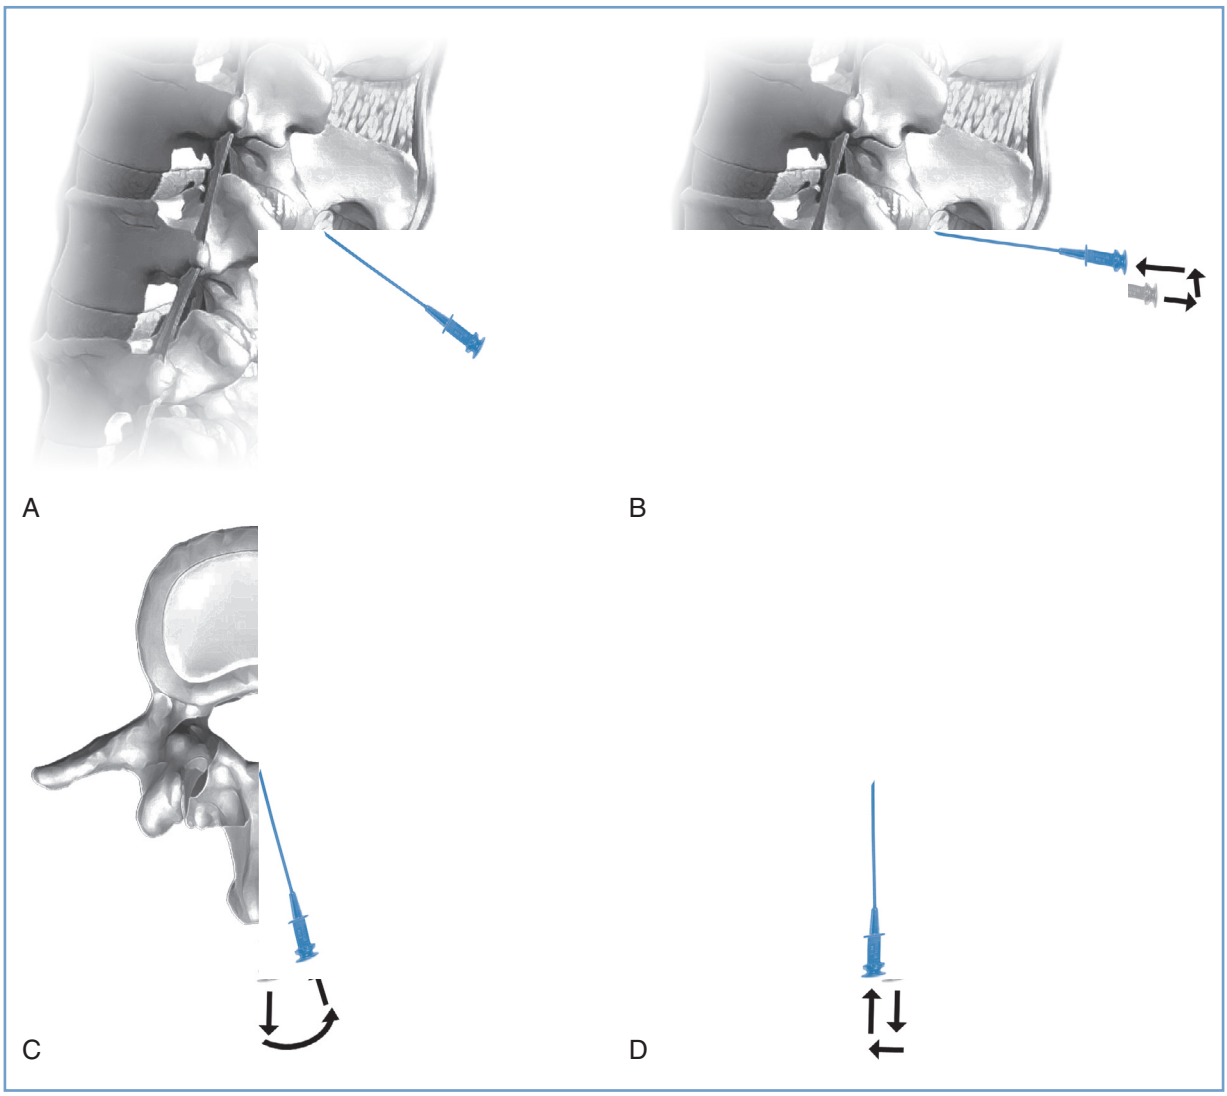

FIGURE 12-9 ■ Troubleshooting contact with bony structures during needle placement. The gray needle represents the initial needle trajectory; the blue needle represents the adjusted needle trajectory. **A,** Assuming correct midline needle placement, the needle can be retracted slightly and angulated to overcome a spinous process. **B,** Alternatively, the needle may be "lifted" after slight retraction while keeping the original trajectory constant. **C,** Assuming the needle is deviating from the midline plane and contacting lamina, an action similar to that in *A* may be executed. **D,** Alternatively a stepwise lateral shift similar in concept to that shown in *B* may correctly achieve midline alignment. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

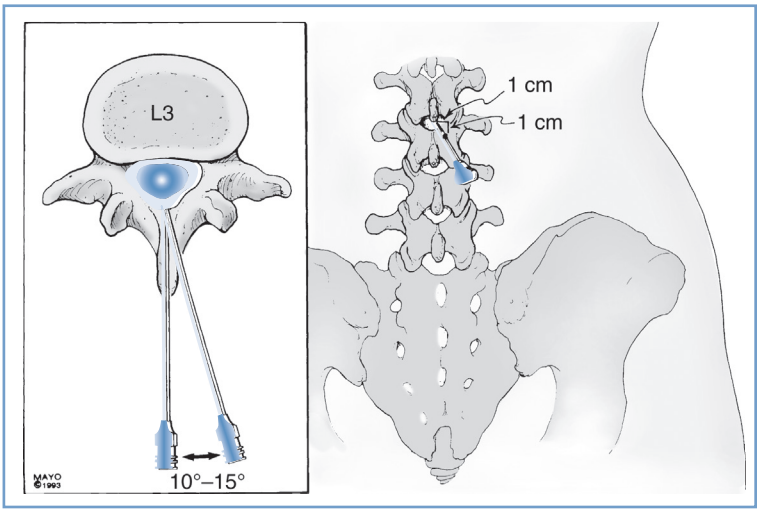

FIGURE 12-10 ■ Vertebral anatomy of midline and paramedian approaches for spinal and epidural anesthesia. The midline approach requires anatomic projection in only two planes: sagittal and horizontal. The paramedian approach also requires consideration of the oblique plane. However, the paramedian approach requires less patient cooperation in reducing lumbar lordosis to allow for successful needle insertion. The paramedian needle insertion site is made 1 cm lateral and 1 cm caudad to the caudad edge of the more cephalad spinous process. The paramedian needle is inserted 10 to 15 degrees off the sagittal plane (*inset*).

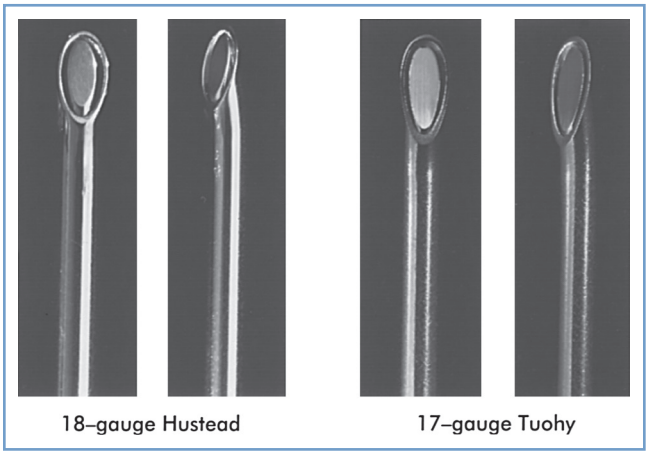

FIGURE 12-11 ■ Epidural needles often used in parturients. Each needle is shown in an open-bevel view and an oblique orientation. The 18-gauge Hustead and 17-gauge Tuohy needles have lateral-facing openings, which direct epidural catheters to enter the epidural space more easily than if a single-shot Crawford needle design is used. (Other sizes and needle designs are available for obstetric epidural anesthesia.)

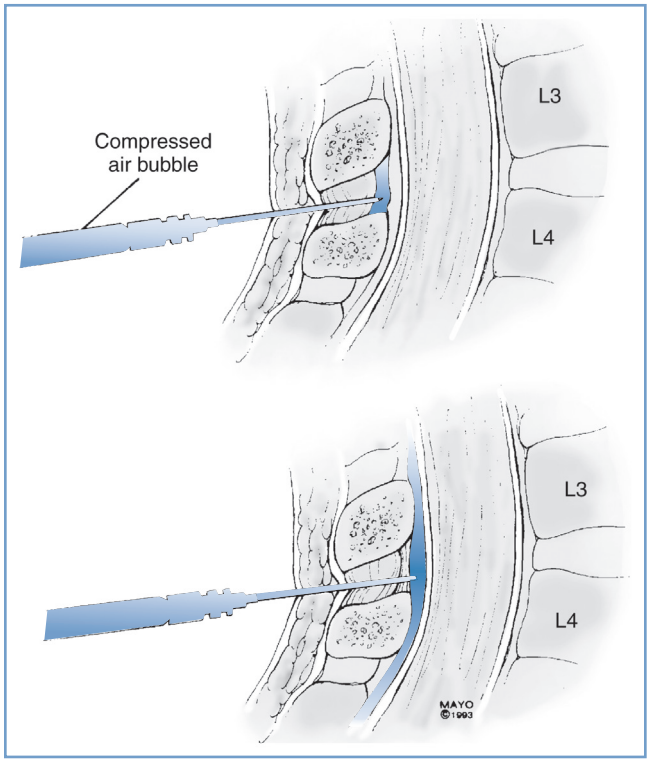

FIGURE 12-12 ■ Loss-of-resistance technique for identifying the epidural space. The needle is first inserted into the interspinous ligament or ligamentum flavum, and a syringe containing an air bubble in saline is attached to the hub. After compression of the air bubble by pressure on the syringe-plunger, the needle is carefully advanced until a loss of resistance to syringe-plunger pressure is noted as the needle enters the epidural space.

Once CSF is obtained, the block is performed as it is with the midline approach.

During the performance of any nerve block technique, needle advancement should stop if the patient complains of pain. If pain is the result of inadequate soft tissue anesthesia, additional local anesthetic should be injected. Pain or paresthesias may also result from needle contact with central nerves or the spinal cord. Patient perception of paresthesias during the initiation of spinal anesthesia may indicate that the needle tip is in the subarachnoid space. The anesthesia provider should remove the stylet and check for CSF. If the paresthesia has resolved, the local anesthetic may be injected. If the paresthesia persists, however, the needle should be withdrawn and repositioned. In any case, the anesthesia provider should never inject the local anesthetic if the patient is complaining of paresthesias or lancinating pain, either of which may signal injection into a nerve or the spinal cord.

Epidural Anesthesia

Special equipment for epidural analgesia or anesthesia includes an epidural needle, an epidural catheter (for a continuous technique), and a loss-of-resistance syringe (for the loss-of-resistance technique to identify the epidural space). Single-shot epidural anesthesia is rarely used in obstetric practice, because the major advantage of epidural over spinal anesthesia is the ability to provide continuous anesthesia or analgesia without puncturing the dura with a large needle. An epidural needle with a lateral opening (e.g., Hustead, Tuohy) is most commonly used because it allows a catheter to be threaded through its orifice (Figure 12-11).

Two methods are used to identify the epidural space during needle advancement: (1) hanging drop method and (2) loss-of-resistance method. The majority of anesthesia providers use the loss-of-resistance method (Figure 12-12).

The traditional loss-of-resistance syringe is a finely ground glass syringe with a Luer-Lok connector. Plastic syringes are now available, and the choice is generally a matter of the anesthesia provider's preference. The syringe is filled with 2 to 4 mL of saline, air, or saline with a small (0.25 to 0.5 mL) air bubble. There is some controversy regarding the use of air versus saline for detecting the point of loss of resistance.[58] Saline causes some syringe plungers to stick and may be confused with CSF during initiation of CSE anesthesia. Conversely, injection of air into the epidural space may contribute to patchy anesthesia,[59] and unintentional pneumocephalus may increase the risk for post–dural puncture headache.[60]

Prior investigations have suggested superiority of loss-of-resistance with saline over air with respect to block success. This conclusion is further supported by the results of a meta-analysis that pooled six controlled trials (n = 1037) in which laboring women were randomized to receive loss-of-resistance to air versus liquid (saline or local anesthetic solution).[61] This analysis suggested an increased risk for unblocked segments when loss-of-resistance to air was used, presumably owing to air bubbles leaking through the intervertebral foramina and residing adjacent to nerve roots.[62] No differences were found with respect to the occurrence of paresthesias or unintentional dural puncture or the need for additional

analgesic medication or epidural catheter replacement. The authors recommended a cautious interpretation of their analysis because many of the endpoints studied (e.g., "block success") do not have widely accepted definitions. In contrast, Schier et al.[63] report a meta-analysis that included both obstetric and nonobstetric patients (n = 4422), which suggested no significant difference between loss-of-resistance to air versus saline in the occurrence of difficult catheter insertion, paresthesias, intravascular catheter insertion, unintentional dural puncture, post–dural puncture headache, and partial block. Lastly, in a retrospective study of loss-of-resistance to air versus saline by Segal and Arendt,[64] no significant differences in block success were found in 929 patients. The authors intentionally chose a retrospective approach to the question; they stated that because "it is impossible to mask the anesthesiologist to the medium used for loss-of-resistance, [they] hypothesized that randomized controlled trials might *overestimate* the difference between air and saline by forcing the operator to use a less-preferred technique in half of the subjects."

Regardless of the technique used, success depends on correct placement of the needle tip within the ligamentum flavum. The needle should be advanced sufficiently into the interspinous ligament before the syringe is attached or before the hanging drop of solution is placed into the needle hub. This approach has at least three advantages. First, it encourages the anesthesia provider to use proprioception while directing and advancing the needle. Second, it shortens the time required for successful identification of the epidural space. Third, it lowers the likelihood of a false-positive loss of resistance. Undoubtedly, this false-positive identification of the epidural space is responsible for many cases of unsuccessful epidural anesthesia; it is even possible to insert a catheter between the interspinous ligament and the ligamentum flavum.

During advancement of the needle-syringe assembly, the needle should be moved toward the epidural space by the provider's nondominant hand while the thumb of the dominant hand applies constant pressure on the syringe plunger, thereby compressing the small air bubble. Alternatively, the intermittent, oscillating technique is typically employed when using the loss-of-resistance to air technique. When the needle enters the epidural space, the pressure applied to the syringe plunger causes the solution or air to flow easily into the epidural space (see Figure 12-12).

In most obstetric cases, the anesthesia provider inserts a catheter and uses an intermittent bolus or continuous infusion technique to maintain analgesia. Most practitioners insert the catheter before injecting local anesthetic to allow for the slow, incremental injection of local anesthetic/opioid solution and the more controlled development of epidural anesthesia. If the principal reason for using an epidural technique is the provision of continuous analgesia, it seems most practical to insert the catheter before injecting the therapeutic dose of local anesthetic so that correct catheter placement can be verified promptly.

Several types of single-use, disposable epidural catheters are available. Catheters are made from plastic materials and differ as to the degree of "stiffness." Wire-embedded catheters are more flexible and are associated with a lower incidence of paresthesias and intravascular placement during catheter insertion.[33,65,66] The single-orifice catheter has one opening at its tip, whereas the multi-orifice catheter has a closed "bullet" tip with three lateral orifices between 0.5 and 1.5 cm from the tip (Figure 12-13).

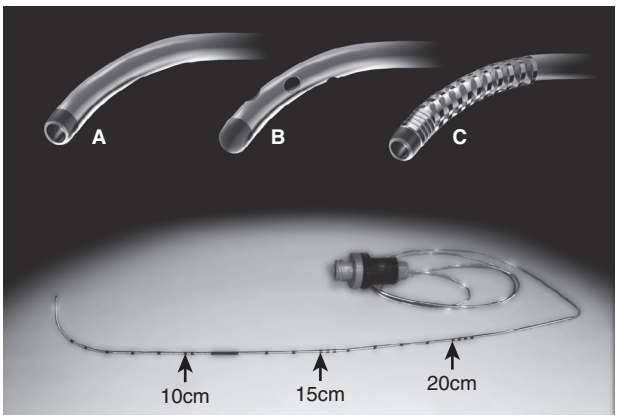

FIGURE 12-13 ■ Epidural catheters. **A,** Single-orifice catheter; **B,** multi-orifice catheter with bullet tip; **C,** coiled wire reinforced catheter. *Bottom,* Epidural catheter with centimeter markings along distal end and Luer-Lok connector at proximal end. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

The proposed advantage of single-orifice, open-end catheters is that the injection of drugs is restricted to a single anatomic site. In theory, this arrangement should facilitate the detection of intravenous or subarachnoid placement of the catheter. Likewise, a theoretical disadvantage of multi-orifice, closed-end catheters is that local anesthetic may be injected into more than one anatomic site (e.g., both the epidural and subarachnoid spaces). A catheter initially placed in the epidural space can migrate into a vein or the subdural or subarachnoid space. Fortunately, this does not seem to be a common clinical problem. Regardless of the choice of catheter, aspiration should be performed before each dose of local anesthetic is injected.

An advantage of the multi-orifice catheter over the single-orifice catheter is the consistent ability to aspirate fluid (either blood or CSF) when the catheter is in a vessel or the subarachnoid space.[67] Multi-orifice catheters may lead to more even distribution of local anesthetic and a lower incidence of "patchy" or unilateral anesthesia when the anesthetic is injected as a bolus.[68] However, during an infusion into the epidural space, the solution exits only the most proximal hole,[69] and multi-orifice catheters thus behave like single-orifice catheters.

If the catheter is placed before the test and therapeutic doses of local anesthetic, it may be helpful to inject 5 to 10 mL of saline before threading the catheter, because this may reduce the incidence of epidural vein cannulation,[33] particularly when using stiffer epidural catheters. Rolbin et al.[70] noted that there was no advantage to the injection of 3 mL of fluid into the epidural space before insertion of the epidural catheter.

Six to eight centimeters of catheter are threaded into the epidural space before the epidural needle is removed. The catheter may then be pulled back until it is at the desired distance at the skin. Occasionally, the anesthesia provider will have difficulty advancing the catheter past the tip of the epidural needle. This difficulty may indicate that the epidural needle tip is not in the epidural space. However, if the provider is convinced that the needle is correctly placed, several maneuvers may facilitate catheter advancement. Often, having the patient take a deep breath allows catheter advancement. Saline may be injected through the epidural needle if this has not been done. Although some providers rotate the epidural needle in an attempt to successfully advance the catheter, we do not recommend this maneuver, because it may increase the risk for dural puncture. Instead, the epidural needle should be withdrawn 0.5 to 1 cm and again advanced into the epidural space.

Many techniques are available for securing the epidural catheter at the skin entry site. If a catheter will be used for prolonged intrapartum or postoperative analgesia, care providers should be able to assess the skin surrounding the catheter. A transparent, sterile adhesive dressing applied over the catheter after application of skin adhesive generally works well, and the periphery of the dressing can be reinforced with tape. The position of the epidural catheter may change significantly with patient movement from the sitting-flexed to the sitting-upright or lateral decubitus position.[71] D'Angelo et al.[72] found that the risk for catheter dislodgement was higher when catheters were inserted 2 cm into the epidural space, but the risk for unilateral blockade was greater when catheters were inserted 6 to 8 cm. Therefore, if the catheter is to be used for a short period (e.g., during cesarean delivery), it should be left 2 to 4 cm into the epidural space. In contrast, if the catheter will be used for many hours (e.g., during labor), it should be left 4 to 6 cm into the space. To minimize catheter movement at the skin, the patient should be positioned sitting upright or in the lateral position before the catheter is secured, especially if the patient is obese.[71]

The potential for the contamination of local anesthetic solutions has prompted the use of micropore filters during the administration of continuous epidural analgesia for labor. There is no evidence that filters decrease the rate of infection or of injection of undesirable foreign substances.[73] Additionally, filters may reduce the reliability of aspiration[74] and absorb local anesthetic solution, unless they are primed.[75] We believe that micropore filters have little use in clinical obstetric anesthesia practice.

Combined Spinal-Epidural Anesthesia

Combined spinal-epidural anesthesia combines the advantages and mitigates the disadvantages of single-shot spinal anesthesia and continuous epidural anesthesia (Box 12-2). Anesthesia is initiated with a subarachnoid injection of local anesthetic and maintained via an epidural catheter. It is useful for both cesarean delivery anesthesia and labor analgesia. For cesarean delivery, the injection of the smaller dose of local anesthetic required for spinal (compared with epidural) anesthesia is inherently safer with regard to the possibility of unintentional intravascular injection. Additionally, the anesthesia provider can inject a local anesthetic dose that is lower than the ED_{95} (effective dose in 95% of cases) without fear of inadequate anesthesia. These lower doses result in less maternal hypotension.[76] If surgical anesthesia is inadequate, the block can be "rescued" with epidural administration of local anesthetic. For example, a randomized trial comparing 7, 8, and 9 mg of intrathecal bupivacaine administered as part of a CSE technique for cesarean delivery produced equivalent latencies to T4 sensory block with lower rates of maternal hypotension in the lowest dose group.[77] The shorter duration of action seen in the low-dose (7 mg) group was easily addressed through the administration of local anesthetic via the indwelling epidural catheter. Compared with conventional epidural anesthesia for cesarean delivery, CSE anesthesia is associated with a more rapid onset of surgical anesthesia, less intraoperative pain and discomfort (e.g., a more dense block), better muscle relaxation, and less shivering and vomiting.[78]

During labor, CSE analgesia is associated with a faster onset of analgesia and is generally achieved with an opioid alone or an opioid combined with a small dose of local anesthetic. Studies differ as to whether CSE analgesia is associated with higher maternal satisfaction and fewer requests for supplemental analgesia. Goodman et al.[79] randomized 100 parous women in early labor to receive either CSE or conventional epidural analgesia. There were no differences in requests for supplemental analgesia, although pain scores were lower in the CSE group within the first 30 minutes. This study harbors

BOX 12-2 Advantages of Combined Spinal-Epidural Anesthetic Technique

Compared with Epidural Anesthesia

- Lower maternal, fetal, and neonatal plasma concentrations of anesthetic agents
- More rapid onset of analgesia and anesthesia
- More dense sensory blockade
- Complete early labor analgesia with opioid alone (no local anesthetic necessary)
- Lower failure rate

Compared with Spinal Anesthesia

- Technically easier in obese individuals: The epidural needle acts as an introducer for the spinal needle (it is easier to advance a rigid epidural needle)
- Ability to titrate anesthetic dose: Start with low subarachnoid dose, and titrate to effect using epidural injection
- Results in less hypotension
- Ability to extend the extent of neuroblockade: Spinal anesthesia for forceps delivery may be extended to epidural anesthesia for cesarean after failed forceps delivery
- Continuous technique: ability to extend duration of anesthesia

limitations echoed by many of its predecessors, including (1) question of equipotency between the techniques, (2) inadequate sample size for assessment of secondary outcomes, and (3) inability to truly blind the study (the difference in analgesia latency readily identifies group allocation). A 2007 systematic review comparing CSE and epidural labor analgesia concluded that onset was faster with the CSE technique, but that there was no evidence for differences in maternal satisfaction, mode of delivery, ability to ambulate, or incidence of hypotension between the two techniques.[80] Several studies have found a lower incidence of failed epidural analgesia after the initiation of analgesia with a CSE technique.[81,82] Presumably, verification of the correct placement of the spinal needle by visualization of CSF increases the likelihood that the tip of the epidural needle is correctly placed in the epidural space.

A disadvantage of the CSE technique is that the correct placement of the epidural catheter in the epidural space cannot be verified until spinal anesthesia wanes. Therefore, if a functioning epidural catheter is important to the safe care of the mother and fetus (e.g., in the setting of a suspected difficult airway or nonreassuring fetal status), a CSE technique may not be the technique of choice.

There are several techniques for initiation of CSE anesthesia/analgesia.[83] The most popular is the needle-through-needle technique, in which the epidural needle is sited in the epidural space and serves as an introducer for the spinal needle. The spinal needle passes through the epidural needle to puncture the dura. After injection of the subarachnoid dose, the spinal needle is removed, and the epidural catheter is threaded through the epidural needle. An alternative technique uses two skin punctures and two different interspaces: the spinal needle and epidural needle and catheter are introduced sequentially in two different interspaces.

The needle-through-needle technique requires a long spinal needle. Typically, a small (25-gauge or smaller) non-cutting needle is used to minimize the risk for post–dural puncture headache. The tip of the spinal needle must protrude 12 to 17 mm beyond the tip of the epidural needle when the two needles are fully engaged (Figure 12-14). Failure to puncture the dura and visualize CSF occurred in 25% of patients when the spinal needle protruded 9 mm, compared with no patients when the needle protruded 17 mm.[84] A 127-mm spinal needle is commonly used with a standard 9-cm epidural needle. However, because of differences in hub configurations among needles, the two hubs may not "mesh," and spinal needle protrusion may vary with specific needle combinations. Alternatively, manufacturers now sell CSE needle "kits," in which the spinal needle is designed for a specific epidural needle. An additional small non–Luer-Lok syringe (1 to 3 mL) is required for the spinal dose.

CSE anesthesia is initiated much like epidural anesthesia. The epidural needle is sited in the epidural space (Figure 12-15). Prior to inserting the epidural catheter, the spinal needle is introduced through the epidural needle with the anesthesia provider's dominant hand, while the nondominant hand is anchored against the patient's back to serve as a brake for further advancement of the spinal needle. The provider usually perceives the tip of the spinal needle passing the tip of the epidural needle as a slight increase in resistance. Spinal needle advancement should stop immediately after the anesthesia provider perceives the dural puncture "pop." Dural puncture is verified by visualization of CSF after removal of the spinal needle stylet. The provider's nondominant hand is anchored on the patient's back, and the spinal and epidural needle hubs are grasped together between the thumb and index finger of this hand. The dominant hand attaches the spinal syringe and injects the drug. We do not attempt to aspirate CSF, because it may not be possible to do so through long, small-bore needles and because attempted aspiration may result in movement of the spinal needle. After removal of the spinal syringe and needle as a unit, the epidural catheter is threaded in the usual fashion.

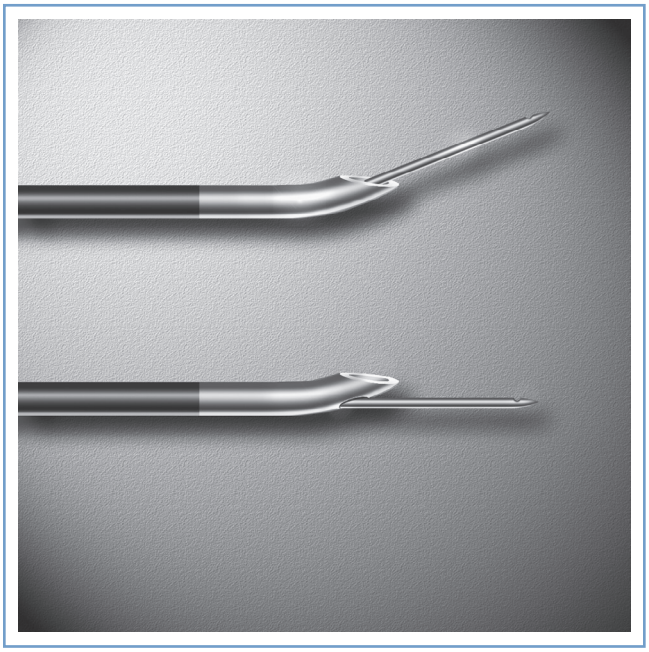

FIGURE 12-14 ■ Combined spinal-epidural needle configuration. *Top,* Spinal needle exits the epidural needle through the normal epidural needle bevel. Because the epidural needle bevel opening faces sideways, the spinal needle exits the epidural needle at a slight angle to the long axis of the epidural needle. *Bottom,* Spinal needle exits the epidural needle through a special orifice. The axes of the spinal and epidural needles are aligned. The spinal needle must protrude from the tip of the epidural 12 to 17 mm when the hubs are engaged, or the ability to puncture the dura with the spinal needle is compromised. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

Failure to puncture the dura with the spinal needle may occur in several circumstances (Figure 12-16). The epidural needle tip may not be located in the epidural space, or the needle tip may be correctly placed, but the spinal needle may fail to puncture the dura or may not reach the dura because of the depth of the posterior epidural space. Alternatively, the epidural needle may be angled away from the midline or in a sagittal plane off the midline and the spinal needle may traverse the lateral epidural space without puncturing the dura. In this latter circumstance, the anesthesia provider may elect to

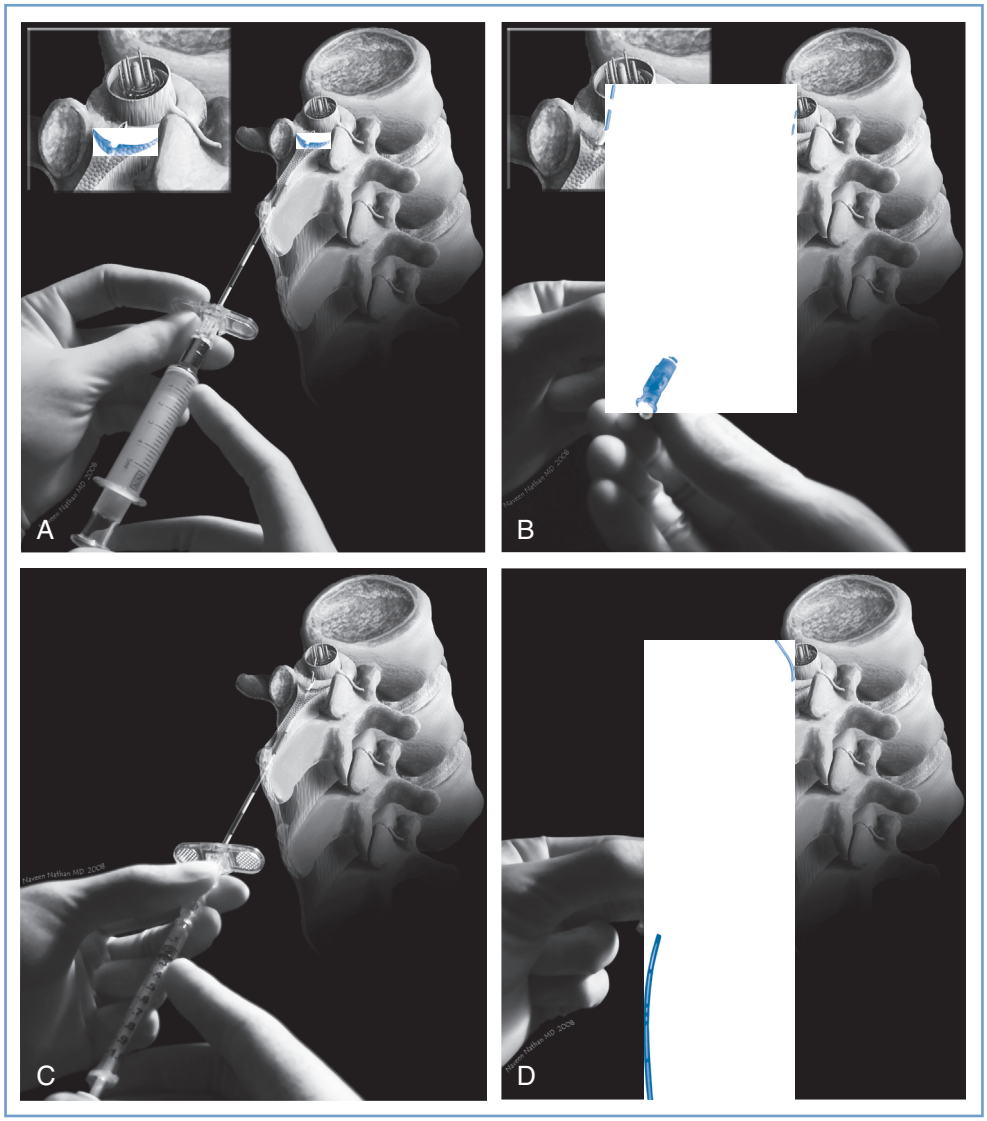

FIGURE 12-15 ■ Needle-through-needle combined spinal-epidural technique. **A,** The epidural needle is sited in the epidural space. **B,** The long spinal needle is passed through the epidural needle and punctures the dura mater. The operator's nondominant hand stabilizes the spinal and epidural needles, and the spinal needle stylet is withdrawn. Cerebrospinal fluid is seen spontaneously dripping from the spinal needle. **C,** The syringe is attached to the spinal needle, and the intrathecal dose is injected. **D,** The spinal needle is withdrawn, and the epidural catheter is threaded through the epidural needle into the epidural space. Anesthesiology 2002; 97:574.)

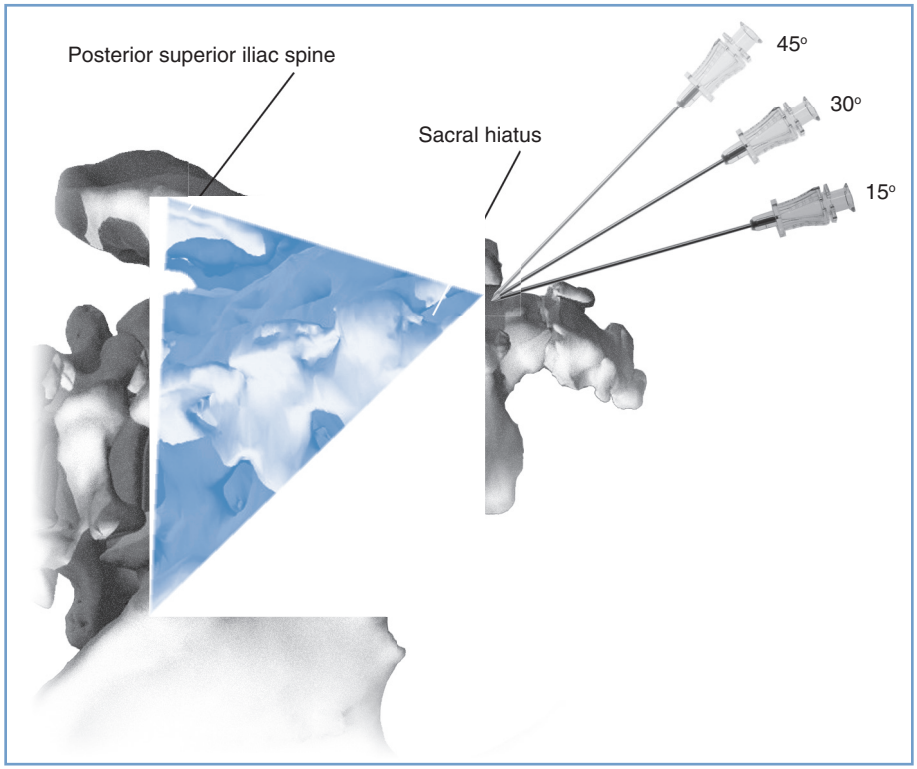

FIGURE 12-17 ■ The location of the sacral hiatus for caudal anesthesia is facilitated by the identification of the posterior superior iliac spines. The posterior superior spines are marked, and a line drawn between them forms one edge of an equilateral triangle. If the triangle is completed as illustrated, the sacral hiatus should underlie the caudad tip of the equilateral triangle. Once the sacral hiatus is identified, the needle is inserted by insertion and withdrawal in a stepwise fashion from an initial 45-degree angle off the coronal plane. In pregnant women, the needle eventually enters the caudal canal at an angle approximately 15 degrees off the coronal plane. If the needle is placed properly, no subcutaneous "lump" develops after the injection of the local anesthetic solution. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

abandon the CSE technique and continue with epidural anesthesia (if convinced that the epidural needle tip is in the epidural space) or to reposition the epidural needle and reattempt the CSE technique.

Caudal Anesthesia

Equipment for caudal anesthesia is similar to that used for lumbar epidural techniques, except that a needle with a lateral-faced opening is not needed. A blunt-tipped needle is satisfactory even when a catheter is used, because the angle of needle insertion allows insertion of the catheter. Successful administration of caudal anesthesia requires the accurate identification of the sacral hiatus. The sacrococcygeal ligament (an extension of the ligamentum flavum) overlies the sacral hiatus between the sacral cornua. Identification of the posterior superior iliac spines facilitates the identification of the sacral cornua; the location of the sacral hiatus is approximated by using the line between them as one side of an equilateral triangle (Figure 12-17). Once the sacral hiatus is identified, the palpating fingers are placed on the cornua, the skin is anesthetized, and the caudal needle is inserted with the hub at an angle approximately 45 degrees from the skin. A decrease in resistance is noted when the needle enters the caudal canal. The needle is advanced until it contacts bone (i.e., the dorsal aspect of the ventral plate of the sacrum). Next, the needle is withdrawn slightly and redirected so that the angle of insertion relative to the skin surface is decreased. In pregnant women, the final angle is approximately 15 degrees from a plane parallel to the sacrum.

Accurate placement of the caudal needle is verified primarily from the "feel" of the needle passing through the sacrococcygeal ligament. An additional maneuver may help providers with less experience to verify correct needle placement: Once the needle is believed to be within the caudal canal, 5 mL of saline is rapidly injected through the needle while the anesthesia provider's other hand is placed over the dorsum of the sacrum. If the needle is placed correctly, no mass or pressure wave is detected over the midline of the sacrum. Conversely, if the needle is malpositioned (often posterior to the caudal canal), a fluid mass or pressure wave is felt by the palpating hand.

The needle should be advanced only 1 to 2 cm into the caudal canal. Dural puncture or unintentional intravascular cannulation is more likely to occur with deeper insertion. A test dose similar to that used during administration of lumbar epidural anesthesia should be administered.

Ultrasonographic Guidance

Traditionally, surface anatomy visualization and palpation have been used to assess landmarks before initiation of

the neuraxial procedure. This landmark-guided technique is effective for the vast majority of patients and, as a consequence, the use of ultrasonography has not played as prominent a role in neuraxial anesthesia as it has in peripheral nerve blockade. There exist, however, unique clinical circumstances in which immediate pre-procedural imaging of epidural anatomy can be highly beneficial. Such may be the case in patients with morbid obesity, derangements of spinal anatomy such as scoliosis or spinal stenosis, or a history of spinal instrumentation, and in patients in whom identification of specific vertebral levels might be warranted (e.g., known preexisting disc herniation or nerve root compression at a specific interspace). Unlike the use of ultrasonography for vascular access and peripheral nerve block techniques, ultrasonography for neuraxial techniques is not used in real time. Indeed, the real-time use of ultrasonography during administration of neuraxial anesthesia can be prohibitively cumbersome, is fraught with a tangible risk for violating aseptic technique, and raises unanswered questions about what untoward effects may result should ultrasound coupling medium (gel) breach neuraxial structures. Most often ultrasonography is a pre-procedural tool to aid the operator in the assessment of needle insertion site, needle angle, and estimated depth of the epidural space.

It remains to be seen whether neuraxial ultrasonography can significantly impact the clinical success of neuraxial procedures, whether that is measured in terms of time to completion of the spinal or epidural anesthesia procedure, or block success and patient satisfaction. Additionally, reductions in the incidence of complications of neuraxial anesthesia, such as unintentional dural puncture, have yet to be realized.

In the obstetric population, four randomized controlled trials have explored outcomes related to block success using the traditional landmark-based technique versus the ultrasound-aided technique.[85-88] Only one, however, divorced the unblinded ultrasonographer from those supervising the block and rendering assessments of success.[88] In this investigation,[88] 370 parturients receiving epidural labor analgesia were randomized to receive pre-procedural ultrasonographic imaging for determination of depth to epidural space or no imaging (control group). The estimated depth to the epidural space was conveyed to 15 first-year residents with little or no previous neuraxial anesthesia experience, who performed the blocks under the supervision of a staff anesthesiologist who was blinded to the group assignment. Obese patients were not excluded from this study, and there were no significant differences between groups in demographic factors. The authors found a significant reduction in the number of attempts needed to place the epidural catheter and in the need for catheter replacement in the ultrasonography group. There was no difference in the rate of unintentional dural puncture, although the study was underpowered for assessment of this outcome. The calculated number of epidural catheter placements with ultrasonography needed to avoid replacing one failed catheter (number needed to treat) was 26. Of note, the residents were not themselves randomized, nor were they tracked according to the number of cumulative procedures with and without ultrasonography. From the perspective of introducing trainees to the technique of neuraxial anesthesia procedures, ultrasonographic imaging may yet play a more substantial educational role.

How does pre-procedural ultrasonographic imaging affect neuraxial anesthesia success for patients anticipated to endure difficult needle placement? Chin et al.[89] identified 120 patients presenting for elective lower extremity orthopedic surgery who were predicted to endure difficult administration of spinal anesthesia. Their basis for qualifying these patients as "difficult" included a body mass index greater than 35 kg/m^2 with nonpalpable spinous processes, the presence of moderate to severe scoliosis, or a history of spinal surgery involving excision of two or more lumbar spinous processes. These subjects were randomized to receive pre-procedural ultrasonographic imaging of epidural anatomy or a conventional landmark-based technique. The total number of attempts required before successful dural puncture was twofold higher in the landmark control group than in the ultrasonography group. Although the average time spent completing the spinal anesthesia procedure was longer in the control group than in the ultrasonography group (mean = 7.3 minutes versus 5.0 minutes, respectively), if one accounted for the pre-procedural ultrasonographic examination, the *total* procedure time was shorter in the control group (7.9 minutes versus 12.2 minutes).

How accurately do pre-procedural ultrasonoanatomic measurements correlate to the actual distance from the skin to the epidural space? In general, although the correlation is high, ultrasonographic measurements of neuraxial anatomy may underestimate the true distance from skin to epidural space in the context of neuraxial procedures.[88,90-92] The factors that influence the small disparity between the two include (1) differences between the angulation of the imaging beam versus the angulation of the needle; (2) differences between the degree of exerted pressure and skin compression of the ultrasound probe versus the needle; (3) current lack of fidelity in the ability of ultrasonography to discriminate between ligamentum flavum, epidural space, and dura mater; and (4) operator dependency of typical onscreen measurement tools such as digital calipers. In a general obstetric population, the mean difference between the needle depth and ultrasonographic depth to the epidural space was 0.01 cm (95% confidence interval, –0.67 to 0.69 cm),[92] whereas in a second study by the same investigators in which subjects were limited to obese parturients, the mean difference was 0.3 cm (95% confidence interval, –0.7 cm to 1.3 cm).[90]

A low-frequency (2- to 5-Hz) curvilinear probe allows visualization of neuraxial structures beneath the skin. Low-frequency waves are preferable owing to the requisite depth of penetration. The curvilinear array allows enough ultrasonic scope to capture lateral structures such as the transverse processes. The ultrasound beam can be used to identify first the spinous processes if these are not palpable, then the interspinous spaces, and, finally, ligamentous structures. The ligamentum flavum and dura mater are dense tissues and will appear hyperechoic (white), like bone, whereas the less dense epidural and subarachnoid spaces will appear hypoechoic (black). A

variety of imaging planes are now well described. Transverse and median sagittal as well as paramedian sagittal approaches have been documented. The transverse-interlaminar view is likely to be of most use when attempting neuraxial procedures using the midline approach. On the other hand, the paramedian sagittal view may be of use if a paramedian approach is anticipated (Figure 12-18). With the median sagittal approach, the spinous process will produce a shadow when the beam is placed directly over it, thus reducing the ability to appreciate any ligaments beyond it.

EPIDURAL TEST DOSE

Epidural catheter placement may be complicated by blood vessel or dural puncture with the needle or catheter. To prevent possible local anesthetic toxicity and high or total spinal anesthesia, the anesthesia provider must recognize the unintentional intravenous or subarachnoid placement of the needle or catheter. The purpose of the test dose is to allow early recognition of a malpositioned catheter. The ideal test dose must be readily available, safe, and effective. Its use should have a high sensitivity (i.e., low false-negative rate) and a high specificity (i.e., low false-positive rate). The intravascular and intrathecal test doses may be combined (a single injection to test for both intravascular and subarachnoid placement) or administered separately. A negative response to an epidural test dose does not guarantee the correct placement of the epidural catheter in the epidural space, nor does it guarantee that the catheter is not malpositioned in a blood vessel or the subarachnoid space. Rather, it decreases the likelihood that

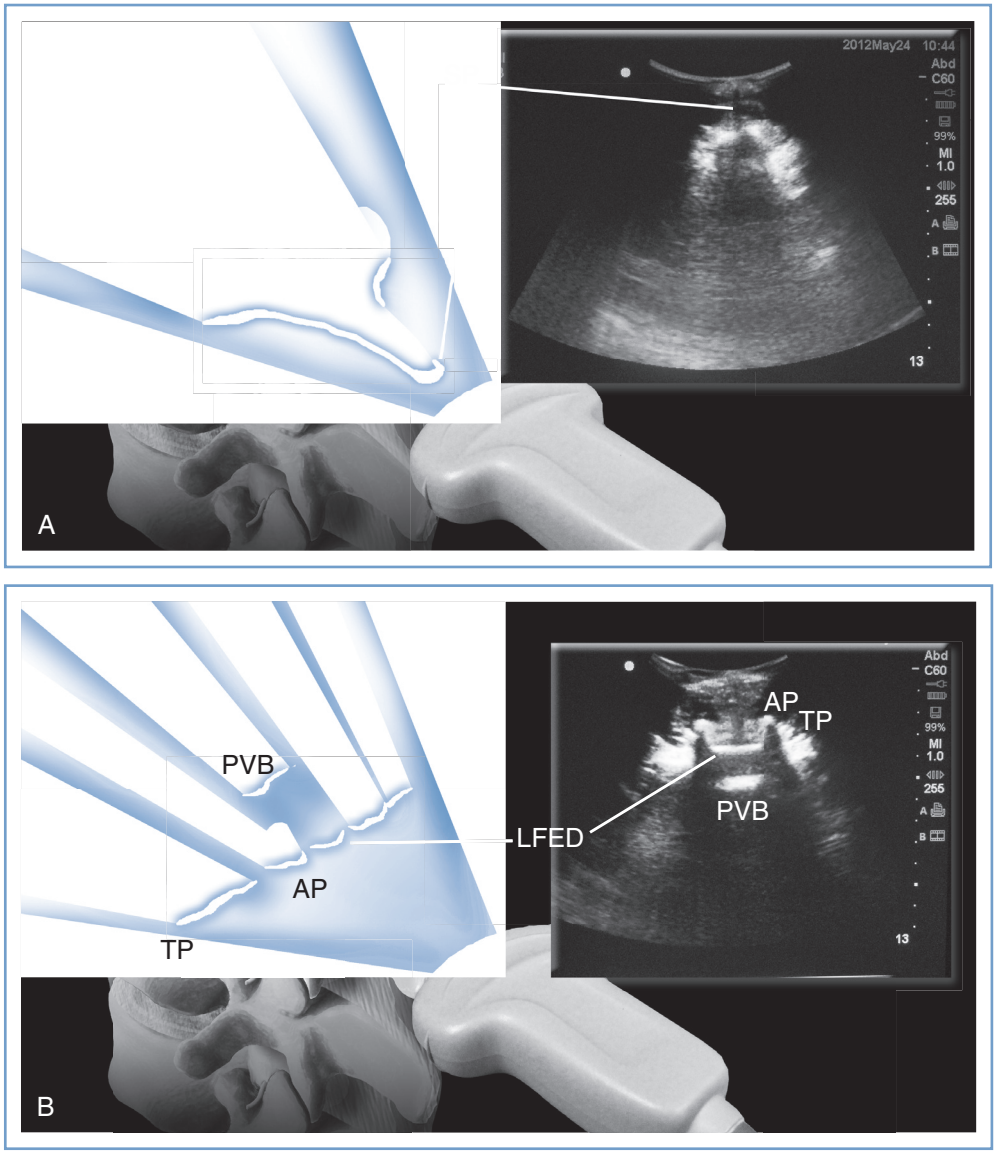

FIGURE 12-18 ■ Use of ultrasonography. **A,** Transverse spinous process view: A long, dark shadow is cast with little to no discernible anatomy beyond the osseous tip of the spinous process (*SP*). **B,** Transverse interlaminar view: ultrasound waves propagate through the interspinous ligament leading to signals partially reflected by the ligamentum flavum–epidural space–dura mater complex (*LFED*). The rays that continue to transmit through this complex encounter the posterior wall of the vertebral body (*PVB*). Articular (*AP*) and transverse processes (*TP*) can be seen as well.

(Drawings by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

the catheter tip is in a blood vessel or the subarachnoid space.

Intravascular Test Dose

The ideal method for excluding intravenous placement of the catheter is controversial. Intravascular placement of the epidural catheter may occur in as many as 7% to 8.5% of obstetric patients.[93] Failure to recognize intravenous placement of the epidural catheter and subsequent intravenous injection of a large dose of local anesthetic may lead to systemic local anesthetic toxicity, with CNS symptoms, seizures, cardiovascular collapse, and death.[94]

The most common intravascular test dose contains epinephrine 15 µg. In normal volunteers, intravenous injection of epinephrine 15 µg (3 mL of a 1:200,000 solution) reliably causes tachycardia.[95,96] An increase in heart rate of 20 beats per minute (bpm) within 45 seconds was 100% sensitive and specific for intravascular injection in unpremedicated patients.[95] An increase in systolic blood pressure of between 15 and 25 mm Hg was also observed. Some anesthesiologists have expressed concerns about the use of an epinephrine-containing test dose in laboring women. Intravenous epinephrine may cause a transient decline in uterine blood flow as a result of alpha-adrenergic receptor–mediated constriction of the uterine arteries (Figure 12-19).[97-99]

However, this decrease in uterine blood flow is transient and comparable to the decrease that occurs during a uterine contraction. Youngstrom et al.[100] noted that this intravenous dose of epinephrine did not worsen fetal condition in acidotic fetal lambs. In healthy parturients, any transient effect of epinephrine on uterine blood flow likely represents a less severe insult than systemic local

anesthetic toxicity. An epinephrine-containing test dose, however, may not be appropriate in parturients with severe hypertension or uteroplacental insufficiency.

Some anesthesiologists argue that the epinephrine-containing test dose lacks *specificity* in laboring women. The maternal tachycardic response to intravenous injection of epinephrine cannot always be distinguished from other causes of tachycardia (e.g., pain during a uterine contraction) (Figure 12-20).[101,102]

Cartwright et al.[101] noted that 12% of laboring women had an increase in heart rate of at least 30 bpm after epidural injection of 3 mL of 0.5% bupivacaine without epinephrine. A study in laboring women compared the intravenous injection of epinephrine (10 to 15 µg) with that of saline; the sensitivity was 100%, the area under the receiver operator curve was 0.91 to 0.93, and the negative predictive value was 100%.[103] However, the positive predictive value was 55% to 73%. The results suggested that if a positive heart rate response to an epinephrine-containing test dose occurs in 20% of patients, 5% to 9% of epidural catheters would be identified incorrectly as intravascular and removed unnecessarily. Colonna-Romano and Nagaraj[104] concluded that the intravenous injection of an epinephrine-containing test dose results in "a sudden and fast acceleration in maternal heart rate within one minute." Thus, careful assessment of the rate of increase in maternal heart rate may help distinguish a contraction-induced increase in heart rate from the effect of intravenously injected epinephrine, thereby improving the *specificity* of the epinephrine test. It is unclear whether such an assessment is clinically practical or will actually reduce the incidence of false-positive results.[105]

Additionally, some anesthesiologists argue that the epinephrine-containing test dose lacks *sensitivity* (the ability to elicit a predictable increase in heart rate when the catheter is intravascular). An increase in maternal heart rate of 25 bpm occurring within 2 minutes of drug injection and lasting at least 15 seconds was observed in only 5 of 10 laboring women who received intravenous epinephrine 15 µg.[106] Detection of intravenous epinephrine injection was improved when the authors retrospectively defined a positive maternal tachycardic response as a 10-bpm increase above the maximum maternal heart rate observed in the 2-minute period preceding the epinephrine injection. Others have confirmed that these

The dose of lidocaine was 0.4 mg/kg. Values are presented as mean ± standard error of mean (SEM) percentage of baseline. (From Chestnut DH, Weiner CP, Martin JG, et al. Effect of intravenous epinephrine on uterine artery blood flow velocity in the pregnant guinea pig. Anesthesiology 1986; 65:633-6.)

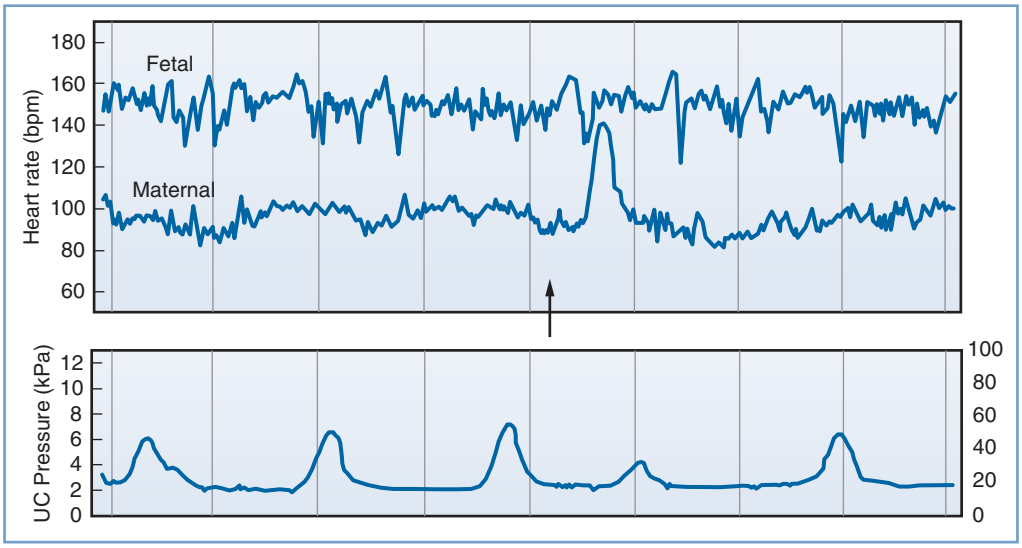

FIGURE 12-20 ■ Heart rate of a laboring patient (maternal heart rate [MHR]), fetal heart rate, and uterine contractions (*UC*) are shown. This tracing was obtained with the use of an FHR monitor with dual heart rate capacity. Note the variability of the MHR with uterine contractions. An intravenous injection of bupivacaine 12.5 mg and epinephrine 12.5 µg was given (*arrow*). Note the marked increase in MHR in response to intravenous injection of the test dose. The maternal tachycardia had a duration of approximately 40 seconds. (From Van Zundert AA, Vaes LE, De Wolf AM. ECG monitoring of mother and fetus during epidural anesthesia. Anesthesiology 1987; 66:584-5.)

TABLE 12-2 **Epidural Test Dose Regimens***

Test Dose Components	Positive Intravascular Test Dose	Positive Intrathecal Test Dose
Combined Intrathecal and Intravenous Test Dose:		
Lidocaine 1.5% with epinephrine 5 μg/mL (1:200,000): 3 mL Bupivacaine 0.25% with epinephrine 5 μg/mL (1:200,000): 3 mL	Increase in heart rate of 20 bpm within 1 minute	Motor blockade at 3-5 minutes†
Intravenous Test Dose:		
Lidocaine 100 mg Bupivacaine 25 mg 2-Chloroprocaine 100 mg	Tinnitus, circumoral numbness, "dizziness"	
Fentanyl 100 μg	Dizziness, drowsiness	
Air 1 mL	Change in Doppler heart sounds over right side of heart	
Intrathecal Test Dose:		
Lidocaine 40-60 mg Bupivacaine 7.5 mg		Motor blockade at 3-5 minutes†

*Test doses may be less sensitive in premedicated patients, patients treated with a beta-adrenergic receptor antagonist, pregnant patients, and anesthetized patients.
†Weakness in hip flexion.
Modified from Yilmaz M, Wong CA. Technique of neuraxial anesthesia. In Wong CA, editor. Spinal and Epidural Anesthesia. New York, McGraw-Hill, 2007:27-73.

revised criteria improve the sensitivity of the epinephrine-containing test dose in laboring women.[103] These findings stress the importance of tracking the chronotropic variability that occurs in laboring patients during neuraxial anesthesia procedures to reduce the risk for misinterpretation of the test dose.

The usefulness of an epinephrine-containing test dose also improves if additional information is obtained. For example, investigators administered intravenous bupivacaine 12.5 mg with epinephrine 12.5 μg or saline to laboring women.[107] They correctly identified the test solution in 39 of 40 women when they assessed maternal heart rate, blood pressure, uterine contractions, the timing of the injection, the presence of analgesia, and subjective signs and symptoms of intravascular injection (e.g., palpitations, lightheadedness, dizziness). The tachycardic response to intravenous epinephrine is not a reliable indicator of intravascular injection in patients who have received a beta-adrenergic receptor antagonist.[95]

Other means of identifying intravascular placement of an epidural catheter have been proposed and may be clinically useful in specific patients (Table 12-2). Intravenous administration of isoproterenol 5 μg consistently results in tachycardia in pregnant women.[108,109] Data from animals[99,110] and noninvasive measurements in parturients[109] suggest that isoproterenol is devoid of the adverse effects of epinephrine on uterine blood flow, and limited neurotoxicity evaluations have not revealed adverse effects.[110,111] However, isoproterenol has not been approved for epidural or intrathecal administration. Given the lack of adequate information regarding potential neurotoxicity, we do not recommend the use of isoproterenol as an epidural test dose.

Leighton et al.[112] have advocated the use of air as an objective marker of intravascular injection. Intravenous injection of 1 or 2 mL of air through a single-orifice catheter consistently produces changes in heart sounds as detected by the use of precordial Doppler ultrasonography.[112] (The external FHR monitor can be used for this purpose.) False-negative results may occur when small volumes of air are injected through a multi-orifice epidural catheter; thus, the air test is not a reliable test for intravascular injection when multi-orifice epidural catheters are used.[113]

Local anesthetic–induced symptoms of subclinical CNS toxicity have also been evaluated as a means of recognizing the unintentional intravenous injection of epidural medications. Colonna-Romano et al.[114] administered intravenous saline, lidocaine 100 mg, or 2-chloroprocaine 100 mg to laboring women. Observers blinded as to which substance was administered recorded the presence of CNS symptoms (i.e., dizziness, tinnitus, funny taste) after intravenous injection of local anesthetic. Lidocaine 100 mg was a reliable marker of intravenous injection when the symptoms of tinnitus and funny taste were considered (sensitivity 100%; specificity 81%). 2-Chloroprocaine was less reliable (sensitivity 81% to 94%; specificity 69% to 81%). In a volunteer study, a dose of 1.5 mg/kg of 2-chloroprocaine was necessary to produce a probability of 90% that the subject would report symptoms of intravenous injection.[115]

Administration of fentanyl 100 μg has been described as a test for intravenous injection.[116] Morris et al.[117] evaluated the accuracy and reliability of the fentanyl test dose in a double-blind study in which either intravenous or epidural fentanyl 100 μg was administered to parturients, and the investigators sought evidence of the occurrence of sedation, dizziness, euphoria, and/or analgesia. Dizziness was the most reliable symptom of intravenous fentanyl injection, with a sensitivity of 92% and a specificity of 92%.

Some situations reduce the reliability of subjective symptoms as a signal of intravenous injection of a drug. Tests that rely on the self-reporting of subjective

symptoms require clear communication with the patient and thus are less useful when the anesthesia provider and patient speak different languages. Patient exhaustion and/or prior opioid administration also may affect the reliability of the test.

Lastly, the epidural catheter design and speed of injection may affect the reliability of the epidural test dose. An epinephrine-containing test dose should be injected rapidly; otherwise rapid redistribution and metabolism of the drug decrease the actual dose administered to chronoreceptors. Multi-orifice epidural catheters have three potential sites of exit for injected fluid or air, and the orifices may lie within two different body compartments. If injected too slowly, air or fluid preferentially exits the proximal orifice. The speed of injection used in clinical practice typically exceeds that required to ensure that fluid will exit all three orifices. In contrast, air must be injected at a much greater speed to ensure that it exits all three orifices; this speed is not practical for clinical use. The distal orifice is both the most difficult to test and the one most likely to be positioned outside the epidural space.[118]

Intrathecal Test Dose

The intrathecal test dose should allow easy identification of subarachnoid (intrathecal) placement of the catheter without causing high or total spinal anesthesia and hemodynamic compromise. Bupivacaine (7.5 mg) and lidocaine (45 to 60 mg) are the local anesthetics most often used for an intrathecal test dose (see Table 12-2; Figure 12-21).[119,120]

In a study of older, nonpregnant patients receiving continuous spinal anesthesia for surgery, Colonna-Romano et al.[120] used plain lidocaine 45 mg plus epinephrine 15 μg and assessed patient perception of lower extremity warmth and heaviness, sensory loss to pinprick, and ability to perform a straight-leg raise. Patients usually perceived warmth in their legs within 1 minute of the intrathecal injection; however, impaired straight-leg raise 4 minutes after an intrathecal test dose injection was the only test that had a sensitivity of 100% for intrathecal injection. The application of these data to pregnant patients is unclear.

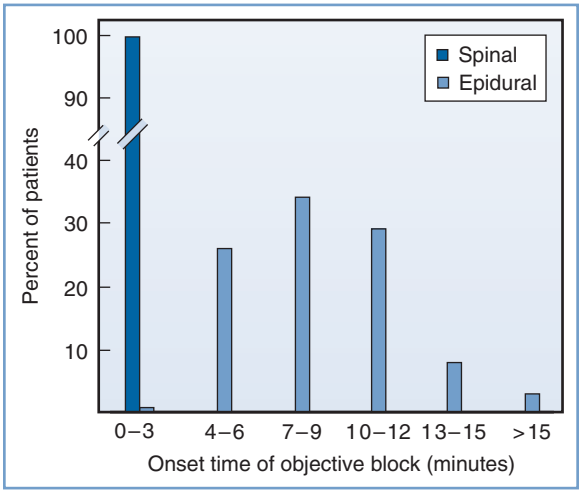

FIGURE 12-21 ■ Percentage of pregnant patients who demonstrated objective evidence of anesthesia (defined as the loss of sensation to pinprick) after epidural injection of 2 to 3 mL of hyperbaric 1.5% lidocaine with 1:200,000 epinephrine (*light teal bars*) (n = 250) or after intrathecal injection of 2 mL of hyperbaric 1.5% lidocaine with 1:200,000 epinephrine (*dark teal bar*) (n = 15). (From Abraham RA, Harris AP, Maxwell LG, et al. The efficacy of 1.5% lidocaine with 7.5% dextrose and epinephrine as an epidural test dose for obstetrics. Anesthesiology 1986; 64:116-9.)

Richardson et al.[121] described the rapid onset (1 to 3 minutes) of high levels of spinal anesthesia with motor block and hypotension in five parturients who had received a test dose of plain lidocaine 45 mg plus epinephrine 15 μg. This solution is slightly hypobaric relative to CSF at body temperature; thus, the upright posture of these parturients during the injection may have contributed to the high levels of spinal anesthesia. The anesthesia provider must recognize the possible range of responses to the dose of local anesthetic used to assess the position of an epidural catheter and should perform a careful assessment of sensory, motor, and sympathetic function 3 to 5 minutes after administration of the test dose before concluding that the intrathecal test dose result is negative. Ropivacaine 15 mg is *not* a useful intrathecal test dose because the slow onset of motor blockade precludes timely diagnosis of intrathecal injection.[122] 2-Chloroprocaine is the only local anesthetic that can be used as a single, combined intravascular and intrathecal test dose; in most patients, 100 mg results in dense, but not total, spinal anesthesia after intrathecal injection and produces systemic signs of subclinical toxicity (tinnitus, funny taste) after intravascular injection.

The epidural injection of local anesthetic for the purpose of ruling out intrathecal or intravascular catheter placement augments *epidural* analgesia and should be considered in the calculation of the initial therapeutic dose of local anesthetic. Several groups of investigators demonstrated that the test dose enhanced the density of epidural blockade and adversely affected the ability to ambulate. A test dose containing lidocaine 45 mg/epinephrine 15 μg adversely affected the ability to ambulate when injected immediately before initiation of epidural analgesia with 0.125% bupivacaine (18.75 mg) with sufentanil (10 μg).[123] Similarly, the same test dose interfered with ambulation when administered immediately after the intrathecal injection of bupivacaine 2.5 mg and fentanyl 25 μg.[124] Finally, a lidocaine 60 mg/epinephrine 15 μg test dose adversely affected the ability to ambulate in women who received neostigmine 500 μg with sufentanil 10 μg for initiation of analgesia.[125]

Techniques to Minimize Local Anesthetic Toxicity

No perfect test dose exists. Some anesthesia providers elect not to administer a test dose because it contributes to motor blockade.[123,124] In addition, aspiration of a *multi-orifice* epidural catheter for blood has 98% sensitivity for detection of an intravascular location.[67] Inadvertent intravascular injection of a solution containing a low

concentration of local anesthetic is unlikely to result in serious morbidity. However, this conclusion depends heavily on the use of small doses of local anesthetic.[126] Laboring women may need large doses of local anesthetic for operative delivery. In some cases, large doses are administered quickly (without incremental injection) for emergency cesarean delivery. The anesthesia provider wants to determine as soon as possible that the epidural catheter is correctly positioned within the epidural space. Even if no morbidity results, it is inconvenient for both the patient and the anesthesia provider to have to repeat the procedure and replace the catheter once the drape has been removed and the patient has been repositioned. The epinephrine-containing test dose provides an objective marker of intravascular injection that has stood the test of time. Thus, we typically give a test dose that contains either bupivacaine 7.5 mg or lidocaine 45 to 60 mg with 15 μg of epinephrine. No matter whether a test dose is injected, drugs should be injected incrementally into the epidural space, because no test is 100% sensitive and catheters may migrate during use. Each incremental dose should be treated as a "test dose" (i.e., the dose should be small enough that it will not cause systemic toxicity if unintentionally injected intravascularly or total spinal anesthesia if injected intrathecally). Pregnant women are very difficult to resuscitate from local anesthetic cardiovascular toxicity.[94]

Steps to minimize the possibility of local anesthetic toxicity are summarized in Box 12-3. They include observation for passive return of CSF or blood (by lowering the proximal end of the epidural catheter below the insertion site), administration of the test dose between contractions, aspiration before each dose, incremental dose administration, maintaining verbal contact with the patient, and assessment for an appropriate level and density of sensory and motor blockade (which indicates correct placement of the catheter in the epidural space).

BOX 12-3 Steps to Decrease Risk for Unintentional Intravenous or Subarachnoid Injection of Local Anesthetic

- Lower the proximal end of the catheter below the site of insertion. Observe for the passive return of blood or cerebrospinal fluid.
- Aspirate before injecting each dose of local anesthetic.
- Give the test dose between uterine contractions.
- Use dilute solutions of local anesthetic during labor.
- Do not inject more than 5 mL of local anesthetic as a single bolus.
- Maintain verbal contact with the patient.
- If little or no block is produced after the injection of an appropriate dose of local anesthetic, assume that the local anesthetic was injected intravenously and remove the catheter.

CHOICE OF DRUG*

The dose requirement of both epidural and spinal local anesthetics is decreased approximately 25% in pregnancy owing to anatomic and physiologic changes (see Chapter 2). These alterations begin to revert to the prepregnancy state within hours of delivery.

Spinal Anesthesia

Anesthesia providers may give spinal anesthesia for cerclage, nonobstetric surgery during pregnancy, instrumental vaginal delivery, cesarean delivery, removal of a retained placenta, or postpartum tubal ligation. Spinal analgesia may be used for labor analgesia. Cesarean delivery represents the most common indication for spinal anesthesia in pregnant women. Most anesthesia providers administer a hyperbaric solution of local anesthetic for spinal anesthesia in obstetric patients. Use of a hyperbaric solution as compared with an isobaric solution results in a faster onset of block and a higher maximum sensory level with a shorter duration of blockade.[127] The urgency and anticipated duration of surgery dictate the choice of local anesthetic agent. The most common choice in the United States is bupivacaine. Other agents include lidocaine and tetracaine. Ropivacaine and levobupivacaine may be used but are not approved for spinal administration in the United States, and levobupivacaine is not available in the United States. Lidocaine provides a short to intermediate duration of action. Bupivacaine, tetracaine, levobupivacaine, and ropivacaine provide intermediate to long durations of action.

Anesthesia providers often add an opioid to the local anesthetic to improve the quality of anesthesia, particularly with regard to visceral stimulation, and to provide postoperative analgesia.[128,129] The addition of an opioid to the local anesthetic decreases the incidence of intraoperative nausea and vomiting. The short-acting, lipid-soluble opioids (i.e., fentanyl, sufentanil) contribute to intraoperative anesthesia, and morphine is often administered for postoperative analgesia. Epinephrine may be added to prolong block duration and perhaps improve block density. It was hoped that other adjuncts (e.g., clonidine, neostigmine) might allow for the administration of a lower dose of local anesthetic and thereby minimize sympatholytic side effects and hasten recovery. Side effects from these other adjuncts, however, have precluded their wide use in obstetric anesthesia practice (see Chapters 23, 26, and 28).

Epidural Anesthesia

Local anesthetic agents available for epidural administration in obstetric patients include 2-chloroprocaine, lidocaine, mepivacaine, bupivacaine, ropivacaine, and etidocaine. Mepivacaine and etidocaine are used infrequently in obstetric anesthesia practice.

Bupivacaine remains the most popular local anesthetic for analgesia during labor and vaginal delivery

*Chapter 13 contains a detailed discussion of anesthetic agents used for neuraxial anesthetic techniques.

because of its differential sensory blockade, long duration of action, low frequency of tachyphylaxis, and low cost. Anesthesia providers infrequently administer bupivacaine for cesarean delivery because of the risk for cardiac toxicity and maternal mortality after unintentional intravascular injection of the drug.

Ropivacaine has gained popularity as an agent for epidural analgesia and anesthesia because it may result in less cardiac toxicity and greater differential sensory blockade than bupivacaine.[130]

Levobupivacaine also has a more favorable safety profile than bupivacaine. Clinical trials have shown that ropivacaine and levobupivacaine have potency[131] and analgesic qualities similar to those of bupivacaine,[132,133] with the probable exception of less motor nerve block.[134]

Bupivacaine, ropivacaine, and levobupivacaine all have longer durations of action than lidocaine, and they may be preferred over shorter-acting agents when a longer duration of anesthesia or analgesia is desirable. They are more commonly used for maintenance of epidural labor analgesia, whereas the shorter-acting agents are used for epidural surgical anesthesia. Despite some variation among reports, published clinical studies suggest no more than slight differences in onset and potency, and no differences in quality or duration of neural blockade, among the three drugs. However, bupivacaine is more cardiotoxic than the other agents *in vitro* and probably after unintentional intravascular administration.[135] It would seem prudent to use ropivacaine or levobupivacaine rather than bupivacaine when a bolus dose of a concentrated solution is being given. When administered as a low concentration infusion, improved safety has not been demonstrated with ropivacaine and levobupivacaine compared with bupivacaine.

The most popular choice of local anesthetic for epidural anesthesia for cesarean delivery is **2% lidocaine with epinephrine.** The addition of epinephrine (5 μg/mL) causes a modest prolongation of the block. The major advantage of epinephrine is that it improves the quality of epidural lidocaine anesthesia. Lam et al.[136] have shown that epidural labor analgesia can be extended to surgical anesthesia for cesarean delivery in 5.2 ± 1.5 minutes (mean ± SD) with the addition of bicarbonate and fentanyl to 2% lidocaine with epinephrine.

Many anesthesia providers reserve **2-chloroprocaine** for cases in which rapid extension of epidural anesthesia for vaginal delivery or urgent cesarean delivery is necessary. The onset of surgical anesthesia was several minutes faster with 2-chloroprocaine compared with lidocaine with freshly mixed epinephrine and sodium bicarbonate in the setting of urgent caesarean delivery after epidural labor analgesia.[137] Therefore, when time is of the essence, 2-chloroprocaine is the drug of choice. Typically, in an emergency, a large volume of concentrated local anesthetic solution is injected quickly. An additional advantage of 2-chloroprocaine in this situation is that it is rapidly metabolized by plasma esterases. Therefore, the unintentional intravascular injection of a large volume of 2-chloroprocaine may be less likely to have serious adverse consequences. A potential disadvantage of 2-chloroprocaine is that it may interfere with the subsequent actions of opioids[138] and bupivacaine,[139] although this possibility is controversial.[140]

As in spinal anesthesia, epidural opioids work synergistically with local anesthetics. Fentanyl 50 to 100 μg or sufentanil 5 to 10 μg is frequently added to an amide local anesthetic for both labor analgesia (allowing a lower dose of local anesthetic and less motor block) and cesarean delivery (resulting in a denser block with better blockade of visceral stimulation). **Sodium bicarbonate** may be added to lidocaine[141] and 2-chloroprocaine[142] (1 mEq/10 mL local anesthetic) to decrease latency.

Caudal Anesthesia

The drugs used for caudal epidural anesthesia are identical to those used for lumbar epidural block. However, a much larger volume (e.g., 25 to 35 mL) of local anesthetic solution must be administered to extend a caudal block for cesarean delivery or labor analgesia. Such large volumes entail a greater risk for systemic local anesthetic toxicity. Additionally, the caudal epidural space is highly vascular, which further predisposes to intravasation of drugs administered via this route.

COMPLICATIONS OF NEURAXIAL TECHNIQUES

Unintentional Dural Puncture

Unintentional dural puncture with an epidural needle occurs at a rate of approximately 1.5% in the obstetric population.[143] Approximately 52% of women will experience a post–dural puncture headache after puncture with an epidural needle (see Chapter 31). Techniques to minimize the incidence of unintentional dural puncture include (1) identification of the ligamentum flavum during epidural needle advancement; (2) understanding the likely depth of the epidural space in an individual patient; (3) advancement of the needle between contractions, when unexpected patient movement is less likely; (4) adequate control of the needle-syringe assembly during advancement of the needle; and (5) clearing the needle of clotted blood or bone plugs. Norris et al.[144] observed that post–dural puncture headache after unintentional dural puncture was less likely to result in headache if the epidural needle bevel faced lateral rather than cephalad. In contrast, Richardson and Wissler[145] found no difference between the two orientations. An *in vitro* study using cadaver dura found that the fluid leakage rate through dural tears was not dependent on the orientation of the dura relative to the needle bevel.[146] We prefer to insert the epidural needle with the bevel oriented in a cephalad direction so that there is no need to rotate the needle bevel within the epidural space. Cephalad bevel orientation also increases the likelihood of successful epidural anesthesia.[147]

The management of unintentional dural puncture depends on the clinical setting. If advancement of an epidural needle results in dural trespass and the free flow of CSF is perceived in the barrel of the epidural syringe, the anesthesia provider should halt advancement of the

epidural needle and either remove the epidural needle if the plan is to resite the epidural catheter or replace the stylet back into the lumen of the epidural needle to prevent further egress of CSF if the plan is to administer intrathecal medication or perform a continuous spinal technique. Reinjection of CSF contained in the syringe should not be entertained because there is a high likelihood that air will concomitantly be introduced into the subarachnoid space and cause pneumocephalus. The risks and benefits of administering an intrathecal dose of anesthetic should be considered. Although intrathecal administration of local anesthetic through the epidural needle will result in rapid analgesia for an uncomfortable patient, the rapid efflux of CSF may render the injectate ineffective. Additionally, spinal analgesia may mask paresthesias during subsequent attempts at neuraxial anesthesia. Furthermore, spinal anesthesia may cause profound hypotension. If the patient is sitting, and likely to remain so for the next few minutes, the anesthesia provider may struggle to manage two problems instead of one (i.e., a challenging neuraxial procedure and maternal hypotension). However, rapid provision of analgesia may enable the patient to better assume an optimal position without moving. One option is to administer intrathecal opioid, thus providing analgesia without the risk for hypotension.

The anesthesia provider has two options after unintentional dural puncture: site the epidural catheter within the subarachnoid space and use a continuous spinal anesthetic technique or site the epidural catheter in a different interspace (i.e., starting afresh). Evidence is conflicting as to whether the insertion of an epidural catheter through the dural puncture site decreases the incidence of post–dural puncture headache.[148] Continuous spinal anesthesia is an attractive option if identification of the epidural space has been difficult or if the anticipated duration of epidural anesthesia or analgesia is relatively short (e.g., cesarean delivery, or vaginal delivery in parous women). The major disadvantage of an intrathecal catheter is the risk that it may be mistaken for an epidural catheter. Given that the local anesthetic dose required for epidural anesthesia is many times greater than that required for spinal anesthesia, unintentional administration of an epidural dose into the subarachnoid space will lead to total spinal anesthesia. Therefore, on a busy labor and delivery unit where multiple providers are giving anesthesia care, it may be safer to use an epidural catheter rather than an intrathecal catheter in women in whom prolonged analgesia is anticipated.

Thus, the anesthesia provider may elect to initiate epidural anesthesia in another lumbar epidural interspace. However, even if the attempt results in a correctly placed catheter, the provider must be wary of an unexpectedly high level of anesthesia after the epidural administration of usual doses of local anesthetic.[149,150] Leach and Smith[150] reported a patient who had an extensive block after unintentional dural puncture and subsequent epidural injection of bupivacaine. They presented radiologic evidence of the spread of local anesthetic from the epidural space to the subarachnoid space. The extent to which a dural tear affects the movement of substances from the epidural space to the subarachnoid space depends on the size of the hole, the lipophilicity of the drug (highly lipophilic drugs cross quickly regardless of the presence of a hole, whereas water-soluble drugs cross more quickly in the presence of a hole),[151] and whether the drug is administered into the epidural space as a bolus or an infusion. Rapid bolus administration of medications through an epidural catheter in a patient with a known dural puncture with a large-bore needle significantly increases the likelihood of high spinal anesthesia.

Unfortunately, there is no reliable method to decrease the risk for post–dural puncture headache once dural puncture occurs. Obese patients appear to be at lower risk than lean patients for the development of headache.[152] A prophylactic blood patch (injection of autologous blood before removal of the epidural catheter and before onset of a headache) does not reduce the risk for post–dural puncture headache.[148,153]

Occasionally, unintentional dural puncture is not recognized until the epidural catheter is threaded and CSF spontaneously appears at the proximal end of the catheter, or the catheter aspiration or intrathecal test dose is positive. Finally, an epidural catheter that has been correctly sited in the epidural space may migrate into the subarachnoid space. The most significant clinical threat in this scenario is the continued use of a large volume infusion of local anesthetic drug intended for epidural administration. Thus, during prolonged epidural labor analgesia, the patient should be monitored for evidence of high or dense neuraxial anesthesia.

Unintentional Intravascular or Subarachnoid Injection

The unintentional injection of large doses of local anesthetics into the subarachnoid space can lead to catastrophe. The rapid onset of high or total spinal anesthesia results in profound hypotension, loss of consciousness, and apnea secondary to hypoperfusion of the brain stem. Prompt treatment necessitates assisted ventilation, volume resuscitation, and pharmacologic support of blood pressure. Administration of chronotropic agents such as epinephrine may also be necessary if blockade of cardiac sympathetic drive results in bradycardia. The patient is at high risk for awareness in this setting, and the judicious use of an amnestic agent such as midazolam should be considered once cardiorespiratory stability has been restored.

The incidence of intravascular catheter placement varies according to catheter type,[33,65] patient population,[154] and proper placement of the epidural needle tip in the midline. Pregnant women are at higher risk for unintentional intravenous cannulation due to the engorgement of epidural veins. Intravascular injection of a local anesthetic may initially result in altered sensorium, tinnitus, and perioral numbness. Higher blood concentrations may result in seizures, and even higher concentrations may cause dysrhythmias and cardiovascular collapse (see Chapter 13). Management of intravascular toxicity includes prompt institution of advanced cardiac life support (ACLS), gamma-aminobutyric acid (GABA)–potentiating agents such as benzodiazepines to mitigate seizure activity, and the use of intralipid emulsion to

detoxify the patient. Several modifications have been made to the conventional ACLS protocol for the specific treatment of local anesthetic-induced cardiac arrest.[155] These include using small, judicious doses of intravenous epinephrine for circulatory support (10 to 100 μg boluses in adults), avoidance of vasopressin, and the use of amiodarone in place of local anesthetics for treatment of ventricular arrhythmias.

Inadequate Anesthesia

Pain during anesthesia represents a higher proportion of obstetric malpractice claims than of nonobstetric claims.[156] During labor, inadequate epidural analgesia may result from the inadequate extent of sensory blockade, nonuniform blockade, or inadequate density of blockade. When called to evaluate breakthrough pain, the anesthesia provider should first evaluate the extent of bilateral sensory blockade in *both the cephalad and caudad directions.* Particularly if labor is progressing quickly, the extent of sacral blockade may not be adequate. In this case, epidural injection of a large volume of local anesthetic may improve sacral blockade. In contrast, if the extent of sensory blockade is adequate but the patient is still experiencing pain, the density of blockade may be insufficient. In this case, the provider should reestablish and maintain analgesia using a more concentrated solution of local anesthetic.

Why do some obstetric epidural anesthetics fail over time? Collier[157] administered epidural radiocontrast dye in 25 parturients reporting unsatisfactory analgesia. The two major causes of inadequate block in this small study were transforaminal migration of the catheter tip and an obstructive barrier in the epidural space. Total block failure usually results from failure to identify the epidural space correctly or from malposition of the catheter tip outside the epidural space (e.g., in a neuroforamen). A unilateral block may occur despite the use of good technique. Unilateral blocks can often be prevented by limiting the length of catheter within the epidural space to 3 cm or less. The problem with limited insertion of the catheter is that, in some patients, the catheter tends to migrate outward over time. (Patients undergoing surgery remain still; by contrast, laboring women change position frequently.) Obese women seem to be at higher risk for outward migration of the catheter tip. Prospective studies suggest that 4 to 6 cm is the optimal depth of epidural catheter insertion in laboring women.[71,72,158]

Whether catheter withdrawal in the setting of breakthrough pain is beneficial is not clear. Beilin et al.[159] compared catheter withdrawal followed by injection of local anesthetic with injection of local anesthetic without catheter withdrawal for the treatment of breakthrough pain. The ability to rescue analgesia was not different between the groups. Gielen et al.[160] performed a radiologic study in which they observed no consistent relationship between catheter position and the asymmetric onset of sympathetic blockade. Unilateral or patchy sensory blockade likely results from the nonuniform distribution of local anesthetic solution in the epidural space.[161] Injection of a large volume of dilute local anesthetic solution into the epidural space usually corrects this problem, regardless of the location of the tip of the epidural catheter (provided it is actually in the epidural space). If analgesia cannot be rescued with a second injection, the catheter should be removed and replaced at another interspace.

The management of inadequate anesthesia is more problematic during cesarean delivery. Failure of spinal anesthesia may result from the maldistribution of local anesthetic within the subarachnoid space.[162,163] If inadequate spinal anesthesia is noted before incision, the anesthesia provider may augment the block with additional local anesthetic by either performing a second spinal anesthetic procedure or placing an epidural catheter. However, care must be taken if performing a second spinal anesthetic procedure. In the ASA Closed-Claims Project database, Drasner and Rigler[162] identified three cases of cauda equina syndrome complicating spinal anesthesia. In two cases, "failed spinal" anesthesia had occurred, followed by a repeat injection of local anesthetic. The researchers recommended that anesthesia providers determine the presence of anesthesia in the sacral dermatomes before giving additional local anesthetic into the subarachnoid space. Additionally, they stated that if CSF was aspirated during the original procedure, it should be assumed that local anesthetic was delivered into the subarachnoid space, and the total dose of local anesthetic be limited to the maximum dose a clinician would consider reasonable to administer in a single injection.[162] If partial blockade is present (even if it is limited to the sacral dermatomes), the second dose should be reduced accordingly. It may also be advisable to perform the second procedure at a different interspace or make other changes to the original procedure (e.g., alter the patient's position, use a local anesthetic with different baricity, or straighten the lumbosacral curvature).

If the patient complains of pain after incision, the anesthesia provider must decide between the administration of inhalation or intravenous analgesia and the administration of general anesthesia. Supplemental analgesia may be provided by giving 60% nitrous oxide in oxygen, small incremental boluses of ketamine (0.1 to 0.25 mg/kg), or small boluses of intravenous opioid. Supplemental infiltration of the wound with local anesthetic is sometimes helpful, especially when spinal anesthesia regresses near the end of an unexpectedly long operation. The anesthesia provider must ensure that the patient remains sufficiently alert to protect her airway. In most cases, severe pain unrelieved by modest doses of analgesic drug requires rapid-sequence induction of general anesthesia followed by endotracheal intubation and general anesthesia.

In some cases, inadequate epidural anesthesia results from failure to give a sufficient dose of local anesthetic or failure to wait a sufficient time after its administration. For example, after the epidural administration of 0.5% bupivacaine, approximately 20 minutes must pass to achieve an adequate level of anesthesia, and additional local anesthetic may be needed to achieve an adequate density of blockade. In urgent cases or in cases with a "missed" segment, local infiltration with a local anesthetic often results in satisfactory anesthesia. Sometimes it is difficult to separate the beneficial effect of the local

infiltration from the beneficial effect of waiting for the obstetrician to obtain, prepare, and inject the local anesthetic solution. Finally, the anesthesia provider should exercise caution when initiating spinal anesthesia after failure of epidural anesthesia because of a greater incidence of high spinal anesthesia in this setting.[164] Presumably, the large volume of local anesthetic within, or near, the epidural space results in decreased lumbar CSF volume, which predisposes to high spinal anesthesia. It may be advisable to reduce the dose of intrathecal local anesthetic, particularly in the presence of partial epidural blockade.

Equipment Problems

The frequency of major equipment malfunction is very low during the administration of neuraxial anesthesia. Most anesthesia providers in the United States use disposable needles, and the plastic needle hubs are attached to the needles' shafts with epoxy. Rarely, a needle breaks at the hub-shaft junction.[165] If a needle should break, the portion of the needle that remains in the patient should be removed, because it may migrate and cause injury.

An epidural or spinal catheter may shear and break off if the catheter is withdrawn through a needle; thus an epidural or spinal catheter should never be withdrawn in this manner. Rather, if the catheter must be withdrawn, the needle and catheter should be withdrawn as a unit. It is also possible to break a catheter during attempts at removing it, although this is rare. If resistance to catheter removal is encountered, the patient should assume a position that reduces lumbar lordosis, thereby lessening the kinking of the catheter between perivertebral structures. If position change is not successful, the catheter should be taped under tension to the patient's back and left undisturbed for several hours. The catheter usually works its way out and is then easy to remove. Once the catheter has been removed successfully, it should be examined to ensure that it has been removed completely. Complete removal of the catheter should be documented in the medical record.

Rarely, catheters do break on removal. We favor aggressive attempts to remove broken *spinal* catheters. However, it may be unnecessary to remove broken *epidural* catheters; rather, in these circumstances, the patient can be informed of the complication and observed over time. The incidence of catheter migration or other delayed sequelae appears to be low. Computed tomography may help identify the precise location of a broken catheter.[166]

During use, an epidural catheter occasionally becomes disconnected from the catheter connector. Options include replacing the epidural catheter or reconnecting the connector to the catheter. Langevin et al.[167] used an *in vitro* model to investigate whether microbial contamination precludes reconnection. They found that an area of the interior of the catheter distal to the disconnection may remain sterile for up to 8 hours if the fluid column within the catheter remains static (i.e., if "fluid does not move within the catheter when it is raised above the level of the patient").[167] Therefore, they concluded that it *may* be safe to decontaminate the exterior of the catheter, cut the catheter with a sterile instrument, and reconnect it to a new sterile connector. However, given the potential catastrophic consequences of neuraxial infection, we recommend replacing the catheter. Also, wire-embedded catheters cannot be cut.

KEY POINTS

- Physiologic changes of pregnancy alter neuraxial anatomy; alterations include accentuation of lumbar lordosis, a "softer" ligamentum flavum, and decreased space in the spinal canal due to vascular engorgement of epidural veins.
- Physiologic changes of pregnancy cause a more pronounced response to neuraxial anesthesia–induced sympathetic blockade than is seen in nonpregnant patients. These include higher baseline sympathetic tone and aortocaval compression.
- Pregnant women, particularly those with neuraxial blockade, should not be cared for in the supine position but rather in lateral tilt or in the full lateral position.
- Correct patient positioning, equipment, and technique are important to the success and safety of neuraxial techniques.
- The midline approach is faster and less painful than the paramedian approach to the epidural or subarachnoid space. However, the paramedian approach may allow for the successful identification of the subarachnoid or epidural space in difficult cases.
- Use of a non-cutting ("pencil-point") needle for spinal anesthesia reduces the incidence of post–dural puncture headache.
- Combined spinal-epidural anesthesia has the advantages of both spinal anesthesia and epidural anesthesia.
- Approximately 20% to 30% less local anesthetic is required for epidural and spinal anesthesia in pregnant patients than in nonpregnant patients.
- Multiple techniques (e.g., test dose, aspiration, incremental dose injection) should be used to reduce the incidence and risk for unintentional subarachnoid or intravascular injection, because no one technique will completely exclude all cases of malpositioned needles or catheters.

CHAPTER 13

Local Anesthetics and Opioids

Brenda A. Bucklin, MD • Alan C. Santos, MD, MPH

CHAPTER OUTLINE

Local anesthetics and opioids are often used for pain relief in obstetric practice. Local anesthetics may be used for infiltration anesthesia, peripheral (pudendal) nerve block, or neuraxial block, whereas opioids are administered both systemically and neuraxially. The physiologic changes that occur during pregnancy may affect the pharmacology of both local anesthetics and opioids. In turn, these analgesic drugs may have effects on the mother and the fetus.

LOCAL ANESTHETICS

Molecular Structure

All local anesthetic molecules except cocaine contain a desaturated carbon ring (aromatic portion) and a tertiary amine connected by an alkyl chain (Figure 13-1). The intermediate alkyl chain, by virtue of its ester or amide linkage, is the basis for the classification of local anesthetics as **amino-esters** (which are hydrolyzed by pseudocholinesterase) and **amino-amides** (which undergo hepatic microsomal metabolism) (Table 13-1). The aromatic ring of the esters, which renders the molecule lipid soluble, is a derivative of benzoic acid. The amide aromatic ring is a homologue of aniline. The tertiary-amine portion acts as a proton acceptor; thus, local anesthetics behave as weak bases. In its quaternary (i.e., "protonated") form, the terminal amine is the water-soluble portion. The Henderson-Hasselbalch equation predicts the relative proportions of local anesthetic that exist in the ionized and un-ionized form. The higher the pK_B (base dissociation constant) relative to physiologic pH, the smaller the proportion of drug that exists in the un-ionized form. All amide local anesthetics (with the exception of lidocaine) exist as stereoisomers because of the presence of an asymmetric carbon adjacent to the terminal amine.

Clinical formulations of local anesthetics are prepared as hydrochloride salts to increase their solubility in water. These solutions are usually acidic (i.e., pH of 4 to 6) to enhance formation of the water-soluble quaternary amine and to prevent oxidation of the epinephrine present in epinephrine-containing solutions.

Chirality

With the exception of lidocaine, amide local anesthetics are known as **chiral compounds** because they have a single asymmetric carbon adjacent to the amino group and thus exist in isomeric forms that are mirror images of each other. The direction in which the isomers rotate polarized light distinguishes them as either dextrorotary (D) or levorotary (L) isomers. This distinction is

important, because individual isomers of the same drug may have different biologic effects. As a rule, the levorotary isomer of a drug has greater vasoconstrictor activity and a longer duration of action but less potential for systemic toxicity than the dextrorotary form.[1]

In the past, single-isomer formulations were costly to produce; and for that reason, local anesthetics used clinically (e.g., **bupivacaine**) have contained a racemic mixture of both the dextrorotary and levorotary forms of the drug. However, with improved techniques of selective extraction, two commercially available single-isomer formulations of local anesthetic are now available, ropivacaine and levobupivacaine. **Levobupivacaine** is the levorotary isomer of bupivacaine; it is currently not marketed in the United States. **Ropivacaine** is a homologue of mepivacaine and bupivacaine, but, unlike these other local anesthetics, it is formulated as a single levorotary isomer rather than as a racemic mixture. A propyl group on the pipechol ring distinguishes ropivacaine from bupivacaine (which has a butyl group) and mepivacaine (which has a methyl group).[2] Thus, it is not surprising that the physicochemical characteristics of ropivacaine are intermediate between those of mepivacaine and bupivacaine.

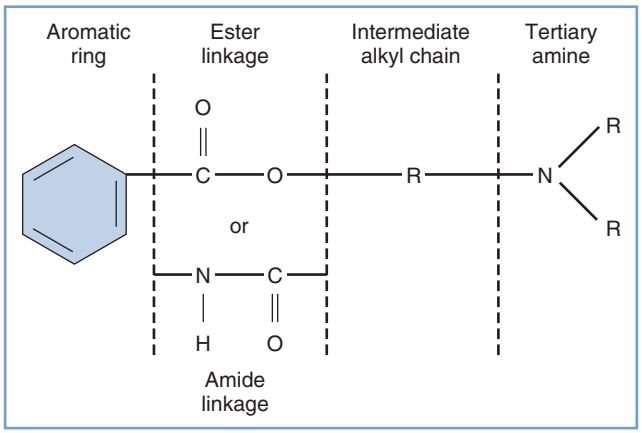

FIGURE 13-1 ■ Structure of the molecule of a local anesthetic. *R,* alkyl group. (Modified from Santos AC, Pedersen H. Local anesthetics in obstetrics. In Petrie RH, editor. Perinatal Pharmacology. Cambridge, MA, Blackwell Scientific, 1989:373.)

The reduction in systemic toxicity observed with administration of the levorotary isomers may be both drug and concentration dependent. For example, one study in isolated guinea pig hearts noted that bupivacaine isomers lengthened atrioventricular conduction time more than ropivacaine isomers did. In contrast to other measured variables, "atrioventricular conduction time showed evident stereoselectivity" for bupivacaine at the lowest concentration studied (0.5 μM) but only at much higher concentrations for ropivacaine (> 30 μM).[3]

Mechanism of Action

At rest, the interior of a nerve cell is negatively charged in relation to its exterior. This resting potential of 60 to 90 mV exists because the concentration of sodium in the extracellular space greatly exceeds that in the intracellular space. The converse is true for potassium. Excitation results in the opening of membrane channels, which allows sodium ions to flow freely down their concentration gradient into the cell interior. Thus, the electrical potential within the nerve cell becomes less negative until, at the critical threshold, rapid depolarization occurs. This depolarization is needed to initiate the same sequence of events in adjacent membrane segments and for propagation of the action potential. Thereafter, sodium channels close and the membrane once again becomes impermeable to the influx of sodium. The negative resting membrane potential is reestablished as sodium is removed from the cell by active transport. At the same time, potassium passively accumulates within the resting cell.

Interference with sodium-ion conductance appears to be the mechanism by which local anesthetics reversibly inhibit the propagation of the action potential. Four major theories attempt to explain this effect. The most prominent hypothesis is that the local anesthetic interacts with receptors in the nerve cell membrane that control channels involved in sodium conductance.[4] There may be more than one site at which local anesthetics bind to sodium-channel receptors (Figure 13-2).

The Meyer-Overton theory offers a second explanation for local anesthetic action. This hypothesis suggests that the lipid-soluble portion of the local anesthetic

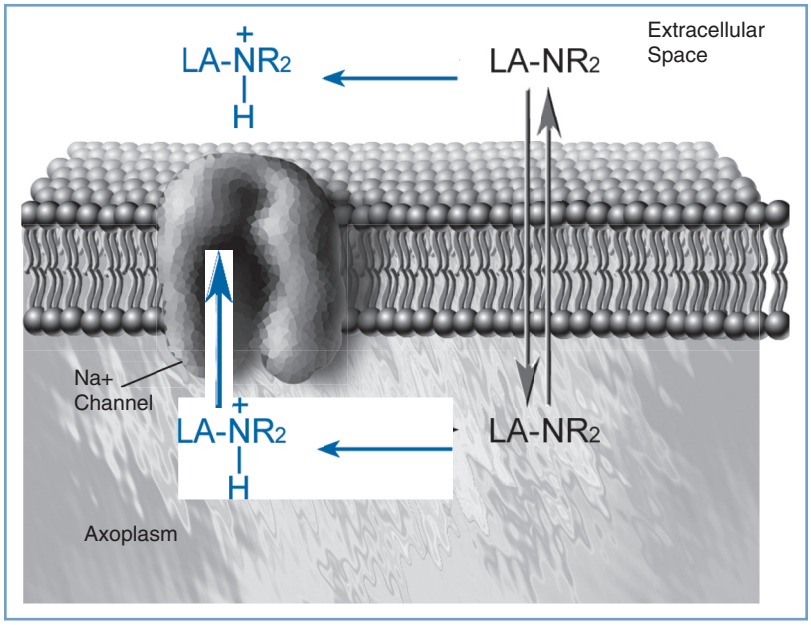

FIGURE 13-2 ■ Local anesthetic access to the sodium channel. The uncharged molecule (LA-NR_2) diffuses most easily across the lipid membrane and interacts with the sodium channel at an intramembranous site. The charged molecule (LA-NR_2H^+) gains access to a specific receptor on the sodium channel in the intracellular space. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

molecule expands the cell membrane and interferes with rapid sodium conductance. A third possibility is that local anesthetics may alter the membrane surface charge, a change that would inhibit propagation of the action potential. Fourth, local anesthetics may displace calcium from sites that control sodium conductance.

Both the un-ionized and ionized forms of a local anesthetic are involved in pharmacologic activity. The un-ionized base, which is lipid soluble, diffuses through the cell membrane, whereas the charged form is much more active in blocking the sodium channel.

Pharmacodynamics

Pregnant women typically require smaller doses of local anesthetic compared with nonpregnant women for neuraxial blockade. This effect may be evident as early as the second trimester.[5,6] This difference has been attributed to enhanced spread of local anesthetic due to epidural venous engorgement. However, mechanical effects alone do not account for the observation that the spread of spinal and epidural analgesia in early pregnancy is similar to that in pregnant women at term.[5-7] In fact, pregnancy may also enhance neuronal sensitivity to local anesthetics. For example, pregnancy increases median nerve susceptibility to lidocaine.[8] *In vitro* studies demonstrated that the onset of neural blockade was faster, and lower concentrations of bupivacaine were required to block vagal fibers, in pregnant rabbits than in nonpregnant rabbits.[9]

Hormonal and biochemical changes may be responsible for the greater susceptibility to neural blockade during pregnancy. For example, one study demonstrated an enhanced effect of bupivacaine in isolated vagus fibers from nonpregnant, ovariectomized rabbits who had received long-term (4 days) but not short-term exposure to progesterone.[10] A higher pH and lower bicarbonate and total carbon dioxide content have been demonstrated in cerebrospinal fluid (CSF) from women undergoing cesarean delivery than in CSF from age-matched nonpregnant controls. A higher pH increases the proportion of local anesthetic that exists as the base form and facilitates diffusion of the drug across nerve membranes.[7]

Pharmacokinetics

Pregnancy is associated with progressive physiologic adaptations that may influence drug disposition (see Chapter 2). However, it is difficult to predict with certainty the effects of pregnancy on the pharmacokinetics of an individual drug.

2-Chloroprocaine

2-Chloroprocaine is hydrolyzed rapidly by plasma pseudocholinesterase to chloroaminobenzoic acid and H_2O. The *in vitro* half-life of 2-chloroprocaine in sera from men is less than 15 seconds.[11] Although pregnancy is associated with a 30% to 40% decrease in pseudocholinesterase activity, the half-life of 2-chloroprocaine in maternal plasma *in vitro* is 11 to 21 seconds. After epidural injection, the half-life of 2-chloroprocaine in the mother ranges from 1.5 to 6.4 minutes.[12] The longer half-life after epidural administration results from continued absorption of the drug from the injection site. Administration of 2-chloroprocaine to patients with low pseudocholinesterase activity may result in prolonged local anesthetic effect and a greater potential for systemic toxicity.[13]

Lidocaine

The volume of the central compartment and the volume of distribution are greater in pregnant ewes than in nonpregnant ewes.[14,15] Bloedow et al.[15] observed that the total body clearance of lidocaine was similar in the two

groups of animals. They concluded that the elimination half-life of lidocaine, which depends on the balance between volume of distribution and clearance, was longer in pregnant ewes.[15] In contrast, Santos et al.[14] concluded that the elimination half-life of lidocaine was similar in the two groups of sheep because the total body clearance of the drug was greater in pregnant animals than in nonpregnant animals. This discrepancy could result from differences in the complexity of the surgical preparation and the allowed recovery period. In pregnant women, the elimination half-life of lidocaine after epidural injection is approximately 114 minutes.[16]

Lidocaine is metabolized to two active compounds, monoethylglycinexylidide (MEGX) and glycinexylidide (GX). Monoethylglycinexylidide can be detected in maternal plasma within 10 to 20 minutes after neuraxial injection of lidocaine, whereas glycinexylidide can be detected within 1 hour of epidural injection but rarely after subarachnoid injection.[17,18] Urinary excretion of unchanged lidocaine is negligible in sheep (i.e., < 2% of the administered dose) and is not affected by pregnancy.[14]

The physiologic changes that occur during pregnancy are progressive. However, little information is available about the pharmacokinetics of local anesthetics before term. In one study, total clearance of lidocaine was similar at 119 and 138 days' gestation in gravid ewes (term is 148 days).[19]

Lidocaine is predominantly bound to alpha$_1$-acid glycoprotein (AAG) in plasma.[20] Pregnancy leads to a decreased concentration of AAG; thus, the free plasma fraction of lidocaine is higher in term pregnant women than in nonpregnant controls.[20] The increase in the free fraction of lidocaine occurs early in gestation and is progressive.[21]

Bupivacaine

At least two studies compared the pharmacokinetics of bupivacaine after epidural administration in pregnant and nonpregnant women.[22,23] The absorption rate, the area under the concentration-time curve, and the elimination half-life (12 to 13 hours) were similar in the two groups. The elimination half-life of bupivacaine after epidural administration is much longer than that reported after intravenous injection, largely because the drug is continuously absorbed over time from the epidural space.

After intravenous injection, the volume of distribution of bupivacaine is lower in pregnant sheep than in nonpregnant sheep.[24] In contrast, ovine pregnancy is associated with a greater volume of distribution of lidocaine.[14,15] The differences in gestational effects on the volume of distribution of the two local anesthetics may result from the greater binding of bupivacaine to plasma proteins during gestation (whereas the converse occurs with lidocaine).[24] In one study, urinary excretion of unchanged bupivacaine was not affected by pregnancy and was less than 1% of the administered dose.[22] Nonetheless, low concentrations of bupivacaine may be detected in the urine of pregnant women for as long as 3 days after delivery.[25]

Bupivacaine undergoes dealkylation in the liver to 2,6-pipecolyxylidide (PPX). After epidural injection of bupivacaine for cesarean delivery, PPX was detected in maternal plasma within 5 minutes and remained detectable for as long as 24 hours.[25] With the lower doses required for labor analgesia, PPX was found only if the block was maintained with multiple reinjections during a period that exceeded 4 hours.[26] Pregnancy may affect metabolism of bupivacaine.[22] For example, pregnant women have higher serum PPX concentrations, but the unconjugated 4-hydroxy metabolite is not produced in significant amounts. The reason for this finding is unclear but may be related to the effects of hormonal changes on hepatic enzyme systems. Both progesterone and estradiol are competitive inhibitors of microsomal oxidases, whereas reductive enzymes are induced by progesterone.[24] Bupivacaine is bound extensively to AAG and albumin.[27] This protein binding is reduced during late pregnancy in humans.[28]

Long-acting pipechol amide local anesthetics, such as bupivacaine, are beneficial for neuraxial labor analgesia because they produce a relative motor-sparing block as compared with other local anesthetics. The effective dose in 50% of cases (ED_{50}) for motor block after intrathecally administered bupivacaine was lower in pregnant than in nonpregnant women (3.96 mg and 4.14 mg, respectively).[29]

Ropivacaine

Pregnant sheep have a smaller volume of distribution and a slower clearance of ropivacaine than nonpregnant animals.[24] However, the relationship between volume of distribution and clearance is such that the elimination half-life is similar in pregnant and nonpregnant animals.

After intravenous injection in laboratory animals, the elimination half-life of ropivacaine is shorter than that of bupivacaine.[24,30] Similar findings have been described after intravenous injection in nonpregnant human volunteers.[31] The shorter elimination half-life of ropivacaine has been attributed to a faster clearance and a shorter mean residence time than for bupivacaine.[24]

Peak plasma concentration (C_{max}) after epidural administration of 0.5% ropivacaine and 0.5% bupivacaine for cesarean delivery are similar (1.3 μg/mL and 1.1 μg/mL, respectively).[32] The elimination half-life of ropivacaine is 5.2 ± 0.6 hours, which is shorter than that for bupivacaine, at 10.9 ± 1.1 hours. No difference in clearance between the two drugs has been noted.

Like bupivacaine, ropivacaine is metabolized by hepatic microsomal cytochrome P450. The major metabolite is PPX, and minor metabolites are 3′- and 4′-hydroxy-ropivacaine.[33]

Ropivacaine is highly bound (approximately 92%) to plasma proteins but less so than bupivacaine (96%).[34] Indeed, at plasma concentrations occurring during epidural anesthesia for cesarean delivery, the free fraction of ropivacaine is almost twice that of bupivacaine.[32] In sheep, pregnancy is associated with a greater binding of ropivacaine (and bupivacaine) to plasma proteins.[24] In pregnant women undergoing epidural analgesia, the free fraction of ropivacaine decreases as the concentration of AAG increases, up to the point at which the receptors are saturated.[35] However, there is little correlation between

the free fraction and umbilical cord blood levels of ropivacaine at delivery.[35]

Effect of Histamine (H_2)-Receptor Antagonists

Histamine (H_2)-receptor antagonists (e.g., cimetidine, ranitidine, famotidine) are administered to increase gastric pH and reduce the parturient's risk for aspiration pneumonitis. Drug disposition may be affected by binding to hepatic cytochrome P450, thereby reducing hepatic blood flow and renal clearance, especially with cimetidine. However, short-term administration of H_2-receptor antagonists does not alter the pharmacokinetics of amide local anesthetics in pregnant women.[36,37]

Effects of Preeclampsia

Pathophysiologic changes associated with preeclampsia (e.g., reduced hepatic blood flow, abnormal liver function, decreased intravascular volume) may also affect maternal blood concentrations of local anesthetics (see Chapter 36). For example, Ramanathan et al.[38] found that total body clearance of lidocaine after epidural injection was significantly lower in preeclamptic women than in normotensive women; however, the elimination half-life of lidocaine was similar in the two groups. Nonetheless, decreased clearance may result in greater drug accumulation with repeated injections of lidocaine in women with preeclampsia. In contrast, long-acting amides have a relatively low hepatic extraction, and changes in liver blood flow with preeclampsia may have less effect on the metabolic clearance.

Effect of Diurnal Variation

Pain may exhibit temporal variation in intensity due to diurnal neuroendocrine or external factors. Further, the pharmacokinetics and pharmacodynamics of local anesthetics may exhibit temporal patterns (i.e., chronobiology). In one study, the duration of action of epidural bupivacaine was approximately 25% longer when it was administered between 7:00 AM and 7:00 PM than between 7:00 PM and 7:00 AM.[39] In contrast, another study found no diurnal variation with intrathecal bupivacaine administered for labor analgesia.[40] The authors suggested that observed temporal differences in duration of analgesia may be explained by external influences such as shift changes for nurses and anesthesiologists.[40]

Toxicity

Systemic absorption or intravascular injection of a local anesthetic may result in local anesthetic systemic toxicity (LAST). Toxicity most often involves the central nervous system (CNS), but cardiovascular toxicity also may occur. Less common are tissue toxicity and hypersensitivity reactions.

Central Nervous System Toxicity

The severity of CNS effects is proportional to the blood concentration of local anesthetic. This relationship is well described for lidocaine (Figure 13-3). Initially, the patient may complain of numbness of the tongue, tinnitus, or lightheadedness. At high plasma concentrations, convulsions occur because of a selective blockade of central inhibitory neurons that leads to increased CNS excitation.[41] At still higher concentrations, generalized CNS depression or coma may result from reversible blockade of both inhibitory and excitatory neuronal pathways. Finally, depression of the brainstem and cardiorespiratory centers may occur.

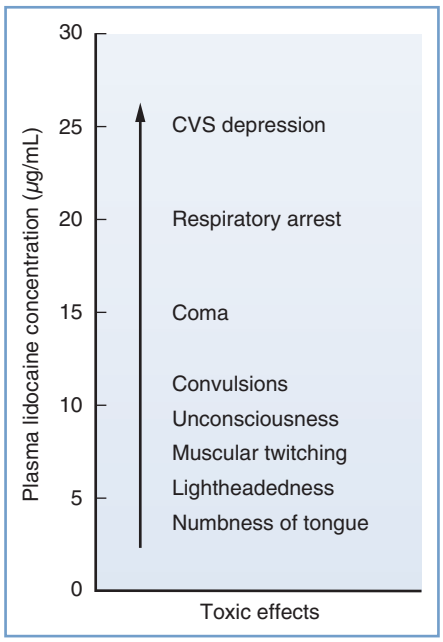

FIGURE 13-3 ■ Signs and symptoms of systemic toxicity with increasing lidocaine concentrations. *CVS,* cardiovascular system. (Modified from Carpenter RL, Mackey DC. Local anesthetics. In Barash PG, Cullen BF, Stoelting RK, editors. Clinical Anesthesia. Philadelphia, Lippincott, 1992:527.)

The relative toxicity of a local anesthetic correlates with its potency. For lidocaine, etidocaine, and bupivacaine, the ratio of the mean cumulative doses that cause convulsions in dogs is approximately 4:2:1, which is similar to their relative anesthetic potencies.[42] The same relative toxicity was demonstrated in human volunteers.[43] Local anesthetics may be ranked in order of decreasing CNS toxicity as follows: bupivacaine, ropivacaine, levobupivacaine, lidocaine, and 2-chloroprocaine.[44] Tetracaine, etidocaine, and mepivacaine are used rarely in obstetric anesthesia practice.

Other factors (e.g., the speed of injection) may affect CNS toxicity. In humans, the mean dose of etidocaine that elicited signs of CNS toxicity was lower during a 20-mg/min infusion than during a 10-mg/min infusion.[43] The seizure threshold also may be affected by metabolic factors. For example, in cats, an increase in $Paco_2$ or a decrease in pH results in a reduction in the seizure-dose threshold for local anesthetics. Respiratory acidosis may result in delivery of more drug to the brain; alternatively, respiratory acidosis may result in "ion trapping" of the local anesthetic and/or an increase in the unbound fraction of drug available for pharmacologic effect.[45-47]

Cardiovascular Toxicity

The cardiovascular system is much more resistant than the CNS to the toxic effects of local anesthetics. Severe, direct cardiovascular depression is rare, especially in association with the use of lidocaine. Prompt administration of oxygen and, if necessary, initiation of ventilatory and circulatory support usually prevent cardiac arrest after unintentional intravenous injection of lidocaine.[48] Progressive depression of myocardial function and profound vasodilation occur only at extremely high plasma concentrations.[48] In contrast, the more potent amide local anesthetics (i.e., bupivacaine) have a more narrow margin of safety, expressed as the ratio between the dose (or plasma concentration) required to produce cardiovascular collapse and the dose (or plasma concentration) required to produce convulsions.[48] A partial explanation is the fact that supraconvulsant doses of bupivacaine (but not of lidocaine) precipitate lethal ventricular arrhythmias.[49-51] These arrhythmias may be caused by exaggerated electrophysiologic effects (e.g., depression of ventricular conduction) out of proportion to bupivacaine's anesthetic potency.[52]

Two theories have been proposed to explain why malignant ventricular arrhythmias occur with bupivacaine but not with lidocaine. Both bupivacaine and lidocaine rapidly block cardiac sodium channels during systole, but bupivacaine dissociates from these channels during diastole at a much slower rate than lidocaine.[52] Thus, at physiologic heart rates, the diastolic period is of sufficient duration for lidocaine to dissociate from sodium channels, whereas a bupivacaine block becomes intensified. This difference makes bupivacaine much more potent than lidocaine in depressing conduction and inducing reentrant-type ventricular arrhythmias. Alternatively, other investigators have suggested that high concentrations of local anesthetic in the brainstem may lead to systemic hypotension, bradycardia, and ventricular arrhythmias.[53] These effects occur more commonly with bupivacaine because of its high lipid solubility, which facilitates transfer across the blood-brain barrier. An echocardiographic study in anesthetized dogs suggested that bolus injection of bupivacaine results in systolic dysfunction, especially involving the right ventricle, which precedes the occurrence of arrhythmias.[54]

Systemic Toxicity of Ropivacaine and Levobupivacaine

In perfused preparations of myocardium, ropivacaine is intermediate between bupivacaine and lidocaine in its depressant effect on cardiac excitation and conduction as well as in its potential to induce reentrant-type ventricular arrhythmias.[34] In dogs, the margin of safety between convulsive or lethal doses and plasma concentrations of drug is greater for ropivacaine than for bupivacaine but less than that for lidocaine.[55] The arrhythmogenicity of ropivacaine in pigs also is intermediate between that of lidocaine and bupivacaine.[56] In sheep, the ratio of fatal doses of bupivacaine, ropivacaine, and lidocaine is 1:2:9.[57] Ropivacaine was found to cause fewer CNS symptoms and was 25% less toxic than bupivacaine (as defined by the doses and plasma concentrations that were tolerated) when administered to healthy male volunteers.[58]

Most studies comparing the systemic toxicity of ropivacaine and bupivacaine have used equal doses of each, and, therefore, cannot resolve the controversy as to whether ropivacaine truly is less cardiotoxic or merely less potent than bupivacaine. This issue would be of concern only if larger doses of ropivacaine than bupivacaine were required to produce comparable regional blocks. Indeed, several studies in laboring women suggest that ropivacaine is 25% to 40% less potent than bupivacaine.[59-61] Thus, the need for a larger dose of ropivacaine may negate the expected benefits of its apparently wider margin of safety. However, results from one laboratory study showed that ropivacaine produces less cardiotoxicity than bupivacaine, even when given at equipotent doses.[62]

Long-acting amide local anesthetics—even the newer drugs—are very potent and may cause cardiac arrest with a misplaced injection or relative overdose. Indeed, several cardiac arrests have been reported with the use of ropivacaine,[63,64] including one in a woman undergoing a cesarean delivery with epidural anesthesia.[65] In contrast to that induced by bupivacaine,[66] resuscitation from a cardiac arrest induced by ropivacaine may be successful more often than not.[63-65]

Evidence suggests that levobupivacaine causes fewer arrhythmias than the racemic drug. Valenzuela et al.[67] demonstrated that levobupivacaine caused less inhibition of inactivated sodium channels than either the dextrorotary or racemic drug. In comparison with dextrorotary and racemic bupivacaine, levobupivacaine resulted in less QRS widening and a lower frequency of malignant ventricular arrhythmias in isolated, perfused rabbit hearts.[68] Similarly, levobupivacaine produced less second-degree heart block and atrioventricular conduction delay than the other two forms of the drug in isolated perfused guinea pig hearts.[3]

In laboratory animals, the systemic toxicity of levobupivacaine is intermediate between that of bupivacaine and ropivacaine.[69] Potency ratio data for epidural bupivacaine, ropivacaine, and levobupivacaine in laboring women are inconsistent, but studies suggest that levobupivacaine is equipotent or less potent than bupivacaine (see Chapter 23).[70,71] Altogether, published data and clinical experience suggest that any benefits from the reduction in risk for systemic toxicity with levobupivacaine are not obtained at the expense of efficacy. Like ropivacaine, levobupivacaine may cause cardiac arrest but is associated with a better response to resuscitation than racemic bupivacaine.[72]

Effects of Pregnancy on Systemic Toxicity

Central Nervous System Toxicity. It is unclear whether pregnancy lowers the seizure threshold for amide local anesthetic agents. In one study, seizures occurred at lower doses of bupivacaine, levobupivacaine, and ropivacaine in pregnant ewes than in nonpregnant ewes.[69] However, the difference was small (10% to 15%) and probably of negligible clinical significance. In studies in sheep and rats,

pregnancy did not reduce the doses required to cause convulsions after intravenous administration of mepivacaine, bupivacaine, or lidocaine.[51,73] Magnesium sulfate, which is frequently used in obstetric practice, does not affect the seizure-dose threshold of lidocaine.[74]

Cardiovascular Toxicity. In 1979, Albright[66] alerted anesthesiologists to several cases of sudden cardiovascular collapse after unintentional intravascular injection of bupivacaine and etidocaine in pregnant women. The fact that cardiac arrest occurred concurrently with or shortly after the onset of convulsions was especially disconcerting. Most of these cases were fatal, and subsequent controversy centered on whether resuscitation was instituted promptly and effectively. Nonetheless, the U.S. Food and Drug Administration (FDA) restricted the use of the highest concentration (0.75%) of bupivacaine in pregnant women.

Several physiologic changes that occur during pregnancy place the parturient at higher risk for refractory cardiac arrest than the nonpregnant patient. First, reduced functional residual capacity and a higher metabolic rate increase the risk for and hasten the onset of hypoxemia during periods of hypoventilation or apnea. Second, aortocaval compression decreases the efficacy of closed-chest cardiac massage in the supine position.[75] Third, a large bolus of drug injected into an epidural vein might reach the heart rapidly through a dilated azygous system. However, none of these factors adequately explains why cardiac arrest and difficult resuscitation are very rare in parturients intoxicated with lidocaine or mepivacaine.[66,76]

Results of laboratory studies of the effects of pregnancy on bupivacaine cardiotoxicity have been contradictory. Pregnancy-related hormones enhance the cardiotoxicity and arrhythmogenicity of bupivacaine *in vitro*.[77,78] For example, the magnitude and severity of bupivacaine-induced electrophysiologic changes are greater in myocardium obtained from nonpregnant rabbits treated with progesterone or beta-estradiol than in myocardium from untreated controls.[77,78] The electrophysiologic effects of lidocaine are less pronounced than those of bupivacaine, even in hormonally treated animals. Studies conducted *in vivo* have been less conclusive. In earlier investigations, significantly lower doses and plasma concentrations of bupivacaine, but not of mepivacaine or lidocaine, were required to produce circulatory collapse in pregnant sheep than in nonpregnant sheep.[49-51] However, a study involving a larger number of sheep and more rigorous methods (e.g., randomization, blinding) failed to confirm that pregnancy enhances the cardiotoxicity of bupivacaine.[69]

Progesterone does not increase myocardial sensitivity to ropivacaine.[79] Likewise, pregnancy does not enhance the systemic toxicity of ropivacaine or levobupivacaine in sheep.[69]

Extrapolation of results of animal studies to obstetric anesthesia practice is difficult, for several reasons. First, in the aforementioned sheep studies, the drug was administered by constant-rate intravenous infusion. In contrast, in pregnant women intoxicated with bupivacaine, cardiac arrest occurred after unintended intravascular injection of a large bolus of drug. Second, a potential for bias existed in the animal studies because randomization and blinding were not used in all studies and some relied on historical controls.[49-51] Third, it is unclear whether resuscitation in the reported clinical cases was accompanied by prompt and effective relief of aortocaval compression.[75]

Nonetheless, bupivacaine remains a popular local anesthetic for obstetric anesthesia. In current practice, heightened vigilance, use of an appropriate test dose, and fractionation of the therapeutic dose have made epidural anesthesia a safe technique for use in obstetric patients (see Chapter 12). In a study of anesthesia-related maternal mortality, Hawkins et al.[80] noted that the number of maternal deaths resulting from local anesthetic toxicity decreased after 1984, the year that the FDA withdrew approval for the epidural administration of 0.75% bupivacaine in obstetric patients. However, LAST has been recognized for decades as an important potential cause of maternal mortality.[81] In our judgment, adherence to the aforementioned clinical precautions—rather than the proscription against the epidural administration of 0.75% bupivacaine—has been responsible for the lower number of maternal deaths due to LAST. Anesthesia providers should be aware that intravenous injection of 0.25% and 0.5% bupivacaine can also cause LAST.

The availability of single levorotary isomers of a local anesthetic may be advantageous because these drugs have a greater margin of safety than bupivacaine, with similar blocking properties, although at a higher cost. From the standpoint of systemic toxicity, the use of these isoforms may be more beneficial in parturients undergoing cesarean delivery, who require higher doses than administered for analgesia during labor. Nonetheless, a greater margin of safety with these new drugs should not be a substitute for proper technique.

Treatment of Systemic Toxicity

Meticulous attention to good technique and adherence to guidelines for maximum recommended dose are mandatory. (The use of a test dose to identify misplaced injections is discussed in Chapter 12.) Incremental injection of the therapeutic dose, careful observation of the patient, and monitoring of vital signs usually provide early warning of an impending reaction. In mild cases, discontinuation of the administration of drug, administration of supplemental oxygen, and maintenance of normal ventilation often limit the severity of the reaction. In 2012, the American Society of Regional Anesthesia and Pain Medicine developed a checklist for managing LAST (Box 13-1). In patients who show signs of CNS excitation, a small dose of an intravenous sedative-hypnotic drug with strong anticonvulsant properties such as a benzodiazepine (diazepam up to 5 mg or midazolam 1 to 2 mg) or propofol (10 to 20 mg) may prevent progression to convulsions.[82] In one study, prophylactic administration of a benzodiazepine reduced the incidence of both convulsions and mortality in mice intoxicated with amide local anesthetics.[83] However, propofol should be avoided in patients with cardiovascular instability because of its cardiovascular depressant properties.[82]

BOX 13-1 Management of Local Anesthetic Systemic Toxicity

- Call for help.
  - Alert obstetrician of possible need for emergency delivery.
- Position patient with left uterine displacement.
- Initial management:
  - Airway management: ventilate with 100% oxygen.
  - Seizure suppression: Benzodiazepines are preferred. (**Avoid** propofol if cardiovascular instability is present.)
  - Alert the nearest facility with cardiopulmonary bypass capability.
- Management of cardiac arrhythmias:
  - Basic and advanced cardiac life support*
  - **Reduce** individual epinephrine doses to < 1 µg/kg.
  - **Avoid** vasopressin, calcium entry-blocking agents, beta-adrenergic blockers, and local anesthetics.
- If clinically unstable or symptoms progress, infuse 20% lipid emulsion.
  - Bolus 1.5 mL/kg (lean body mass) intravenously over 1 min (approximately 100 mL)
  - Continuous intravenous infusion 0.25 mL/kg/min (approximately 18 mL/min)
  - Repeat bolus once or twice for persistent cardiovascular collapse.
  - Double the infusion rate to 0.5 mL/kg/min if blood pressure remains low.
  - Continue infusion for at least 10 min after cardiovascular stability is achieved.
  - Maximum dose: approximately 10 mL/kg over the first 30 min

*Advanced cardiac life support should be modified for pregnancy (see Chapter 55).

Modified from Neal JM, Mulroy MF, Weinberg GL. American Society of Regional Anesthesia and Pain Medicine checklist for managing local anesthetic systemic toxicity: 2012 version. Reg Anesth Pain Med 2012; 37:16-18.

If convulsions should occur, oxygenation and ventilation must be maintained to prevent hypoxemia, hypercarbia, and acidosis.[45,46,82,84] Patency of the airway must be restored. It may be necessary to suction the airway first in some patients. Management should consist of administration of 100% oxygen and tracheal intubation, if required. Convulsions may be terminated quickly with a small dose of a benzodiazepine. Maternal circulation should be supported by maintenance of left uterine displacement and administration of a vasopressor as needed. Because a high plasma concentration of local anesthetic may cause myocardial depression and vasodilation, a mixed alpha- and beta-adrenergic agonist (e.g., ephedrine) may be preferable to a pure alpha-adrenergic agonist. Vasopressin, calcium entry-blocking agents, beta-adrenergic blocking agents, and local anesthetics should be avoided.[82] Fortunately, convulsions induced by intravenous injection of a relatively small dose of local anesthetic are usually self-limited because of rapid redistribution of the drug.

Persistent hypotension and bradycardia may require administration of epinephrine. However, individual epinephrine doses should not exceed 1 µg/kg.[82] In a dog study of bupivacaine toxicity,[85] amrinone was superior to epinephrine in improving cardiac contractility depressed by bupivacaine. Bupivacaine-induced ventricular arrhythmias should not be treated with lidocaine, because local anesthetic toxicity is additive.

Cardiac arrest should be treated according to the American Heart Association's Advanced Cardiac Life Support (ACLS) guidelines, modified for pregnancy (see Chapter 55).[86] The pelvis should be tilted leftward to prevent or relieve aortocaval compression, which renders cardiac massage ineffective. Prompt cesarean delivery of the infant may be necessary to relieve aortocaval compression (venous return) and restore maternal circulation. Prolonged resuscitation may be needed until myocardial washout of bupivacaine has occurred.[52]

Lipid emulsion therapy has been incorporated into guidelines for the treatment of LAST.[82,86] The salutary effect of lipid emulsion therapy may be related to the greater affinity of bupivacaine for the lipid and the dissociation of bupivacaine from the cardiac sodium channels or to the binding of plasma bupivacaine by the lipid fraction in the blood. Alternatively, others have proposed that bupivacaine poisons the normal energy transport mechanisms in the mitochondria and that lipid emulsion bypasses those mechanisms to provide energy substrate.[87] In a suspected case of bupivacaine intoxication in a parturient, manifested by facial and limb twitching and unconsciousness, prophylactic administration of 100 mL of lipid emulsion prevented progression to full cardiovascular collapse.[88] At least one case report has described the successful use of lipid emulsion to treat refractory cardiac arrest due to LAST.[89]

The timing of lipid emulsion administration is controversial.[82] Early treatment may prevent cardiovascular collapse, but only a few patients progress to cardiovascular collapse. The decision to administer lipid emulsion should be based on "clinical severity and rate of progression of LAST."[82] Propofol should *not* be used to treat LAST; its lipid content is inadequate, and the cardiodepressant effects of the drug are detrimental during resuscitation from LAST. A protocol for treatment of LAST, including the administration of lipid emulsion, is presented in Box 13-1.

After maternal recovery, fetal condition should be assessed promptly. In theory, a delay in delivery may allow back-diffusion of local anesthetic from the fetus to the mother, which may be of benefit to the neonate by decreasing neonatal plasma bupivacaine levels. Laboratory studies have demonstrated this phenomenon after the administration of bupivacaine[90] but not lidocaine.[91]

Tissue Toxicity

Neurologic complications of neuraxial anesthesia are rare and result mostly from direct neural trauma, infection, injection of toxic doses of local anesthetic, or the injection of the wrong drug.

In 1980, several cases of prolonged or permanent sensory and motor deficits after subarachnoid injection of a large dose of 2-chloroprocaine intended for epidural block were described.[92] Studies comparing the neurotoxicity of 2-chloroprocaine with that of other local anesthetics have yielded conflicting results, most likely related

to the use of different methodologies and different species.[93,94] It has been suggested that neurotoxicity was caused by sodium metabisulfite, an antioxidant present in the commercial formulation used in the reported cases.[93] The pH of this formulation was between 2.7 and 4.0. In CSF rendered more acidic by 2-chloroprocaine, metabisulfite generates sulfur dioxide, which is lipid soluble and can diffuse into the nerve cells.[95] Intracellular hydration of sulfur dioxide generates sulfurous acid, which may cause profound intracellular acidosis and irreversible damage.

Subsequently, the manufacturer released another preparation of 2-chloroprocaine, which was free of bisulfite but contained ethylenediaminetetraacetic acid (EDTA). This was followed by several reports of severe, incapacitating paralumbar pain and spasm associated with epidural injection of large volumes of drug.[96] The etiology is unclear, although chelation of calcium by disodium EDTA may result in a reduced tissue calcium concentration and local tetany of the affected muscles.

In a 2004 study, Taniguchi et al.[97] suggested that sodium bisulfite was the "scapegoat" for 2-chloroprocaine neurotoxicity. They concluded that neurologic deficits associated with unintentional intrathecal injection of 2-chloroprocaine likely resulted from a direct effect of the 2-chloroprocaine, not the sodium bisulfite.

The current preparation of 2-chloroprocaine that is marketed for *epidural* administration does not contain EDTA or other preservatives. It is packaged in colored vials to reduce the oxidation of the 2-chloroprocaine. Low-dose, preservative-free 2-chloroprocaine (30 to 60 mg) is now being studied as a possible alternative to lidocaine for spinal anesthesia.[98]

Lidocaine has been used for spinal anesthesia for more than 50 years, in thousands upon thousands of patients, with apparent safety. However, **cauda equina syndrome,** sacral nerve root deficits, or transient neurologic toxicity can occur after subarachnoid injection of lidocaine.[99,100] Neurotoxicity of local anesthetics is concentration dependent[101] and is not unique to lidocaine.[102,103] Some investigators have speculated that slow injection of local anesthetic through a spinal microcatheter results in maldistribution and pooling of high concentrations of hyperbaric lidocaine in the cauda equina area, resulting in neurotoxicity and cauda equina syndrome.[99,100]

Milder manifestations of neurotoxicity also may occur. As early as 1954, mild, transient neurologic symptoms were reported after spinal anesthesia with lidocaine.[104] **Transient neurologic symptoms** (TNS) (dysesthesia or low back pain radiating to the buttocks, thighs, and calves) have been observed in surgical patients even after conventional (i.e., single-shot) spinal anesthesia with hyperbaric 5% lidocaine (see Chapter 32).[100] In response to concerns that intrathecal injection of hyperbaric 5% lidocaine might be associated with TNS, in 1994 the FDA Advisory Committee on Anesthetic Drugs recommended that the injected drug concentration be reduced by dilution with an equal volume of either preservative-free saline or CSF. However, Pollock et al.[105] reported that there was no difference in the incidence of TNS when spinal lidocaine 50 mg was diluted to 2%, 1%, or 0.5% solutions before administration and that the overall incidence of TNS did not differ from that of historic controls given 5% lidocaine.

Interestingly, the exposure of frog sciatic nerve to lidocaine results in a progressive, irreversible loss of impulse activity beginning at a concentration of 1%.[101] The investigators in this study noted that "the range of lidocaine that produces such changes in mammalian nerve awaits determination."[101] Meanwhile, it seems prudent to take the following precautions[99,106]:

1. Dilute the commercial 5% lidocaine for intrathecal injection as recommended by the FDA.
2. Administer the lowest possible dose.
3. Avoid the use of hyperbaric lidocaine in clinical conditions (e.g., obesity) or situations (e.g., the lithotomy position) that may be associated with a higher incidence of TNS.

Generally, if pencil-point, side-hole spinal needles are used, it is recommended that the injection port should be directed cephalad. However, an epidemiologic survey did not implicate dose and needle bevel direction as factors that affect the risk for TNS.[106] A meta-analysis of randomized controlled trials comparing spinal lidocaine with other local anesthetics (bupivacaine, prilocaine, procaine, and mepivacaine) found that the relative risk (RR) for development of TNS was higher with lidocaine than with the other local anesthetic agents (RR, 4.35; 95% confidence interval [CI], 1.98 to 9.54).[107] It has not been conclusively proven that TNS are manifestations of neurotoxicity.

Pregnancy may be associated with a reduced risk for TNS. Studies suggest that the incidence of TNS after spinal anesthesia with lidocaine or bupivacaine is equally low (< 3%) in women having cesarean delivery and those undergoing postpartum tubal ligation.[108,109]

Allergic Reactions

True allergy to a local anesthetic is rare.[110] Further, anaphylactic and anaphylactoid reactions may be the result of additives such as methylparaben and metabisulfite.[110,111] Clinical criteria are important in the diagnosis because there is often a delay in obtaining confirmatory laboratory data. The alleged allergy to a local anesthetic can be substantiated in only 15% of patients by a history of urticaria, bronchospasm, facial edema, and/or cardiovascular instability.[112] Adverse reactions (e.g., CNS and cardiovascular symptoms) may mimic hypersensitivity but may not actually be a result of hypersensitivity. These symptoms may be caused by hyperventilation or vasovagal syncope during injection of the drug, sympathetic stimulation (e.g., palpitations, tachycardia) from epinephrine, or edema related to the injection itself (Box 13-2).

Some pregnant women claim to be allergic to "Novocaine" or "the caine" drugs. Obstetricians should refer such patients to an allergist and an anesthesiologist for appropriate evaluation well before the expected date of delivery. In many cases, a carefully obtained history excludes true hypersensitivity. If IgE-mediated hypersensitivity is suspected, patients should be referred to an allergist for further evaluation. Phillips et al.[111] recommended testing with skin prick or intradermal testing

BOX 13-2 Non–IgE-Mediated Reactions to Local Anesthetics

- Psychomotor responses
  - Vasovagal episode
  - Hyperventilation or panic attack
  - Endogenous sympathetic stimulation
- Responses to procedural trauma
- Delayed hypersensitivity reaction
- Non–IgE-mediated reaction to another agent
  - Epinephrine
  - Metabisulfite and other additives
- IgE-mediated reaction to another agent
  - Additives and preservatives
  - Latex
  - Antibiotic

TABLE 13-2 A Protocol for Provocative Dose Testing with Local Anesthetics

Step	Route	Volume (mL)	Dilution*
1	Skin prick		Undiluted
2	Subcutaneous	0.1	Undiluted
3	Subcutaneous	0.5	Undiluted
4	Subcutaneous	1.0	Undiluted
5	Subcutaneous	2.0	Undiluted

*See text for initial dilution suggestions for patients with a history of severe allergy.

From Chandler MJ, Grammer LC, Patterson R. Provocative challenge with local anesthetics in patients with a prior history of reaction. J Allergy Clin Immunol 1987; 79:885.

using appropriate positive (diluted histamine) and negative (normal saline) controls. Intradermal testing is more sensitive but is associated with a false-positive rate of 8% to 15%.[110] If the skin testing is negative, subcutaneous provocative dose testing is a useful method to confirm that the drug is safe to use clinically.[111] Alternatively, if skin testing is positive, the testing sequence (skin testing followed by provocative subcutaneous testing) should be repeated with an alternative agent.

The subcutaneous provocative test can be performed by any physician qualified to manage hypersensitivity reactions. Appropriate emergency equipment and drugs (e.g., epinephrine, H_1- and H_2-receptor antagonists) should be immediately available for resuscitation. Although not mentioned in many protocols, establishing intravenous access before testing seems prudent. The back and the ventral aspects of the forearm are the preferred sites for testing. Areas with abnormal skin coloration or dermographia should be avoided. A history of recent treatment with antihistamines, salicylates, or corticosteroids may alter the test results.[113]

The following protocol has been proposed by Chandler et al.[114] (Table 13-2) and has been used successfully in at least one published case.[115] After a negative needle-prick test, increasing volumes of undiluted local anesthetic (typically 1% concentration) are injected subcutaneously at 15-minute intervals. In patients with an especially strong history of a severe reaction, the series may be preceded by injection of diluted solutions (e.g., a 1:100 solution, followed by a 1:10 solution). A fresh syringe and a 30-gauge needle should be used for each subsequent injection. Additional refinements may consist of the use of both a negative control and a positive control injection. A local anesthetic that is not in the same class as the drug in question should be tested; if an ester is suspected as the offending agent, testing should be performed with an amide agent, and vice versa. If possible, the drug tested should be suitable for local infiltration and for epidural and subarachnoid block.

The test is considered positive if there is a change in the patient's clinical status or if a skin wheal more than 10 mm in diameter, with or without a flare, arises within 10 minutes of injection and persists for at least 30 minutes.[113] If provocative dose testing is completed without a reaction, the local anesthetic used and the final dose given should be recorded; the patient (and the referring physician) should be informed that her risk for an adverse reaction to subsequent administration of that drug and dose is no greater than that for the general population.[114,115]

Management of an Allergic Reaction. Pharmacologic therapy of a severe allergic reaction involves (1) inhibition of mediator synthesis and release, (2) reversal of the effects of these mediators on target organs, and (3) prevention of the recruitment of other inflammatory processes. In general, catecholamines, phosphodiesterase inhibitors, antihistamines, and corticosteroids have been used for this purpose (Box 13-3).[116] Higher doses of catecholamines may be required in a patient who has received sympathetic blockade. In addition, pregnancy itself decreases responsiveness to catecholamines.[117] Despite its potential adverse effect on uterine blood flow, epinephrine remains the cornerstone of therapy for allergic reactions. In one reported case, a mother was treated successfully with epinephrine 100 µg without any apparent adverse effects on the newborn.[118]

Effects on the Uterus and Placenta

Uterine Blood Flow

The association of paracervical block anesthesia with fetal bradycardia has been attributed to the high concentration of local anesthetic deposited in the vicinity of the uterine arteries (see Chapter 24). Human uterine artery segments obtained at the time of cesarean hysterectomy constrict when exposed to high concentrations of lidocaine,[119] mepivacaine,[119] or bupivacaine.[120]

These findings also have been confirmed in laboratory animals. Fishburne et al.[121] observed a dose-related decrease in uterine blood flow during uterine arterial infusion of 2-chloroprocaine, lidocaine, or bupivacaine in gravid ewes. A 25% reduction in uterine blood flow occurred at the following calculated plasma

BOX 13-3 Management of Anaphylaxis

Initial Therapy

- Stop administration of antigen.
- Maintain airway with 100% oxygen.
- Discontinue all anesthetic agents.
- Start intravascular volume expansion: 2-4 L of crystalloid/colloid (25-50 mL/kg) to treat hypotension.
- Give epinephrine:
  - 5-10 μg intravenously for treatment of hypotension; titrate as needed
  - 0.5-1.0 mg intravenously for treatment of cardiovascular collapse

Secondary Treatments

- Catecholamine infusions (starting doses):
  - Epinephrine: 4-8 μg/min (0.05-0.1 μg/kg/min)
  - Norepinephrine: 4-8 μg/min (0.05-0.1 μg/kg/min)
  - Isoproterenol: 0.05-0.1 μg/min
- Antihistamines: 0.5-1.0 mg/kg of diphenhydramine
- Corticosteroids: 0.25-1.0 g of hydrocortisone; alternatively, 1-2 g (25 mg/kg) of methylprednisolone
- Bicarbonate: 0.5-1.0 mEq/kg in patients with persistent hypotension or acidosis
- Airway evaluation (before extubation)

From Levy JH. Anaphylactic Reactions in Anesthesia and Intensive Care. Stoneham, MA, Butterworth-Heinemann, 1992:162.

concentrations of local anesthetic: bupivacaine, 7 μg/mL; 2-chloroprocaine, 11.5 μg/mL; and lidocaine, 19.5 μg/mL. However, when plasma local anesthetic concentrations mimic those that occur in ordinary clinical practice, local anesthetics have no adverse effect on uterine blood flow.[122-124] In pregnant ewes, uterine blood flow remained unchanged during an intravenous infusion of lidocaine or bupivacaine that resulted in plasma concentrations of 0.81 to 4.60 and 1.5 to 2.0 μg/mL, respectively.[122,124] Similarly, intravenous injection of 2-chloroprocaine, 0.67 and 1.34 mg/kg, did not reduce uterine blood flow velocity in pregnant guinea pigs.[123]

Pregnancy may enhance uterine vascular reactivity to local anesthetic agents. Isolated human uterine artery segments obtained from term parturients constrict at a lower lidocaine concentration than uterine artery segments from nonpregnant patients.[119,125] Uterine artery sensitivity to local anesthetics increases as early as the second trimester of pregnancy and may be related to an increase in estrogen levels.[119,121] However, these studies were performed before the recognition of the importance of intact vascular endothelium in the *in vitro* assessment of vascular tone.

The exact mechanism by which high concentrations of local anesthetics cause uterine artery vasoconstriction (while causing dilation in other vascular beds) is unclear. This vasoconstriction may result from modulation of calcium-channel regulation because verapamil and nifedipine ablate the response.[125] Alternatively, local anesthetics may affect cyclic nucleotides and alter the ionic content and contractility of uterine vascular smooth muscle.[126] Clinical experience with the use of local anesthetics supports the view that clinical concentrations of these drugs do not adversely affect the uterine vasculature (see Chapter 3).[127,128]

All local anesthetics can reduce uterine blood flow at plasma concentrations that greatly exceed those occurring during the routine practice of obstetric anesthesia.[121] There has been an added concern that the levorotary isomers of local anesthetics, which produce vasoconstriction at clinical doses,[129] may reduce uteroplacental perfusion and adversely affect fetal well-being. It is reassuring to note that ropivacaine, even at plasma concentrations that are almost two times greater than would be expected to occur during clinical use, does not reduce uterine blood flow or affect fetal heart rate (FHR), blood pressure, or acid-base measurements in pregnant sheep.[122] In humans, Doppler velocimetry studies have shown that ropivacaine has little effect on the uteroplacental or fetal circulation when it is administered to provide epidural anesthesia for cesarean delivery.[127] Similarly, clinically relevant plasma concentrations of levobupivacaine had no adverse effect on uterine blood flow.[122]

Umbilical Blood Flow

Fetal well-being also depends on the adequacy of fetal perfusion of the placenta. The regulatory mechanisms that control flow through the umbilical vessels are poorly understood. Lidocaine does not affect spiral strips obtained from human umbilical artery segments at concentrations up to 5 μg/mL, but it produces relaxation in concentrations from 30 to 900 μg/mL.[130] Bupivacaine also does not constrict umbilical artery segments at clinically relevant concentrations of 0.3 and 1 μg/mL.[130] At higher concentrations, the effect of bupivacaine appears to be biphasic. Constriction occurs at concentrations of 5 to 25 μg/mL, and relaxation occurs at concentrations greater than 125 μg/mL.[130,131] Hypercarbia but not hypoxemia lessens the contractile response of umbilical vessels to bupivacaine *in vitro*.[132]

Decreases in umbilical blood flow of as much as 43% accompany intravenous administration of lidocaine 4 mg/kg in pregnant sheep.[133] However, plasma concentrations of the drug were higher than would be expected with clinical use, and all ewes exhibited signs of CNS toxicity, which may reduce umbilical blood flow.

Advances in noninvasive Doppler imaging have facilitated clinical assessment of umbilical cord blood flow velocity. The ratio of the systolic (S) peak to the diastolic (D) trough of the umbilical artery waveform is used as a measure of vascular resistance. The S/D ratio in the umbilical artery decreases during normal pregnancy, and high ratios usually are associated with fetal compromise (see Chapter 6). Local anesthetics administered for epidural anesthesia do not adversely affect the umbilical artery S/D ratio.[134,135] In fact, labor epidural analgesia with 1.5% lidocaine or 2% 2-chloroprocaine resulted in a decrease in the S/D ratio.[134,135] This favorable change may have resulted from pain relief. Other investigators have noted no appreciable change or a slight decrease in the S/D ratio after the epidural administration of amide local anesthetics for elective cesarean delivery.[127,128,136]

Uterine Tone and Contractility

Changes in uterine tone and contractility may affect uteroplacental perfusion. Local anesthetics exert direct effects on uterine smooth muscle. One study reported that exposure to high concentrations of local anesthetic *in vitro* led to contraction of human myometrial segments obtained at the time of cesarean delivery.[137] These findings have been corroborated in laboratory animals.[138] Further, Belitzky et al.[139] observed that direct intramyometrial injection of 1% procaine resulted in uterine hyperstimulation and fetal compromise in pregnant women. In all of these reports, the myometrium was exposed to higher than normal concentrations of the drug. In other studies, however, intravenous infusion of lidocaine or bupivacaine that resulted in clinically relevant plasma concentrations did not affect uterine tone or uterine activity in pregnant ewes.[122,124] In a recent study using electrohysterogram monitoring, levobupivacaine caused less uterine muscle relaxation after intramyometrial injection in rats than did bupivacaine.[140]

Drug Interactions with 2-Chloroprocaine and Lidocaine

Epidural 2-chloroprocaine may affect the efficacy of other drugs administered in the neuraxis. Previous administration of 2-chloroprocaine (even a test dose) may reduce the quality and duration of analgesia produced by subsequent epidural injection of morphine or fentanyl.[141,142] Several hypotheses have been proposed for this antagonism. The low pH of the 2-chloroprocaine solution may result in acidification of the epidural space and thus may favor formation of the poorly diffusible, charged form of the opioid. Second, it has been suggested that 2-chloroprocaine (or its metabolite, chloroaminobenzoic acid) may act as a specific μ-opioid receptor antagonist because a κ-opioid receptor agonist (e.g., butorphanol) is not antagonized by 2-chloroprocaine.[141] However, using an *in vitro* hippocampal slice model, Coda et al.[143] concluded that 2-chloroprocaine opioid antagonism did not appear to act through a μ-opioid receptor. Third, a "window" may be caused by the rapid regression of 2-chloroprocaine before the onset of analgesia with epidural morphine.[144] This mechanism is supported by the results of a study[145] in which women who received spinal bupivacaine anesthesia for cesarean delivery were randomly assigned to receive either epidural morphine with 2-chloroprocaine or epidural morphine with saline-placebo. There was no difference in post–cesarean delivery epidural morphine analgesia between the two groups; presumably the spinal bupivacaine provided adequate analgesia until the onset of epidural morphine analgesia.[145]

2-Chloroprocaine also reduces the subsequent efficacy of bupivacaine.[146] Corke et al.[147] suggested that chloroaminobenzoic acid is responsible for this effect. Administration of buffered 2-chloroprocaine does not prevent the antagonism of epidural bupivacaine.[148]

The use of neuraxial opioids alone or in combination with local anesthetics has become ubiquitous in obstetric anesthesia for enhancing analgesia during labor or for providing effective pain relief after cesarean delivery. Lidocaine is a frequently used drug for epidural anesthesia during cesarean delivery. In a recent study,[149] epidural administration of 20 to 35 mL of epidural 2% lidocaine with fentanyl 1 hour before administration of extended-release epidural morphine increased the peak plasma concentration(C_{max}) of morphine when compared with similar women who received a combined spinal-epidural (CSE) technique (intrathecal bupivacaine and fentanyl) with no epidural medication for cesarean delivery (see Chapter 28).

Potency of Bupivacaine, Ropivacaine, and Levobupivacaine

The levorotary compounds ropivacaine and levobupivacaine were developed because of the concerns about the safety of high doses of bupivacaine. Many studies have addressed the question of relative potency among the three drugs. Ropivacaine is approximately 10 times less lipid soluble (*N*-heptane/buffer) than bupivacaine, a difference that is important for two reasons.[2] First, ropivacaine may penetrate more slowly into the large, heavily myelinated motor neurons, resulting in less motor block than occurs with bupivacaine. Second, the issue raises questions as to whether ropivacaine is equipotent to bupivacaine. Indeed, a higher dose of ropivacaine is required to produce a sensory and motor block comparable with that produced by bupivacaine after spinal injection.[150,151] Similarly, the EC_{50} (the local anesthetic concentration at which 50% of women have pain relief, also known as the minimum local anesthetic concentration [MLAC]) of epidural ropivacaine is almost twice as great as that of epidural bupivacaine in laboring women.[59] Critics of the use of EC_{50} data to compare potency argue that it provides no information on the shape and slope of the dose-effect relationship, which can vary with drug concentration, and further, that it provides no information on the effective clinical dose (ED_{95} [effective dose in 95% of cases]).[152]

Studies of the EC_{50} of epidural levobupivacaine are conflicting; one study found that levobupivacaine was essentially equipotent to bupivacaine,[70] whereas others suggest that ropivacaine and levobupivacaine have similar potency.[153,154] Levobupivacaine may have a greater motor-sparing effect than bupivacaine when given for the initial intrathecal injection. For example, in one study, none of 37 women who received intrathecal levobupivacaine 2.5 mg (with sufentanil and epinephrine) had evidence of motor block.[155] In contrast, 13 of 38 (34%) women given intrathecal bupivacaine 2.5 mg demonstrated a Bromage grade 1 motor block.

In obstetric anesthesia practice, the clinical effects of epidural levobupivacaine and ropivacaine are indistinguishable from those of epidural bupivacaine for labor analgesia.[156] The choice of bupivacaine, levobupivacaine, or ropivacaine does not affect the method of delivery or neonatal condition.[156] For cesarean delivery, epidural levobupivacaine 0.5% is virtually identical to epidural bupivacaine 0.5%.[157] The levorotary isomers (ropivacaine and levobupivacaine) may provide a greater margin of

safety when large volumes of a concentrated solution of local anesthetic are required (e.g., epidural anesthesia for cesarean delivery). However, there may be little advantage to using levobupivacaine or ropivacaine when dilute solutions are used for epidural labor analgesia or when a small dose is used for spinal anesthesia.

Placental Transfer

Most drugs, including local anesthetics, cross the placenta. The factors that influence the placental transfer of a drug include (1) the physicochemical characteristics of the drug, (2) the concentration of free drug in the maternal blood, (3) the permeability of the placenta, and (4) the hemodynamic events occurring within the fetal-maternal unit.

Local anesthetics cross placental membranes by a process of simple (i.e., passive) diffusion. The rate of transfer (not necessarily the amount) of a particular drug is described by the Fick equation, as follows:

$$\frac{Q}{t} = \frac{K \times A(C_m - C_f)}{D}$$

where Q/t is the rate of diffusion; K is the diffusion constant for the drug; A is the surface area available for transfer; C_m is free drug concentration in the maternal blood; C_f is the free drug concentration in the fetal blood; and D is the thickness of the trophoblastic epithelium. In general, K is affected by molecular size, lipid solubility, and the degree of ionization.

Molecular Size

Compounds with a molecular weight of less than 500 Da cross the placenta easily, whereas drugs like digoxin, which have a molecular weight higher than 500 Da, have a slower rate of diffusion.[158] Molecular weights of local anesthetics range from 234 to 288 Da (see Table 13-1). These small differences in molecular weight should not affect the rate of placental transfer because the diffusion constant (K) is inversely proportional to the square root of the molecular weight.[159]

Ionization and Lipid Solubility

Local anesthetics are weak bases; they have a relatively low degree of ionization and considerable lipid solubility at physiologic pH. The basic un-ionized local anesthetic molecule is more lipid soluble than the ionized moiety and determines placental transfer in a protein-free perfusate.[160]

The relationship between pH and pK_B may affect drug accumulation in the fetus. For the amide local anesthetics, pK_B values are close enough to physiologic pH that changes in fetal pH may alter the balance between ionized and un-ionized drug. In the acidotic fetus, a greater proportion of drug in the ionized form results in a larger total amount of local anesthetic in fetal plasma, because of "ion trapping" (Figure 13-4).[161-163] Elimination of lidocaine from fetal blood is slower in the asphyxiated fetus than in the nonasphyxiated fetus.[133] Accumulation of lidocaine may be greater in fetal tissues, where the pH is even lower than that in fetal blood.[163]

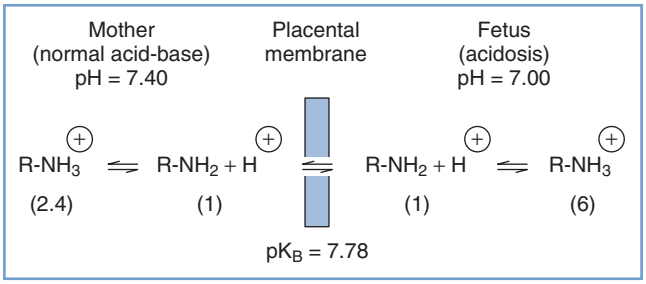

FIGURE 13-4 ■ "Ion trapping" of a local anesthetic. The numbers in parentheses represent relative numbers of molecules. (From the American College of Obstetricians and Gynecologists. Obstet Gynecol 1976; 48:29.)

Protein Binding

Perhaps most confusing and least understood are the effects of protein binding on placental transfer. Amide local anesthetics are bound predominantly to AAG and to a much lesser extent to albumin.[20] The extent of protein binding varies among the local anesthetic agents (see Table 13-1). For a given local anesthetic, the proportion of free drug increases as blood concentration increases because of the saturation of binding sites. Binding of local anesthetics in the fetal plasma is approximately half that in the mother.[90,91]

The fetal-to-maternal (F/M) blood concentration ratios of amide local anesthetic agents are listed in Table 13-1. The lower F/M blood concentration ratios of highly protein-bound drugs (e.g., bupivacaine) have been attributed to their more restricted placental transfer compared with less protein-bound drugs (e.g., lidocaine). Indeed, the rate of bupivacaine transfer across rabbit placenta perfused *in situ* is lower than that of lidocaine transfer.[164,165] Some investigators have suggested that protein binding in the maternal plasma should not affect the diffusion of drugs across the placenta because the dissociation from plasma proteins is essentially instantaneous.[159,166] In more recent studies, the relatively low umbilical vein–to–maternal vein blood concentration ratio for bupivacaine has been attributed to differences in protein binding between maternal plasma and fetal plasma (Figure 13-5).[90,91,167,168] Let us assume that the total concentration of lidocaine or bupivacaine in the maternal plasma is 2 mg/L. Lidocaine and bupivacaine are approximately 50% and 90% bound to maternal plasma proteins, respectively. Thus, the free concentrations of drug available for placental transfer are 1.0 and 0.2 mg/L, respectively. At equilibrium, the concentration of free drug is equal on the two sides of the placenta. In the fetus, however, lidocaine and bupivacaine are approximately 25% and 50% bound to fetal plasma proteins, respectively. Thus, the total lidocaine concentration in fetal plasma is 1.33 mg/L, resulting in an F/M ratio of 0.67; for bupivacaine, the corresponding values are 0.4 mg/L and 0.2.

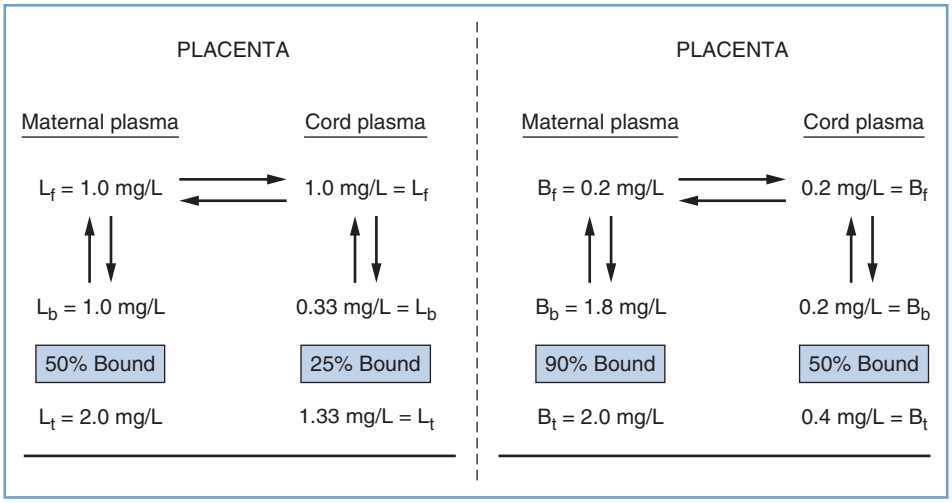

FIGURE 13-5 ■ Demonstration of how distribution of local anesthetics across the placenta may be predicted from differences in drug protein binding in maternal and fetal plasma. *Left,* lidocaine (*L*); *f, b, t,* free, bound, and total drug concentrations, respectively. *Right,* bupivacaine (*B*). Lidocaine umbilical cord–to–maternal plasma ratio (F/M) = 0.67; bupivacaine F/M = 0.20. (From Tucker GT, Mather LE. Properties, absorption, and disposition of local anesthetic agents. In Cousins MJ, Bridenbaugh PO, editors. Neural Blockade in Clinical Anesthesia and Management of Pain. 2nd edition. Philadelphia, Lippincott, 1988:95.)

Substantial accumulation of bupivacaine occurred in human fetuses whose mothers received the drug for epidural anesthesia.[25] After delivery, measurable plasma and urine concentrations persisted for as long as 3 days.[25] *In vitro* studies using a perfused human placental model have found that the placental transfer of ropivacaine is similar to that of bupivacaine.[169] Intravenous infusion of ropivacaine or bupivacaine to pregnant sheep results in steady-state maternal plasma concentrations of 1.5 to 1.6 μg/mL and fetal concentrations of approximately 0.28 μg/mL.[122] Tissue concentrations of ropivacaine in fetal heart, brain, liver, lung, kidneys, and adrenal glands were similar to those of bupivacaine.[122] Datta et al.[32] noted that the free fraction of ropivacaine at delivery was approximately twice that of bupivacaine in neonates whose mothers received the drug for epidural anesthesia during labor or cesarean delivery.

Maternal Blood Concentration of Drug

The maternal blood concentration of local anesthetic is determined by (1) the dose, (2) the site of administration, (3) metabolism and excretion, and (4) the effects of adjuvants such as epinephrine (see later discussion). For a given local anesthetic, the maternal blood concentration determines fetal drug exposure and is the only variable of the Fick equation that may be influenced by the clinician.

Dose. In general, higher doses result in higher maternal and fetal blood concentrations. For example, Kuhnert et al.[18] found that doubling the mean (± SD) dose of epidural lidocaine from 300 ± 195 mg to 595 ± 127 mg almost doubled the concentration in umbilical cord blood. The elimination half-life of amide local anesthetics is relatively long; thus, repeated epidural injection or continuous infusion of the drug may lead to accumulation in the maternal plasma. This statement does not apply to 2-chloroprocaine, however, which is rapidly hydrolyzed by pseudocholinesterase.[12]

Site of Administration. The rates of absorption and peak plasma concentrations depend on the vascularity at the site of administration. The peak plasma concentration of lidocaine is achieved within 9 to 10 minutes after paracervical block. In contrast, absorption from the lumbar epidural space, which is less vascular, occurs at a slower rate; the peak plasma concentration is not achieved until 25 to 40 minutes after administration.[18,170] Injection of local anesthetic into the caudal rather than the lumbar epidural space may result in higher blood levels because of the need for a higher drug volume to provide comparable anesthesia to that provided by lumbar epidural injection.[171]

In the past, it was thought that subarachnoid administration of a local anesthetic resulted in less systemic absorption than epidural administration. However, peak blood concentrations of lidocaine have been reported to be similar after subarachnoid and epidural administration.[172] In another study, subarachnoid administration of lidocaine 75 mg for cesarean delivery resulted in low but measurable fetal plasma concentrations of the drug.[17]

Placenta

Maturation of the placenta may affect the rate of drug transfer. In pregnant mice, diazepam and its metabolites cross the placenta more rapidly in late pregnancy.[173] Uptake and metabolism of drugs by the placenta would be expected to reduce transfer to the fetus. However, placental drug uptake of local anesthetics is limited, and it is unlikely that this organ metabolizes the amide local anesthetic agents.[174] This may not be true for the ester local anesthetics. For example, cocaine is biotransformed when it is incubated with human

placental microsomal fraction, presumably because of cholinesterase activity within the placenta.[175] Placental metabolism of para-aminobenzoic acid also has been demonstrated.[176]

Teratogenicity

The teratogenicity of anesthetics is not an issue during parturition, but local anesthetics often are used for procedures during the first trimester of pregnancy. *In vitro* studies have suggested that local anesthetics may have some adverse developmental effects. Even at low concentrations, these agents have caused reversible reduction of cell division in tissue culture.[177-182] However, structural anomalies have not been observed in intact animals.[183-185] Mid-pregnancy administration of lidocaine or mepivacaine in rats has been associated with behavioral changes in the offspring.[186,187]

Extrapolation of laboratory findings to humans is tenuous for several reasons. First, a drug may be teratogenic in one species but not in others. Second, a 1-hour drug exposure in a pregnant rat (with a gestation of 21 days) is excessive and not analogous to several hours of clinical anesthesia during human pregnancy. Third, the doses of local anesthetics used in animal studies greatly exceed those administered for clinical anesthesia. Indeed, a large, multicenter study demonstrated that the risk for congenital anomalies in humans was not increased by the administration of benzocaine, procaine, tetracaine, or lidocaine during early pregnancy.[188] However, a twofold increase in the incidence of congenital anomalies was noted in infants whose mothers had received mepivacaine. The small number of patients who received mepivacaine in this study (n = 82) and the fact that no adverse effects occurred with the use of other amide agents have raised doubts about the validity of this observation.[189]

Fetal and Neonatal Effects

Pharmacokinetics

Local anesthetics, once transferred across the placenta, are distributed in the fetus. Factors that influence tissue uptake of the drug include (1) fetal plasma protein binding, (2) lipid solubility, (3) the degree of ionization of the drug, and (4) hemodynamic changes that affect the distribution of fetal cardiac output. The fetal plasma protein-binding capacity of local anesthetics is approximately 50% that of maternal plasma.[90,91,190] Thus, at any given total plasma concentration of local anesthetic, there is greater availability of free drug in the fetus than in the mother.[90,91,190-192] Studies have examined the distribution of lidocaine in fetal tissues after an intravenous injection of the drug to animals.[19,193] The higher concentration of lidocaine in the liver, myocardium, and brain (compared with other fetal tissues) reflects rapid distribution of the drug to highly perfused tissues. The only organ in which lidocaine concentrations in the fetus have been found to exceed those in the mother is the liver. This finding is not surprising, given the high lipid content of the fetal liver and the fact that it receives most of the blood returning from the placenta by means of the umbilical vein.[193] Fetal acidosis and hypoxemia result in circulatory adaptations that increase blood flow to vital organs (e.g., brain, heart, adrenal glands).[194] The concentration of lidocaine in these organs is higher in asphyxiated fetuses than in healthy fetuses.[163,194]

Any drug that reaches the fetus undergoes metabolism and excretion. The term newborn has the hepatic enzymes necessary to metabolize local anesthetics.[17,18,195-197] Nonetheless, the elimination half-life of these drugs is longer in the neonate than in the adult.[196,197] The use of mepivacaine in obstetric epidural analgesia fell into disfavor after a report indicating that the elimination half-life of the drug in the neonate was approximately 9 hours, or three times as long as the neonatal half-life for lidocaine.[198] It is ironic that it was later discovered that the neonatal elimination half-life for bupivacaine may be as long as 14 hours.[199]

Morishima et al.[197] compared the pharmacokinetics of lidocaine among adult ewes and fetal and neonatal lambs. The metabolic (hepatic) clearance in the lambs was similar to that in adults, and renal clearance was greater than that in adults. Nonetheless, the elimination half-life was more prolonged in the lambs. This latter finding has been attributed to a greater volume of distribution in the lamb. Thus, at any given time, a smaller fraction of lidocaine accumulated in the body is available for clearance by hepatic metabolism. The greater renal clearance noted in neonates is a result of decreased protein binding, which increases the proportion of drug available to the kidneys for excretion.

The elimination half-life of local anesthetics in the fetus is similar to that in the adult because, unlike the newborn, the fetus can excrete drug across the placenta back to the mother.[90,197] With bupivacaine, this transfer may occur even though the total plasma drug concentration in the mother may exceed that in the fetus.[90]

Systemic Toxicity

In general, the neonate is more sensitive than the adult to the depressant effects of drugs. However, the seizure threshold for local anesthetics in the neonate appears to be similar to that in the adult.[200]

Morishima et al.[201] compared the relative CNS toxicity and cardiovascular toxicity of lidocaine in adult ewes and fetal and neonatal lambs. Greater doses (when calculated on a milligram-per-kilogram basis) were required to elicit toxic manifestations in the fetus and neonatal lamb than in the adult. However, the plasma concentrations of the drug associated with toxic manifestations were similar in the three groups of animals. The greater dose tolerated by fetuses than by neonates and adults was attributed to placental clearance of drug back to the mother and better maintenance of blood gas tensions during convulsions. In the neonate, a large volume of distribution is most likely responsible for the high doses of local anesthetic required to have toxic effects.

Studies of bupivacaine cardiotoxicity are inconsistent. *In vitro*, the sinoatrial node of neonatal guinea pigs was found to be more sensitive than that of adults to the cardiodepressant effect of bupivacaine.[202] In contrast, 2-day-old piglets demonstrated greater resistance than

older animals to the arrhythmogenic and CNS effects of bupivacaine.[203]

Fetal Heart Rate

Changes in FHR after administration of local anesthetics are most often related to indirect effects such as maternal hypotension and uterine tachysystole (see Chapter 23). Local anesthetics probably have little direct effect on FHR, except perhaps after paracervical block. Rather, labor itself may be the single most important factor that alters FHR patterns.[204] Transient changes in FHR variability and an increase in the incidence of periodic decelerations have been observed during administration of neuraxial analgesia in laboring women.[205,206] In contrast, in the absence of labor, FHR patterns are not affected even by the larger doses of local anesthetics required during administration of epidural anesthesia for cesarean delivery.[204] The FHR changes noted in laboring women were transient and did not affect the condition of their newborns.[205,206] In a recent study, investigators found no significant difference in the number or type of fetal electrocardiographic ST-segment changes (ST-waveform analysis [STAN] events) in women with a high-risk singleton gestation who received epidural analgesia for labor when compared with a control group of women who did not receive epidural analgesia.[207]

Neurobehavioral Tests

Neurobehavioral tests have been developed to detect subtle changes in organized behavior in the newborn. These tests include the Brazelton Neonatal Behavioral Assessment Scale (NBAS), the Early Neonatal Neurobehavioral Scale (ENNS), and the Neurologic and Adaptive Capacity Score (NACS). All the tests are subjective and complex and lack specificity.

Other perinatal factors appear to have a more important effect on neonatal test performance than the choice of local anesthetic.[208] Indeed, neurobehavioral tests have been shown not to be a reliable measure of drug effect in the newborn.[209]

Preterm Fetus and Newborn

It has become axiomatic that the preterm infant is more vulnerable than the term infant to the effects of analgesic and anesthetic drugs. Causes of enhanced drug sensitivity in the preterm newborn that have been postulated are as follows: (1) less protein is available for drug binding, (2) higher levels of bilirubin are present and may compete with the drug for protein binding, (3) greater access of the drug to the CNS occurs because of a poorly developed blood-brain barrier, (4) the preterm infant has greater total body water and less fat content, and (5) the preterm infant has a diminished ability to metabolize and excrete drugs. Unfortunately, few systematic studies have determined the maternal and fetal pharmacokinetics and pharmacodynamics of drugs throughout gestation; nevertheless, these deficiencies of the preterm infant may not be as serious as we have been led to believe. Although the plasma albumin and AAG concentrations are lower in the preterm fetus, these factors primarily affect drugs that are highly bound to these proteins. Most local anesthetics, however, exhibit only low to moderate degrees of binding in fetal plasma.[90,91]

The placenta efficiently eliminates fetal bilirubin. Thus, the hyperbilirubinemia of prematurity normally occurs in the postpartum period. Bupivacaine has been implicated as a possible cause of neonatal jaundice.[210,211] High affinity of the drug for fetal erythrocyte membranes may lead to a decrease in filterability and deformability, which may render red blood cells more prone to hemolysis.[211] However, increased bilirubin production has not been demonstrated in newborns whose mothers received bupivacaine for epidural anesthesia during labor and cesarean delivery.[212,213]

Greater total body water in the preterm fetus results in a larger volume of distribution for drugs. Thus, to achieve equal blood concentrations, the immature fetus must receive a greater amount of drug transplacentally than the mature fetus.

The diminished ability to metabolize or excrete drugs associated with prematurity is certainly not a universal phenomenon. One study of the pharmacokinetics of lidocaine in preterm newborns noted that plasma clearance was similar to that in adults.[196]

During anesthesia for preterm labor, concerns about drug effects on the newborn are far less important than the prevention of asphyxia and trauma to the fetus. Indeed, healthy preterm fetal lambs tolerated clinically relevant plasma concentrations of lidocaine (e.g., approximately 1.5 μg/mL) as well as mature ones.[19,214]

Asphyxia

Circulatory adaptations important for fetal survival during asphyxia result in increased blood flow and oxygen delivery to vital organs (e.g., heart, brain, adrenal glands).[194] Little information exists about the effects of local anesthetics on these fetal responses. Adaptation to asphyxia was unaffected in mature fetal lambs exposed to lidocaine.[194] In contrast, lidocaine adversely affected asphyxiated preterm fetal lambs, which experienced a further deterioration of acid-base status and a reduction in cardiac output and blood flow to the brain and heart (Figure 13-6).[215] Also in asphyxiated preterm fetal lambs, exposure to bupivacaine reduced blood flow to vital organs; however, FHR, blood pressure, and acid-base measurements did not change.[216]

After performing an *in vitro* study using perfused human placentas, Johnson et al.[217] suggested that bupivacaine might be preferable to lidocaine in the presence of fetal acidosis because the greater maternal protein binding of bupivacaine may limit its placental transfer. However, this methodology does not consider the potential for greater fetal tissue uptake of bupivacaine (than of lidocaine) because bupivacaine is more lipid soluble and more protein bound than lidocaine.

In 1997, Santos et al.[216] reported that the effects of bupivacaine appeared less severe than those of lidocaine in asphyxiated preterm fetal lambs. However, the lidocaine data were generated in a separate experiment reported in 1989.[215] There are inherent limitations in a

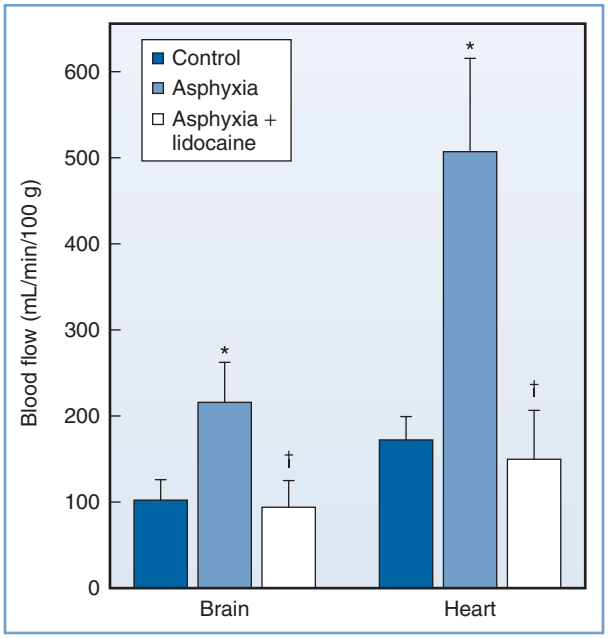

FIGURE 13-6 ■ Blood flow to the brain and heart in the preterm fetal lamb before and during asphyxia and during exposure to lidocaine while asphyxiated (mean ± SEM). *Significantly different from control. †Significantly different from asphyxia. historical comparison of two studies performed 8 years apart. Further, it is unclear whether these findings are applicable to humans because both lidocaine and bupivacaine have enjoyed a long history of safe use in obstetric anesthesia practice; prospective clinical studies are required before one drug can be recommended over the other in the setting of fetal asphyxia.

OPIOIDS

Neuraxial opioid administration is unique in that it produces analgesia without loss of sensation or proprioception. Opioids are often co-administered with local anesthetic agents during intrapartum administration of neuraxial analgesia and anesthesia.

The term *opioid* refers to a series of compounds that are related to opium. These compounds may be classified as follows: (1) naturally occurring (e.g., morphine), (2) semisynthetic compounds (e.g., dihydromorphone), and (3) synthetic compounds (e.g., fentanyl) (Box 13-4). The only three naturally occurring opioids of clinical significance are morphine, codeine, and papaverine. These substances can be obtained from the poppy plant known botanically as *Papaver somniferum.* Development of synthetic drugs with morphine-like properties has led to development of the broad term *opioid.* These substances bind to several subpopulations of opioid receptors with resulting morphine-like effects. More than 30 years ago, identification of a dense concentration of opioid receptors in the dorsal horn of the spinal cord led to the use

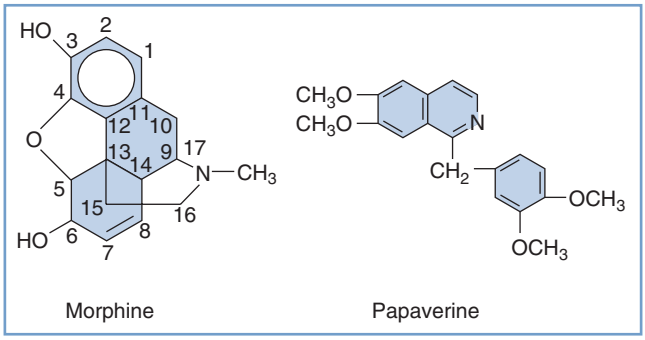

FIGURE 13-7 ■ Naturally occurring opioids: phenanthrenes (e.g., morphine) and benzylisoquinolines (e.g., papaverine).

BOX 13-4 Classification of Opioid Compounds

Naturally Occurring Compounds
- Morphine
- Codeine
- Papaverine
- Thebaine

Semisynthetic Compounds
- Heroin (diamorphine)
- Dihydromorphone
- Thebaine derivatives (e.g., etorphine, buprenorphine)

Synthetic Compounds
- Morphinan series (e.g., levorphanol, butorphanol)
- Diphenylpropylamine series (e.g., methadone)
- Benzomorphan series (e.g., pentazocine)
- Phenylpiperidine series (e.g., meperidine, fentanyl, sufentanil, alfentanil, remifentanil)

of neuraxial opioids as important adjuncts in obstetric anesthesia.

Molecular Structure

Naturally occurring opioids of significance can be divided into two distinct chemical classes, phenanthrenes (e.g., morphine) and benzylisoquinolines (e.g., papaverine) (Figure 13-7). The phenanthrenes are five-ring structures, and the benzylisoquinolines are three-ring structures. The semisynthetic opioids are morphine derivatives that have undergone relatively simple modification of the morphine molecule. For example, substitution of an ester for the hydroxyl group on carbon 6 of morphine results in hydromorphone (Figure 13-8). Synthetic opioids can be classified into the following four groups: (1) morphinan derivatives (e.g., levorphanol), (2) diphenyl or methadone derivatives (e.g., methadone, D-propoxyphene), (3) benzomorphan derivatives (phenazocine, pentazocine), and (4) phenylpiperidines (e.g., meperidine, fentanyl, sufentanil).

Structurally, opioids are complex three-dimensional compounds that often exist as two optical isomers (e.g., morphine).[218] Usually the levorotary isomer is the only

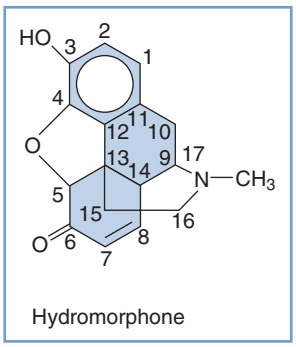

FIGURE 13-8 ■ Semisynthetic opioids are morphine derivatives. For example, substitution of an ester for the hydroxyl group on carbon 6 of morphine results in hydromorphone.

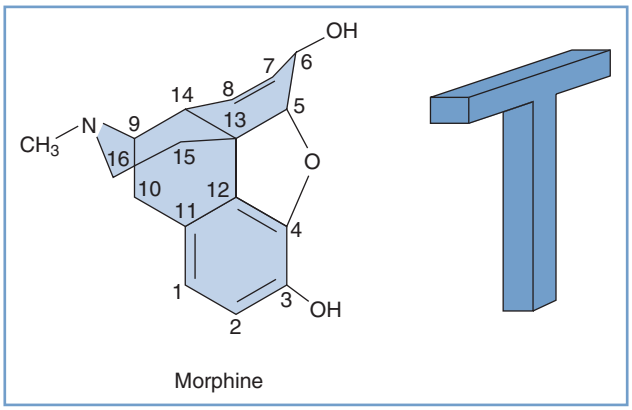

FIGURE 13-9 ■ The T-shaped molecule of morphine.

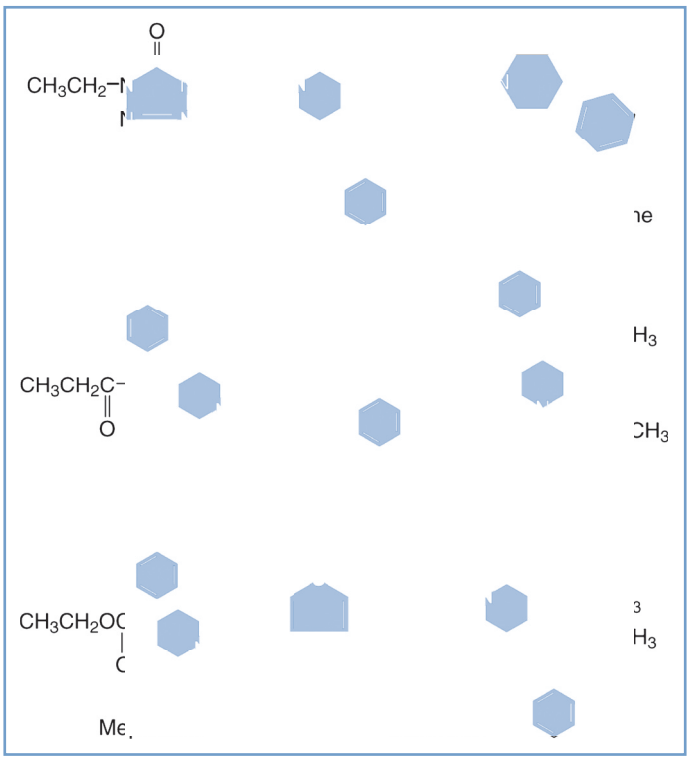

FIGURE 13-10 ■ Chemical structures of phenylpiperidine, meperidine, and the 4-anilinopiperidine derivatives fentanyl, sufentanil, alfentanil, and remifentanil.

isomer capable of producing analgesia. Analgesic activity of the opioid compound depends on its stereochemical structure.[219] Even relatively minor molecular alterations (e.g., extent of ionization) can produce significant alterations in the pharmacologic activity of the opioid.

Morphine is the prototypical opioid. It is a five-ring structure that conforms to a T shape.[220] Three of the rings lie in one plane, and the other two rings are perpendicular to the plane. This forms the basis for the T (Figure 13-9). Morphine demonstrates several other characteristics that are common to other opioids: (1) a tertiary, positively charged basic nitrogen; (2) a quaternary carbon that is separated from the basic nitrogen by an ethane chain and attached to a phenyl group; (3) a phenolic hydroxyl group (morphine derivatives) or a ketone group (meperidine); and (4) the presence of an aromatic ring.[220]

A phenylpiperidine structure (i.e., an aromatic ring attached to a six-member ring containing five carbons and one nitrogen) is also part of the morphine molecule and is present in some other opioids (e.g., fentanyl) (Figure 13-10).[220] Phenylalanine and tyrosine moieties are structural elements that are important to all opioids, including endogenous neurotransmitters and modulators.[221,222] The poppy plant synthesizes morphine from two tyrosine molecules; many opioids contain a structure that is similar to alanine.[220]

Mechanism of Action

Since first described in 1979,[223] neuraxial opioid administration has become a mainstay in obstetric anesthesia practice. Clinical and laboratory research has focused on the mechanisms of synaptic transmission as well as the study of opioids and neurotransmitters that modulate this transmission.

Pain perception involves a complex series of nociceptive transmissions that begin with stimulation of sensory nerves in the periphery, resulting in generation of action potentials within the spinal cord and synaptic transmission to other supraspinal sites. Intraspinal administration of an opioid exploits the pharmacology of pain-modulating and pain-relieving systems that exist within the spinal cord (see Figure 20-9). In early studies, Yaksh[224] demonstrated that morphine could produce selective suppression of nociceptive processing without affecting motor function, sympathetic tone, or proprioception when it was administered to the superficial layers of the dorsal horn of the spinal cord. However, when small amounts of opioid were administered to the cortex, the effects on nociceptive processing were negligible. Collectively, this work demonstrated that small doses of opioid can be selectively administered to a receptor site (i.e., spinal cord) and produce profound analgesia. In contrast, systemic administration of a much larger dose of opioid results in activation of multiple central and peripheral receptors to produce analgesia, but with unwanted side effects.

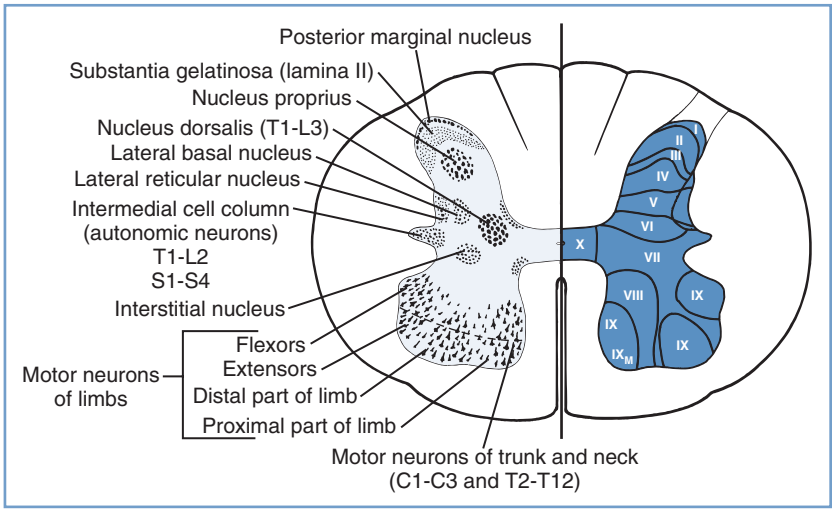

FIGURE 13-11 ■ Architecture of the spinal cord, showing the gray matter nuclei (*left*) and Rexed laminae (*right*). (From Ross BK, Hughes SC. Epidural and spinal narcotic analgesia. Clin Obstet Gynecol 1987; 30:552-65.)

All opioids produce analgesia by binding to G protein–coupled opioid receptors. Activation of opioid receptors subsequently inhibits both adenylate cyclase– and voltage-gated calcium channels. Inhibition of these calcium channels inhibits the release of excitatory afferent neurotransmitters, including glutamate, substance P, and other tachykinins.[225,226] The result is inhibition of ascending nociceptive stimuli from the dorsal horn of the spinal cord.

Opioid receptors are nonuniformly distributed throughout the CNS. Although parenterally administered opioids most likely have both direct spinal and supraspinal effects, neuraxially administered opioids block the transmission of pain-related information by binding at presynaptic and postsynaptic receptor sites in the dorsal horn of the spinal cord (i.e., Rexed laminae I, II, V) (Figure 13-11). However, the rate and extent of neuraxial analgesia depends largely on the specific drug's physicochemical properties and ability to reach the opioid receptors in the spinal cord.

The following three broad classes of opioid receptors have been identified: (1) mu (μ) receptor for morphine type, (2) kappa (κ) receptor for ketocyclazocine type, and (3) delta (δ) receptor.[225] A fourth receptor, the opioid receptor–like-1 (ORL-1) receptor, has structural homology to the classic opioid receptors, but its endogenous ligand, orphanin (OFQ) (also called nociceptin [N]), binds poorly to the classic opioid receptors.[227] Its role in pain modulation is not well characterized but appears distinctive from that of the classic opioid system.[225] Each opioid receptor is encoded by a different gene and mediates different physiologic effects (Table 13-3). Although all of these receptors may be involved with pain processing, the μ or κ receptors have the most important clinical pharmacologic effects.

The distinct receptor subtypes have significance in neuraxial opioid administration and drug development. Common pharmacologic effects (e.g., analgesia, respiratory depression) of morphine are mediated by μ-opioid receptors. Functional subclasses of μ-opioid receptors have been characterized; however, only one gene has been identified for the μ-opioid receptor. Some specific functions have been ascribed to μ-opioid receptor subtypes, including mediation of respiratory depression and spinal opioid analgesia by μ_2 receptors and production of supraspinal analgesia by μ_1 receptors.[228] Although subtype-specific μ agonists may have greater efficacy and less toxicity, no receptor-specific agents have been developed for clinical use.

Morphine also has effects at κ- and δ-opioid receptors when higher doses are administered. Responsible for analgesic, sedative, dysphoric, and diuretic effects,[225] κ receptors are located both within the CNS and peripherally.[229] Peripheral κ-opioid receptor agonists have been shown to modulate visceral pain, particularly in conditions that involve inflammation.[229]

The δ receptor is responsible for mediating some of the analgesic effects of the endogenous opioids (e.g., enkephalins, prodynorphan, pro-opiomelanocortin, pro-orphanin, endomorphins) in the spinal cord.[230] Few of the opioids have effects at the δ receptor in clinically relevant

TABLE 13-3 Subtypes of Opioid Receptors

Receptor Type	Physiologic Response	Receptor Agonist
Mu (μ)	Analgesia Miosis Bradycardia Sedation Respiratory depression Decreased gastrointestinal transit	Morphine Fentanyl Sufentanil Meperidine
Kappa (κ)	Analgesia Sedation Respiratory depression Diuresis Psychotomimesis	Buprenorphine Pentazocine
Delta (δ)	Analgesia	Prodynorphin Endomorphins Enkephalins

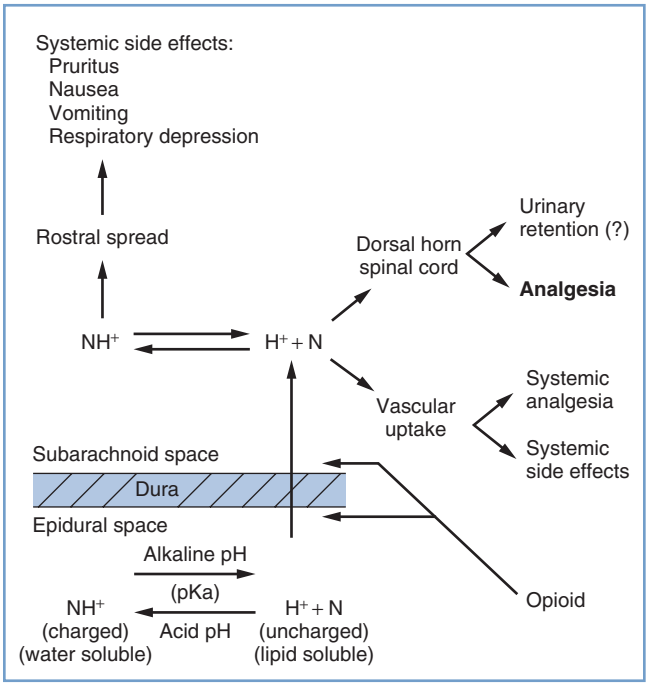

FIGURE 13-12 ■ Epidural opioids traverse the dura and arachnoid membranes, diffuse through cerebrospinal fluid, and cross the pia membrane before reaching the spinal cord. Several factors, including physicochemical properties (e.g., pKa), affect the distribution of opioids within the neuraxis. (From Ross BK, Hughes SC. Epidural and spinal narcotic analgesia. Clin Obstet Gynecol 1987; 30:552-65.)

doses, but if a μ agonist is administered in a high enough dose to treat an opioid-tolerant patient, the drug may be less selective and produce δ effects.

Pharmacokinetics and Pharmacodynamics

Many of the pharmacologic differences observed among neuraxially administered opioids depend on an opioid's ability to reach opioid receptors. An opioid's physicochemical properties, especially lipophilicity or hydrophilicity, largely determine the bioavailability of neuraxially administered opioids as well as the drug's ability to produce spinally mediated analgesia.

Before G protein–receptor activation can occur, the opioid must undergo a series of complex processes. Although several mechanisms have been proposed to explain the movement of opioids from the epidural space to the spinal cord, studies demonstrate that the only relevant mechanism is diffusion through the spinal meninges.[231-233] The opioid must traverse the dura and arachnoid membranes, diffuse through the CSF, and cross the pia membrane to reach the spinal cord (Figure 13-12). Once the drug reaches the surface of the spinal cord, it must diffuse through the white matter and then the gray matter to reach the site of action, the dorsal horn.[234] The rate and extent of opioid transfer to receptors largely depend on a drug's physicochemical properties, particularly lipid solubility, because competing processes (e.g., uptake into the epidural fat or systemic circulation) limit the agent's diffusion to opioid receptors. Greater lipid solubility of a drug results in more rapid onset of analgesia. For example, fentanyl is a highly lipid-soluble opioid (i.e., 600 times more lipid soluble than morphine); therefore, it has a more rapid onset of action than morphine (Table 13-4).

TABLE 13-4 **Physicochemical Properties of Opioids Used for Neuraxial Analgesia**

Opioid	Lipid Solubility*	pKa	Protein Binding (%)
Morphine	1.4	7.9	35
Meperidine	39	8.5	70
Diamorphine	280	7.8	40
Fentanyl	816	8.4	84
Sufentanil	1727	8.0	93

Data from Camu F, Vanlersberghe C. Pharmacology of systemic analgesics. Best Pract Res Clin Anaesthesiol 2002; 16:475-88; and McLeod GA, Munishankar B, Columb MO. Is the clinical efficacy of epidural diamorphine concentration-dependent when used as analgesia for labour? Br J Anaesth 2005; 94:229-33.

Latency, potency, and duration are also affected by other physicochemical properties, including molecular weight, pKa, and protein binding. For example, the lower the pKa, the greater the percentage of opioid existing in uncharged form (i.e., the anionic base) at a pH of 7.4. In the uncharged form, opioids penetrate the dura mater and dorsal horn more easily, resulting in a more rapid onset of analgesia.

The boundaries of the epidural space are the vertebral bodies, ligaments, and spinal meninges. Fat and the epidural venous plexus account for a large volume of the epidural space. The spinal meninges consist of the dura, arachnoid, and pia mater. Of these membranes, the arachnoid is the primary barrier for drug transfer from the epidural space to the spinal cord.[235] The arachnoid mater has multiple layers of overlapping cells that represent both a hydrophilic domain (consisting of extracellular and intracellular fluid) and a hydrophobic domain (the cell membranes).[232] For an opioid to navigate the arachnoid, it must diffuse through both domains before entering the CSF. Therefore, drugs of intermediate hydrophobicity move most readily across the arachnoid. Other physical characteristics of drugs (e.g., molecular weight) do not appear to play an important role in determining redistribution from the epidural space to the subarachnoid space.[232]

The efficacy of a drug also depends on its physicochemical properties, particularly lipid solubility. For example, the amount of drug that is sequestered in the epidural fat is entirely dependent on the drug's octanol-to-buffer distribution coefficient.[236] Consequently, lipophilic drugs (e.g., fentanyl) with a high octanol-to-buffer coefficient may never reach the arachnoid membrane and may partition in epidural fat. This lack of drug transfer across the meninges results in poor CSF bioavailability. To evaluate movement of opioids from the epidural to the subarachnoid space, Bernards et al.[236] used a porcine

model to continuously sample opioid concentrations in the epidural and intrathecal spaces. Using microdialysis techniques, the investigators measured the redistribution of morphine, alfentanil, fentanyl, and sufentanil out of the epidural space. (These opioids were administered by epidural bolus injection.) Opioid concentrations were measured over time in the epidural space, subarachnoid space, systemic venous plasma, and epidural venous plasma. Results suggested that there was a strong linear relationship between lipid solubility and mean residence time, indicating that more lipid-soluble opioids spent a longer time in the epidural space. Consequently, these drugs partition themselves into the epidural fat with ongoing slow release back into the epidural space. Because of their long residence time in the epidural space, more lipid-soluble drugs are found in lower concentrations in the CSF (i.e., decreased bioavailability to opioid receptors in the dorsal horn).

Several human studies have evaluated whether epidurally administered fentanyl produces analgesia by a selective spinal mechanism or by systemic absorption and redistribution. Results of studies of lipophilic opioids (administered by epidural infusion) have suggested that low concentrations of lipophilic opioids are subject to rapid vascular uptake from the epidural space or sequestration in epidural fat, thereby limiting access to the spinal cord.[237-239] However, other studies have suggested the occurrence of a spinal effect when lipophilic opioids are administered by epidural bolus injection[240] or by epidural infusion of short duration.[241] Ginosar et al.[242] compared the analgesic effects of epidural bolus injection and epidural infusion of fentanyl in human volunteers. Study results suggested that epidural fentanyl infusion produced analgesia by uptake into the systemic circulation with redistribution to brain and peripheral opioid receptors. However, epidural bolus administration of fentanyl produced analgesia by selective spinal mechanisms. These results were consistent with previous reports that an epidural fentanyl bolus results in a larger amount of fentanyl in the epidural space than occurs at any time during an epidural infusion, leading to the greater availability of drug to activate opioid receptors in the dorsal horn of the spinal cord.

Although hydrophilic drugs (e.g., morphine) are subject to less systemic and epidural fat uptake than lipophilic drugs, the transfer of the former into the CSF is an inefficient process because they have difficulty in crossing the lipid bilayer of the arachnoid. However, despite these inefficiencies, morphine content in the spinal cord is significantly greater than lipophilic drug (e.g., fentanyl) content,[243] and morphine has much greater bioavailability in the spinal cord than do fentanyl and sufentanil.[236,243] In summary, although morphine clearly produces analgesia via a spinal mechanism, the extent of spinal analgesia produced by the neuraxial administration of fentanyl is less clear.

After a drug reaches the subarachnoid space, either by diffusion across the meninges or by direct injection into the CSF, its effects depend on its lipid solubility. All opioids produce at least some analgesia by spinal-specific mechanisms. Movement of these drugs within the CSF depends on their physicochemical properties. Drugs can diffuse within the CSF in either a cephalad or a caudad direction. Both morphine and fentanyl have been shown to move rapidly within the CSF.[244] Lipophilic drugs can also return to the epidural space by traversing previously mentioned structures.

Ummenhofer et al.[243] used a porcine model to investigate intrathecal administration of opioids. These investigators found that lipophilic opioids have a very large volume of distribution compared with hydrophilic drugs; the volume of distribution of sufentanil was 40 times greater than that of morphine. The reason is sufentanil's extreme lipid solubility, with the drug rapidly leaving the CSF and entering the epidural fat, from which it is absorbed systemically.[245]

The ultimate goal of neuraxial opioid administration is for the drug to penetrate the dorsal horn of the spinal cord and activate μ-opioid receptors. A drug's ability to move from the CSF to the dorsal horn depends on its physicochemical properties. Of the clinically relevant opioids, morphine has the most favorable physicochemical properties to allow penetration of the dorsal horn of the spinal cord (i.e., gray matter). Because of its extreme lipid solubility, sufentanil redistributes itself or partitions itself on the superficial layer (i.e., white matter) of the spinal cord.[243] Data suggest that the spinal bioavailability of the hydrophilic drugs (e.g., morphine, hydromorphone) is greater than that of hydrophobic opioids (e.g., fentanyl, sufentanil).

An extended-release formulation of morphine has been developed to prolong the duration of a single epidural injection of morphine or obviate the need for a continuous catheter. Multivesicular liposomal preparations gradually release morphine so that a larger epidural dose can be administered, providing analgesia for up to 48 hours (see Chapter 28). Studies that have compared extended-release epidural morphine (EREM) 10 to 15 mg with conventional epidural morphine for provision of analgesia after cesarean delivery have determined that EREM provided superior and prolonged analgesia.[246,247] The most recent American Society of Anesthesiologists Practice Guidelines for the Prevention, Detection, and Management of Respiratory Depression Associated with Neuraxial Opioid Administration state that "the literature reports no significant difference in the frequency of respiratory depression when [EREM] is compared with conventional (i.e., immediate release) epidural morphine."[248] However, in a study of patients undergoing cesarean delivery, Atkinson Ralls et al.[149] observed that epidural administration of 20 to 35 mL of epidural lidocaine 2% with fentanyl 1 hour before administration of EREM (8 mg) increased the mean (± SD) peak plasma concentration (C_{max}) in the EREM group (11.1 ± 4.9 ng/mL) compared with a group that received a CSE anesthetic technique without epidural medication (8.3 ± 7.1 ng/mL) ($P = .038$). Further, the EREM group had an increased incidence of vomiting, hypotension, and use of supplemental oxygen. Patients who receive EREM should be monitored at least once every hour during the first 12 hours after administration and at least once every 2 hours for the next 12 hours (i.e., from 12 to 24 hours).[248] After 24 hours, monitoring should be performed at least once every 4 hours for a minimum of 48 hours. Increased

intensity and duration of monitoring should be considered in patients at increased risk for respiratory depression (e.g., obesity) or in the setting of concomitant administration of opioid analgesics or sedative-hypnotics by other routes. Extra precautions should be taken when patients receive EREM within 1 hour of large doses of local anesthetic[149] or when unintentional spinal administration occurs.[249]

In summary, the onset and duration of analgesia as well as side effects produced by neuraxial opioid administration depend on the specific type of opioid receptor that is activated as well as the dose, lipid solubility, and rate of movement and clearance of the opioid in the CSF.

Pharmacogenetics

Pain associated with labor and delivery is influenced by a multitude of physiologic, psychosocial, and environmental factors. However, genetic variations have also been suggested to alter a patient's sensation, experience, and perception of pain. Recent advances in genomic research have led to identification of more than 100 variants (polymorphisms) in the μ-opioid receptor gene (*OPRM1*).[250] Although inconsistent, results of some studies suggest that a single-nucleotide polymorphism (SNP) in *OPRM1* at position 118 (initially known as 118A>G, now annotated 304A>G; rs1799971) may influence responses to opioid analgesics.[251] The allelic frequency of the 304A>G polymorphism is population dependent; it is more common in Asians and less frequent in whites and blacks.

The role of the 304A>G polymorphism has been investigated in obstetric anesthesia. Using both up-down sequential allocation and random allocation methods, Landau et al.[252] estimated the ED_{50} of intrathecal fentanyl, administered as part of a CSE technique for labor analgesia in nulliparous women with and without the 304A>G variant. The ED_{50} of intrathecal fentanyl in women with the variant allele was *lower* than in women without the allele (1.5- to 2-fold difference). However, when Wong et al.[253] investigated the effect of the 304A>G allele on the duration of intrathecal fentanyl labor analgesia (25 μg), they found no significant difference in the duration of analgesia or in the treatment of breakthrough pain in women with the variant allele. Camorcia et al.[254] examined the effect of the 304A>G variant on the ED_{50} of epidural sufentanil in nulliparous women. Similar to the findings of the Landau et al. study,[252] the estimated ED_{50} was significantly lower in women with the variant allele (20.2 μg; 95% CI, 14.2 to 23.6) compared with women without the variant (25.2 μg; 95% CI, 23.2 to 26.4) ($P = .03$).

The potential role of the 304A>G polymorphism in influencing opioid analgesic requirements after cesarean delivery has been investigated in several studies. Wong et al.,[253] in a mixed race/ethnicity population, found no difference in duration of intrathecal morphine analgesia or need for supplemental analgesia in women carrying the variant allele. In contrast, Sia et al.[255] reported that Asian women with the variant allele had *increased* breakthrough pain (as assessed by patient-controlled intravenous morphine requirements) after intrathecal administration of morphine compared with women without the variant allele. In a second study, the variant allele was found to independently predict increased postoperative morphine use in women undergoing cesarean delivery.[256]

The results of these studies are difficult to reconcile.[257] Although genetic components may influence patients' responses to nociceptive stimuli, current evidence suggests that genetic polymorphism in *OPRM1* plays a minor role, if any, in opioid pain management.[251,257] A recent meta-analysis examining the 304A>G variant of *OPRM1* failed to identify a strong association between this variant allele and the response to opioids in different clinical settings.[251]

Toxicity

Any agent that is injected into the epidural or subarachnoid space should be administered with caution owing to the potential for neurotoxicity and permanent neurologic damage. Although there is concern about injecting any type of medication into the neuraxis, the epidural space is more forgiving than the subarachnoid space (see Chapter 32). In many cases, clinicians have injected medications that were not well tested in animal models. Yaksh and Collins[258] have urged careful administration of neuraxial drugs, stating that "studies in animals should precede human use of spinally administered drugs."

The most commonly administered neuraxial opioids in obstetric patients are preservative-free morphine, fentanyl, and sufentanil. Preservative-free morphine is commercially available for both epidural and intrathecal administration. To evaluate preservative-free morphine for potential neurotoxicity, Abouleish et al.[259] examined the short- and long-term effects of intrathecal morphine injection in monkeys. The meninges, nerve roots, and dorsal root ganglia were examined macroscopically and microscopically in both the study and the control groups. The researchers found no evidence of demyelination, arachnoiditis, or necrosis in either group.

Fentanyl is also available in a preservative-free formulation. Despite its widespread clinical use, few studies have assessed the histologic, physiologic, or clinical evidence of neurotoxicity with spinally administered fentanyl. One *in vitro* study evaluated the effects of fentanyl administration on nerve conduction.[260] Histopathologic studies of isolated rabbit vagus nerve axons did not show localized nerve damage after nerves were bathed in an isotonic solution of fentanyl. When axons were bathed in a hypotonic solution of fentanyl, permanent conduction deficits were noted. However, *in vivo*, relatively large doses of fentanyl would be required to create a hypotonic intrathecal environment.

Although no formal neurotoxicology studies have evaluated sufentanil administration in humans, there are no clinical reports of neurotoxicity despite its widespread use. In one study, sufentanil was administered to cats through an indwelling intrathecal catheter over 5 days.[261] Sabbe et al.[262] administered clinically relevant doses of intrathecal sufentanil to dogs over several weeks and reported no histopathologic changes. In a sheep model, Rawal et al.[263] demonstrated dose-dependent spinal cord

TABLE 13-5 Incidence of Adverse Side Effects after Intrathecal Injection of 0.5 or 1.0 mg of Morphine

	Incidence (%)		
Side Effect	MORPHINE 0.5 mg (n = 12)	MORPHINE 1 mg (n = 18)	OVERALL (n = 30)
Pruritus	58	94	80
Nausea/vomiting	50	56	53
Urinary retention	42	44	43
Drowsiness	33	50	43
Respiratory depression	0	6	3

Modified from Abboud TK, Shnider SM, Dailey PA, et al. Intrathecal administration of hyperbaric morphine for the relief of pain in labour. Br J Anaesth 1984; 56:1351-60.

histopathologic changes after intrathecal administration of sufentanil (50 to 100 μg) every 6 hours for 72 hours. These doses are much larger than those used in clinical practice. It is possible that these findings reflect an artifact of experimental design (e.g., the frequent administration of a large-volume, hypotonic preparation).

Despite the paucity of data about possible neurotoxicity, both fentanyl and sufentanil are widely used in clinical practice. These drugs are not approved by the FDA for neuraxial use. However, there are no published reports of neurologic deficits after epidural or intrathecal administration of either agent in humans, and these drugs appear to be safe for neuraxial administration. In general, anesthesia providers should exercise extreme caution before injecting any untested agent into the spinal or epidural space, in order to prevent irritation or damage to neural structures.

Side Effects

Neuraxial opioid administration is associated with beneficial effects as well as potential complications and side effects. Intrathecal administration of relatively large doses of morphine is associated with a high incidence of side effects, including somnolence, nausea and vomiting, pruritus, and respiratory depression (Table 13-5). However, epidural and intrathecal injection of more lipid-soluble opioids have fewer side effects.

Sensory Changes

An early study evaluating intrathecal sufentanil in laboring women reported sensory changes and hypotension, although no local anesthetics were administered.[264] Other investigators have reported high cervical sensory blockade associated with mental status changes, dysphagia, dyspnea, and automatisms after intrathecal sufentanil injection.[265-268] These symptoms are likely to be related to a dose-dependent opioid effect rather than neuraxial blockade–induced sympathectomy.[269] Further, these changes do not predict the quality or duration of analgesia or degree of hemodynamic change.[269] These sensory changes can be clinically significant, especially when they extend to the cervical dermatomes. Patients may feel that they cannot breathe or swallow, an effect that can be distressing. Fortunately, neither intrathecal sufentanil nor fentanyl affects the efferent limb of the nervous system, and motor function is not impaired. Patients should be reassured that their respiratory efforts are not impaired and that these symptoms will subside in 30 to 60 minutes. One report described the use of naloxone to treat the sensory changes associated with intrathecal sufentanil.[265]

Nausea and Vomiting

Nausea and vomiting are common during labor and delivery. Intrapartum nausea and vomiting can occur from a variety of causes, including pregnancy, physiology of labor itself, pain associated with labor, and parenteral administration of an opioid that may have preceded the neuraxial opioid administration. Therefore, it is difficult to determine the incidence of nausea and vomiting as direct side effects of neuraxial analgesia. Although the mechanism of neuraxial opioid–mediated nausea is unclear, there are suggestions that it may be caused by modulation of afferent input to the area postrema (i.e., the chemoreceptor trigger zone) or at the nucleus of the tractus solitarius, a key relay station in the visceral sensory network.[270] Interestingly, nausea is more common after intrathecal administration of opioids to patients who have undergone cesarean delivery than in patients who received the same intrathecal regimen during labor and delivery. Norris et al.[271] reported that women receiving epidural or intrathecal opioid analgesia during labor had an incidence of nausea and vomiting of only 1.0% and 2.4%, respectively.

A number of treatments are available with minimal side effects. A meta-analysis suggested that **metoclopramide** administration (10 mg) before initiation of spinal anesthesia or after delivery resulted in a significant reduction in intraoperative nausea and vomiting as well as early postoperative nausea and vomiting.[272] One explanation for metoclopramide's efficacy is that it promotes gastric emptying. **Ondansetron** is also used in many centers for prophylaxis and treatment of opioid-induced nausea. In a study comparing transdermal scopolamine 1.5 mg, intravenous ondansetron 4 mg, and placebo, **scopolamine** was an effective prophylactic medication against nausea in parturients who received intrathecal morphine for analgesia after cesarean delivery.[273] However, the use of scopolamine may be limited by bothersome side effects, including dry mouth, drowsiness, and blurred vision. George et al.[274] performed a systematic review of randomized, controlled trials comparing prophylaxis or treatment of nausea and vomiting using one of the 5-hydroxytryptamine-3 (5-HT_3) receptor antagonists or placebo in women receiving spinal anesthesia with intrathecal morphine for cesarean delivery. The authors determined that 5-HT_3 receptor antagonists reduced the incidence of postoperative nausea and vomiting as well as the need for postoperative rescue antiemetic therapy when compared with placebo.

Although **droperidol** is effective for the treatment of nausea, the FDA has issued a "black box" warning against

its use because of concern for QT-interval prolongation in association with droperidol administration. Intravenous **cyclizine** 50 mg was shown to be superior to **dexamethasone** 8 mg in reducing nausea after intrathecal morphine administration for cesarean delivery.[275] Another systematic review of randomized controlled trials compared dexamethasone with placebo for the prevention of postoperative nausea and vomiting in patients receiving neuraxial morphine as part of a neuraxial technique.[276] Results suggested that dexamethasone is an effective antiemetic agent, and doses used for antiemetic prophylaxis enhanced postoperative analgesia compared with placebo.

Pruritus

Pruritus is the most common side effect of neuraxial opioid administration.[264,277] Presentation is highly variable, but the incidence and severity seem to be dose dependent, especially with epidural opioid administration.[278] Onset of the pruritus occurs shortly after analgesia develops, and even small doses of intrathecal sufentanil may produce significant pruritus.[279] Some observers have noted a segmental pruritus, especially with lipophilic opioids. For example, patients often complain of perineal and truncal pruritus after intrathecal sufentanil injection.[264] Pruritus occurs more commonly with intrathecal opioid administration than with epidural administration (in one study,[271] 41.4% versus 1.3%, respectively). The incidence and severity of pruritus may be reduced by administration of a lower dose of opioid[279,280] or co-administration of the opioid with a local anesthetic.[281] Many patients do not complain about the pruritus and appear asymptomatic; however, when questioned, they acknowledge the symptom.

Although the cause of opioid-induced pruritus is unknown, it appears to be unrelated to histamine release.[282] Some investigators have suggested that pruritus results from a perturbation of sensory input resulting from rostral spread of the opioid within the CSF to the trigeminal nucleus or subnucleus caudalis.[282] Itch-specific neuronal pathways may interact with pain pathways so that continuing activity of the pain-processing system suppresses activity in the spinal itch-processing neurons. Consequently, if pain is inhibited, pruritus can be unmasked (e.g., intrathecal morphine–induced pruritus). Pruritus can also be inhibited by pain (e.g., antipruritic effect of scratching).[283]

The serotoninergic system may contribute to modulation of pain by providing a balance between nociception and anti-nociception in the network of pain-processing neurons.[284,285] The dorsal horn of the spinal cord and the spinal tract of the trigeminal nerve are abundant in 5-HT_3 receptors. Because morphine is known to activate 5-HT_3 receptors by a mechanism independent of opioid receptors,[286] it is postulated that morphine may directly stimulate 5-HT_3 receptors and may cause intrathecal morphine–induced pruritus. Consequently, occupation of 5-HT_3 receptors by a 5-HT_3–receptor antagonist potentially prevents the pruritus.

Iatrou et al.[287] performed a randomized, double-blind, placebo-controlled study to evaluate the prophylactic effects of **ondansetron** and **dolasetron** in the treatment of intrathecal morphine–induced pruritus. Study results demonstrated that patients who received preemptive 5-HT_3–receptor antagonists reported significantly less pruritus and pruritus of less severity during the first 8 postoperative hours than patients who received placebo. The frequency of pruritus was reduced by 48% and 70% for ondansetron and dolasetron, respectively, compared with placebo. A quantitative systematic review evaluated the efficacy of prophylactic 5-HT_3 receptor antagonists for the prophylaxis and treatment of neuraxial opioid-induced pruritus. The investigators determined that prophylactic 5-HT_3 receptor antagonists did not alter the incidence of pruritus compared with placebo but did reduce the incidence of *severe* pruritus and the need for therapy.[274] Additionally, 5-HT_3 receptor antagonists were efficacious for the treatment of established pruritus.

Other treatments of intrathecal opioid–induced pruritus include administration of intravenous **naloxone** (40 to 80 μg) or **diphenhydramine** (25 mg). Despite the probability that the pruritus is unrelated to histamine release, there may be some benefit from the modest sedation that follows diphenhydramine administration. Administration of **nalbuphine** (2.5 to 5 mg intravenously[288,289] or 10 mg subcutaneously[288,290]) may also be helpful in reducing symptoms. The advantage of nalbuphine compared with naloxone is that it is less likely to reverse neuraxial opioid analgesia.[289] Although propofol 10 to 20 mg was found effective for the treatment of pruritus in several studies in nonobstetric patients, its efficacy was no better than placebo in an obstetric study.[291] Regardless of the chosen treatment, pruritus can contribute significantly to patient dissatisfaction and should be treated promptly upon request.

Hypotension

Decreased blood pressure was reported in early studies that evaluated intrathecal opioid administration.[264,269] Although hypotension occurs in 5% to 10% of parturients who receive intrathecal opioids,[264,269] the incidence is higher when a local anesthetic or clonidine is added to the opioid. Early reports suggested that hypotension was due to a sympathectomy, but later work suggests that hypotension results from pain relief[292] and decreased maternal levels of catecholamines, especially epinephrine.[293] Wang et al.[294] demonstrated that intrathecal opioids block the afferent information from A-delta and C-fibers to the spinal cord but that efferent nerve impulses (e.g., sympathetic efferents) are not directly blocked.

Respiratory Depression

All opioids can cause respiratory depression regardless of their route of administration. When opioids are administered either epidurally or intrathecally, the following factors affect the risk for respiratory depression: (1) choice of drug and its pharmacokinetics, (2) drug dose, and (3) concomitantly administered CNS depressants. The most important factor affecting the onset time of respiratory depression induced by intrathecal opioids

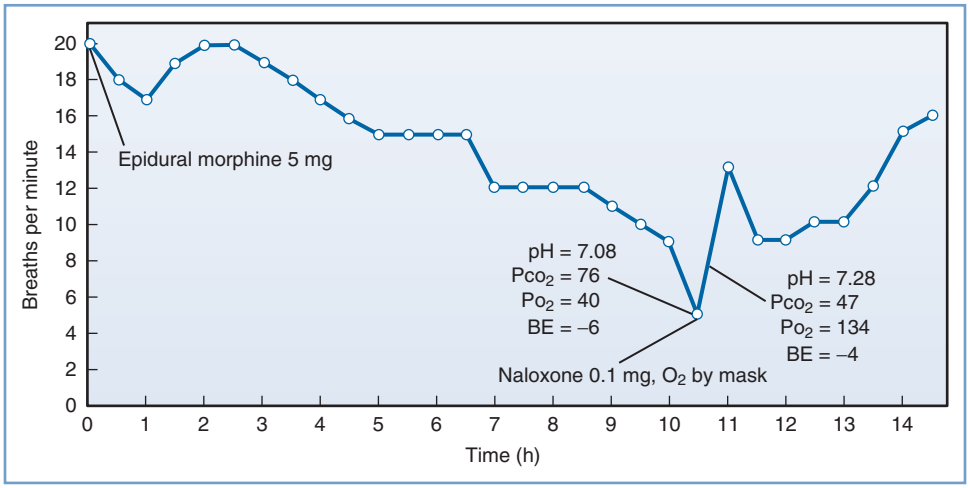

FIGURE 13-13 ■ Respiratory rate of an obstetric patient who received 5 mg of morphine after cesarean delivery and who experienced delayed respiratory depression. (From Leicht CH, Hughes SC, Dailey PA, et al. Epidural morphine sulfate for analgesia after cesarean section: a prospective report of 1000 patients [abstract]. Anesthesiology 1986; 65:A366.)

is lipid solubility.[270] Respiratory depression may occur within minutes after the administration of a lipophilic opioid (e.g., fentanyl, sufentanil) because of rapid absorption of the opioid from the CSF to lipophilic tissues.[234] Its subsequent clearance and elimination are similar to those of the drug when injected intravenously; thus the "time frame" for respiratory depression is short. In contrast, hydrophilic drugs (e.g., morphine, hydromorphone) are associated with a delayed onset of respiratory depression. This potentially serious side effect occurs because these hydrophilic opioids remain in the CSF for several hours. Although this characteristic improves the bioavailability of these opioids, rostral migration and absorption of the drug into the respiratory centers in the brainstem can produce respiratory depression 6 to 12 hours after injection (Figure 13-13).

The dose of opioid has also been shown to be an important factor in the occurrence of respiratory depression. The usual dose of intrathecal morphine for analgesia after cesarean delivery is 0.1 to 0.2 mg. Not surprisingly, an early report of respiratory depression occurred after administration of intrathecal morphine 1 mg.[295] In a dose-response study, Palmer et al.[296] concluded that there was little justification for giving more than 0.1 mg of intrathecal morphine for analgesia after cesarean delivery. In a dose-response study of epidural morphine administration after cesarean delivery, investigators concluded that the quality of analgesia increases as the dose of epidural morphine increases to 3.75 mg but that increasing the dose to 5 mg does not improve analgesia.[297]

Studies in nonobstetric surgical patients suggest that the risk for respiratory depression after the epidural administration of EREM is also dose related.[298,299] Carvalho et al.[247] compared EREM (10 mg) administration with standard epidural morphine (4 mg) administration in healthy women undergoing cesarean delivery and found that EREM reduced opioid consumption for 48 hours without significant risk for respiratory depression. However, the authors cautioned that the study's small sample size may not accurately reflect the true incidence of respiratory depression in obstetric patients who have received the extended-release preparation.

Although most cases of respiratory depression associated with sufentanil administration occur with larger doses, respiratory depression has also been reported with as little as 10 μg of intrathecal sufentanil administered for labor analgesia.[300,301] Larger doses (e.g., 15 μg) have not been found to produce better or more prolonged analgesia but do result in increased plasma opioid concentrations and a higher risk for respiratory depression. In a female volunteer study, Lu et al.[245] reported that doses of intrathecal sufentanil larger than 12.5 μg did not produce a proportionate increase in intensity or duration of analgesia. Similarly, there is little benefit to increasing the dose of intrathecal fentanyl beyond 25 μg when it is used as the sole agent for labor analgesia. These higher doses (i.e., more than 10 μg of sufentanil or more than 25 μg of fentanyl) should not be used in routine clinical practice. Respiratory depression has been reported with as little as 100 μg of epidural fentanyl.[302]

Several case reports have implicated previous parenteral administration of opioid as a contributing factor in respiratory arrest associated with intrathecal sufentanil administration in laboring women.[303,304] For example, Jaffee et al.[305] reported a case of apnea and unresponsiveness in a parturient who had received several doses of intravenous fentanyl in the 4 hours before intrathecal sufentanil administration. Although the pregnancy-induced increase in respiratory drive continues throughout labor and into the postpartum period and may provide some protection against respiratory depression, respiratory depression is the most serious side effect of neuraxial opioid administration.

Practice guidelines from the American Society of Anesthesiologists recommend that all patients who receive neuraxial opioids should be monitored for adequacy of **ventilation** (e.g., respiratory rate, depth of respiration), **oxygenation** (e.g., pulse oximetry when appropriate), and **level of consciousness**.[248] In patients who receive a single neuraxial injection of a lipophilic opioid (e.g., fentanyl), monitoring should be continual

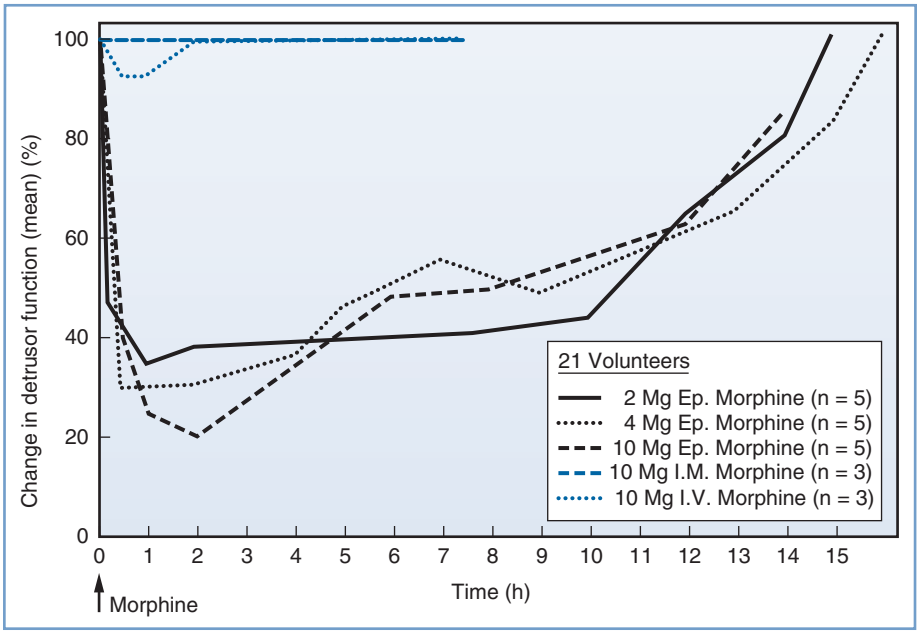

FIGURE 13-14 ■ Urodynamic effects of epidural (Ep.), intramuscular (I.M.), and intravenous (I.V.) morphine administration in male volunteers. Depression of detrusor muscle function persisted for many hours after epidural morphine administration. This did not occur with parenteral opioids and may represent a local spinal cause (i.e., opioid receptors). (From Rawal N, Mollefors K, Axelsson K, et al. An experimental study of urodynamic effects of epidural morphine and of naloxone reversal. Anesth Analg 1983; 62:641-7.)

for the first 20 minutes after administration, followed by monitoring at least once per hour until 2 hours have passed. In patients who receive a single neuraxial injection of a hydrophilic opioid (e.g., morphine), monitoring should be performed at least hourly for the first 12 hours and then at least every 2 hours for the next 12 hours after opioid administration (and then every 4 hours for *another* 24 hours in patients who receive epidural EREM). For patients who receive a continuous infusion of a neuraxial opioid, monitoring should be performed hourly during the first 12 hours, every 2 hours for the next 12 hours, and then every 4 hours for the duration of the opioid infusion. In addition, the guidelines state that greater duration and intensity of monitoring and/or additional methods of monitoring may be indicated in patients at increased risk for respiratory depression (e.g., obesity, obstructive sleep apnea, concomitant administration of opioid analgesics by other routes).

Urinary Retention

Urinary retention is a bothersome side effect of intraspinal opioid administration. The incidence varies widely. It is more common with neuraxial opioid administration than with intramuscular or intravenous administration of equivalent doses. Urinary retention is unrelated to systemic absorption and is dose independent. The onset of urinary retention appears to parallel the onset of analgesia. Evidence suggests that the rapid onset of this side effect is produced by relaxation of the detrusor muscle (Figure 13-14),[306] which most likely results from the sacral spinal action of opioids. Urinary retention can be treated with naloxone; however, because many parturients require catheterization for other reasons, urinary retention is often treated with bladder catheterization.

Delayed Gastric Emptying

Labor may delay gastric emptying, and opioids may further exacerbate this delay (see Chapter 29). Parenterally administered opioids are known to delay gastric emptying in laboring women.[307] However, clinically useful doses of epidural fentanyl have minimal effects on gastric emptying. Intrathecal administration of fentanyl produces greater delays in gastric emptying than epidural administration.[308] Delays in gastric emptying may increase the risk for nausea and vomiting and also increase the risk for aspiration if general anesthesia is necessary for emergency cesarean delivery.

Recrudescence of Herpes Simplex Virus Infections

Genital herpes infection (herpes simplex virus [HSV]) is the most common type of herpes-virus infection during pregnancy[309]; however, oral HSV infections (common cold sore or fever blister) resulting from reactivation of latent HSV infection also occur during pregnancy. Reports have suggested a relationship between neuraxial opioid administration and reactivation of oral herpes infection.[310] Crone et al.[311] reported a 10% incidence of reactivation after cesarean delivery in patients who had received epidural morphine, compared with a 1% incidence in similar patients who did not receive epidural morphine. These observations have been confirmed in two prospective studies.[312,313] Davies et al.[314] reported an increased incidence of postpartum herpes infection in patients with a history of HSV-1 who had received intrathecal morphine. Two case reports have reported an association between intraspinal administration of fentanyl and meperidine and reactivation of oral herpes infection.[315,316]

The mechanism of herpes reaction is unknown.[310] Viral reactivation is known to occur with exposure to ultraviolet light, immunosuppression, trauma, and fever. Proposed causes include (1) a skin trigger mechanism, whereby pruritus and scratching trigger reactivation; (2) an altered immunologic response[317]; and (3) a ganglion trigger mechanism, whereby the intraspinal opioid spreads rostrally and binds to the trigeminal nerve.[318] The ganglion trigger mechanism involves an alteration of sensory modulation that results in reactivation. We are unaware of any serious maternal or neonatal complications that have resulted from neuraxial administration of an opioid and reactivation of oral herpes infection.

Placental Transfer and Fetal and Neonatal Effects

Neuraxial opioid administration may have a direct effect on the infant (i.e., respiratory depression at delivery) that results from systemic absorption of the opioid followed by transplacental transfer. The fetus may also be affected indirectly by opioid-related maternal side effects (i.e., hypoxemia, respiratory depression).

Neonatal Depression

Systemic opioid absorption can result in neonatal respiratory depression, which is sometimes observed after systemic opioid administration during labor.[319,320] Neuraxial opioid analgesia techniques may result in better Apgar scores and umbilical cord blood gas and pH measurements at delivery. Despite the rapid systemic uptake of intrathecally administered opioids, the neuraxial analgesia requires the administration of smaller doses of opioid.

Several studies have evaluated neonatal outcome after continuous maternal epidural infusion of opioids and local anesthetics.[321-323] Collectively, these studies have demonstrated that maternal epidural opioid administration by continuous infusion rarely results in drug accumulation and subsequent neonatal depression. Reynolds et al.[324] performed a systematic review of randomized and nonrandomized studies comparing epidural with systemic opioid analgesia. They reviewed 12 trials with a total study population of 2102 parturients. Epidural analgesia was associated with better umbilical cord blood acid-base measurements than systemic opioids, suggesting that placental perfusion and gas exchange was well preserved despite maternal sympathetic blockade and effective analgesia. Although not all of the studies used neuraxial opioid infusions, the researchers suggested that replacement of systemic opioids with modest doses of neuraxial opioids not only produces superior analgesia but also may have a favorable effect on neonatal outcome.[324]

Fetal Heart Rate Abnormalities

Although epidural or intrathecal opioid administration has little direct effect on FHR,[325] worrisome abnormalities such as late decelerations and fetal bradycardia have been observed after intrathecal lipophilic opioid administration. Several reports have described the abrupt onset of fetal bradycardia after intrathecal administration of fentanyl or sufentanil.[326-328] Clarke et al.[327] suggested that the bradycardia is an indirect effect of decreased circulating maternal epinephrine associated with the rapid onset of analgesia. Epinephrine has a tocolytic effect and causes uterine relaxation by stimulating β_2-adrenergic receptors. Consequently, reduced epinephrine levels may lead to increased uterine tone. Because uteroplacental perfusion occurs during periods of uterine diastole (i.e., uterine relaxation), uterine tachysystole may result in diminished uteroplacental perfusion and fetal hypoxia. Norepinephrine is known to have a uterine-stimulating effect[329]; thus the decrease in epinephrine concentration alongside an unchanged norepinephrine concentration may produce uterine hyperactivity and fetal compromise.

Other mechanisms may also be relevant. Van de Velde et al.[330] questioned the catecholamine imbalance theory, because intrathecal bupivacaine combined with low-dose sufentanil (1.5 μg) produced analgesia similar to that provided by intrathecal sufentanil (7.5 μg), but the incidence of fetal bradycardia was higher with sufentanil 7.5 μg. Russell et al.[331] demonstrated that intravenous opioids have central effects, altering the release of oxytocin and vasopressin and inducing uterine hyperactivity. Lipid-soluble opioids undergo rapid systemic redistribution after neuraxial injection; therefore, even neuraxial opioids may have central effects.

Initial reports indicated that the incidence of FHR abnormalities with intrathecal opioid analgesia was 15% to 20%.[264,332] One published report suggests that uterine tachysystole and fetal bradycardia may follow administration of either intrathecal or epidural analgesia during labor.[333] FHR tracings were assessed after administration of either intrathecal sufentanil or epidural bupivacaine. There were no observed differences in the incidence of FHR abnormalities (i.e., recurrent late decelerations and/or bradycardia) between groups (22% in the intrathecal sufentanil group versus 23% in the epidural bupivacaine group).[333] In contrast, Mardirosoff et al.[334] performed a systematic review of all randomized trials comparing intrathecal with non-intrathecal administration of opioids in laboring women. Twenty-four trials met criteria; the study population included 3513 women. The relative risk for FHR abnormalities in patients receiving spinal opioids was 1.81 (95% CI, 1.04 to 3.14). The risks of cesarean delivery for FHR abnormalities were similar in the two groups (6.0% for intrathecal administration versus 7.8% for other methods).

In a prospective study, Van de Velde et al.[330] investigated whether intrathecal sufentanil 7.5 μg produced more FHR abnormalities than either conventional epidural analgesia or intrathecal bupivacaine combined with sufentanil 1.5 μg. The high-dose sufentanil group had more FHR abnormalities (i.e., late decelerations, fetal bradycardia) but less hypotension than the low-dose sufentanil/bupivacaine group. The incidence of FHR abnormalities was similar in the low-dose sufentanil/bupivacaine and conventional epidural analgesia groups. The rates of cesarean delivery for FHR abnormalities were similar in the three groups. Although FHR

abnormalities are worrisome, most published trials have not reported a higher risk for emergency cesarean delivery with intrathecal opioid analgesia.[330,334,335] However, Gambling et al.[336] reported more operative deliveries for nonreassuring fetal status after administration of intrathecal sufentanil 10 μg than with parenteral meperidine analgesia. The study's conclusions, however, were limited in that the two study groups differed in frequency of FHR assessment.

In a randomized trial, Abrao et al.[337] evaluated the effects of CSE versus traditional epidural analgesia on basal uterine tone and the occurrence of FHR abnormalities. Use of the CSE technique was the only independent predictor of an increase in basal intrauterine pressure of 10 mm Hg or more (OR, 3.53; 95% CI, 1.21 to 10.36; $P = .022$). The authors also demonstrated that the only predictor of FHR abnormalities was an increase in intrauterine pressure after initiation of analgesia (OR, 18.62; 95% CI, 4.46 to 77.72). A decrease in visual analog scale pain scores immediately after administration of analgesia was also correlated with an increased probability of increased intrauterine pressure and FHR abnormalities. Although there were no emergency cesarean deliveries that resulted from either neuraxial technique, the authors concluded that more studies are needed to better understand the effects of the CSE technique on labor progress and fetal physiology.[337] However, in a letter-to-the-editor, Landau et al.[338] suggested that the analgesic techniques were not equipotent. Additionally, monitoring for FHR abnormalities was only performed for 15 minutes. Given that the onset of analgesia is slower with epidural compared with CSE techniques, FHR abnormalities may occur earlier after intrathecal analgesia.

Given the potential risk for fetal bradycardia after neuraxial analgesia in laboring women, the FHR should be monitored before and after the initiation of epidural and intrathecal analgesia. FHR changes are usually transient and may be managed successfully with conservative measures, including (1) supplemental oxygen administration, (2) position changes to relieve aortocaval compression, (3) vasopressor therapy to treat hypotension, (4) discontinuation of oxytocin infusion, (5) intravenous fluid bolus administration, and (6) administration of a tocolytic agent for persistent uterine tachysystole.

Historically, intravenous or subcutaneous **terbutaline** was used to treat persistent uterine tachysystole. More recently, **nitroglycerin** has been used with some success. Nitroglycerin has several advantages compared with terbutaline. First, nitroglycerin has a short duration of action and labor resumes shortly after the period of tachysystole. In addition, nitroglycerin rarely produces significant hypotension, and if hypotension occurs, it is easily treated. Several studies have evaluated nitroglycerin for the treatment of uterine hypertonus. Mercier et al.[339] described consistent success in treating FHR abnormalities resulting from uterine tachysystole after the administration of one or two doses of nitroglycerin (60 to 90 μg), and Bell[340] described the successful use of sublingual nitroglycerin (400 μg) in the treatment of uterine tachysystole. In a randomized trial comparing intravenous terbutaline 250 μg to nitroglycerin 400 μg for the treatment of intrapartum tachysystole and nonreassuring FHR tracings, acute intrauterine resuscitation success rates were similar between the two groups (72% versus 64% for terbutaline and nitroglycerin, respectively; $P = .38$), but the incidence of tachysystole 10 minutes after drug administration was lower in the terbutaline group.[341] Therefore, if there is no response within 2 to 3 minutes of nitroglycerin administration, terbutaline 0.25 mg (250 μg) should be administered and preparations should be made for emergency cesarean delivery if the fetal bradycardia does not resolve.

ADJUVANTS

Epinephrine

Epinephrine is often added to epidural and spinal local anesthetic solutions to increase the duration of anesthesia, reduce peak plasma drug concentrations, improve block reliability, and intensify analgesia/anesthesia.[342-344] Uptake of epinephrine varies with the choice and concentration of local anesthetic as well as the concentration of epinephrine. The effect of epinephrine is greater when it is combined with lidocaine than when it is combined with bupivacaine.[159,198] Even concentrations of epinephrine as low as 3.3 μg/mL (1:300,000) have been shown to be effective in reducing the plasma concentrations of lidocaine.[344]

The efficacy of epinephrine depends on the specific local anesthetic as well as the site of injection. Epinephrine prolongs the duration of epidural lidocaine anesthesia by reducing uptake of local anesthetic into the systemic circulation through constriction of the epidural venous plexus. This effect helps maintain the concentration of local anesthetic at the site of injection. During epidural administration, epinephrine provides optimal results when added to lidocaine in a concentration of 5 μg/mL (1:200,000); this concentration of epinephrine nearly doubles the duration of epidural lidocaine anesthesia.[345] In contrast to lidocaine, the addition of epinephrine 3.3 μg/mL to epidural bupivacaine 0.5% had no effect on maternal venous plasma concentrations of drug in laboring women.[346] Similarly, Reynolds et al.[347] observed no effect when epinephrine 5 μg/mL was added to bupivacaine during administration of epidural anesthesia for cesarean delivery. Epinephrine did not prolong the epidural anesthesia produced by ropivacaine,[348] nor did it alter absorption of lidocaine after subarachnoid injection.[349] In contrast, one group reported that the addition of epinephrine to bupivacaine resulted in a 50% decrease in maternal plasma concentrations of bupivacaine after *paracervical* block.[350]

Greater reliability and intensity of the block are sometimes observed when epinephrine is added to epidurally administered local anesthetics. Epinephrine has intrinsic analgesic effects that are produced by stimulation of α_2-adrenergic receptors. These presynaptic adrenergic receptors are found at the terminals of primary afferent neurons. They can also be found centrally on neurons in superficial laminae of the spinal cord and in several brainstem nuclei.

In addition to the intrinsic analgesic effects of epinephrine, the inherent lipid solubility of each local anesthetic affects the degree of sensory blockade. Each local anesthetic has a lipid-to-water partition coefficient that determines the drug uptake between the aqueous and lipid phases within the spinal canal. The outcome of competition between these lipid and aqueous phases depends on the lipid solubility of the local anesthetic. If a local anesthetic is more lipid soluble, the advantage of adding epinephrine to the local anesthetic is less significant. For example, the lipid-to-water partition coefficient of lidocaine is 2.7. When epinephrine is added to lidocaine, there is marked improvement in the intensity of the block. However, because bupivacaine has a lipid-to-water partition coefficient 10 times greater than that of lidocaine, the effect of epinephrine on a bupivacaine block is less pronounced. Because ropivacaine has a lipid-to-water partition coefficient similar to that of lidocaine, epinephrine will intensify a ropivacaine block. However, the duration of the block remains unchanged.

Despite the advantages of epinephrine, concern remains about the effects of epinephrine on uterine blood flow and the maternal cardiovascular system. In healthy fetuses, epidural administration of epinephrine does not affect umbilical cord blood flow. However, in fetuses with increased vascular resistance, epidural epinephrine administration can increase the umbilical artery S/D ratio.[351] Studies of the effects of epinephrine on the placental transfer of local anesthetics have yielded contradictory results. In rabbits, epinephrine did not affect the F/M ratio of bupivacaine.[352] As a result of the addition of epinephrine, the F/M ratio for bupivacaine has been found to be increased[353] or unchanged.[346,350,354] For lidocaine, the F/M ratio has variously been reported to be increased,[198,355] decreased,[344] or unchanged.[356]

Bicarbonate

The addition of sodium bicarbonate to a local anesthetic solution increases the pH closer to the pKa of the local anesthetic. This change increases the proportion of drug in un-ionized form that is available to penetrate the nerve sheath and membrane, thereby accelerating the onset of the block and decreasing the minimum concentration required for conduction blockade.[357] Most studies have demonstrated that the addition of sodium bicarbonate to lidocaine, bupivacaine, or 2-chloroprocaine hastens the onset of epidural blockade by as much as 10 minutes.[148,358-360] The speed of onset of a ropivacaine block does not seem to be affected by alkalinization, but as with the other local anesthetics, evidence suggests that alkalinization intensifies epidural ropivacaine anesthesia and improves spread to sacral dermatomes.[361] The effects of alkalinization are most pronounced in epinephrine-containing solutions, particularly commercially prepared epinephrine-containing formulations. These solutions are prepared at a lower pH, ranging from 3.2 to 4.2.[362] The lower pH of these solutions helps preserve the epinephrine but increases the latency of onset.

Sodium bicarbonate 1 mEq/mL (8.4%) may be freshly added to local anesthetic solutions shortly before use (Table 13-6). Alkalinization of bupivacaine must be performed carefully because the margin between satisfactory alkalinization and complete precipitation is very narrow. All local anesthetics have a tendency to precipitate, so solutions containing bicarbonate should be inspected for precipitation before being administered.

TABLE 13-6 Alkalinization of Local Anesthetic Solutions

Local Anesthetic	Sodium Bicarbonate (mL)*
Lidocaine	1.0
Bupivacaine	0.1
2-Chloroprocaine	0.3

*Sodium bicarbonate 8.4% (1 mEq/mL) added to 10 mL local anesthetic solution. Suggested doses are from Warren DT, Neal JM, Bernards CM. Neuraxial anesthesia. In Longnecker DE, Newman MF, Brown DL, Zapol WM, editors. Anesthesiology. 2nd edition. New York, McGraw-Hill, 2012. Available at http://www.accessanesthesiology.com/content/56638559. Accessed August 2013..

Hypotension occurs more frequently with epidural administration of an alkalinized local anesthetic than with administration of an unbuffered solution.[363] This likely results from an accelerated onset of sympathetic blockade. Carbonated salts of local anesthetics can also be administered for a rapid onset of epidural blockade. However, these drugs have limited availability. Like alkalinized local anesthetics, these preparations are more likely to produce hypotension.

Clonidine

α_2-Adrenergic agonists (e.g., **clonidine**) have been investigated as adjuvants to local anesthetics and opioids to improve analgesic efficacy without increasing side effects. The advantage of clonidine is its ability to provide analgesia without affecting sensation or producing motor blockade.[364] However, epidural and intrathecal administration of α_2-adrenergic agonists are known to produce hypotension, probably by acting on α_2-adrenergic receptors on preganglionic cholinergic neurons.[365] In addition, α_2-adrenergic agonists produce dose-dependent sedation, which results from α_2-adrenergic stimulation in the locus ceruleus.[366]

Neuraxial clonidine has been administered for labor as well as analgesia after cesarean delivery. It exerts its effects by binding to α_2-adrenergic receptors located on primary afferent terminals of the spinal cord, substantia gelatinosa, and brainstem nuclei[367] as well as via a cholinergic mechanism.[368] Conduction blockade is produced by increases in potassium conductance and in acetylcholine and norepinephrine in the CSF, leading to decreased release of substance P and subsequent analgesia.[369]

Approximately 70% of alpha-adrenergic receptors on human myometrium are α_2-adrenergic receptors[370]; therefore, the potential effects of clonidine on labor and delivery have been evaluated. In an *in vitro* study, clonidine directly enhanced the frequency and amplitude of human myometrial contraction.[371] α_2-Adrenergic receptor stimulation in the uterus could theoretically enhance uterine contractions and decrease uterine blood

flow.[365] Indeed, in animal studies, large doses of clonidine produced a decrease in FHR.[372] This effect probably resulted from direct fetal transfer of drug and from direct and indirect effects on baroreflexes. However, this effect is unlikely to occur with clinical doses of neuraxial clonidine.

Multiple studies have evaluated neuraxial clonidine administration in humans as an analgesic adjunct during labor and delivery (see Chapter 23). When combined with local anesthetics and opioids, lower doses may be used, resulting in less hypotension and sedation. The FDA has issued a "black box" warning against its use in obstetric patients because of concerns about hemodynamic instability after its use. Therefore, clonidine is rarely used for labor analgesia in North America; however, it is more widely used in some European countries. Clonidine may be particularly useful in women in whom other epidural analgesics are contraindicated or in those who have breakthrough pain with standard local anesthetic/opioid solutions despite a functioning epidural catheter. In this setting, the bolus administration of clonidine 75 μg without a local anesthetic is not usually associated with hypotension. It appears safe to add small doses of intrathecal clonidine (15 to 30 μg) to opioids or local anesthetics, but side effects must be treated promptly to avoid fetal compromise.

Epidural clonidine has been administered for analgesia after cesarean delivery. One study suggested that epidural clonidine (400 to 800 μg) provided postoperative analgesia, but a continuous infusion was required after 6 hours.[373] Others have demonstrated that epidural clonidine (75 to 150 μg) lengthens the duration of postoperative analgesia without increasing the incidence of side effects.[374,375]

Neostigmine

Both nicotinic and muscarinic cholinergic receptors are present in the dorsal horn of the spinal cord. Neostigmine prevents breakdown of acetylcholine in the spinal cord. The acetylcholine then binds to muscarinic and nicotinic receptors of the spinal cord.[376-378] Stimulation of muscarinic receptors facilitates release of gamma-aminobutyric acid (GABA) in the dorsal horn of the spinal cord, resulting in analgesia.[368,379] Neostigmine and clonidine use a common pathway to produce analgesia mediated through acetylcholine release.

Several studies have evaluated the addition of neostigmine to intrathecal labor analgesics. Although results of these studies were inconsistent in terms of prolonging the duration of labor analgesia, all studies found that intrathecal administration of neostigmine produced severe nausea unresponsive to standard antiemetics.[380,381] These important gastrointestinal side effects limit its clinical use despite its ability to potentiate the analgesic effects of intrathecal opioids and clonidine.

Epidural neostigmine alone has limited efficacy. Neostigmine appears to be more effective at alleviating somatic pain than visceral pain.[382,383] Visceral afferents are located deep within the spinal cord. Because neostigmine has low lipid solubility, it has a limited ability to traverse biologic membranes. When it is administered without other agents, it is unable to reach these visceral afferents responsible for much of labor pain.[384] This accounts for the limited efficacy of neostigmine epidurally administered as the sole agent. However, when combined with epidural sufentanil or clonidine for initiation of analgesia, neostigmine produces selective analgesia without side effects.[385,386] Large doses of neostigmine can potentially reduce uteroplacental blood flow by CNS activation and direct stimulation of uterine contractions.[387] When administered for analgesia after cesarean delivery, epidural neostigmine (75 to 300 μg) produced modest analgesia without nausea or vomiting, but the incidence of sedation was increased.[388] Neostigmine is not routinely used in clinical practice, and its neuraxial administration is not approved by the FDA.

KEY POINTS

- Pregnancy enhances the effect of local anesthetic agents.
- Appropriate administration of epidural anesthesia does not adversely affect uterine tone or uterine or umbilical blood flow.
- Bupivacaine has greater cardiotoxicity than lidocaine because of its greater electrophysiologic effects, which predispose to ventricular arrhythmias.
- Single (levorotary) isomer formulations of amide local anesthetics, such as ropivacaine and levobupivacaine, have a lower potential for cardiotoxicity than racemic bupivacaine.
- The decision to initiate lipid therapy for treatment of local anesthetic systemic toxicity should be based on clinical severity and rate of progression of symptoms.
- Fetal acidosis results in a greater accumulation of amide local anesthetic in the fetus.
- Local anesthetics, as used clinically, are not teratogenic.
- The elimination half-life of amide local anesthetics is longer in the newborn than in the adult because the former has a greater volume of distribution.
- The fetus and newborn seem to be no more vulnerable to the toxic effects of local anesthetics than the adult.
- Neonatal neurobehavior depends on many factors other than the choice of local anesthetic.
- Alkalinization of a local anesthetic solution shortens the latency of neural blockade but increases the risk for hypotension during administration of epidural anesthesia.
- Neuraxial opioid administration produces analgesia without loss of sensation or proprioception.
- The combination of a neuraxial local anesthetic and an opioid increases block density and allows

for administration of a lower total dose of local anesthetic and a lower incidence of side effects.

- Spinal bioavailability of the hydrophilic drugs (e.g., morphine, hydromorphone) is greater than that of hydrophobic (lipophilic) opioids (e.g., fentanyl, sufentanil).
- The most common side effects of neuraxial opioid administration are pruritus and nausea and vomiting. Fetal bradycardia and maternal respiratory depression are the most serious complications.

PART V

ANESTHESIA BEFORE AND DURING PREGNANCY

Donald Caton, MD

During the early years of obstetric anesthesia, physicians were primarily concerned with its effect on neonatal respiration. Almost 25 years passed before some investigators began to suspect that anesthesia might cause other problems. In fact, it was the suspicion that chloroform caused icterus neonatorum that originally stimulated Paul Zweifel to study placental transmission.

Icterus neonatorum was not Zweifel's original interest. Under the guidance of Adolf Gusserow, one of the preeminent obstetricians in Europe, Zweifel had been studying glucose metabolism during pregnancy. In the course of his work, Zweifel unexpectedly found a reducing compound in the urine of infants whose mothers had received chloroform during labor. At first he suspected that the compound might be glucose, thinking that the metabolism of this compound had somehow been altered by chloroform. After further testing, however, he learned that the reducing substance was not glucose but chloroform itself.

Zweifel thought that chloroform, transmitted to the fetus during labor, might explain some cases of neonatal jaundice. By 1876, physicians already knew that chloroform affected the liver. To cause icterus neonatorum, sufficient quantities of the drug would have to traverse the placenta during the course of a normal labor; the rapidity of transfer was a point of contention among clinicians. To establish the possibility, Zweifel performed experiments that identified chloroform in fetal blood and urine.[1,2]

Zweifel later discounted chloroform as a cause of icterus neonatorum, and the issue was dropped. Another 75 years passed before physicians began to appreciate that drug exposure during pregnancy might have deleterious effects. Events that called attention to the problem included (1) sequelae from radiation exposure after the first use of the atomic bomb; (2) the skeletal deformities associated with the use of thalidomide, a drug once used to treat the nausea of early pregnancy; and (3) the high incidence of genital tumors among daughters of women who had been given diethylstilbestrol during pregnancy. By then the public had also been alerted through the publication of Rachel Carson's *Silent Spring*, which contained graphic descriptions of the environmental effects of the indiscriminant use of insecticides. Physicians also knew more about embryology and toxicology, better techniques for testing drugs were available, procedures for collecting information were standardized, and information about complications was disseminated. Undoubtedly, greater public awareness of these developments contributed to the resurgence of natural childbirth after 1950.

CHAPTER 14

Pharmacology and Nonanesthetic Drugs during Pregnancy and Lactation

Tony Gin, MBChB, MD, FANZCA, FHKAM • Jerome Yankowitz, MD

CHAPTER OUTLINE

Drug therapy during pregnancy can be complex because the physiologic changes of pregnancy may alter drug disposition and effect. Maternal medications may have direct effects on the fetus after placental transfer or indirect effects through changes in placental and uterine function. Even after delivery, drug transfer to breast milk may be a concern. Nevertheless, pregnant women still require medications to treat many acute and chronic conditions. The challenge is finding the balance between the benefits and risks of therapy.

It would seem prudent to use only drugs considered safe in pregnancy. Unfortunately, the potential adverse effects of many drugs remain unclear. Pregnant women are not usually included in early clinical trials, and because of the low incidence of some complications, the first suggestion of adverse effects may be revealed only from post-marketing surveillance and registries of complications. This uncertainty about safety, and the difficulties in determining what public information is reliable, may convince mothers to refuse appropriate drug treatment. New improved drugs are available in many areas of therapeutics, but many prescribers prefer to use older drugs that have a longer empirical history of safety.

Maternal variations in drug effect are not usually difficult to manage, and a change in dosing regimen or the choice of drug may be all that is required. The greatest fears and concerns are for potential fetal effects that may manifest as teratogenicity with fetal loss or congenital malformations, fetal growth restriction (also known as intrauterine growth restriction), preterm labor, and other complications. Impaired development and behavioral problems may manifest after delivery.

The anesthesia provider should understand the implications of pregnancy on drug disposition and effect. Although not usually responsible for primary maternal drug therapy, he or she will encounter women taking many different medications and may sometimes need to

administer a variety of nonanesthetic drugs during the peripartum period, either for maintenance of chronic therapy or for acute indications, especially when managing critically ill patients.

In this chapter, how maternal physiology affects pharmacology is summarized, teratology and fetal effects of the main classes of drugs the anesthesia provider is likely to encounter are addressed, and drug transfer to breast milk is reviewed. The more common perioperative drugs are used as examples. Specific drugs used in the management of individual obstetric conditions are discussed in other chapters.

CHANGES IN DRUG DISPOSITION AND EFFECT

Pharmacogenetics

Genetic differences are responsible for some of the variation in drug response among individuals. Pregnancy does not obviously modify these pharmacogenetic differences, although some obstetric conditions such as preeclampsia are related to complex genetic factors. There are, however, some examples in which underlying genetic differences do affect obstetric management.[1]

The metabolism of codeine to morphine is greatly affected by polymorphisms of the cytochrome P450 (CYP) isoenzyme CYP2D6. It has been recognized only recently that mothers who are ultrarapid metabolizers may produce and transfer sufficient morphine through breast milk to cause neonatal central nervous system (CNS) depression and even death.[2]

Two of the possible changes at the β_2-adrenergic receptor are an arginine-to-glycine substitution at codon 16 (Arg16Gly) and a glutamine-to-glutamate substitution at codon 27 (Glu27Gln). When β_2-receptor agonists were used for tocolysis, Arg16 homozygotes had longer gestation and better neonatal outcome.[3] In the management of hypotension during spinal anesthesia for cesarean delivery, Gly16 homozygotes and Glu27 homozygotes required less ephedrine.[4]

The μ-opioid receptor gene may have an adenine-to-guanine substitution at nucleotide position 118 (A118G). There have been many studies of the effects of this polymorphism on opioid dose requirements and response, although the studies in obstetric patients have had conflicting results. For example, laboring women who were AA homozygous had an increased intrathecal fentanyl requirement for analgesia.[5] In contrast, AA homozygous women receiving intrathecal morphine for postcesarean analgesia reported less pain and required less patient-controlled morphine but had a higher incidence of nausea and vomiting.[6] Wong[7] summarized the conflicting evidence and noted that the true effect of this polymorphism is probably small. Many other genetic factors influence opioid disposition and response, and even more factors influence pain perception. Indeed, a meta-analysis found that A118G polymorphism only explained 7% of the variability in opioid requirements.[8] Thus, at present there are no indications for pharmacogenetic testing in routine obstetric practice.[9]

Pharmacokinetic Changes

The major physiologic changes during pregnancy would be expected to alter drug disposition.[10,11] However, the magnitude and time course of these changes vary throughout pregnancy and among individuals. The results of many older studies are unreliable because the studies were often of low quality. Thus, making generalizations about the effects of pregnancy on drug disposition can be difficult, and individualized dosing is important.

Maternal Pharmacokinetics

Absorption and Uptake. Oral absorption and bioavailability are not usually affected by pregnancy, although nausea and vomiting may limit oral intake. Intestinal motility is decreased during pregnancy, but gastric emptying is only delayed during labor or after opioid administration. Cardiac output is increased by 30% to 50% during pregnancy, and the increased blood flow to skin and mucous membranes will enhance absorption from these sites. Reduced functional residual capacity and increased minute ventilation lead to increased pulmonary uptake of inhalational anesthetic agents.

Distribution. The increased cardiac output during pregnancy increases distribution of drug to all tissues. Drugs acting peripherally (e.g., neuromuscular blockers) will be delivered to their site of action more quickly. However, the onset of intravenous and inhalational anesthetics is dependent on the time course of their cerebral drug concentrations. A delay in the increase in arterial and brain anesthetic concentrations will result from increased peripheral perfusion. Increased peripheral perfusion will, however, increase the return of drug during the elimination phase. Total body water increases on average by 8 L, and intravascular plasma volume is increased by 40%, whereas extravascular volume increases by a variable amount, depending on weight gain and edema. Thus, hydrophilic drugs, such as neuromuscular blockers, will have a small increase in the volume of distribution. Body fat is increased on average by 4 kg, but this is unimportant given the large volume of distribution of lipophilic drugs.

Changes in protein binding are more important clinically. Plasma albumin concentration is reduced to about 70% of normal, whereas α_1-acid glycoprotein concentration is largely unchanged. Protein binding of drugs may be reduced by increased concentrations of free fatty acids and other endogenous displacing substances. This leads to increased concentrations of free drug, but with chronic drug administration this is offset by increased clearance of that free drug. The total (free + bound) concentration of drug will decrease, and it may be necessary to reset the therapeutic target range lower to compensate. Thus, it is important to know whether monitored concentrations are for free or total drug. Only a few drugs (e.g., theophylline, phenytoin) require monitoring and modification of dose because of changes in protein binding.

Metabolism. Most drugs are metabolized in the liver, and the rate of metabolism may depend on hepatic blood flow or intrinsic enzyme activity. Although cardiac output

is increased in pregnancy, it is not clear whether blood flow to the liver is significantly increased. Two studies using clearance of markers concluded that hepatic blood flow was unchanged,[12,13] whereas another using Doppler ultrasonography reported unchanged hepatic arterial flow during pregnancy but increased portal venous flow after 28 weeks' gestation.[14] More importantly, some cytochrome P450 isoenzymes (CYP3A4, CYP2D6, and CYP2C9) and uridine diphosphate glucuronosyltransferase (UGT) isoenzymes (UGT1A4 and UGT2B7) have increased activity during pregnancy,[10,15] which increases the metabolism of drugs such as phenytoin (CYP2C9), midazolam (CYP3A4), and morphine (UGT2B7). Other isoenzymes (CYP1A2 and CYP2C19) have decreased activity, which reduces the metabolism of drugs such as caffeine and theophylline (CYP1A2).

Elimination. Renal blood flow is increased by 60% to 80% and glomerular filtration rate is increased by 50% in pregnancy; thus, the renal excretion of unchanged drugs such as cephalosporin antibiotics is increased. There is also increased activity of transporter proteins such as renal P-glycoprotein, which may contribute to the increased clearance of digoxin in pregnancy.[16] Increased minute ventilation enhances elimination of inhalational anesthetic agents.

The physiologic changes of pregnancy will affect individual drugs depending on their physicochemical characteristics and metabolic pathways. Bioavailability is not usually changed significantly. Changes in volume of distribution as a result of changes in protein binding may affect drugs such as phenytoin, but monitoring and modification of therapy is usually straightforward. Drugs metabolized by the liver may require increases or decreases in dose, depending on the metabolic pathway involved. Drugs excreted unchanged by the kidneys often require an increased dose.

Placental Transfer and Metabolism

Our understanding of placental transfer and metabolism is rapidly improving (see Chapter 4). Early research was often limited to measuring drug concentrations in the umbilical vessels and maternal vein at delivery. Results were variable and difficult to interpret, especially for drugs such as anesthetic agents that are administered shortly before delivery. Umbilical blood samples are obtained at variable times after drug exposure, well before steady-state conditions are achieved. The theory of a placental barrier was proposed because maternal and fetal concentrations were often different. However, differences in concentrations of binding proteins are mainly responsible for the fetal-maternal distribution of drugs at steady state.[17] The fetal concentration of albumin is slightly greater than in the mother, but α_1-acid glycoprotein concentration is only a third of the maternal value at term. Umbilical-to-maternal blood ratios of total drug may be misleading because it is the free drug that equilibrates across the placenta. Maternal-to-fetal ratios of drugs do not provide information on the rate of drug transfer or the amount of drug that has already been transferred to the fetus.

Drug transfer across the placenta was previously thought to occur mainly by diffusion. This would favor the movement of lipophilic drugs, and placental perfusion would be an important factor affecting transfer. Fetal pH is lower than maternal pH, so that weak bases become more ionized in the fetus, thus limiting their transfer back across the placenta. Normally, the difference in pH is only 0.1 and this "ion trapping" is irrelevant, but fetal acidosis can significantly increase the fetal concentration of drugs such as local anesthetics.

It is now known that the placenta contains many drug transporters that can modify fetal drug exposure, and these are particularly relevant when trying to use transplacental pharmacotherapy to deliver drugs to the fetus.[18,19] For example, in the treatment of sustained fetal tachyarrhythmia, placental P-glycoprotein, an adenosine triphosphate–dependent drug efflux pump, will reduce net transfer of substrates such as digoxin and verapamil from the mother. With maternal human immunodeficiency virus (HIV) infection, treatment of the fetus is also required, but drug transporters limit the transfer of some antiviral drugs, such as protease inhibitors.

The placenta also contains many enzymes, especially those such as UGT that catalyze phase II conjugation reactions.[19,20] Clearance of substrates by UGT in full-term placentas may be sufficient to contribute to overall maternal metabolism.

Fetal and Neonatal Elimination. The fetus and neonate metabolize drugs, but at a reduced rate compared with adults.[21,22] The fetal circulation guides drug transferred across the placenta to undergo first-pass hepatic metabolism, but some drug will bypass the liver. Renal blood flow is minimal until near term, and any excreted products would just pass into the amniotic fluid to be swallowed. Elimination of drugs by the fetus is thus mainly reliant on placental transfer. It would seem prudent to minimize the amount of drug transferred to the neonate and choose drugs that are eliminated rapidly. Relatively large minute ventilation promotes neonatal elimination of inhalational anesthetic agents, and this may be further increased by assisted ventilation.

Pharmacodynamic Changes

Changes in the concentrations of various hormones may alter the response to other substances. In particular, progesterone and endorphins may enhance sedation and antinociception, respectively. A pharmacodynamic difference specifically refers to a change in response to a given effect-site concentration, but it is difficult during pregnancy to carry out the high-fidelity studies necessary for accurate pharmacokinetic-pharmacodynamic modeling. Thus, the demonstrations of pharmacodynamic changes in pregnancy have been limited to specific experimental designs where there are large differences in effect.

General Anesthesia

Early animal studies showed that maternal anesthetic requirements were reduced during pregnancy. Minimum alveolar concentration (MAC) values for inhalational

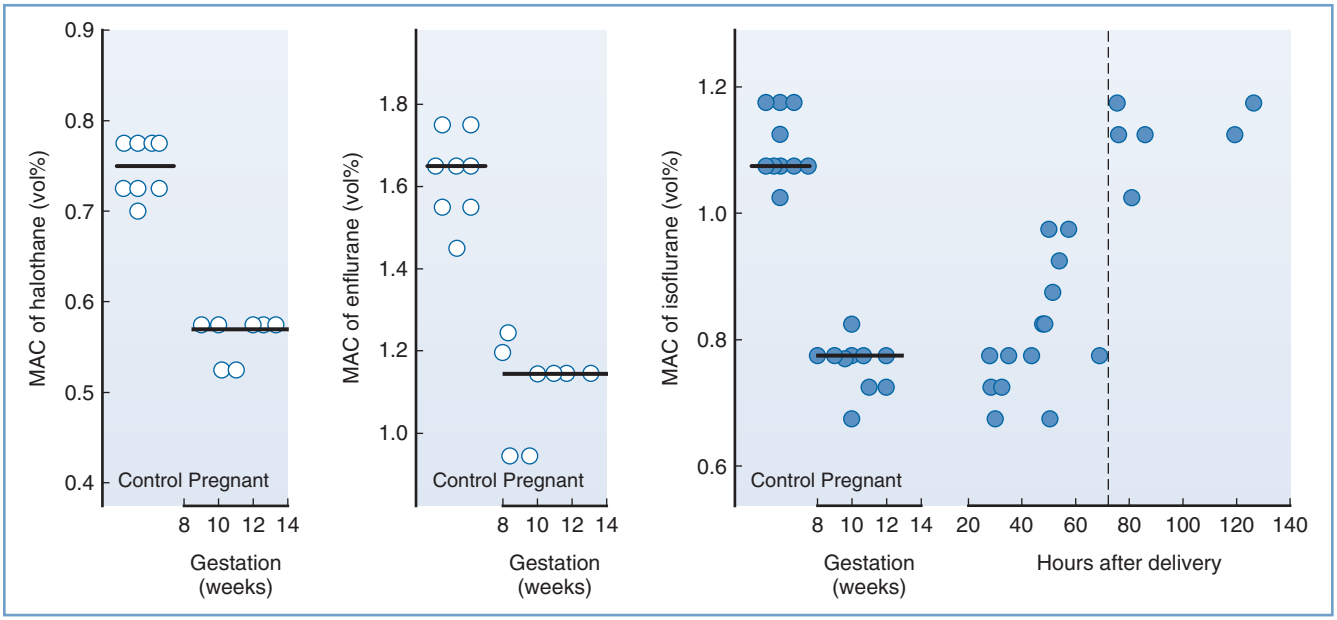

FIGURE 14-1 ■ Changes in minimum alveolar concentration (MAC), determined by response to transcutaneous electrical stimulation, for halothane, enflurane, and isoflurane in early pregnancy and for isoflurane in the early postpartum period. (Reproduced with permission from Gin T. Obstetric pharmacology. In Evers AS, Maze M, Kharasch ED, editors. Anesthetic Pharmacology: Basic Principles and Clinical Practice, 2nd edition. Cambridge, Cambridge University Press, 2011:948-62. Original data from references 25, 26, and 27.)

agents were reduced by 25% to 40% in pregnant ewes[23] and by 16% to 19% in pregnant rats.[24] Ethical and practical difficulties with research in pregnant women delayed confirmation of this finding in humans. Isoflurane MAC (determined using transcutaneous electrical stimulation instead of the classic skin incision) was decreased by 28% in women undergoing termination of pregnancy at 8 to 12 weeks' gestation.[25] Similar reductions in MAC were found for enflurane (30%) and halothane (27%).[26] MAC was reduced by 30% in the immediate postpartum period, with a return to nonpregnant values by 12 to 72 hours after delivery (Figure 14-1).[27,28]

Progesterone is probably the cause of the reduced anesthetic requirements during pregnancy; chronic progesterone administration reduced MAC in rabbits, dogs, and sheep.[29-31] Although human studies have not found a good correlation between progesterone concentrations and the reduction in anesthetic requirement, a poor correlation may be expected if the effect of progesterone is not dose-dependent; it is possible that progesterone concentrations only need to exceed a low threshold to decrease anesthetic requirements. Lower concentrations of sevoflurane were required to maintain anesthesia in nonpregnant women during the luteal phase of the menstrual cycle, when progesterone concentrations are elevated, compared with during the follicular phase.[32] The progesterone concentrations during pregnancy are much greater than those seen during the luteal phase of the menstrual cycle. The reduced MAC during pregnancy may also be a result of the increased endogenous endorphins that mediate the increase in nociceptive threshold during pregnancy; it is well known that opioids reduce MAC.

Pregnancy also alters other measures of anesthetic effect. In early pregnancy, the isoflurane concentration required for hypnosis was reduced by 31% and the bispectral index (BIS) was decreased at isoflurane concentrations over the range 0.1% to 2.0%.[33] During the second trimester, the sevoflurane concentration required to achieve a targeted BIS of 50 was reduced by 31%.[34] Both in early and term pregnancy, the median concentration of nitrous oxide required for loss of consciousness (MAC_{awake}) was reduced by 25% to 27%.[35] One study did not show any difference in electroencephalographic (EEG) measures between women having cesarean delivery or gynecologic surgery, but there were many confounding factors such as the study being conducted partly during and partly after surgery, the concurrent use of significant doses of fentanyl, large variations in EEG measures, and small sample size.[36]

The data for intravenous anesthetic agents are more variable, partly because of methodologic challenges. It is difficult to produce a stable effect-site concentration of intravenous drugs to allow accurate measurement of drug effect. Increased cardiac output usually results in an increase in intravenous anesthetic dose requirements to produce central effects, and this change would counter any decrease in requirements with pregnancy. The bolus dose of thiopental for hypnosis (failure to open eyes to command) was 17% lower, and that for anesthesia (no purposeful movement to a transcutaneous electrical stimulus) was 18% lower in early pregnancy compared with nonpregnant women (Figure 14-2).[37] A similar reduction was found in the early postpartum period, less than 60 hours after delivery.[38]

Studies using target-controlled infusions may not be reliable because the pharmacokinetic models may not be accurate in pregnancy, and they are known to predict concentrations poorly at induction of anesthesia. These methodologic problems may be the reason one study

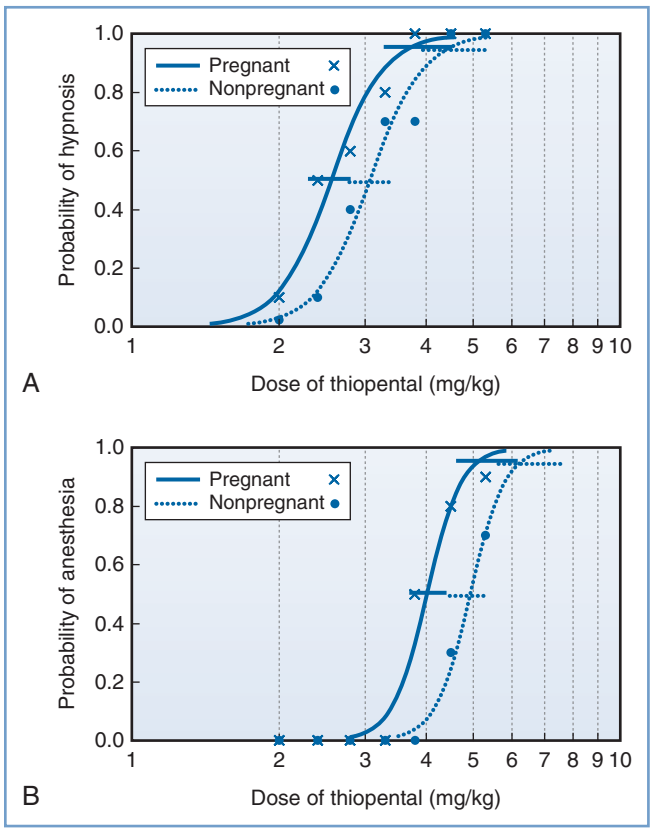

FIGURE 14-2 ■ Calculated dose-response curves (log[dose] scale) for thiopental for hypnosis (**A**) and anesthesia (**B**) in pregnant and nonpregnant women. The 95% confidence intervals for the values of ED_{50} and ED_{95} are also displayed, slightly offset for clarity. Raw data are shown for pregnant women (x) and nonpregnant women (●). (Modified with permission from Gin T, Mainland P, Chan MTV, Short TG. Decreased thiopental requirements in early pregnancy. Anesthesiology 1997; 86:73-8.)

found no differences in the concentration of propofol required for loss of consciousness in early pregnancy.[39] Another study used a slow infusion of propofol for induction of anesthesia and found that the dose and calculated effect-site concentrations at loss of consciousness were 8% lower than in nonpregnant women.[40] The reduction in anesthetic requirement for intravenous agents appears to be less (8% to 18%) than that for inhalational agents (approximately 30%). It is not known whether this reflects real differences between the drugs or the methodologic problems just outlined.

Local Anesthesia

The spread of neuraxial block is increased in pregnant women (see Chapter 2). This has been shown as early as the first trimester for epidural anesthesia[41] and the second trimester for spinal anesthesia.[42] One small study suggested that although the spread of epidural block was increased, the latency and density of sensory and motor block were not.[43] However, two more recent studies showed that the median effective dose of intrathecal bupivacaine for motor block was decreased by 13% to 35% in pregnant women at term.[44,45] Magnetic resonance imaging has confirmed that pregnant women have increased epidural blood volume, decreasing the capacity of the epidural space and decreasing the volume of lumbar cerebrospinal fluid.[46,47] These mechanical factors would explain the increased spread of local anesthetic. However, several studies have also shown that there is increased sensitivity to local anesthetics during pregnancy. The onset of conduction block in the vagus nerve with bupivacaine was faster in pregnant versus nonpregnant rabbits.[48,49] Sciatic nerve block was of longer duration and the lidocaine content in the nerves was lower at the time of return of deep pain in pregnant versus nonpregnant rats.[50] Sensory nerve action potentials were inhibited to a greater extent during median nerve block at the wrist with lidocaine in pregnant versus nonpregnant women.[51] The increased sensitivity may be caused by progesterone because exogenously administered progesterone increased the susceptibility of rabbit vagus nerves to bupivacaine.[52] One study found no changes in conduction block in pregnant rats and suggested that enhanced block may be due to pregnancy-induced changes that facilitate diffusion of local anesthetic or an interaction with endogenous analgesic systems.[53]

Analgesia

Pregnancy is associated with increases in nociceptive response thresholds that are mediated by endogenous opioid systems.[54,55] The changes in threshold can be reproduced using exogenous progesterone and estrogen and appear to involve spinal cord kappa (κ) and delta (δ) opioid receptors and descending spinal α_2-noradrenergic pathways.[56] Early human studies produced mixed results, probably because of methodologic problems. Recent controlled studies showed that heat pain threshold was increased in term pregnant women, and this persisted during the first 24 to 48 hours after delivery.[57,58] Given the many different factors that influence pain behavior, especially those unique to pregnancy and delivery, it is difficult to determine how this change in pain threshold influences perioperative analgesic requirements.

DRUG USE DURING PREGNANCY

General Teratology

Teratology is the study of abnormal development or birth defects. Teratogens are substances that act to irreversibly alter growth, structure, or function of the developing embryo.[59] Ideally, preclinical studies would identify teratogens, but drug teratogenicity unfortunately can be markedly species-specific. For example, **thalidomide** produces phocomelia in primates but not in rodents.

In the United States, major malformations affect 2% to 3% of neonates.[60] A *major malformation* is defined as one that is incompatible with survival (e.g., anencephaly), one that requires major surgery for correction (e.g., cleft palate, congenital heart disease), or one that causes mental retardation. If all minor malformations (e.g., ear tags, extra digits) are included, the incidence of congenital anomalies may be as high as 7% to 10%. Exogenous causes of birth defects (e.g., radiation, infections,

maternal metabolic disorders, drugs, environmental chemicals) account for almost 10% of all major birth defects and therefore affect only 0.2% to 0.3% of all births. Drug exposure explains only 2% to 3% of birth defects, and the majority of birth defects are of unknown etiology.

To avoid unnecessary and potentially teratogenic exposures, nonpharmacologic techniques should be used when possible and drugs should be used only when necessary. The risk-to-benefit ratio should justify the use of a drug given to a pregnant woman, and the minimum effective dose should be employed. Long-term effects of fetal drug exposure may not become apparent for many years. Therefore, physicians and patients should exercise caution in the use of any drug during pregnancy. On the other hand, the physician should ask the following question: what would be the appropriate treatment in the nonpregnant patient with the same condition? In most cases, the answer is the same as that for women who are pregnant.[61]

Sensitive serum pregnancy tests can diagnose pregnancy as early as 1 week after conception. Before drug therapy is started, a sensitive test should be used if there is any question about drug safety during a potential pregnancy.

It is also important to remember that the male partner may be taking teratogenic drugs and the drug may be present in semen at low concentrations. Although the magnitude of fetal risk is unclear, men are advised to avoid drugs such as **thalidomide**, **ribavirin**, and **isotretinoin** if their partners could become pregnant.

The maternal and fetal genotype and phenotype can affect individual susceptibility to an agent. For example, fetuses with low levels of the enzyme epoxide hydrolase are more likely to manifest fetal hydantoin syndrome than those with normal levels of this enzyme.[62]

Drug teratogenicity is affected by the timing of exposure. Teratogen exposure in the first 2 weeks after conception is generally thought to be an all-or-nothing phenomenon (i.e., having either no effect or resulting in spontaneous fetal loss). Among women with a 28-day menstrual cycle, the classic period of susceptibility to teratogenic agents is during the period of organogenesis, which occurs primarily at 2½ to 8 weeks after conception (31 to 71 days, or 4 to 10 weeks, after the first day of the last menstrual period) (Figure 14-3). During organogenesis, each organ system has different critical periods of sensitivity and there may be striking differences in effect. When administered between 35 and 37 days' gestation, thalidomide produces ear malformations; when administered between 41 and 44 days' gestation, it produces amelia or phocomelia. After this period, embryonic development is characterized primarily by increasing organ size; thus, the principal effect of exposure consists of growth restriction and/or effects on the nervous system and gonadal tissue. For example, diethylstilbestrol exposure during the second trimester results in uterine anomalies that do not become apparent until after puberty. Fetal alcohol syndrome may occur with chronic exposure to alcohol during pregnancy.

The drug dosing regimen can influence teratogenicity. In most cases, administration of a low dose has no effect whereas malformations may occur at intermediate doses and death may occur at higher doses. Fetal death may allow organ-specific teratogenic activity to go unnoticed. Small doses administered over several days may have an effect different from that observed with the same total dose administered at one time. Sequential drug administration may induce the production of an enzyme that metabolizes the drug and thus results in less exposure. Constant exposure may destroy cells that would have catabolized the drug if it had been administered in periodic doses. Combinations of agents may produce different degrees of malformation and growth restriction from those that occur with drugs administered individually. For example, fetuses whose mothers receive combination anticonvulsant therapy are at the highest risk for malformations, including neural tube defects and facial dysmorphic features.

U.S. Food and Drug Administration Categories

In 1979, the U.S. Food and Drug Administration (FDA) introduced a drug classification system to discourage nonessential use of medications during pregnancy (Box 14-1).

Unfortunately, maternal anxiety related to medication use can lead to unnecessary pregnancy terminations. Several characteristics of the FDA drug classification system contribute to public perception—and *misperception*—of the dangers of using medication during pregnancy. Although only 20 to 30 commonly used drugs are known teratogens, 7% of all the medications that are listed in the *Physicians' Desk Reference* are classified as Category X.[63,64] All new medications are classified as Category C, leading to an exaggerated impression of

BOX 14-1 U.S. Food and Drug Administration Drug Classification System

Category A

Controlled studies have shown no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.

Category B

No evidence of human fetal risk exists. Either animal reproduction studies have not demonstrated fetal risk but no controlled studies in pregnant women have been reported or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of risk in later trimesters).

Category C

Risk cannot be ruled out. Either studies in animals have revealed adverse effects on the fetus (teratogenic, embryocidal, or other) but no controlled studies in women have been reported, or studies in women and animals are not available. These drugs should be given only if the potential benefit justifies the potential risk to the fetus.

Category D

Positive evidence of human fetal risk exists. However, the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed for a life-threatening condition or for a serious disease for which safer drugs cannot be used or are ineffective).

Category X

Contraindicated in pregnancy. Studies in animals or human beings have demonstrated fetal abnormalities, or evidence exists of fetal risk based on human experience, or both, and the risk in pregnant women clearly outweighs any possible benefit. These drugs are contraindicated in women who are or may become pregnant.

Modified from Friedman JM. Report of the Teratology Society Public Affairs Committee symposium on FDA classification of drugs. Teratology 1993; 48:5-6.

the danger of many medications. In addition, the manufacturer's prescribing information for many drugs may state that the drug is not approved for use in pregnancy despite a long history of uncomplicated unlicensed or "off-label" use.[65]

The FDA categories imply a progressive fetal risk from Category A to X; however, the drugs in different categories may pose similar risks but may be listed in different categories on the basis of risk-to-benefit considerations. In addition, the categories create the impression that drugs within a category present similar risks whereas the category definition permits inclusion (in the same category) of drugs that vary in type, degree, and extent of risk.

Use of potentially teratogenic drugs in pregnancy is surprisingly commonplace. Over 63% of pregnant patients in Canada filled a prescription for at least one drug, with almost 8% filling a prescription for a Category D or X medication.[66]

When counseling patients or responding to queries from physicians, we prefer to avoid referring to the *Physicians' Desk Reference*. Rather, we use specific descriptions in teratogen databases to provide the best information available. Many resources are freely available online, in addition to the commercially available databases (Table 14-1).

The Teratology Society has suggested abandonment of the FDA classification scheme.[63] In 1997, the FDA held a public meeting to discuss labeling of drugs. There was consensus that the current classification scheme is probably oversimplified and confusing, does not address the range of clinical situations or the range of possible effects, and should be replaced with narrative labeling. Subsequently, a concept paper was presented that outlined a new model for labeling and included sections such as "clinical management statement," "summary risk assessment," and "discussion of data" for both pregnant and breast-feeding women.[67] This proposal has not yet been implemented. The FDA Office of Women's Health has created a pregnancy registry website, which lists a variety of registries that women who have used specific medications during pregnancy can consult (see Table 14-1). In 2008, the FDA stated they will eliminate the A, B, C, D, X classification system.[68] As of 2013, the new system has yet to be implemented despite completion of the 90-day comment period some time earlier.[69]

Analgesics

There is no known teratogenic risk associated with the use of **acetaminophen** (**paracetamol**),[70] which is the preferred mild analgesic or antipyretic during pregnancy.

Nonsteroidal anti-inflammatory drugs (NSAIDs) have not been associated with an increased risk for birth defects overall, but the occasional review has suggested an association with specific defects.[71] For example, **aspirin** is not associated with an overall increase in rates of congenital malformations, but one review suggested a higher risk for gastroschisis.[72] Aspirin is not usually the first choice of NSAID, but low-dose aspirin may still have a role in some situations, such as preventing fetal loss associated with antiphospholipid antibody syndrome.[73] Studies of the use of NSAIDs and aspirin in the first trimester have reported increased risk for pregnancy loss (adjusted odds ratio [OR], 1.8 to 8.1).[71] In the second trimester, their use has been associated with fetal cryptorchidism. In the third trimester, NSAIDs and aspirin are usually avoided because of significant fetal risks, such as renal injury, oligohydramnios, and intrauterine constriction of the ductus arteriosus, an effect that increases with advancing gestational age.[74] Renal injury, necrotizing enterocolitis, and intracranial hemorrhage are other potential complications.

Opioids such as **propoxyphene** and **codeine** have no known teratogenic risk,[75] but they have well-known potential for addiction. Excessive antepartum use can also lead to neonatal opioid-withdrawal symptoms.[76] Surprisingly, a recent case-control study found that maternal

opioid treatment (mostly codeine and **hydrocodone**) between 1 month before pregnancy and the first trimester was associated with an increased OR of 1.8 to 2.7 for various cardiac birth defects, spina bifida, and gastroschisis.[77]

Tramadol has analgesic effects from weak opioid activity and inhibition of serotonin and norepinephrine uptake. Despite availability in some countries for more than 30 years, few data are available regarding potential adverse effects in pregnancy. Tramadol exposure in early pregnancy was associated with a higher number of spontaneous abortions, and it should be avoided in the first trimester.[78] Chronic tramadol use in later pregnancy may result in neonatal withdrawal syndrome.

Sedatives

Human epidemiologic studies of the possible teratogenic effects of various tranquilizers are inconsistent. One report of nearly 400 patients found a 12% incidence of birth defects in the offspring of **meprobamate** users.[79] Another study of similar size did not identify any higher risk for malformations.[80] These latter two articles found similar results for **chlordiazepoxide**.[79,80] A recent study evaluating meprobamate used in high doses to attempt suicide did not show any teratogenic or fetotoxic effects.[81] A sample of 35 pregnant women who self-poisoned with chlordiazepoxide showed no association with congenital abnormalities but did show dose-related fetal growth restriction.[82]

Some studies have suggested that first-trimester exposure to **diazepam** increases the risk for cleft lip with or without cleft palate, neural tube defects, intestinal atresia, and limb defects.[83] Other reports have *not* suggested an increase in rate of congenital abnormalities after fetal exposure to benzodiazepines. In a case-control study of 611 infants with cleft lip or cleft palate and 2498 controls with other birth defects, after adjustment of the data for potential confounders, no association between diazepam and cleft palate was found (OR, 0.8 for cleft lip with or without cleft palate, with 95% confidence interval [CI] of 0.4 to 1.7, and OR, 0.8 for cleft palate alone, with 95% CI of 0.2 to 2.5).[84] Reanalysis of the Hungarian Case-Control Surveillance of Congenital Abnormality data also showed a weak relationship between exposure to diazepam in early pregnancy and neural tube defects, limb deficiency defects, and possibly intestinal atresia or stenosis.[83] One study found no difference in the incidence of congenital anomalies between 460 women exposed to benzodiazepines during pregnancy and 424 control women without such exposure (i.e., 3.1% versus 2.6%, respectively).[84] Perinatal use of diazepam has been associated with hypotonia, hypothermia, and respiratory depression.[85] Overall, it appears that the teratogenic risk of benzodiazepines is small at most,[86,87] but there may be a small risk for preterm birth and low birth weight.[88] Benzodiazepines should only be used in the first trimester if the perceived benefit offsets the possible teratogenic risks and later neonatal effects of continued use. Some benzodiazepines such as **temazepam** are classified as FDA Category X.

Anticonvulsants

Epilepsy is the most common serious neurologic problem during pregnancy.[89] It has been estimated that 3 to 5 births per thousand will be to women with epilepsy.[90] All anticonvulsants cross the placenta. The fetal congenital anomaly rate in pregnant women with epilepsy who ingest anticonvulsant drugs is 4% to 8%, compared with a background incidence in the general population of 2% to 3%.[91,92] A twofold higher risk for minor

malformations also exists in this population.[92] Cleft lip, with or without cleft palate, and congenital heart disease are especially common. Administration of valproic acid or carbamazepine entails a 1% risk for neural tube defects and other malformations; thus, alpha-fetoprotein screening and targeted ultrasonography are appropriate for patients taking these agents. In addition, the offspring of epileptic women have a 2% to 3% incidence of epilepsy, which is five times that of the general population.

Holmes et al.[93] attempted to refute the unproven theory that women with epilepsy have a genetic propensity to have children with a higher risk for birth defects that is separate from the greater risk associated with the use of anticonvulsants. These investigators studied children of women who had a history of seizures but took no medications during the pregnancy. There was no difference in physical features or cognitive function between these children and a group of matched controls. In a second study, Holmes et al.[94] screened 128,049 pregnant women at delivery to identify the following three groups of infants: (1) those exposed to anticonvulsant drugs, (2) those unexposed to anticonvulsant drugs but with a maternal history of seizures, and (3) those unexposed to anticonvulsant drugs with no maternal history of seizures (control group). The frequency of anticonvulsant embryopathy was higher in the 223 infants exposed to one anticonvulsant drug than in the 508 control infants (20.6% versus 8.5%, respectively; OR, 2.8; 95% CI, 1.1 to 9.7). The frequency was also higher in 93 infants exposed to two or more anticonvulsant drugs than in the controls (28.0% versus 8.5%; OR, 4.2; 95% CI, 1.1 to 5.1). The 98 infants whose mothers had a history of epilepsy but took no anticonvulsant drugs during pregnancy did not have a higher frequency of abnormalities than the control infants. The investigators concluded that "a distinctive pattern of physical abnormalities in infants of mothers with epilepsy is associated with the use of anticonvulsant drugs during pregnancy, rather than with epilepsy itself." A more recent meta-analysis also did not support the view that epilepsy *per se* represents a teratogenic risk.[95]

Possible causes of these congenital malformations include genetic differences in drug metabolism, the specific drugs themselves, and deficiency states (e.g., decreased folate levels) induced by the drugs. No congenital malformations appear to be unique to any one anticonvulsant. The characteristics of these syndromes are so similar that the broad term **fetal anticonvulsant syndrome**, consisting primarily of orofacial, cardiovascular, and digital malformations, has been applied to almost every anticonvulsant drug.[96]

Among women taking **phenytoin**, there is a 2% to 5% risk for major congenital anomalies, primarily midline heart defects, orofacial clefts, and urogenital defects.[91] **Fetal hydantoin syndrome** is a constellation of minor anomalies, such as craniofacial abnormalities (short nose, flat nasal bridge, wide lips, hypertelorism, ptosis, epicanthal folds, low-set ears, and low hairline) and limb anomalies (distal digital hypoplasia, absent nails, and altered palmar crease). In addition, neonatal growth and performance delays have been documented. The risk for fetal hydantoin syndrome for the child of a woman taking phenytoin is approximately 10%.[94] Phenytoin may act as a competitive inhibitor of the placental transport of vitamin K. This results in a decrease in fetal coagulation factors II, VII, IX, and X. In addition, phenytoin may induce fetal hepatic metabolism of the coagulation factors. The resulting reduction in fetal coagulation factors is associated with a higher risk for hemorrhagic disease of the newborn.[97] To help prevent this coagulopathy, some physicians advocate oral vitamin K supplementation (10 mg daily) for pregnant epileptic patients during the last month of pregnancy in addition to the parenteral administration of vitamin K to the neonate at birth.[98] Several anticonvulsant medications have metabolites that typically are eliminated by the enzyme epoxide hydrolase. In one study, 19 women taking phenytoin underwent amniocentesis. All 4 of the women with low enzyme activity in amniocytes had affected fetuses. The 15 fetuses with normal amniocyte epoxide hydrolase activity did not have the characteristics of fetal hydantoin syndrome.[62]

Carbamazepine is used to treat all types of seizure disorders, with the exception of petit mal epilepsy. It is most commonly used in the treatment of psychomotor (temporal lobe) epilepsy and grand mal epilepsy. In a prospective study involving 72 women with epilepsy who were taking carbamazepine, the incidence of congenital anomalies was higher in the 35 fetuses exposed only to this drug. There was an 11% incidence of craniofacial defects, a 26% incidence of fingernail hypoplasia, and a 20% incidence of developmental delay.[99] This constellation of fetal effects, named **fetal carbamazepine syndrome**, closely resembles the malformations seen in cases of fetal hydantoin syndrome. In addition, maternal carbamazepine exposure has been specifically associated with spina bifida. An analysis of all available data involving cohorts of pregnant women ingesting carbamazepine supports the conclusion that fetal exposure to this drug carries a 0.5% to 1% risk for spina bifida.[100] Although it is generally agreed that the use of carbamazepine in pregnancy is associated with a risk for neural tube defects and other anomalies, the exact magnitude of the risk from use of carbamazepine alone is unclear.[101-104]

Phenobarbital is used in the treatment of partial and generalized tonic-clonic seizures and status epilepticus.[105] Fetal exposure to phenobarbital has been associated with major malformations, such as congenital heart defects and orofacial clefting. **Fetal phenobarbital syndrome** is characterized by minor dysmorphic features similar to those seen with fetal hydantoin syndrome.[91] Fetal exposure to phenobarbital has also been associated with decreased intellectual and cognitive development in neonates and children. Maternal phenobarbital use during pregnancy can result in hemorrhagic disease of the newborn and neonatal withdrawal symptoms after delivery. The withdrawal symptoms consist mostly of irritability, begin at about 7 days of life, and usually last for 2 to 6 weeks.[105]

Valproic acid is used to treat absence and generalized tonic-clonic seizures. Infants exposed to valproic acid have a 1% to 2% risk for spina bifida. The neural tube defect tends to be lumbosacral. Fetal valproic acid exposure has also been associated with cardiac defects,

orofacial clefting, and genitourinary anomalies. **Fetal valproate syndrome** has been described; it is characterized by dysmorphic features, including epicanthal folds, shallow orbits, hypertelorism, low-set ears, flat nasal bridge, upturned nasal tip, microcephaly, thin vermillion borders, downturned mouth, thin overlapping fingers and toes, and hyperconvex fingernails.[91] Jentink et al.[106] found a markedly increased risk for spina bifida (OR, 12.7) craniosynostosis, cleft palate, atrial septal defect, and hypospadias. They concluded that valproic acid monotherapy should be avoided during pregnancy. A report of the Quality Standards Subcommittee and Therapeutics and Technology Subcommittee of the American Academy of Neurology and the American Epilepsy Society concluded that valproic acid and polytherapy should be avoided if possible during the first trimester to decrease the risk for major congenital malformations.[107] They also concluded that, if possible, avoidance of valproic acid and polytherapy throughout pregnancy should be considered, and avoidance of phenytoin and phenobarbital throughout pregnancy may be considered, to prevent poor cognitive outcomes.[107] Other reviews have also confirmed that valproic acid and carbamazepine are associated with neural tube defects and that valproic acid is associated with hypospadias, thus lending further support to limiting its use in women of reproductive age.

There are insufficient data to establish risks for birth defects with the newer anticonvulsants.[108,109] **Felbamate** was approved by the FDA for monotherapy, but later its use was severely restricted because of its association with aplastic anemia and hepatic failure. **Gabapentin** was initially released in the United States as an adjunctive treatment for partial seizures and secondarily generated tonic-clonic seizures. This agent inhibits dopamine release in the CNS. **Lamotrigine** appears to have efficacy comparable to that of carbamazepine in the monotherapy for partial epilepsy. An inhibitor of dihydrofolate reductase, lamotrigine decreases embryonic folate levels in experimental animals. This finding raises the concern that human use of lamotrigine may result in developmental toxicity. The manufacturer has established a registry to evaluate this possibility. A preliminary report from this registry has described a 6% rate of congenital malformations in fetuses exposed to this drug; this rate does not represent a clear increase in the baseline rate of malformations. However, there have not been sufficient numbers of fetal exposures to support any definitive conclusions.[110-112]

Many patients who present to prenatal clinics are already taking these newer anticonvulsants. Patients should be counseled that even though little information is available, no clear evidence of their teratogenicity exists. Some investigators have suggested avoiding the newer anticonvulsants until evidence of their safety is accumulated.[105] Even in the two decades since newer agents such as lamotrigine were introduced, definitive evaluation of their teratogenic potential has not been published.

Some women may be taking anticonvulsant drugs without having been reevaluated recently for their need to continue drug therapy. If a patient with idiopathic epilepsy has been seizure-free for 2 years and has normal EEG findings, the neurologist may try to withdraw the drug before pregnancy.[113]

If a patient first presents for care during pregnancy, most authorities agree that the benefits of anticonvulsant therapy during pregnancy outweigh the risks of discontinuing the drug. The blood level of the drug should be monitored to minimize the dose needed to ensure a therapeutic level of drug.

Antidepressants

A summation of 14 studies assessing the effect of fetal exposure to **tricyclic antidepressants** evaluated 414 cases of first-trimester exposure[114]; when the study data were pooled or viewed individually, no significant association between fetal exposure to tricyclic antidepressants and congenital malformations was found.[114] In a surveillance study of Michigan Medicaid recipients,[115] 467 neonates had been exposed to amitriptyline and 75 neonates had been exposed to imipramine during the first trimester; there was no association between tricyclic antidepressant use and congenital anomalies. However, a large review of data from the Swedish Medical Birth Register reported that use of tricyclic antidepressants was associated with a greater risk for congenital malformations compared with other antidepressants.[116] Results of the latter study are making their way into reviews that state a concern about tricyclic antidepressants.[117] Overall, tricyclic antidepressants have been replaced by **selective serotonin reuptake inhibitors** (SSRIs) as first-line therapy for depression (see Chapter 51).[118]

The SSRIs include **sertraline**, **paroxetine**, **fluoxetine**, and **citalopram**. No higher risk for major malformations or developmental (language and behavior) abnormalities was identified with their use in earlier studies.[119-121] In a multicenter evaluation of birth defects, use of SSRIs was not associated with a higher risk for cardiac defects.[122] However, in analyses of the individual medications, sertraline was associated with an increased risk for septal defects (OR, 2.0; 95% CI, 1.2 to 4.0), and paroxetine was associated with a higher risk for right ventricular outflow tract obstruction (OR, 3.3; 95% CI, 1.3 to 8.8). Sertraline was also associated with an increased risk for omphalocele, but this association was based on only three subjects. Another study found significantly higher risks for craniosynostosis, omphalocele, and anencephaly in association with exposure to SSRIs as a group; this study also found an association between paroxetine and right ventricular outflow tract lesions.[123] The association of septal heart defects with sertraline[124,125] and citalopram has been seen in other studies.[124]

A cohort study compared postnatal outcome for infants exposed to fluoxetine in late gestation (up to the time of delivery) with that for infants whose exposure was limited to the first trimester.[126] Infants exposed in the third trimester had a greater incidence of perinatal complications, including preterm delivery, admission to the special care nursery, poor neonatal adaptation, lower mean birth weight, and shorter body length.[126] A subsequent study suggested an association between the maternal use of SSRIs in late pregnancy and a higher risk for persistent pulmonary hypertension of the newborn (PPNH).[127] The association between SSRIs and PPHN has been confirmed in other studies, which showed an increase from

the background rate of 1.2/1000 neonates to about 3/1000, and appears to be a class effect.[128]

The American College of Obstetricians and Gynecologists (ACOG) has recommended that use of paroxetine in pregnant women (and in women planning pregnancy) be avoided, if possible.[129] In addition, it was suggested that fetal echocardiography should be considered in women who have used paroxetine during early pregnancy. Further, the ACOG has stated that treatment with all SSRIs should be individualized.[129] A report from the American Psychiatric Association and the ACOG concluded that although antidepressant use in pregnancy is well studied, available research has not yet adequately controlled for other factors such as maternal illness and behaviors that can adversely affect pregnancy.[130]

Lithium

In the International Registry of Lithium Babies, 25 of 217 (11.5%) infants exposed to lithium during the first trimester of pregnancy were malformed.[131] Eighteen infants had cardiovascular anomalies, and six had the rare Ebstein anomaly, which occurs only once in 20,000 nonexposed pregnancies. Subsequent studies have suggested that ascertainment bias may have flawed the findings; the reported risk for anomalies after lithium exposure is much less than that reported by the registry.

In a cohort study linking the Swedish Birth Registry with the records of women with bipolar disorder, 59 infants were identified whose mothers had been treated with lithium early in pregnancy.[132] Four (6.8%) of the 59 infants exposed to lithium had congenital heart disease, compared with 2 (0.9%) of 228 infants not exposed to lithium (relative risk [RR], 7.7; 95% CI, 1.5 to 41.2). None of the infants had Ebstein anomaly. In a prospective cohort study of 148 women treated with lithium during the first trimester and 148 controls not exposed to any known teratogen, there was no significant difference between groups in the incidence of major congenital anomalies or cardiac malformations,[132] although one lithium-exposed infant did have Ebstein anomaly. The investigators concluded that lithium is not a major human teratogen, but they recommended that women exposed to lithium be offered ultrasonography and fetal echocardiography.[133] If the data are pooled, these two cohort studies do not suggest a statistically significant increase in risk for congenital malformations or cardiac malformations in women exposed to lithium during pregnancy. Although the risk for congenital malformations associated with intrauterine lithium exposure is likely to be lower than previously reported, an absence of risk cannot be assumed from the available data. Recent reviews of available data have come to the same conclusion that the risk for anomalies is small, but it is prudent to perform fetal echocardiography after first-trimester exposure.[134]

Two published cases associated polyhydramnios with maternal lithium treatment.[135,136] Nephrogenic diabetes insipidus has been reported in adults taking lithium; thus, the presumed mechanism of polyhydramnios is fetal diabetes insipidus. Polyhydramnios may signal fetal lithium toxicity.

Pregnancy accelerates the excretion of lithium, so serum lithium levels should be monitored in pregnant women.[137] Perinatal effects of lithium include hypotonia, lethargy, and poor feeding in the infant. In addition, complications (e.g., goiter, hypothyroidism) similar to those seen in adults taking lithium have been noted in neonates.

Some authorities recommend discontinuation of lithium and substitution with another medication during pregnancy. However, the discontinuation of lithium is associated with a 70% chance of relapse of the affective disorder in 1 year, as opposed to a 20% risk for relapse with continuation of lithium therapy.[131]

Cardiovascular Drugs

There are no reports of teratogenicity related to the use of inotropic agents such as **dopamine**, **dobutamine**, or **digoxin**. Physicians should monitor the maternal digoxin level to ensure a therapeutic level of drug during pregnancy.

Methyldopa and **labetalol** are often used to treat mild chronic hypertension during pregnancy. There is no evidence of teratogenicity or other adverse fetal effects with either of these drugs. In one randomized double-blind trial of 152 women with hypertension, there were no malformations in either the labetalol group or the placebo group, although the exposure to labetalol occurred in the second and third trimesters.[138]

In a large analysis of published trials involving beta-adrenergic receptor antagonist therapy, there was little or no information on teratogenicity for the multiple agents studied, including **atenolol**, **labetalol**, **metoprolol**, **oxprenolol**, **pindolol**, and **propranolol**.[139] Maternal administration of propranolol may result in modest fetal growth restriction.[140] It seems prudent to use ultrasonography to assess intrauterine fetal growth in women receiving propranolol. Maternal administration of propranolol within 2 hours of delivery may result in neonatal bradycardia.[75] Atenolol was associated with lower birth weight and a trend toward more frequent preterm delivery than with other antihypertensive drugs and with no therapy. These effects were more pronounced when the drug was administered earlier in pregnancy and for a long duration.[141] In one study, treatment of hypertension (mostly with atenolol) reduced the risk for severe hypertension and preterm labor.[141] In a randomized clinical trial, the same group observed that atenolol prevented preeclampsia but resulted in the birth of infants who weighed 440 g less than infants in the placebo group.[142]

The **angiotensin-converting enzyme (ACE) inhibitors** initially did not appear to be teratogenic when administered during the first trimester.[143] However, a 2007 study suggested an increase in the incidence of congenital anomalies, particularly cardiac and CNS defects, after first-trimester exposure to ACE inhibitors.[144] Some authorities contend that this study had major limitations.[145] A very large epidemiologic database study of 465,754 mother-infant pairs showed no difference in abnormality rate between women who used ACE inhibitors during the first trimester, those who used other antihypertensive agents, and those who had hypertension but

used no medications.[146] The authors postulated that any increased risk for birth defects may be due to the hypertension. A different set of investigators made the same conclusion.[147] Later in pregnancy, ACE inhibitors can cause fetal renal failure and oligohydramnios, which may result in fetal limb contractures, craniofacial deformities, and pulmonary hypoplasia[148]; therefore, use of ACE inhibitors should be avoided if possible during this period.

Amiodarone is structurally similar to thyroxine and contains 37% iodine by weight. In a review of 64 reported pregnancies in which amiodarone was administered to the mothers, there was no clear increase in the incidence of malformations. However, 11 (17%) infants had evidence of hypothyroidism, and two (3%) neonates had goiter.[149,150] The use of amiodarone in pregnancy was associated with mild abnormalities of neurodevelopment in some of the hypothyroid infants, although this was also observed in some euthyroid infants.[150] This agent is most often used during pregnancy to treat fetal arrhythmias, and first-trimester exposure is rare.

Respiratory Drugs

Maternal asthma is relatively common in pregnancy, affecting 4% to 8% of pregnant women. It is important to maintain appropriate treatment because asthma can increase the risk for adverse fetal and maternal outcomes.[151]

Inhaled **β_2-adrenergic receptor agonists**, **cromolyn sodium**, and **corticosteroids** have not been associated with congenital malformations. Currently, **albuterol** is the preferred short-acting β_2-receptor agonist, and **salmeterol** is the preferred long-acting β_2-receptor agonist. **Budesonide** is the recommended inhaled corticosteroid because it has a long history of safe usage, but there is no evidence against the other options, which include **beclomethasone**, **ciclesonide**, **fluticasone**, **flunisolide**, **mometasone**, and **triamcinolone**.

Severe persistent asthma may require systemic oral corticosteroid therapy, and this has been associated with low birth weight and a three- to five-fold increase in the relative risk for cleft lip and palate.[152,153] However, other studies have found no adverse effects and, given the risks from severe asthma, oral corticosteroids should be used if required.

The **5-lipoxygenase inhibitors** and **leukotriene receptor antagonists** are newer agents with no evidence of teratogenicity.[154] Women using **montelukast** enrolled in several teratogen information services around the world showed no increased risk for birth defects in 160 live births.[155]

Methylxanthines such as **theophylline** and **aminophylline** have no adverse fetal effects, but the protein binding and metabolism of theophylline are both reduced during pregnancy, making it necessary to monitor drug concentrations and adjust maintenance doses.

Anticoagulants

Warfarin use in early pregnancy can result in an embryopathy similar to the X-linked chondrodysplasia punctata. The embryopathy can occur with fetal exposure between 6 and 12 weeks' gestation. Because deficiency of arylsulfatase E is responsible for the chondrodysplasia, the embryopathy may result from inhibition of arylsulfatase E by warfarin. The period between 6 and 9 weeks' gestation is especially critical. Fetal warfarin syndrome consists of nasal hypoplasia, depressed nasal bridge (often with a deep groove between the alae and nasal tip), stippled epiphyses, nail hypoplasia, mental retardation, and growth restriction. Second- and third-trimester exposures can result in other adverse fetal effects, including microcephaly, blindness, deafness, and growth restriction. Three prospective studies of women exposed only in the second and third trimesters found that the incidence of malformations must be exceedingly low because there was no evidence of fetal or neonatal CNS or eye abnormalities.[156] Some evidence suggests that a lower dose (< 5 mg/day) has less teratogenic potential.[157]

Heparin is a large, water-soluble molecule that does not cross the placenta. Maternal administration does not have an adverse effect on the fetus, and heparin is the drug of choice for most pregnant women who require anticoagulation daily. Daily administration of 20,000 units of **standard unfractionated heparin** for more than 20 weeks may be associated with maternal bone demineralization.[158] Unfractionated heparin should be used for prolonged periods only when it is clearly necessary.

Low-molecular-weight heparin (LMWH) has some advantages over standard unfractionated heparin.[159] LMWH does not cross the placenta and has a longer half-life than standard unfractionated heparin, which typically allows once-daily dosing in nonpregnant patients. In addition, LMWH has a more predictable dose-response relationship in nonpregnant patients, which obviates monitoring. However, pregnancy is associated with a higher volume of distribution and accelerated clearance of LMWH. Use of LMWH thromboprophylaxis during pregnancy requires adjustments in the dose of LMWH to accommodate for the changes in the pharmacokinetics of this drug that occur during pregnancy. For example, pregnant women may require twice-daily doses.[160]

Full anticoagulation is necessary in pregnant women with cardiac valve prostheses. In a systematic review of anticoagulation in pregnant women with mechanical heart valves, Chan et al.[161] evaluated outcomes with the following three anticoagulation regimens: (1) oral anticoagulants (most commonly warfarin) given throughout pregnancy, (2) heparin administered during the first trimester and then warfarin for the duration of pregnancy, and (3) heparin administered throughout pregnancy. The data demonstrated progressively higher rates of maternal death with regimens 1, 2, and 3 (1.8%, 4.2%, and 15.0%, respectively). The use of warfarin throughout pregnancy was associated with warfarin embryopathy in 6.4% of live-born infants. The substitution of heparin at or before 6 weeks' gestation eliminated that risk.[161]

For women with prosthetic heart valves, the American College of Chest Physicians (ACCP) has recommended use of one of the following three regimens: (1) adjusted-dose LMWH twice-daily throughout pregnancy, with doses adjusted to achieve the manufacturer's peak anti–factor Xa LMWH levels 4 hours after subcutaneous

injection; (2) adjusted-dose unfractionated heparin administered subcutaneously every 12 hours throughout pregnancy, with doses adjusted to keep the mid-interval activated partial thromboplastin time at least twice control or to attain an anti–factor Xa heparin level of 0.35 to 0.70 units/mL; or (3) unfractionated heparin or LMWH as just described until the 13th week of pregnancy, with substitution by vitamin K antagonists until close to delivery, when unfractionated heparin or LMWH is resumed.[160] In women at very high risk for thromboembolism in whom there is concern about the efficacy and safety of unfractionated heparin or LMWH, it is suggested to administer vitamin K antagonists throughout pregnancy with replacement by unfractionated heparin or LMWH close to delivery.[160] In high-risk women with prosthetic heart valves, it is suggested to add low-dose aspirin 75 to 100 mg/day.[160]

Antiemetics

Most women in early pregnancy have nausea, with or without vomiting (see Chapter 2 and Chapter 16).[162] Complementary therapies such as acupressure and ginger may be effective, but approximately 10% of women will require drug therapy. Although many different drugs can be effective, **vitamin B_6** should be the drug of choice.[163] A combination of vitamin B_6 with the antihistamine **doxylamine** was previously available as Bendectin, but this was withdrawn by the manufacturer in 1983 because of allegations of teratogenicity that were later found to be false. Other formulations are now available, and there is no evidence of teratogenicity with them or other antihistamines. **Trimethobenzamide** is structurally related to antihistamines such as **diphenhydramine**, but it has only weak antihistamine activity. The mechanism of action is unclear, but it probably acts at the chemoreceptor trigger zone. It has few side effects but also variable efficacy. Nausea and vomiting can also be treated with phenothiazines, but they may cause sedation.

The prokinetic agent and dopamine antagonist **metoclopramide** is not sedating, but it has a "black box" warning because chronic usage has been associated with rare cases of tardive dyskinesia. There are no specific safety concerns during pregnancy. A multicenter study did not observe an increased incidence of anomalies,[164] and a large trial of 3458 women exposed to metoclopramide in the first trimester found no association with increased risk for birth defects, low birth weight, preterm delivery, or perinatal death.[165]

The 5-hydroxytryptamine receptor antagonists are widely used and very effective antiemetics with few side effects, so they are also increasingly being used in pregnancy. Ondansetron was similar in efficacy to promethazine for the treatment of hyperemesis gravidarum but less sedating.[166] There is no evidence that it has a teratogenic effect.[167]

Corticosteroids such as **dexamethasone** are now commonly used for postoperative and chemotherapy-induced nausea and vomiting. **Methylprednisolone** has been used for refractory nausea and vomiting during pregnancy. However, a meta-analysis concluded that the use of glucocorticoids before 10 weeks' gestation was associated with a threefold to fivefold increased risk for cleft lip with or without cleft palate[152]; and thus, they should not be used during this period.

Antihistamines

Some pregnant patients may be treated with antihistamines for allergies or upper respiratory tract infections. These drugs provide symptomatic therapy with no influence on the course of the disease. If considered necessary, combinations of drugs should be avoided if possible. Topical nasal sprays result in less fetal exposure than systemic medication. One study suggested an association between pseudoephedrine and defects attributable to vascular disruption, including gastroschisis, small intestinal atresia, and hemifacial microsomia.[168] Physicians should discourage the use of nonprescription drugs for trivial indications because the long-term fetal effects of the chronic maternal use of these drugs are unknown.

Sedating or first-generation antihistamines are available in over-the-counter medications and have not been reported to increase fetal risk.[169] Examples include **chlorpheniramine**, **diphenhydramine**, **methapyrilene**, **thonzylamine**, **pyrilamine**, **tripelennamine**, **phenyltoloxamine**, and **buclizine**. Despite conflicting reports, a meta-analysis found no evidence to implicate **brompheniramine** as a teratogen.[170] In the Boston Collaborative Program,[171] none of the sedating antihistamines was associated with malformations. Two combination products—**triprolidine with pseudoephedrine** (Actifed) and **phenylpropanolamine with chlorpheniramine** (Ornade)—were not associated with malformations. In a cohort of 1502 women, antihistamines were not associated with congenital malformations.[172] **Azatadine** was not found to be teratogenic among 127 Michigan Medicaid recipients.[115]

Limited safety information is available for the nonsedating antihistamines. In a cohort study, 114 women exposed to **astemizole** were matched with 114 women exposed to known nonteratogens.[173] There were two major malformations in the astemizole group and two in the control group. In a study of 39 women exposed to **cetirizine**, the rate of malformations was no higher than in a control group.[174] This finding was replicated in a study performed through a teratogen information service.[175] There are no controlled human studies for **loratadine** or **fexofenadine**. Desloratadine is the major metabolite of loratadine; most data do not point to a risk for congenital abnormalities.[169]

Several antihistamines have primary indications not directly related to upper respiratory complaints. **Hydroxyzine** is used for treatment of pruritus, **meclizine** for dizziness, **diphenhydramine** for sleep and pruritus, and **doxylamine** (a component of the former Bendectin) for treatment of nausea and vomiting of pregnancy. A meta-analysis of antihistamines used mostly for morning sickness in early pregnancy found a protective effect against malformations (OR, 0.76; 95% CI, 0.60 to 0.94).[176] This apparent benefit may have resulted from an association between maternal nausea and good fetal outcomes rather than from a direct effect of antihistamines.

Anti-infective Drugs

Sepsis is a leading cause of maternal mortality. When administering perioperative antibiotics, anesthesia providers should be aware of the considerations regarding their use during pregnancy.[177] Although **penicillins** and **cephalosporins** are considered first-line treatment because of their long safety record, therapy is ultimately guided by local microbiology policies and bacterial sensitivity.

Tetracyclines should not be administered after the fifth week of pregnancy. They bind to developing enamel and cause discoloration of the teeth. They affect deciduous teeth when administered between approximately 26 weeks' gestation and 6 months of age in the infant, and they affect permanent teeth only if administered to children between approximately 6 months and 5 years of age. In addition, tetracyclines deposit in developing osseous sites and inhibit bone growth beginning in the second trimester.[177]

Quinolones (e.g., **ciprofloxacin**, **norfloxacin**) should not be used in pregnancy or in children. They have a high affinity for bone tissue and cartilage and may cause arthropathies in children. However, no malformations or musculoskeletal problems were noted in 38 infants exposed during the first trimester.[177]

Malaria is a significant cause of maternal and fetal death. Pregnant women should avoid traveling to malaria-endemic areas, but **chloroquine** or **mefloquine** can be used for malaria chemoprophylaxis. They are not associated with an increase in spontaneous abortions or congenital malformations. **Doxycycline**, **primaquine**, and **atovaquone-proguanil** are not to be used in pregnancy.

Treatment of herpes simplex and herpes zoster infections in the first trimester with **acyclovir** or **valacyclovir** has not been associated with an increased risk for birth defects.[178]

Zidovudine has been studied because of its role in the treatment of acquired immunodeficiency syndrome (AIDS). In a prospective cohort study, children exposed to it during the perinatal period in the Pediatric AIDS Clinical Trials Group Protocol 076 (PACTG 076) were studied to a median age of 4.2 years; no adverse effects were observed.[179] Combination antiretroviral therapy has not been associated with major infant toxicity, even when the therapy was initiated in the first trimester of pregnancy.[180]

The Antiretroviral Pregnancy Registry was established in 1989 to detect any major teratogenic effect of the **antiretroviral drugs**. Each year it enrolls approximately 15% of all HIV-positive women who give birth to live infants in the United States plus a small number from other countries. It depends on voluntary reporting of prenatal exposure; therefore, drug-associated adverse events may not necessarily reflect true rates. Results of retrospective and clinical studies are also reviewed. Through January 2013, no apparent increase in the frequency of birth defects after first-trimester exposure to antiretroviral drugs compared with population-based comparators was reported.[181] A modest but statistically significant elevation of defect rates with **didanosine** and **nelfinavir** was reported, the clinical relevance of which is unclear.

It is generally appropriate to administer **vaccinations** during pregnancy because the risks of the disease may outweigh the risk of the vaccine. No evidence exists of risk to the fetus from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. However, live vaccines pose a theoretical risk to the fetus, so vaccination with live attenuated virus (e.g., **varicella**, **measles-mumps-rubella** [MMR]) or tuberculosis (e.g., **bacillus Calmette Guérin** [BCG]) is considered contraindicated.[182] Influenza vaccination is recommended with the inactivated virus preparation.[183] Prevention and treatment of influenza with either **zanamivir** or **oseltamivir** is possible during pregnancy[184]; no adverse fetal effects have been reported.[185]

Caffeine

No evidence suggests that caffeine has teratogenic effects in humans. Early uncontrolled studies suggested that heavy ingestion of caffeine was associated with an increased incidence of spontaneous abortion, low birth weight, preterm delivery, and stillbirth. However, these studies did not control for the use of tobacco and alcohol. A contemporary meta-analysis showed no association with caffeine consumption and preterm birth.[186] In 2010, the ACOG published a committee opinion based on studies of caffeine use in pregnancy.[187] They concluded that (1) daily intake of less than 200 mg of caffeine was not associated with an increased risk for miscarriage, but contradictory data did not allow for a recommendation regarding daily intake above this level; (2) moderate caffeine intake does not appear to contribute to preterm birth; and (3) the association between caffeine intake and fetal growth restriction was equivocal. A subsequent review concluded with more certainty that moderate or even high amounts of caffeine-containing foods and beverages did not increase the risk for congenital malformations, miscarriage, or growth restriction.[188]

Smoking Cessation Therapies

Smoking during pregnancy is clearly linked to multiple adverse fetal, neonatal, and childhood effects. Drug interventions to stop smoking include nicotine replacement therapy, antidepressants, **bupropion** (dopamine and norepinephrine reuptake inhibitor and nicotine antagonist), **bromocriptine** (dopamine agonist), **varenicline** (nicotine partial agonist), and **cytisine** (plant alkaloid). Bupropion and bromocriptine therapy were not associated with congenital malformations or other adverse outcomes.[189] Animal data show no increase in malformations with varenicline, but there are no human data.

Specific Highly Teratogenic Drugs

Some drugs are so highly teratogenic that two simultaneous forms of reliable contraception are recommended or required during treatment of either partner, sometimes to be continued for months or years after stopping the

drug. Some examples are (1) **thalidomide**, which is still used for erythema nodosum leprosum and multiple myeloma; (2) the antiviral **ribavirin**, which is used for hepatitis C and viral hemorrhagic fevers; (3) **isotretinoin**, which is used for cystic acne; and (4) **acitretin**, which is used for severe psoriasis.

DRUG USE DURING LACTATION

General Principles

Nursing mothers are understandably concerned about the transfer of drugs and chemicals to breast milk. Correct advice is important to prevent them from unnecessarily stopping breast-feeding or discontinuing appropriate drug treatment. Unfortunately, it can be difficult to decide which of the many, sometimes conflicting, sources of public information to trust. Pharmaceutical information leaflets from the manufacturers often discourage the use of drugs during breast-feeding simply as a general precaution. The most comprehensive up-to-date information is found in the Drugs and Lactation database (LactMed) of the National Library of Medicine's Toxicology Data Network (TOXNET).[190] The American Academy of Pediatrics (AAP) has published policy statements on the benefits of breast-feeding[191] and the use of drugs during lactation.[192] The Centers for Disease Control and Prevention (CDC) provides online information regarding breast-feeding and various toxins and infectious diseases.[193]

Only a few types of drugs such as cytotoxic and immunosuppressive drugs (e.g., **cyclophosphamide**, **methotrexate**) and radioactive compounds are strongly contraindicated during breast-feeding.[59] Mothers breast-feeding infants with glucose-6-phosphate-dehydrogenase (G6PD) deficiency should avoid drugs such as **sulfonamides**, including the combination of **sulfamethoxazole and trimethoprim**, **nitrofurantoin**, and **primaquine**.

Maternal drugs may also affect lactation, and some are used therapeutically for this purpose. Drugs that increase the secretion of prolactin can stimulate milk production; these include dopamine antagonists such as **phenothiazines**, **haloperidol**, **metoclopramide**, and **domperidone**, as well as **sulpiride**, **risperidone**, and **methyldopa**. Drugs that decrease the production of milk include diuretics, estrogen, and dopamine agonists such as **bromocriptine**, **cabergoline**, **lisuride**, and **quinagolide**. Bromocriptine is no longer approved for postpartum lactation suppression because of its association with puerperal seizures, stroke, and myocardial infarction. Women who smoke also have lower milk production.

Drug transfer to breast milk occurs by passive diffusion, but transporter systems are also present.[194] The rate of passive transfer into breast milk depends on the lipid solubility, molecular weight, degree of ionization, and protein binding of the drug. Nonionized molecules of small molecular weight (e.g., **ethanol**) are readily transferred into breast milk. Drugs that have more than 85% maternal protein binding are often not detectable in the infant.[195]

The amount of a drug in breast milk is a variable fraction of the maternal blood concentration, which is proportional to the maternal dose. Quoted maternal milk-to-plasma ratios can vary because drug transfer is a time-dependent process. Even when calculated under steady-state conditions, there can be large individual variation. Absolute infant dose (μg/kg/day) can be calculated as the product of the average concentration in milk and the estimated daily volume of milk intake, and relative infant dose can be estimated by dividing absolute infant dose by the maternal dose.[196] It has been suggested that a relative infant dose less than 10% is generally safe,[196] but this will also depend on the oral bioavailability of the drug in the infant and the relative toxicity of individual agents. However, physicians and patients should be aware of the following disclaimers. First, in the case of toxic drugs, any exposure may be inappropriate. Second, the infant may be allergic to a drug consumed by the mother. Third, there may be unknown, long-term effects of even small doses of drugs. Fourth, individual variability in drug disposition may lead to unexpectedly high maternal blood and breast milk concentrations. Finally, infants have immature enzyme systems and metabolic pathways and some drugs are eliminated more slowly. The benefits of breast-feeding are well known, and the risk of drug exposure must be weighed against these benefits.

Lactation is not fully established during the first several days postpartum. The neonate receives only a small volume of colostrum, and little drug is excreted through milk at this time. Thus, only very small amounts of drugs administered after vaginal or cesarean delivery would reach the neonate and significant effects should be unlikely. However, neonatal metabolism and elimination are also poorly developed, and several days of maternal opioid analgesia with drugs such as **meperidine (pethidine)** and **codeine** may result in neonatal accumulation and side effects.

When a mother requires a daily dose of a drug during lactation, the minimum effective dose should be used. Some mothers requiring long-term therapy would already have been taking drugs during pregnancy, and the fetus would have been exposed to concentrations much greater than those achieved in the infant through breast-feeding. Thus, if a drug has been acceptable during pregnancy, it is often reasonable to continue it during breast-feeding unless there are drug-specific factors to the contrary.[197] For example, poor neonatal elimination of **lamotrigine** may eventually lead to drug accumulation in the infant and adverse effects. In general, medications should be taken after breast-feeding, and long-acting preparations should be avoided. If the infant nurses less frequently overnight, ingestion of a drug dose at night after nursing will decrease the infant's exposure.

Anesthetic Drugs

There are generally no concerns regarding anesthetic drugs and perioperative medicines in the breast milk of women who require an anesthetic.[198,199] However, the prolonged use of postoperative medications such as analgesics will obviously increase the infant dose, the potential effects of which are discussed next.

Analgesics

No harmful effects of **acetaminophen** or **NSAIDs** have been noted except for **aspirin**.[71] Some NSAIDs specifically recommended as compatible with breast-feeding are ibuprofen, flurbiprofen, naproxen, and celecoxib. Other NSAIDs may be discouraged simply because of limited information, although there are some concerns about diflunisal and carisoprodol based on animal data.[192] Surprisingly, the FDA has singled out **ketorolac** with a "black box" warning that it is "contraindicated in nursing mothers because of the potential adverse effects of prostaglandin-inhibiting drugs on neonates"; the basis for this decision is unclear. Theoretically, NSAIDs with antiplatelet effects should be avoided by mothers who are breast-feeding neonates with platelet dysfunction. With aspirin, there is limited transfer of salicylic acid into breast milk because it exists mostly in the ionized form. After single oral doses, peak milk levels occur at approximately 3 hours with milk-to-plasma concentration ratios between 0.03 and 0.05.[200] However, maternal ingestion of *high doses* (e.g., more than 16 tablets per day) may result in maternal and breast milk concentrations sufficiently high to affect platelet aggregation in the infant. Reduced neonatal clearance of salicylic acid may lead to drug accumulation and toxic effects, even when repeated exposures are small.[201] Because of these concerns, the World Health Organization (WHO) Working Group on Human Lactation has classified salicylates as unsafe for use by nursing women.[202] Low doses of aspirin prescribed as anti-platelet therapy may be acceptable.[192]

It was thought previously that opioids used by nursing mothers were highly unlikely to have adverse effects on breast-fed infants. Normal maternal doses of **codeine**, **morphine**, **tramadol**, and **meperidine** do not have obvious adverse effects on most nursing infants.[78,192] The dose detectable in breast milk is 1% to 2% of the mother's dose and is unlikely to have significant pharmacologic activity. However, in one patient who took **propoxyphene** in a suicide attempt, the breast milk concentration of propoxyphene was half that of the maternal serum level.[203] Theoretically, a breast-feeding infant could receive up to 1 mg of propoxyphene per day if the mother were to consume the maximum dose.

Neonates are particularly vulnerable because their drug metabolism and elimination are poorly developed. Neonates of mothers receiving meperidine by intravenous patient-controlled analgesia after cesarean delivery had significant neurobehavioral depression by the third day.[204] The cumulative maternal meperidine dose at 48 hours postpartum was 14 mg/kg. No neonatal depression was seen in a morphine group in whom the cumulative maternal dose at 48 hours was 2.1 mg/kg. Both opioids and their major metabolites accumulated in colostrum. In a subsequent study,[205] the cumulative opioid doses at 48 hours were lower (meperidine 4.7 mg/kg and morphine 0.54 mg/kg), but infants in the morphine group were still more alert and oriented. With lower maternal morphine doses, concentrations in colostrum may even be undetectable.[206]

Recently, it has been recognized that infants of breast-feeding mothers taking **codeine** may have CNS depression. In 2006, the full-term 13-day-old infant of a mother taking a modest dose of codeine for episiotomy pain died of an apparent morphine overdose. It was discovered that the mother was heterozygous for a CYP2D6*2A allele with CYP2D6*2×2 gene duplication, making her an ultrarapid metabolizer of codeine. This condition resulted in a breast milk morphine concentration of 87 ng/mL, compared with the expected typical range of 1.9 to 20.5 ng/mL.[207] This case prompted the FDA to release a Public Health Advisory advising caution in the use of codeine-containing medications by breast-feeding women.[208] The FDA recommended that the lowest effective dose for the shortest necessary duration should be used and that women should be taught how to recognize signs of high morphine levels in their infants. The number of ultrarapid metabolizers is estimated to vary between 1 and 28 per 100 people.[208] In addition, genetic variability in UGT2B7 may increase the formation of active morphine-6-glucuronide. It is estimated that 1.4% of Western European women would have both the CYP2D6 and UGT2B7 variants promoting neonatal depression.[209]

Ultra-rapid metabolism has been reported as a problem for breast-feeding only with codeine, although the FDA suggested that "it has the potential to affect other opioids."[208] Maternal oxycodone for postpartum analgesia has been associated with neonatal depression.[210] However, polymorphisms have less effect on the metabolism and analgesic effects of oxycodone, hydrocodone, and tramadol than codeine.[211]

Sedatives

Long-acting drugs such as **diazepam** are metabolized slowly in the infant, and accumulation can lead to sedation and poor feeding. Perinatal use of diazepam has been associated with hypotonia, hypothermia, and respiratory depression.[85] If a sedative must be used in a lactating woman, a relatively short-acting agent with inactive metabolites, such as **oxazepam**, **lorazepam**, **alprazolam**, or **midazolam**, is recommended.[212] The infant should be monitored for sedation during maternal drug use and for withdrawal symptoms after the medication is stopped or after discontinuation of breast-feeding.[213]

Anticonvulsants

Carbamazepine and **valproic acid** have low excretion into breast milk and are considered the safest choices.[214] Studies have detected only small amounts of **phenytoin**, **phenobarbital**, and **diazepam** in breast milk.[215,216] However, infants eliminate phenobarbital and diazepam slowly, so these agents may accumulate. Women taking a barbiturate or a benzodiazepine should observe their infants for evidence of sedation and withdrawal.[92,192] There are conflicting recommendations for the newer anticonvulsants. **Lamotrigine** concentrations in breast-fed infants can be very high, and some recommend that the drug should be avoided.[214] However, other authors note that the mother has usually been taking this drug throughout pregnancy already and that there is no evidence to recommend stopping the drug.[217]

Cruikshank et al.[218] measured breast milk magnesium concentrations in 10 preeclamptic women who were

receiving magnesium sulfate 1 g/h intravenously for 24 hours after delivery. The mean breast milk magnesium concentration was 6.4 ± 0.4 mg/dL, compared with 4.8 ± 0.5 mg/dL in controls. Breast milk calcium concentrations were not affected by magnesium sulfate therapy.

Antidepressants and Lithium

Psychotropic agents may be of concern because many of these medications have long half-lives and the effect of even small doses on the developing nervous system is not known. Nevertheless, the many medications available to treat depression or postpartum depression appear to have little if any immediate effect on the infant.[219] Many antidepressants have low milk-to-plasma ratios. There are few reports of neonatal problems with the use of SSRIs and related drugs.[220] **Fluoxetine** and its metabolite have relatively long elimination half-lives, so other drugs such as **sertraline** and **paroxetine** are preferred.[221]

Breast milk concentrations of **lithium** are one third to one half of maternal serum concentrations,[222,223] and infant serum concentrations during breast-feeding are much lower than fetal serum concentrations that occur when mothers take lithium during pregnancy. Neonatal clearance of lithium is reduced, and it may be useful to monitor neonatal lithium concentrations.

Cardiovascular Drugs

Amiodarone concentrations in the infant are unpredictable but may be sufficiently high to cause cardiac effects. Iodine released during its metabolism may cause thyroid dysfunction. Amiodarone has a very long half-life and is still excreted in breast milk weeks after stopping the drug.

Beta-adrenergic receptor antagonists with low protein binding have relatively higher transfer to breast milk, and those excreted renally are more likely to accumulate in neonates. Thus, **atenolol** with 10% protein binding and 85% renal excretion would not be the best choice. Breast milk concentrations of atenolol are approximately three times maternal plasma concentrations.[224] Even though the total infant dose is only 1% of the maternal therapeutic dose, and the infant plasma concentration would not normally cause side effects in the infant, atenolol has been associated with neonatal cyanosis and bradycardia.

Other common drugs such as ACE inhibitors and antihypertensives are considered safe. However, diuretics may reduce milk production. Maternal protein binding of **digoxin** limits infant drug exposure; after a maternal dose of 0.25 mg, a peak breast milk concentration of 0.6 to 1.0 ng/mL occurs and the milk-to-plasma concentration ratio at the 4-hour peak is between 0.8 and 0.9 ng/mL. In 24 hours an infant might receive approximately 1% of the maternal digoxin dose,[225] and no adverse effects have been reported in nursing infants of mothers taking this drug. Breast milk **clonidine** concentrations are almost twice maternal serum concentrations. However, this exposure does not seem to have any adverse effects on the infant.[226]

There are no safety data for **statins**, but they are not recommended during breast-feeding because of concerns that they may disrupt infant lipid metabolism.

Respiratory Drugs and Corticosteroids

Salbutamol, **terbutaline**, and **salmeterol** inhalers are considered compatible with breast-feeding. Maximum milk concentrations of **theophylline** are achieved between 1 and 3 hours after an oral dose. It has been calculated that the nursing infant receives less than 1% of the maternal dose. Such exposure appears to have no adverse effects.

Inhaled and oral corticosteroids are also considered safe. Katz and Duncan[227] obtained breast milk 2 hours after an oral dose of 10 mg of **prednisone** in one nursing mother. They detected breast milk concentrations of prednisone and prednisolone that would be unlikely to result in any deleterious effect on the infant. McKenzie et al.[228] administered 5 mg of radioactive prednisolone to seven patients and found that 0.14% (a negligible quantity) of the radioactive label was secreted in the milk in the subsequent 60 hours. Thus, breast-feeding is not contraindicated in mothers taking corticosteroids. Even at a maternal dosage of 80 mg/day, the nursing infant would ingest a dose equivalent to less than 10% of its endogenous cortisol production.[229]

Anticoagulants

Most mothers who require anticoagulation may continue to nurse their infants with no problems. **Warfarin** is 98% protein bound. Orme et al.[230] reported no warfarin in breast milk or infant plasma in seven women taking warfarin 5 to 12 mg/day. Similarly, de Swiet and Lewis[231] found that warfarin appears in breast milk in insignificant quantities. **Heparin** does not cross significantly into breast milk and is not active when administered orally.

Antihistamines

No harmful effects have been noted with maternal use of antihistamines.[232] These drugs do not appear to affect the milk supply. Little antihistamine is excreted into breast milk, further confirming safety of use during lactation.[169]

In theory, histamine type 2 (H_2)-receptor antagonists might suppress gastric acidity or cause CNS stimulation in the infant, but these effects have not been confirmed in published studies. **Famotidine**, **nizatidine**, and **roxatidine** are less concentrated in breast milk and may be preferable to cimetidine.[233]

Anti-infective Drugs

Penicillin and its derivatives are safe in nursing mothers. With the usual therapeutic doses of **ampicillin**, the milk-to-plasma concentration ratio is 0.2 or less and no adverse effects are noted in nursing infants.[234] Theoretically, infant diarrhea or candidiasis might occur with prolonged therapy. **Cephalosporins** appear in trace amounts in breast milk and are also safe.

Sulfonamides displace bilirubin from binding sites on albumin, so these drugs are best avoided during the first 5 days of life or in mothers of preterm infants with hyperbilirubinemia. Sulfonamides appear in breast milk in

small amounts. **Sulfasalazine** has been associated with diarrhea and bloody diarrhea in an infant.[192] Sulfonamides should be avoided in infants with G6PD deficiency.

Tetracyclines are normally avoided during breast-feeding because of the potential for tooth staining and delayed bone growth. The breast milk concentration of tetracycline is about half the maternal plasma concentration, but tetracycline has a high affinity for both calcium and protein, and the amount of free tetracycline available for systemic absorption is very small. Thus, some references consider a short course of tetracyclines to be compatible with breast-feeding. Similarly, **quinolones** are usually avoided in pregnancy, but there is disagreement over their safety during breast-feeding.

Maternal administration of **acyclovir** does not contraindicate breast-feeding. If a mother takes 1 g/day, the infant probably receives less than 1 mg/day, a very low dose.[235]

Most vaccines, except for yellow-fever and smallpox, can be administered during breast-feeding.[192]

Caffeine

Moderate maternal intake of caffeine does not adversely affect the breast-fed infant. One study noted that breast milk contains only 1% of the total maternal dose of caffeine.[236] If a mother drinks excessive amounts of coffee, caffeine might accumulate in the infant and the infant might show signs of caffeine stimulation (e.g., irritability, poor sleeping pattern). Nursing mothers should limit their intake to a moderate level of caffeinated beverages (e.g., 2 to 3 cups per day).[192]

KEY POINTS

- Physiologic changes of pregnancy can alter drug disposition and drug effect.
- Maternal drug therapy is relatively easy to manage by changing the dose or switching the drug.
- General and local anesthetic requirements are reduced during pregnancy.
- Appropriate maternal treatment is essential to maintain fetal health.
- Mothers are concerned about many adverse fetal outcomes, including teratogenic effects, fetal loss, fetal growth restriction, preterm labor, and other complications of pregnancy.
- The basis of safety for many drugs during pregnancy is a long history of uneventful use.
- The critical period of organ development extends from approximately day 31 to day 71 after the first day of the last menstrual period.
- Administration of anticonvulsants is associated with an increased risk for congenital anomalies. Monotherapy is associated with less risk than therapy with two or more drugs.
- Many psychotropic drugs are not recommended for use during pregnancy.
- Heparin does not cross the placenta. Low-molecular-weight heparin is generally the anticoagulant of choice during pregnancy.
- Most antibiotics are safe during pregnancy. Tetracyclines should be avoided during pregnancy because they cause tooth discoloration and inhibit bone growth in the fetus. Quinolones are contraindicated during pregnancy.
- Vaccination is recommended in pregnant women except for live vaccines.
- Prevention and treatment of influenza with zanamivir and oseltamivir is possible.
- Most drugs are safe for use during lactation. Typically only 1% to 2% of the maternal dose appears in breast milk.
- Codeine can be rapidly converted to morphine by some mothers, leading to large amounts in breast milk and significant neonatal opioid depression.

CHAPTER 15

In Vitro Fertilization and Other Assisted Reproductive Technology

Lawrence C. Tsen, MD

CHAPTER OUTLINE

In 1978, Steptoe and Edwards[1] reported the first live birth of an infant produced from *in vitro* fertilization (IVF) techniques. Their case highlighted the laparoscopic recovery of a single oocyte just before ovulation in a natural menstrual cycle; after *in vitro* insemination, the resulting embryo was grown in culture media for 2.5 days to the eight-cell stage and was transferred to the uterine cavity (i.e., embryo transfer [ET]).

IVF techniques were initially developed as a treatment for infertility secondary to chronic fallopian tube disease. Current indications for this emerging spectrum of new techniques, which as a group are referred to as assisted reproductive technology (ART), include (1) inadequate oocyte quality or number (donor oocyte therapy), irreparability or absence of the uterus (surrogate uterus programs), and significant co-morbidities (embryo and ovarian tissue cryopreservation) in women; (2) sperm deficiencies in men; and (3) certain genetic aberrations in couples.[2]

In 1981, Edwards[3] estimated that 15 to 20 infants would be born worldwide through the use of IVF and ET techniques. Advances in the science and international acceptance of ART procedures have resulted in a dramatic increase in the number of infants born globally (Figure 15-1).[4] A similar increase in the use of these technologies has been witnessed in the United States (Figure 15-2); in 2011, the initiation of 163,038 ART cycles resulted in the birth of 61,610 infants.[5]

Despite the application of ART procedures to more diverse and challenging causes of infertility, the probability of a live birth after a cycle of hormonal stimulation has increased from 6% in 1985 to 30% in 2011.[5] Attention to subtle differences in culture media as well as improvements in laboratory methods, retrieval routes, and transfer techniques are primarily responsible for these improved results.[6] Given the importance of small alterations to the overall success of ART, coupled with the associated costs (i.e., approximately $10,000 for each cycle that progresses to transfer and limited insurance coverage for these procedures),[7] it is prudent for anesthesia providers to be aware of the potential effects that anesthetic agents may have on gametes or embryos.

ASSISTED REPRODUCTIVE TECHNOLOGY PROCEDURES

Hormonal Stimulation

Although the success of IVF was initially limited by the *single* preovulatory oocyte generated with each natural menstrual cycle,[1] the introduction of follicular hormonal stimulation has significantly increased the probability of a live birth through the retrieval of *multiple* oocytes per cycle. Hormonal regimens typically initiate a cycle with gonadotropin-releasing hormone agonist to induce pituitary and ovarian suppression, followed by follicle-stimulating hormone and human menopausal gonadotropin to stimulate the development and growth of multiple ovarian follicles. Human chorionic gonadotropin (hCG) is later added to induce maturation and demargination of the oocyte from the follicular wall before retrieval. Although the goal of these regimens is the generation of 10 to 15 oocytes, superovulation can occur, resulting in the production of as many as 70 oocytes. All visible ovarian follicles are aspirated (see later discussion), with each follicle usually containing a single oocyte.

After oocyte retrieval, pituitary function is usually insufficient to provide adequate hormonal support to the growing corpus luteum. For this reason, parenteral progesterone is often provided daily until either the results of the pregnancy test are known or the first trimester of pregnancy is completed.

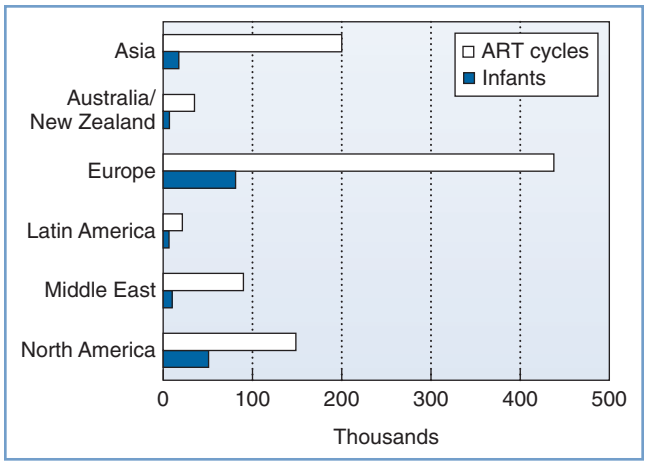

FIGURE 15-1 ■ Numbers of initiated assisted reproductive technology (*ART*) cycles and infants born worldwide by region in 2011 (from data accumulated in 2003 from 54 countries) as reported by the International Committee for Monitoring Assisted Reproductive Technology (ICMART). (Data from Nygren KG, Sullivan E, Zegers-Hochschild F, et al. International Committee for Monitoring Assisted Reproductive Technology (ICMART) world report. Assisted Reproductive Technology 2003. Fertil Steril 2011; 95:2209-22, 22.e1-17.)

Oocyte Retrieval

Originally conducted with direct visualization of the ovarian follicles through pelvic laparoscopy,[1] the majority of oocyte retrievals are currently performed through a transvaginal approach with ultrasonographic guidance (Figure 15-3).[8] Laparoscopic oocyte retrieval is typically reserved for situations in which tubal transfer is planned (i.e., gamete intrafallopian transfer [GIFT] or zygote intrafallopian transfer [ZIFT]; see later discussions).

Oocyte retrieval is performed 34 to 36 hours after hCG administration. Retrieval must be performed promptly to prevent spontaneous ovulation from reducing the number of mature oocytes. With the use of a transvaginal ultrasound probe to visualize the ovary, mature follicles are punctured and aspirated with a needle introduced through the vaginal fornix. Oocytes are immediately washed in culture media and examined microscopically to determine their stage of meiosis. Oocytes are classified as postmature metaphase II, mature metaphase II, metaphase I, or prophase I on the basis of their nuclear, cytoplasmic, and extracellular composition.

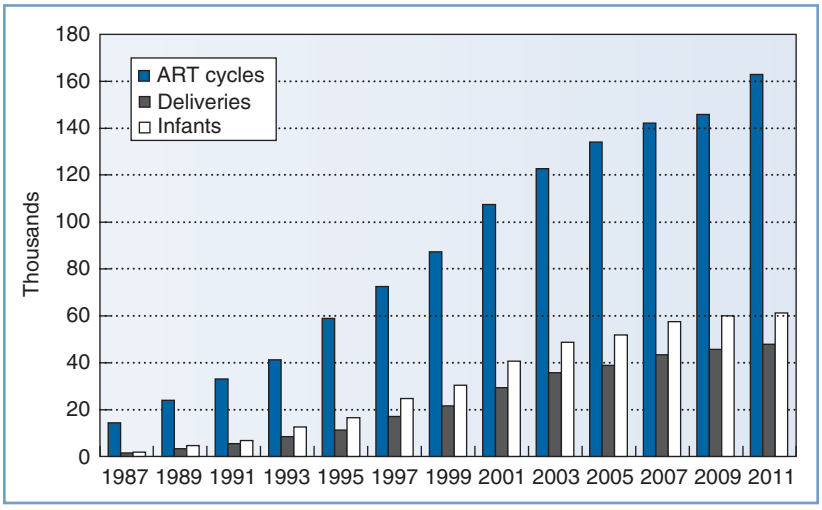

FIGURE 15-2 ■ Numbers of assisted reproductive technology (*ART*) cycles performed, live-birth deliveries, and infants born in the United States using ART from 1987 through 2011, as reported to the Centers for Disease Control and Prevention, Division of Reproductive Health, and the Society for Assisted Reproductive Technology Registry. (Data from U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, Division of Reproductive Health. 2011 Assisted Reproductive Technology [ART] Report. Atlanta, CDC/DRH, 2013.)

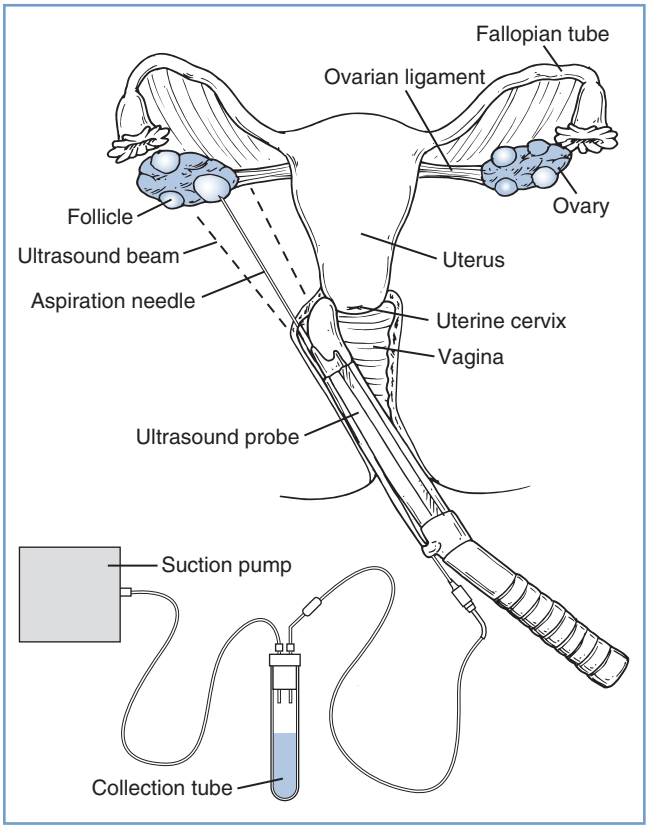

FIGURE 15-3 ■ Transvaginal ultrasound-guided oocyte retrieval. The ultrasound probe is placed in the vagina and advanced into the posterior fornix. The needle, previously inserted through the needle guide, is advanced through the vaginal wall and ovarian capsule. (Redrawn from Steinbrook R. Egg donation and human embryonic stem-cell research. (Redrawn from Veeck LL. Atlas of the Human Oocyte and Early Conceptus. Baltimore, Williams & Wilkins, 1991:43.)

In Vitro Fertilization

Although the term *in vitro fertilization* is often used synonymously with any aspect of ART, technically it applies only to the process of oocyte fertilization with spermatozoa in culture media. After a microscopic examination, oocytes are incubated for 4 to 6 hours in culture media that resembles human fallopian tube fluid and are then inseminated. The insemination process is sometimes delayed with immature oocytes (e.g., metaphase I) in an attempt to increase the probability of normal (i.e., monospermic) fertilization.

At 16 to 20 hours after insemination the oocytes are examined for evidence of fertilization (i.e., the presence of two pronuclei and two polar bodies in the perivitelline space) (Figure 15-4).[9] The advantages of IVF include the ability to document the process of fertilization and to use techniques to improve sperm motility or penetration (e.g., intracytoplasmic sperm injection). IVF followed by ET represents approximately 99% of the ART procedures used in the United States[5]; less than 1% occurs via GIFT or ZIFT procedures (see later discussions). Male factor infertility is present in approximately 35% of the couples seeking ART procedures, and intracytoplasmic sperm injection is currently used in more than 65% of the cases treated annually in the United States.[5]

Embryo Transfer

Embryos resulting from IVF may be transferred into the fallopian tubes (i.e., ZIFT) or the uterine cavity (IVF-ET). Most ET procedures are performed transcervically 3 days after retrieval, with the embryos transferred via a catheter. The advantages of transcervical ET are (1) simplicity—it does not require laparoscopy or anesthesia; (2) low cost, especially compared with laparoscopic intrafallopian transfer procedures; and (3) the ability to proceed without patent fallopian tube(s). The primary disadvantage of transcervical ET is that the probability of successful pregnancy is slightly less than that with an ET performed directly into the fallopian tubes (i.e., ZIFT). Embryos in excess of those required for transfer may be frozen in 1,2-propanediol or glycerol and stored for possible later transfer.

Gamete Intrafallopian Transfer

GIFT procedures consist of the transabdominal or transvaginal collection of oocytes followed by a microscopic inspection of the oocytes' quality and maturation in a laboratory adjacent to the operating room. Mature oocytes are aspirated into a transfer catheter with washed partner or donor sperm, and the contents (gametes) are injected into the distal 3 to 6 cm of one or both fallopian tubes. The catheter is subsequently inspected microscopically to verify that oocytes have not been retained. The GIFT procedure does not involve IVF, because fertilization occurs *in vivo* in the natural milieu of the fallopian tube.

Specific advantages of the GIFT procedure include (1) the convenience of oocyte retrieval and ET occurring within a single operative event, (2) the elimination of IVF, and (3) the fact that the embryos reach the uterine cavity at a potentially more appropriate (i.e., later) stage of

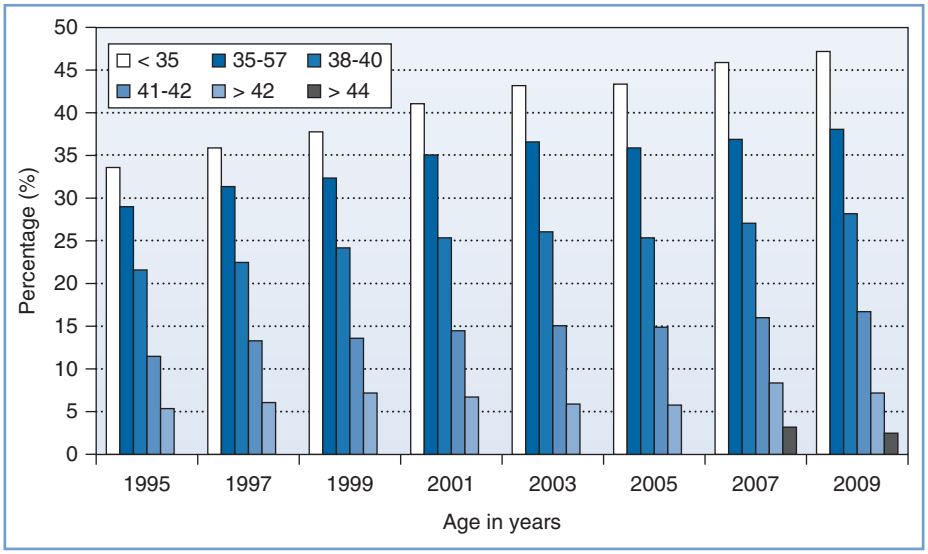

FIGURE 15-5 ■ Percentage of transfers that resulted in live births with assisted reproductive technology (ART) cycles using fresh nondonor eggs or embryos, according to the women's age in the years from 1995 to 2009, as reported to the Centers for Disease Control and Prevention, Division of Reproductive Health, and the Society for Assisted Reproductive Technology Registry. The first year in which data for women older than 42 were subdivided into ages 43 to 44 and older than 44 was in 2007. (Data from U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, Division of Reproductive Health. 2009 Assisted Reproductive Technology (ART) Report. Atlanta, CDC/DRH, 2011.)

development than with IVF-ET.[10] The primary disadvantage is that fertilization cannot be documented; an issue that may be critical when this capacity is in question (e.g., couples with male or immunologic factors). Normally, 50% to 70% of inseminated oocytes become fertilized[11]; however, lower fertilization rates are often observed in couples with severe male factor infertility or in women with antisperm antibodies. Other limitations are the required presence of at least one patent fallopian tube and the requirement for laparoscopic surgery.

Zygote Intrafallopian Transfer

ZIFT (also known as pronuclear stage transfer [PROST]) consists of oocyte retrieval followed by IVF. At 16 to 20 hours after insemination the oocytes are examined for the presence of two distinct pronuclei (i.e., the pronuclear stage; see Figure 15-4), which indicates that fertilization has occurred. The patient is anesthetized for laparoscopy, and pronuclear stage embryos (usually no more than four) are transferred through a catheter into the distal portion of a fallopian tube (as described for GIFT). Advantages of ZIFT include (1) the documentation of fertilization, (2) the avoidance of laparoscopy if fertilization is not successful (approximately 13% of inseminations),[5] (3) a shorter exposure to the laboratory environment than with IVF-ET, and (4) the potential for embryos to reach the uterine cavity at a more appropriate stage of development than with IVF-ET (i.e., approximately the fifth day after insemination). Its disadvantages and limitations include (1) the added inconvenience and cost of a two-stage procedure, (2) the requirement for laparoscopic surgery, and (3) the presence of at least one patent fallopian tube.

SUCCESS OF ASSISTED REPRODUCTIVE TECHNOLOGY

The Society for Assisted Reproductive Technology (SART) and the American Society for Reproductive Medicine (ASRM) collaborate with the Centers for Disease Control and Prevention (CDC) to maintain a data registry and analyze the results of all ART cycles initiated during each calendar year in the United States.[5]

Maternal age is the dominant factor in determining the likelihood of a successful pregnancy after an ART procedure (Figure 15-5). For example, in 2010, 41.5% of IVF cycles in women younger than 35 years led to the delivery of one or more infants.[5] By contrast, in a similar group of women older than 42 years who met optimal fertility criteria, only 6% of these procedures resulted in a live birth.[5] In 2010, the average age of a woman having an ART procedure in the United States was 36 years.

Although pregnancy and delivery rates have historically been greater for tubal transfers (i.e., GIFT, ZIFT) than for transcervical uterine transfers (IVF-ET), greater parity in these rates has developed in recent years.[5,11] The early postovulatory uterine environment has been postulated to be unfavorable to early embryo growth.[11] Tubal transfer procedures allow embryos 3 to 5 days to reach the uterine cavity, when the environment for implantation may be more receptive. Lower implantation rates after transcervical ET may also be explained by (1) adverse uterine effects produced by the transfer procedure, (2) uterine contractions expelling transfer fluid and embryos,[12] and (3) the absence of yet undiscovered tubal factors that promote early embryo growth and implantation.[11,13]

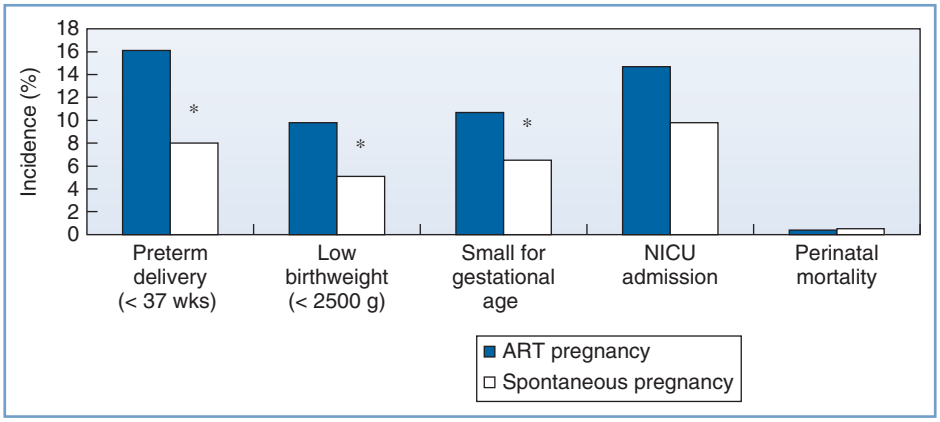

FIGURE 15-6 ■ Outcomes associated with singleton births from assisted reproductive technology (*ART*) and spontaneous pregnancies in the general population. *$P < .05$. *NICU,* Neonatal intensive care unit. (Data from D'Angelo DV, Whitehead N, Helms K, et al. Birth outcomes of intended pregnancies among women who used assisted reproductive technology, ovulation stimulation, or no treatment. Fertil Steril 2011; 96:314-20.)

OBSTETRIC COMPLICATIONS

ART hormonal stimulation regimens are associated with increased coagulation and decreased fibrinolysis when evaluated by individual hemostatic markers and global assessment tools (i.e., thromboelastography).[14,15] These alterations are especially significant in the setting of the most common ovarian stimulation complication, a phenomenon termed *ovarian hyperstimulation syndrome* (OHSS). Mild cases of OHSS may manifest as abdominal discomfort, bilateral ovarian enlargement, and ascites, whereas severe cases may result in follicular rupture and hemorrhage, pleural effusion, hemoconcentration, oliguria, and thromboembolic events.[16-18] The anesthetic implications of OHSS include increased free drug concentrations (see later discussion) and greater perioperative pain from larger follicle numbers. The fullest expression of the syndrome usually occurs after oocyte retrieval, particularly if the decision is made to proceed with an ET, which maintains exposure to endogenous and exogenous hormones. Rarely, an emergency laparoscopy or laparotomy is required for excision of a ruptured ovarian cyst or the release of an ovarian pedicle torsion.[18] Abdominal paracentesis and thoracentesis may be necessary before the induction of general anesthesia in patients with respiratory compromise due to massive ascites or pleural effusions.

Multiple-gestation pregnancies represented 31% of the deliveries that followed ART procedures in the United States in 2010, of which 91% were twins.[5] The transfer of a greater number of embryos or oocytes increases both the probability of a live birth and the likelihood of a multifetal pregnancy. Although many infertile couples would prefer a twin or triplet pregnancy, maternal and perinatal morbidity and mortality for multiple versus singleton gestation pregnancies is at least doubled.[19] In addition, overall medical costs escalate with each additional fetus, particularly if the birth occurs preterm. Within the United States in 2006, 62% of ART twins and 97% of ART triplets were delivered preterm, resulting in an estimated financial burden of $1 billion.[20] In an effort to reduce the incidence and sequelae of multifetal pregnancies, many ART programs and societies, and even some countries, have mandated a limit on the number of embryos or oocytes that are transferred.[21] In the presence of triplet or higher-order gestation pregnancies, selective reductions can be performed; however, these procedures are subject to a number of medical and ethical considerations.

Ectopic pregnancies occur up to five times more frequently in ART pregnancies than with natural pregnancies (2%), primarily owing to the greater prevalence of fallopian tube disease among infertility patients.[22] The transfer site (uterine versus fallopian tube) *per se* does not appear to be a predisposing factor in the development of ectopic pregnancies; however, a greater number occur after uterine transfer, because women with bilateral tubal disease are not candidates for GIFT or ZIFT procedures. In approximately 10% of ectopic pregnancy cases, the ectopic embryo develops in conjunction with an ongoing intrauterine pregnancy and requires a termination or surgical removal within the first trimester.[22]

Preterm delivery, low birth-weight, and small-for-gestational-age infants are more common with ART singleton pregnancies than with natural pregnancies, although the prevalence of admission into the neonatal intensive care unit, duration of infant hospital stay after birth, and the incidence of infant death appear similar (Figure 15-6).[23] The difference appears to be a result of infertility per se rather than the ART procedures, because previously infertile women who conceive independent of ART also are at greater risk for preterm delivery.[23]

EFFECTS OF ANESTHESIA ON REPRODUCTION

General Considerations

In 1987, Boyers et al.[24] reported that oocytes recovered by laparoscopic techniques in patients who had received

general anesthesia (i.e., isoflurane or enflurane with a 50% nitrous-oxygen mixture) were less likely to be fertilized if the duration of the procedure was prolonged. Specifically, fertilization rates for the first- and last-recovered oocytes were 69% and 54%, respectively, when the difference in exposure time exceeded 5 minutes. The investigators advanced the following two plausible explanations for this difference: (1) the acidification of follicular fluid by intraperitoneal carbon dioxide and (2) the effects of anesthesia. This study prompted an assessment of anesthetic agents and techniques used during ART procedures.

Ideally, anesthetic techniques and agents used for ART procedures should not interfere with oocyte fertilization or early embryo development and implantation. Although anesthetic agents have been reported to interfere with some aspects of reproductive physiology in some species under certain conditions, the literature must be interpreted with caution. For example, one study concluded that oocyte cleavage rates were significantly lower with general anesthesia than with epidural anesthesia.[25] However, a laparoscopic (instead of transvaginal) retrieval method was used in the general anesthesia group, and carbon dioxide pneumoperitoneum may significantly decrease both follicular fluid pH and oocyte fertilization rates. Another report commented on the effects of different anesthetic techniques, but it did not disclose the actual anesthetic agents that were administered in the study.[26] In addition, conclusions based on animal data may not reflect the human experience owing to interspecies and assay method differences.[27]

Assessment of specific anesthetic drugs must also be interpreted in context; relevant factors include (1) the method of administration, (2) dose of anesthetic agents, (3) combination with other drugs, (4) timing of administration, and (5) duration of exposure. For example, local anesthetic agents yield dissimilar pharmacokinetic profiles when administered via paracervical, epidural, and intrathecal techniques. Anesthetic agents may also affect unfertilized oocytes and fertilized embryos differently; thus, studies of anesthetic agents used for a GIFT (prefertilization) procedure should not be directly compared with studies of agents used for a ZIFT (postfertilization) procedure. Finally, significantly greater free concentrations of certain agents (e.g., bupivacaine) exist during ART stimulation because of a decrease in plasma protein binding capacity.[28] Thus, when selecting anesthetic techniques or agents for an ART procedure, the clinician should weigh their known benefits (e.g., greater hemodynamic stability, less nausea, less psychomotor impairment) and hypothetical risks (e.g., lower delivery rates).

Local Anesthetic Agents

In animal models, the effect of local anesthetic agents on reproductive physiology appears to be related to the agent, timing, and dose of exposure. Using mouse oocytes incubated for 30 minutes in culture media with known concentrations of lidocaine, bupivacaine, or 2-chloroprocaine, Schnell et al.[29] demonstrated that lidocaine and 2-chloroprocaine adversely affected both fertilization and embryo development at concentrations of

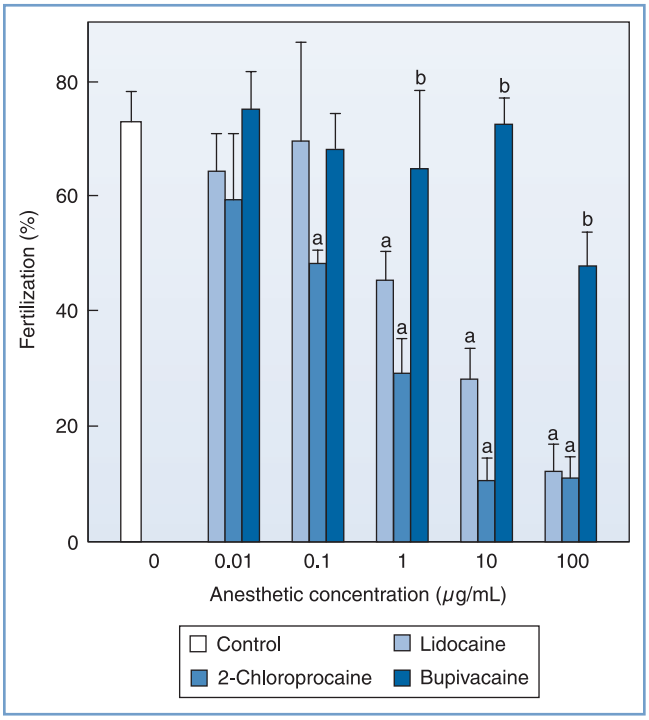

FIGURE 15-7 ■ Fertilization of mouse oocytes at 48 hours (mean ± SD) for each anesthetic exposure group. *a, P* < .05 (anesthetics compared with control); *b, P* < .05 (lidocaine and 2-chloroprocaine compared with bupivacaine). (Modified from Schnell VL, Sacco AG, Savoy-Moore RT, et al. Effects of oocyte exposure to local anesthetics on in vitro fertilization and embryo development in the mouse. Reprod Toxicol 1992; 6:323-7, with permission from Elsevier Science, Kidlington, UK.)

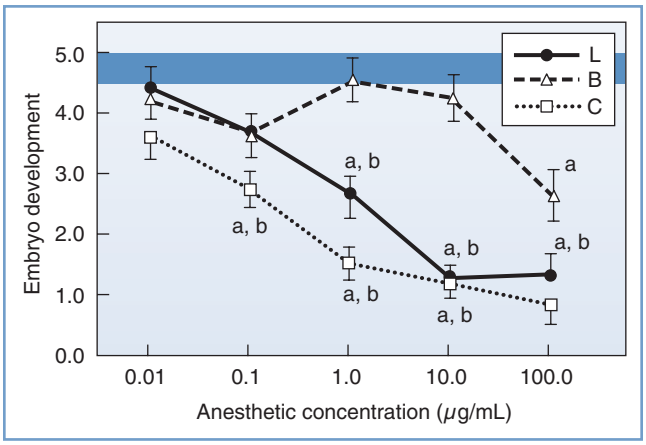

FIGURE 15-8 ■ Embryo development scores (mean ± SD) at 72 hours as a function of anesthetic concentration. Shaded area represents embryo development score (4.75 ± 0.28) for the control mouse embryos. *a, P* < .01 (lidocaine [*L*], bupivacaine [*B*], and 2-chloroprocaine [*C*] compared with control); *b, P* < .01 (bupivacaine compared with lidocaine and 2-chloroprocaine). (Modified from Schnell VL, Sacco AG, Savoy-Moore RT, et al. Effects of oocyte exposure to local anesthetics on in vitro fertilization and embryo development in the mouse. Reprod Toxicol 1992; 6:323-7.)

1.0 and 0.1 μg/mL, respectively (Figures 15-7 and 15-8). In contrast, bupivacaine produced adverse effects only at the greatest concentration studied (100 μg/mL). Similarly, Del Valle et al.[30] demonstrated that after 48 hours of culture, 24% of mouse embryos exposed to lidocaine

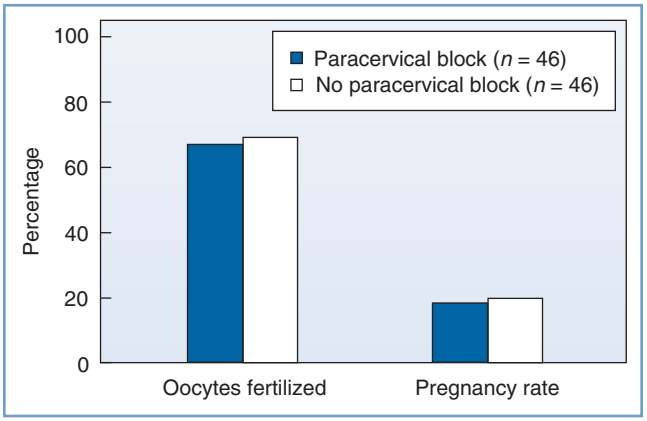

FIGURE 15-9 ■ Fertilization and pregnancy rates after transvaginal oocyte retrieval with and without lidocaine paracervical block. Fertilization and cleavage rates did not differ in the two groups. (Modified from Wikland M, Evers H, Jakobsson AH, et al. The concentration of lidocaine in follicular fluid when used for paracervical block in a human IVF-ET programme. Hum Reprod 1990; 5:920-3.)

10 µg/mL, in comparison with none in the control group, showed evidence of degeneration. Finally, Ahuja et al.[31] noted that hamster oocytes exposed to procaine or tetracaine demonstrated impaired zona reactions, potentially allowing additional sperm to enter the oocyte and create abnormal chromosomal numbers (polyploidy).

These *in vitro* findings may have limited clinical relevance, however, given the lower anesthetic concentrations that occur in clinical practice and the washing and screening procedures that oocytes undergo before fertilization and transfer. Human trial data corroborate the minimal effect that local anesthetic agents have on oocytes or embryos during oocyte retrieval, GIFT, or ZIFT procedures. Wikland et al.[32] reported that the incidence of oocyte fertilization and clinical pregnancy was not reduced among women who received a modified paracervical block with lidocaine for transvaginal oocyte retrieval (Figure 15-9). Favorable pregnancy rates have also been reported after GIFT procedures performed during epidural lidocaine anesthesia.[25]

Opioids and Benzodiazepines

Fentanyl, alfentanil, remifentanil, and meperidine do not appear to interfere with either fertilization or preimplantation embryo development in animal and human trials.[33,34] When given during oocyte retrieval, fentanyl and alfentanil were detected in extremely low (or undetectable) follicular fluid concentrations.[35] With alfentanil, a 10:1 ratio between serum and follicular fluid was observed 15 minutes after the initial bolus dose.[36] Morphine appears unique in terms of adverse effects; when sea urchin eggs were incubated in morphine (equivalent to a human dose of 50 mg), more than one sperm entered approximately 30% of the oocytes.[37]

Midazolam administered systemically in preovulatory mice did not impair fertilization or embryo development *in vivo* or *in vitro*, even when given in doses up to 500 times those used clinically.[38] When used in small bolus or infusion doses for anxiolysis and sedation for ART in humans, midazolam has not been detected in follicular fluid and does not appear to be teratogenic.[39,40]

Propofol, Thiopental, and Ketamine

Most animal and human trials suggest minimal to no detrimental effects of propofol on fertilization and early embryo development,[41-45] despite accumulating in a dose- and duration-dependent manner within the follicular fluid.[46-48] General anesthesia provided with propofol and a 50% oxygen-air mixture was associated with fertilization, embryo cleavage, and implantation rates similar to those produced by a paracervical block with mepivacaine.[44] Hamster oocytes exposed to very high concentrations of propofol (20 µg/mL) demonstrated no DNA damage—even through two metaphases—when evaluated by sister chromatid exchange assays, a sensitive index of genotoxic effects.[49] These concentrations were 40 times greater than those detected clinically in the follicular fluid of patients undergoing oocyte retrieval.[46,47] The induction and maintenance of general anesthesia with propofol for GIFT procedures demonstrated negligible differences in reproductive outcomes from women receiving other forms of anesthesia.[42] By contrast, a smaller incidence of ongoing pregnancies was observed among women given propofol–nitrous oxide anesthesia for ZIFT procedures when compared with thiopental–nitrous oxide–isoflurane anesthesia.[50] Further investigation is necessary to further elucidate the full effects of propofol on various reproductive outcomes.

Both thiopental and thiamylal (5 mg/kg) can be detected in follicular fluid as early as 11 minutes after their administration for induction of general anesthesia in patients undergoing GIFT procedures.[51] No adverse reproductive effects have been observed with these agents, and when they were specifically compared with propofol (2.7 mg/kg) for GIFT procedures, no differences in clinical pregnancy rates were noted.[43]

Ketamine (0.75 mg/kg), administered with midazolam (0.06 mg/kg), has been reported to be an acceptable alternative to general anesthesia with isoflurane for oocyte retrieval.[52] No differences in reproductive outcomes were observed; however, the study was inadequately powered to adequately assess this result.

Nitrous Oxide

Nitrous oxide reduces methionine synthetase activity, nonmethylated folate derivatives, and DNA synthesis in animals and humans.[53,54] Nitrous oxide also impairs the function of mitotic spindles in cell cultures.[55] Although Warren et al.[56] reported that two-cell mouse embryos exposed to nitrous oxide within 4 hours of the expected onset of cleavage were less likely to develop to the blastocyst stage (Figure 15-10), this difference had resolved by later stages of embryo development.[34]

Clinical studies of anesthesia for laparoscopic ART procedures support the administration of nitrous oxide during GIFT and ZIFT procedures.[42,50,57] In a multicenter study, Beilin et al.[42] observed a delivery rate of 35% among women given nitrous oxide for GIFT

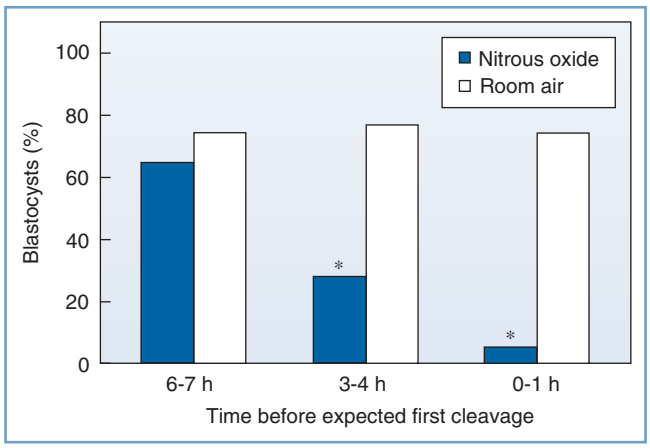

FIGURE 15-10 ■ Developmental outcome of two-cell mouse embryos exposed to 60% nitrous oxide/40% oxygen for 30 minutes in vitro. Administration of nitrous oxide within 4 hours of anticipated cleavage decreased the percentage of embryos reaching the blastocyst stage. **P* < .05 compared with the room air (i.e., control) group. (Modified from Warren JR, Shaw B, Steinkampf MP. Effects of nitrous oxide on preimplantation mouse embryo cleavage and development. Biol Reprod 1990; 43:158-61.)

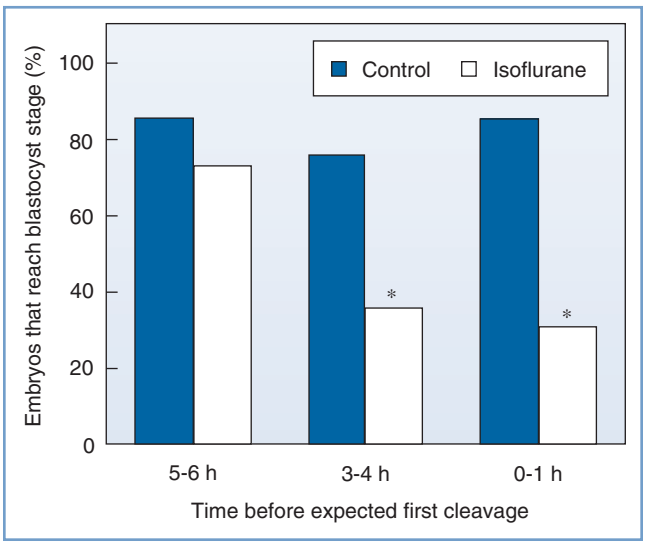

FIGURE 15-11 ■ Developmental outcome of two-cell mouse embryos exposed in vitro to 3% isoflurane for 30 minutes at various times in relation to expected onset of the first cleavage in vitro. **P* < .01. (Modified from Warren JR, Shaw B, Steinkampf MP. Inhibition of preimplantation mouse embryo development by isoflurane. Am J Obstet Gynecol 1992; 166:693-8.)

procedures, compared with 30% among women who did not receive nitrous oxide. In women undergoing oocyte retrieval, Handa-Tsutsui and Kodaka[58] reported lower target-controlled propofol doses with a 50% oxygen–nitrous oxide mixture than with an oxygen-air mixture. The authors reported that there were no alterations in pregnancy rates, but the study was not adequately powered to determine this difference.

Volatile Halogenated Agents

Volatile halogenated agents have been observed to depress DNA synthesis and mitosis in cell cultures.[59,60] Sturrock and Nunn[59] noted that volatile halogenated agents prevent cytoplasmic cleavage during mitosis, leading to a greater number of abnormal mitotic figures (e.g., tripolar and tetrapolar nuclear phases). Isoflurane adversely affects embryo development *in vitro*.[34,61] Warren et al.[61] reported that two-cell mouse embryos exposed to 3% (but not 1.5%) isoflurane for 1 hour were less likely to develop to the blastocyst stage (Figure 15-11), but only when isoflurane was given within 4 hours of the predicted onset of cleavage. It is questionable whether studies of two-cell mouse embryos are applicable to human oocytes and spermatozoa exposed during GIFT procedures or to one-cell embryos exposed during ZIFT procedures.

Volatile halogenated agents may also affect ART outcomes through an increase in prolactin levels. High prolactin levels have been associated with diminished oocyte development and uterine receptivity (see later discussion); whether volatile halogenated agents can affect mature oocytes in the process of being retrieved, however, is questionable. Critchlow et al.[62] observed dramatic rises in plasma prolactin levels with an enflurane in nitrous oxide–oxygen technique for GIFT procedures, although these changes did not occur until 4 to 10 minutes after induction and did not affect follicular fluid prolactin levels or fertilization rates.

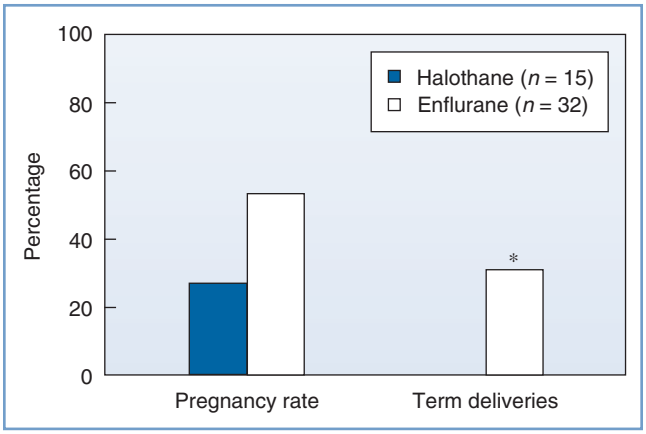

FIGURE 15-12 ■ Pregnancy and term delivery rates after halothane and enflurane anesthesia for gamete intrafallopian transfer (GIFT). The percentage of term pregnancies after GIFT was greater after enflurane–nitrous oxide anesthesia than after halothane–nitrous oxide anesthesia. **P* < .05 compared with the halothane group. (Modified from Critchlow BM, Ibrahim Z, Pollard BJ. General anaesthesia for gamete intra-fallopian transfer. Eur J Anaesthesiol 1991; 8:381-4.)

Volatile anesthetic agents have been compared in clinical studies. Fishel et al.[63] reported that pregnancy rates were significantly lower among women given halothane anesthesia for ET than in a similar group of women given enflurane; of interest, the anesthesia was administered in an attempt to decrease uterine activity during ET. Similarly, Critchlow et al.[62] reported lower pregnancy and delivery rates among women who received halothane for GIFT procedures than in women who received enflurane (Figure 15-12). General anesthesia with volatile halogenated agents has also been compared with monitored

anesthesia care (MAC). In a retrospective sequential study design, Wilhelm et al.[33] noted lower pregnancy rates in patients undergoing oocyte retrieval with general anesthesia (i.e., isoflurane or propofol in combination with 60% nitrous oxide in oxygen) than in subsequent patients who received a remifentanil-based MAC technique. The investigators acknowledged that the success rates of ART programs have improved over time and that it is possible that physician-related factors may have played a role in the improved success during the second MAC phase of the study.[33]

These data suggest that volatile halogenated anesthetic agents can affect ART outcomes, with known and potential differences associated with the selected agent. For example, the metabolic byproduct of sevoflurane, compound A, has been associated with genotoxic ovarian cell effects, although reproductive outcomes have not been assessed.[64] As a consequence, although volatile agents continue to be used for ART procedures, caution is advised in the selection of newer agents, such as sevoflurane, desflurane, and isodesox (a combination of 1% desflurane, 0.25% isoflurane, and 60% oxygen in nitrogen),[65] until further work has been done.

Antiemetic Agents

At least one study noted that droperidol and metoclopramide rapidly induce hyperprolactinemia with subsequent impairment of ovarian follicle maturation and corpus luteum function.[66] When these agents are given as a single dose immediately prior to oocyte retrieval, it is unlikely that the mature oocyte will be affected; however, if they are given on a routine basis after retrieval, the uterine receptivity to the embryo could be affected. Forman et al.[67] demonstrated that low plasma prolactin concentrations during ART procedures were associated with a higher incidence of pregnancy.

ANESTHETIC MANAGEMENT

Because most patients undergoing ART procedures are young and otherwise healthy, many institutions do not require preoperative laboratory studies, electrocardiograms, or chest radiographs before the procedure. However, the application of ART procedures to patients with a growing spectrum of pathologic processes, such as morbid obesity, cancer (with oocyte retrieval performed prior to chemotherapy or radiation therapy), and severe cardiac, pulmonary, or renal morbidities (with oocyte retrieval performed for ET in surrogate gestational carriers), has created special concerns that should be addressed individually.[68]

All patients should follow the fasting guidelines typically used for patients undergoing ambulatory surgery. In patients with risk factors for pulmonary aspiration of gastric contents, a nonparticulate antacid should be given before the procedure. On occasion, a patient may not adhere to strict fasting guidelines; and although delay or cancellation of the procedure is an option, the decision should be made after careful analysis of the potential risks and benefits. If the window for maximal oocyte retrieval (34 to 36 hours after hCG administration) is missed, spontaneous ovulation with loss of oocytes can occur, invalidating the considerable effort and expense that have been incurred to that point. Moreover, if oocyte retrieval is not performed, the patient would be at increased risk for OHSS, with its potential for significant morbidity. In contrast, the risk for pulmonary aspiration of gastric contents is low, particularly when spinal anesthesia is administered (see later discussion).

As with other ambulatory surgery cases, the ideal anesthetic technique provides effective pain relief with minimal postoperative nausea, sedation, pain, and psychomotor impairment.

Ultrasonographic-Guided Transvaginal Oocyte Retrieval

Although transvaginal oocyte retrievals can be performed under paracervical, spinal, epidural, and general anesthetic techniques, MAC is the most commonly used technique.[69,70] It is usually adequate for surgical analgesia, but MAC may need to progress to loss of consciousness (i.e., general anesthesia) to prevent patient movement at critical times; this problem has been observed in highly anxious patients.[71] The need for additional pain relief should be anticipated when the needle penetrates the cul-de-sac and, later, each ovary. Of interest, one report noted a greater rate of hospital admission after oocyte retrieval, mostly secondary to intra-abdominal bleeding, when MAC was used than when general anesthesia was used.[72] Self-administered inhalational analgesia with isodesox (see earlier discussion) by face mask was associated with less effective analgesia and less patient satisfaction than physician-administered intravenous analgesia.[65]

Because paracervical anesthesia incompletely blocks sensation from the vaginal and ovarian pain fibers, additional analgesia is required, even when greater doses of local anesthetic are used.[73] Epidural and spinal techniques provide excellent pain relief with minimal oocyte exposure to anesthetic agents. Compared with sedation with propofol and mask-assisted ventilation with nitrous oxide, epidural bupivacaine anesthesia resulted in fewer complications, especially nausea and emesis.[74] Spinal anesthesia may be preferable to epidural anesthesia owing to the reduced anesthetic failure rate, reduced systemic and follicular concentrations of anesthetic agent, and faster recovery profile.[75] Spinal administration of 1.5% hyperbaric lidocaine (60 mg) is associated with significantly shorter recovery times than spinal administration of 5% hyperbaric lidocaine (60 mg) in patients undergoing ART procedures.[76] The addition of intrathecal fentanyl 10 μg to lidocaine 45 mg improves postoperative analgesia for the first 24 hours, with no increase in time to urination, ambulation, and discharge, in comparison with intrathecal lidocaine alone.[77] Low-dose spinal bupivacaine has been evaluated for use in these patients, given the frequent association of spinal lidocaine with postoperative transient neurologic symptoms. However, the prolonged time to urination and discharge may prevent this agent from becoming a commonly used alternative.[78]

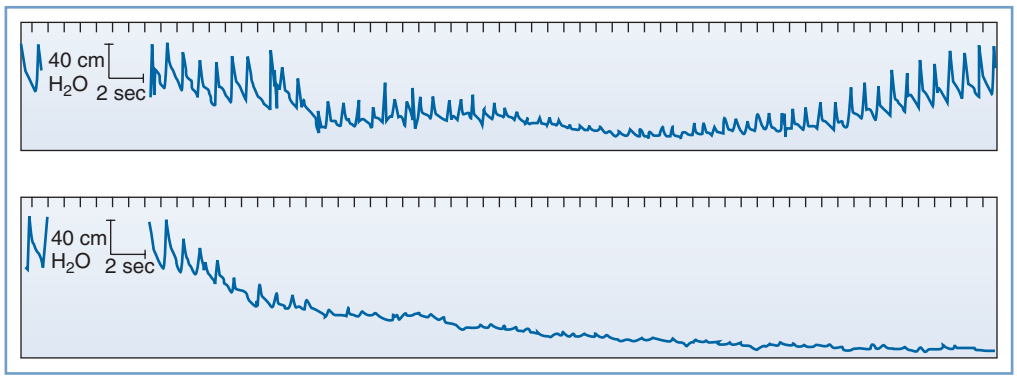

FIGURE 15-13 ■ Arterial tracings after rapid intravenous injection of 7.5 mL/kg of carbon dioxide (*top*) and helium (*bottom*). Recovery occurs within 1 minute after the carbon dioxide injection, but complete cardiovascular collapse occurs after the helium injection. (Modified from Wolf JS, Carrier S, Stoller ML. Gas embolism: helium is more lethal than carbon dioxide. J Laparoendosc Surg 1994; 4:173-7.)

General anesthesia can be provided by total intravenous anesthesia (TIVA) using propofol (titrated) and fentanyl (50 to 100 µg). Midazolam (1 to 2 mg) can be used as an optional premedication. With TIVA, most patients can be managed with spontaneous ventilation via high-flow oxygen mask and the use of carbon dioxide analysis.[40] (Individuals with significant risk factors for aspiration should undergo tracheal intubation with a cuffed endotracheal tube.) This anesthetic technique can produce mean bispectral index scores that range from 47 to 53 and modified Ramsay sedation scores that are consistent with general anesthesia[79] and results in greater patient satisfaction than MAC, owing to better pain relief and less awareness during the surgical procedure.[40] Alternatively, tracheal intubation and maintenance of anesthesia with a volatile halogenated agent has been used successfully; however, greater rates of nausea and emesis and more unplanned admissions have been observed with this technique than with a propofol, alfentanil, and air-oxygen mixture.[80]

Novel analgesic measures have been investigated during oocyte retrieval. One study evaluated electroacupuncture as an alternative to intravenous alfentanil, although both groups also received a paracervical block, and the acupuncture group experienced greater degrees of preoperative stress and longer periods of discomfort during oocyte aspiration.[81]

Embryo Transfer

Described as relatively painless, transcervical ET procedures are most commonly performed without analgesia or anesthesia; however, on rare occasion, intravenous sedation or regional or general anesthesia may be requested. In contrast, transabdominal gamete or embryo transfer procedures (i.e., GIFT, ZIFT) are usually performed via laparoscopy under local, neuraxial, or general anesthesia. The anesthetic management for these procedures and the associated concerns with regard to the laparoscopic technique and the Trendelenburg position are described here. Major intraoperative complications associated with laparoscopy are rare but include gastric or intestinal perforation, hemorrhage, pneumothorax, pneumopericardium, mediastinal emphysema, gas embolism, and cardiac arrest.[82]

Pneumoperitoneum and the Trendelenburg Position

Carbon dioxide is the gas most commonly used to establish pneumoperitoneum. The high blood solubility of carbon dioxide facilitates absorption from the peritoneal cavity after laparoscopic surgery and may represent a life-saving property of the gas in the rare but potentially catastrophic event of gas embolization. For example, rapid intravenous injection of 5 to 10 mL/kg of carbon dioxide produces only transient (<1 minute) hypotension in anesthetized dogs (Figure 15-13),[83] whereas intravascular administration of a similar volume of a less soluble gas (e.g., helium, oxygen, nitrogen) is usually fatal.

Signs of embolization of large quantities of carbon dioxide (or any other gas) in anesthetized patients may include hypocapnia, hypotension, hypoxemia, ST-segment and T-wave changes, arrhythmias, and audible changes in the heart sounds.[84] Initial treatment of carbon dioxide embolism should include release of the pneumoperitoneum and pharmacologic support of the circulation. If initial resuscitation efforts are unsuccessful, aspiration of gas from the right atrium (using a multi-orifice central venous catheter) should be considered. Although the use of the left lateral recumbent position (Durant's maneuver), with or without head-down positioning, has been suggested to facilitate removal of the postulated air lock from the right side of the heart,[85] laboratory evidence suggests that this maneuver may have a detrimental effect on cardiac function after venous gas embolism.[86]

Nearly as soluble in blood as carbon dioxide, nitrous oxide is associated with less peritoneal and diaphragmatic irritation[87] and has been suggested for the establishment of pneumoperitoneum in awake patients undergoing laparoscopy. A major disadvantage of nitrous oxide is its ability to support combustion, which could increase the possibility of an explosion if the surgeon uses electrocautery.

GIFT and ZIFT procedures are often performed with the patient in the Trendelenburg position to facilitate

visualization of the fallopian tubes and other pelvic structures. Although their use is controversial, shoulder braces placed to prevent the patient from moving cephalad on the operating table should be positioned with padding against the acromioclavicular joints to prevent brachial plexus damage. The adduction of the patient's arms against her trunk has been suggested to reduce the risk for a brachial plexus injury, but the efficacy of this precaution is unproven.

Both pneumoperitoneum and the Trendelenburg position produce physiologic changes. Hemodynamic effects of moderate pneumoperitoneum (< 20 mm Hg) in a patient in the Trendelenburg position include increased mean arterial and central venous pressures, increased systemic vascular resistance, and decreased stroke volume and cardiac output.[88] Heart rate usually does not change, but in some patients pneumoperitoneum may elicit sinus bradycardia, heart block, or even cardiac arrest. Finally, pneumoperitoneum aggravates the respiratory effects of the Trendelenburg position (e.g., reduced chest wall compliance, increased venous admixture). Overall, most healthy patients easily tolerate the cardiovascular and pulmonary effects of intra-abdominal pressures lower than 20 mm Hg.

Laparoscopic-Assisted Reproductive Technology

The anesthetic plan for GIFT procedures is typically dictated by the method (i.e., transabdominal or transvaginal) of oocyte retrieval. Many ART programs harvest oocytes transabdominally during pelvic laparoscopy, the principal advantage being that the patient is positioned and anesthetized once for both the retrieval and transfer portions of the procedure. The major disadvantage of this technique is that oocytes are exposed to both carbon dioxide pneumoperitoneum and anesthetic agents. The induction of general anesthesia for GIFT procedures can be delayed until just before the skin incision in an effort to minimize unnecessary exposure to these agents. Induction is usually performed with intravenous propofol, lidocaine, fentanyl, and either succinylcholine or rocuronium. After tracheal intubation, the anesthesia provider may decompress the patient's stomach with a suction catheter or Salem sump tube to reduce the risk for gastric perforation during instrumentation. Subsequently, a volatile halogenated agent in oxygen and air, with or without a short-acting muscle relaxant, is given to maintain anesthesia. The use of a propofol–nitrous oxide technique has been associated with less postoperative sedation, lower pain scores, and less emesis than an isoflurane–nitrous oxide technique.[50]

Alternatively, oocytes can be retrieved transvaginally and transferred—as oocytes or embryos—laparoscopically. Of interest, this is the technique most commonly used with ZIFT procedures, whereby oocyte retrieval and IVF occur on the day before the ZIFT procedure. Advantages to the combined transvaginal/transabdominal approach include (1) the avoidance of laparoscopy in the 1% to 2% of cases in which oocyte quality or number is inadequate to justify proceeding with a tubal transfer[3] and (2) the elimination of oocyte exposure to the carbon dioxide pneumoperitoneum. Disadvantages of this method include (1) the need to reposition the patient before laparoscopy and (2) a prolonged total operative time if performed on the same day (GIFT) or the need for a second procedure if performed on consecutive days (ZIFT).

A few patients prefer spinal or epidural anesthesia for GIFT procedures.[89,90] Healthy, nonobese patients have been reported to successfully undergo laparoscopic surgery in the Trendelenburg position with high thoracic (i.e., T2 to T4) spinal or epidural anesthesia.[89-92] Limiting intraperitoneal pressure to less than 10 mm Hg may facilitate the use of neuraxial anesthesia for these procedures. Obese women are not ideal candidates for neuraxial anesthesia in laparoscopic surgery.

Adequate analgesia for laparoscopic ART procedures has also been reported with the use of local anesthesia supplemented with intravenous sedation.[93-96] Padilla et al.[93] observed that the quality of intraoperative analgesia can be improved by limiting maximal intra-abdominal pressure to 8 to 10 mm Hg, reducing the rate of carbon dioxide insufflation to 1 L/min, and minimizing ovarian manipulation. The difficulty and pain frequently associated with cannulation of the fallopian tubes, however, may make local anesthesia an unwise choice for laparoscopic ART procedures. Waterstone et al.[94] noted that all 21 patients undergoing local anesthesia for laparoscopy experienced some discomfort when their fallopian tubes were mobilized. The use of local anesthesia should not be interpreted as being devoid of risk for serious complications (e.g., bradycardia, cardiac arrest). These life-threatening complications are rare, but the management and outcome are greatly assisted by individuals skilled in airway management and cardiopulmonary resuscitation.[97]

Postoperative Management

The incidence of anesthetic or surgical complications requiring hospital admission after ART procedures is low. Oskowitz et al.[72] reported admission rates after oocyte retrieval and GIFT procedures of 0.16% and 0.18%, respectively. The most common indications for hospitalization were hemoperitoneum and syncope after oocyte retrieval, and nausea, vomiting, and bowel injury after laparoscopic GIFT procedures. Abdominal pain and uterine cramping occur commonly after oocyte retrieval. Incisional pain and referred shoulder pain as a result of diaphragmatic irritation can also occur after laparoscopic ART procedures. Postprocedural discomfort is related primarily to the number of follicles retrieved (rather than the hormonal alterations induced by the stimulation cycle); and when it follows an anesthetic regimen that includes an opioid, it is graded as minimal to moderate. Abdominal discomfort can be managed with the use of a heating pad and small doses of intravenous fentanyl (25 to 50 μg) or oral analgesic agents (acetaminophen 500 mg to 1 g).[98] The use of nonsteroidal anti-inflammatory drugs should be avoided because changes in the prostaglandin milieu can affect embryo implantation.[99]

Nausea and emesis can also occur; however, exposure to droperidol and metoclopramide should be limited (see earlier discussion); treatment with nondopaminergic

agents can be considered. Prior to discharge, patients should be able to drink and retain liquids, ambulate, and void. Patients undergoing anesthesia for an ART procedure should be called 24 hours after the procedure to allow assessment of recovery and potential complications.

FUTURE CONSIDERATIONS

The use of ART procedures has been extended to include patients within a broader range of ages and co-morbidities. Check et al.[100] reported the successful delivery of infants through the use of donor oocytes, IVF, and ET in two postmenopausal women who were 51 years old; women in the seventh decade have also successfully delivered infants. In addition, more programs are participating in the preservation of ovarian tissue, as a means of extending reproductive capability. Future studies should assess the short- and long-term maternal and perinatal consequences of ART procedures as well as the obstetric and anesthetic implications.[101]

Technical improvements in ultrasonography as well as fiberoptic methods of oocyte retrieval and fallopian tube cannulation could potentially make laparoscopic interventions less invasive or unnecessary. For example, small-diameter laparoscopes with optical views comparable to conventional instruments have allowed "mini-laparoscopic" procedures to be performed for GIFT procedures.[96] These alterations may allow for changes in anesthetic options.

The identification of agents and techniques that provide optimal analgesia or anesthesia with negligible impact on ART success is an important process to which anesthesia providers can and should contribute.

KEY POINTS

- Assisted reproductive technology (ART) includes techniques that are being applied to an increasingly diverse population of patients with a wide range of co-morbidities.
- ART procedures usually involve a regimen of hormonal stimulation and oocyte retrieval followed by either *in vitro* fertilization with embryo transfer (IVF-ET) or gamete intrafallopian transfer (GIFT) procedures.
- Hormonal stimulation creates a number of oocytes for retrieval. On occasion, ovarian hyperstimulation syndrome can occur, with severe cases being associated with ascites, pleural effusion, hemoconcentration, oliguria, and thromboembolic events.
- Oocyte retrieval must be performed promptly, or ovulation will reduce the number of mature oocytes available for harvesting. Embryo transfer usually occurs transcervically; however, laparoscopic techniques (zygote intrafallopian transfer [ZIFT]) can be used.
- Monitored anesthesia care (MAC), neuraxial anesthesia, and general anesthesia have all been used successfully to anesthetize women for ART procedures. MAC may have to progress to loss of consciousness (i.e., general anesthesia) to prevent patient movement at critical times during the procedure.
- Laboratory studies have suggested that local anesthetic agents, nitrous oxide, and the volatile halogenated agents interfere with some aspects of reproductive physiology *in vitro*. However, few clinical data show that brief administration of any contemporary anesthetic agent (except halothane) for an ART procedure adversely affects live-birth rates.
- The identification of agents and techniques that provide optimal analgesia or anesthesia with negligible impact on ART success is an important process to which anesthesia providers can and should contribute.

CHAPTER 16

Problems of Early Pregnancy

Katherine W. Arendt, MD

CHAPTER OUTLINE

Obstetric disease of early pregnancy may result in significant maternal morbidity and even mortality. Safe care of patients with obstetric disease involves a thorough understanding of the physiologic changes of early pregnancy as well as the specific issues associated with each pathologic condition.

PHYSIOLOGIC CHANGES OF EARLY PREGNANCY

Respiratory System

The respiratory system undergoes profound physiologic changes during early pregnancy. Increased progesterone concentration stimulates respiratory efforts by increasing the sensitivity of the respiratory center to carbon dioxide. Minute ventilation increases by at least 15% by 12 weeks' gestation and by 25% by 20 weeks' gestation. This results from an increase in tidal volume (respiratory rate is unchanged) and exceeds the increase in oxygen consumption. The result is a respiratory alkalosis with maternal arterial partial pressure of carbon dioxide decreasing to 30 to 33 mm Hg by 10 to 12 weeks' gestation. Moreover, maternal arterial partial pressure of oxygen increases to 106 to 108 mm Hg in the first trimester. Decreased bicarbonate concentration partially compensates for the modest respiratory alkalosis that results from the physiologic hyperventilation, leading to a maternal pH that is slightly above normal (i.e., approximately 7.44). There is little or no change in lung capacities during the first half of pregnancy. Women in early pregnancy who undergo mechanical ventilation require increased minute ventilation.

Cardiovascular System

The cardiovascular system also undergoes profound changes early in pregnancy. Cardiac output increases 20% to 25% by 8 weeks' gestation and 35% to 40% by 20 weeks' gestation. Systemic vascular resistance decreases 30% by 8 weeks' gestation. Maternal mean arterial pressure decreases approximately 6 mm Hg at 16 to 24 weeks' gestation and returns to normal near term.

Aortocaval compression typically occurs after 18 to 20 weeks' gestation, when the uterine fundus reaches the umbilicus and is large enough to compress the aorta and vena cava when the patient is supine. Left uterine displacement is rarely needed in early pregnancy, but when the uterine size is equivalent to an 18- to 20-week gestation, left uterine displacement should be attained by elevating the right hip 15 degrees off midline with a wedge or blankets. The need for left uterine displacement occurs earlier in gestation in the presence of multiple gestation, polyhydramnios, or gestational trophoblastic disease.

Blood volume increases throughout pregnancy; the average prepregnancy blood volume of 4350 mL (76 mL/kg) increases to 4700 mL (81 mL/kg) at 12 weeks' gestation, to 5500 mL (89 mL/kg) at 20 weeks' gestation, and

to approximately 6600 mL (97 mL/kg) at term. The increase in blood volume is primarily the result of greater plasma volume because red blood cell volume increases to a smaller degree (27 mL/kg). Because pregnant women have an expanded blood volume, they typically tolerate a blood loss of 500 to 1500 mL during the first half of pregnancy. A blood loss of 500 to 1500 mL rarely requires blood transfusion, provided that the blood loss is replaced with an adequate volume of crystalloid or colloid.

Gastrointestinal System

An increased progesterone level causes relaxation of lower esophageal sphincter tone as early as the first trimester. Fasting gastric volume is approximately 30 mL in both nonpregnant women and women in early pregnancy. Metoclopramide 10 mg, administered intravenously 15 to 30 minutes before anesthesia, can reduce this volume by 50%.[1] In a study of 100 pregnant women undergoing general anesthesia by mask at 6 to 22 weeks' gestation, a pH electrode showed reflux of gastric contents into the esophagus in 17% of patients.[2] Most episodes of reflux occurred in patients who experienced hiccups. Only 2% had regurgitation of gastric contents into the pharynx, and no patient demonstrated clinical evidence of pulmonary aspiration.

General anesthesia may be safely administered by means of a mask or a laryngeal mask airway by experienced anesthesia providers in selected obstetric patients during early pregnancy. Many anesthesia providers are comfortable managing an airway without tracheal intubation until 18 to 20 weeks' gestation, when the uterus moves out of the pelvis. The latter movement leads to anatomic and intragastric pressure changes that predispose to gastroesophageal reflux. Some anesthesia providers prefer to intubate the trachea of pregnant women who require general anesthesia as early as 12 to 14 weeks' gestation, given that hormonal changes leading to sphincter relaxation are present early in pregnancy. Patients who receive general anesthesia during the first half of pregnancy should be intubated if they are at increased risk for gastric content aspiration (e.g., history of gastroesophageal reflux, morbid obesity, food ingestion within 6 to 8 hours). Pharmacologic prophylaxis (e.g., sodium citrate, a histamine-2 (H_2) receptor antagonist, and/or metoclopramide) is likely to further reduce the risk for aspiration pneumonia (see Chapter 29). Neuraxial anesthesia is associated with a lower risk for aspiration than general anesthesia.

Nervous System

During early pregnancy, the nervous system is more sensitive to general and local anesthetic agents. The minimum alveolar concentration (MAC) for volatile anesthetic agents is decreased by approximately 30%, although the underlying mechanism for this change is unclear. A recent study that compared patients undergoing cesarean delivery with nonpregnant patients undergoing elective gynecologic surgery found no difference between groups in electroencephalographic measures during general anesthesia with similar end-tidal concentrations of sevoflurane.[3] Because it is well-proven that MAC decreases in pregnancy, this study implies that MAC in pregnant women may not correlate well with depth of anesthesia. Further research is needed in this area.

ECTOPIC PREGNANCY

Ectopic pregnancy occurs when the fertilized ovum implants outside the endometrial lining of the uterus. Death, infertility, and recurrent ectopic pregnancy are possible sequelae. The frequency of ectopic pregnancy in the United States increased fourfold to fivefold between 1970 and 1992 but appears to have stabilized at a rate of approximately 16 per 1000 pregnancies.[4,5] A higher prevalence of associated risk factors, especially pelvic inflammatory disease, as well as earlier diagnosis of previously unrecognized ectopic pregnancies may account for the reported increase.

Ruptured ectopic pregnancy is a leading cause of pregnancy-related maternal death during the first trimester and accounts for 6% of all pregnancy-related maternal deaths in the United States.[6,7] Most deaths result from hemorrhage (93%); infection (2.5%), embolism (2.1%), and anesthetic complications (1.3%) are less common causes.[8] More than 30% of women who have had an ectopic pregnancy subsequently suffer from infertility, and 5% to 23% have a second ectopic pregnancy.[9]

The number of deaths from ectopic pregnancy decreased in the United States from 1970 through 2007. The case-fatality rate decreased from 35.5 deaths per 10,000 ectopic pregnancies in 1970 to 3.8 per 10,000 in 1989,[10] and the ectopic pregnancy mortality ratio decreased from 1.15 deaths per 100,000 live births in 1980 through 1984 to 0.5 death per 100,000 live births in 2003 through 2007.[11] The U.S. Centers for Disease Control and Prevention attributes this decline to "improvements in the sensitivity, accuracy, and use of pregnancy testing, ultrasound for diagnosis, and improvements in therapeutic modalities, including laparoscopic surgery and medical management of ectopic pregnancy."[12] However, a recent cluster of 11 maternal deaths from ectopic pregnancy in Florida between 2009 and 2010 increased Florida's ectopic pregnancy mortality ratio from 0.6 death per 100,000 live births in 1999 through 2008 to 2.5 deaths per 100,000 live births in 2009 through 2010.[12] Because these women collapsed (likely from acute rupture and hemorrhage) without ever seeking health care, it was believed that limited access to early care may have contributed to the adverse outcomes. Further, of the 11 women who died, 6 tested positive for illicit drugs at autopsy. Ectopic pregnancy deaths historically have been more common in teenagers[10] and are 3 to 18 times higher in African-American women than in white women.[6,8,10]

Factors that alter the normal fallopian tube transport system for the fertilized ovum increase the risk for ectopic pregnancy. These factors include (1) previous ectopic pregnancy; (2) previous tubal surgery; (3) pelvic inflammation, especially infection with *Chlamydia trachomatis;* (4) congenital anatomic distortion such as that caused by

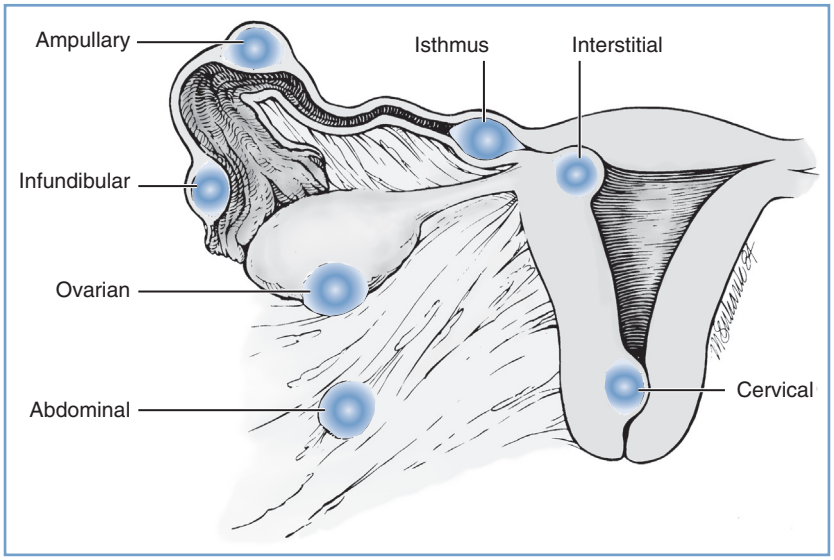

FIGURE 16-1 ■ **Potential locations of ectopic pregnancies. The majority occur in the ampullary portion of the fallopian tube.** (Reprinted from Chantigian RC, Chantigian PDM. Problems in early pregnancy. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009. Modified from DeCherney AH, Seifer DB. Ectopic pregnancy. In Gabbe SG, Niebyl JR, Simpson JL, editors. Obstetrics: Normal and Problem Pregnancies. 2nd edition. New York, Churchill Livingstone, 1991:811.)

exposure to diethylstilbestrol *in utero;* (5) previous pelvic or abdominal surgery; (6) use of a contraceptive intrauterine device, which may be associated with interstitial ectopic pregnancy; (7) delayed ovulation; (8) hormonal changes associated with ovulation induction or progestin-only oral contraceptives; (9) lifestyle factors (e.g., smoking, vaginal douching); (10) history of infertility; and (11) assisted reproductive technology (ART) procedures (e.g., zygote transfer into the fallopian tube or uterine cavity).[13] However, one third of patients with ectopic pregnancies have no identifiable risk factors.

The fertilized ovum can implant anywhere along the path of migration or in the abdominal cavity (Figure 16-1). Most ectopic pregnancies (98%) are **tubal** (infundibular or fimbrial, 6%; ampullary, 78%; isthmic, 12%; interstitial or cornual, 2%). The remaining 2% implant on the **cervix, vagina,** or **ovary** or elsewhere in the **abdomen.**[14] An increasing number of **cesarean scar** ectopic pregnancies, which may be on a continuum with **early placenta accreta,** are being reported.

In patients who undergo ART procedures, ectopic pregnancies have been reported in approximately 2% of pregnancies.[13] Most of these pregnancies are tubal; however, approximately 6% are ovarian, abdominal, or cervical, and 12% to 15% are **heterotopic** (see later discussion).[14]

Clinical Presentation

The clinical presentation of the patient with an ectopic pregnancy depends on the gestational age, site of implantation, and extent of hemorrhage. Prior to rupture, the signs and symptoms are often subtle. Classic clinical signs of impending rupture or a ruptured tubal pregnancy include abdominal or pelvic pain (95%), delayed menses (75% to 95%), and vaginal bleeding (60% to 80%). Vaginal bleeding results from the breakdown and shedding of the decidual lining of the uterine wall, which is probably associated with decreased hormone production by the corpus luteum and inadequate human chorionic gonadotropin (hCG) production by the ectopic trophoblast. Pain often precedes vaginal bleeding. Patients with hemorrhage (with or without tubal rupture) may experience dizziness or syncope, may have the urge to defecate because of the effect of blood in the cul-de-sac, and may have shoulder pain from diaphragmatic irritation by intra-abdominal blood.

Physical findings include abdominal tenderness with or without rebound (80% to 95%), a uterus that is smaller than expected for dates (30%), and a tender adnexal mass (30% to 50%). A bulging cul-de-sac suggests hemoperitoneum. With significant hemorrhage there may be signs of shock, but some patients may appear hemodynamically stable despite a hemoperitoneum volume of 1000 to 1500 mL; presumably, these patients have an ectopic pregnancy with slow bleeding and are able to compensate for the gradual blood loss.

Diagnosis

Ectopic pregnancy should be excluded in any patient who has pelvic pain and a positive pregnancy test. In a woman of reproductive age, the symptoms of ectopic pregnancy must be differentiated from (1) a threatened, inevitable, or incomplete abortion; (2) infection after attempted abortion; (3) pelvic inflammatory disease; (4) a degenerating fibroid; (5) appendicitis and other gastrointestinal diseases; (6) ovarian torsion; (7) a ruptured or bleeding ovarian cyst; (8) a trapped retroverted uterus in pregnancy; and (9) nephrolithiasis.

Current tests allow early diagnosis of ectopic pregnancy and prompt treatment that decreases morbidity and mortality.[9] Diagnostic algorithms include the following guidelines:

1. Ultrasonography can reliably confirm only the presence of an intrauterine pregnancy. The ectopic pregnancy itself may be difficult to visualize.[15] **Transvaginal ultrasonography** is the current modality of choice because it can detect an intrauterine gestational sac as soon as 21 days after conception (when the beta-hCG concentration is greater than 1400 mIU/mL with use of the International Reference Preparation [IRP] standard). **Transabdominal ultrasonography** can visualize an intrauterine pregnancy when the serum beta-hCG concentration is higher than 6000 to 6500 mIU/mL IRP.[16]
2. A serial beta-hCG concentration that decreases, plateaus, or shows a subnormal increase (< 53% over 48 hours) usually indicates a nonviable pregnancy—either an ectopic pregnancy or an impending abortion.[17] With a spontaneous abortion, a decline in beta-hCG concentration of at least 21% to 35% should be seen over 2 days. A slower decline is suggestive of an ectopic pregnancy. A beta-hCG concentration greater than 100,000 mIU/mL is usually associated with a viable intrauterine pregnancy.[18]
3. A serum progesterone concentration greater than 25 ng/mL is usually associated with a viable pregnancy. A concentration less than or equal to 5 ng/mL usually indicates a nonviable pregnancy but cannot distinguish a spontaneous abortion from an ectopic pregnancy.[19] Most ectopic pregnancies are associated with progesterone levels between 5 and 25 ng/mL, a fact that limits the usefulness of this test.
4. Uterine curettage can be performed when nonviability is established. Identification of trophoblastic villi confirms miscarriage of an intrauterine pregnancy. Absence of villi signals either a complete spontaneous abortion (confirmed by rapidly decreasing beta-hCG concentration) or an ectopic pregnancy.

In the past, culdocentesis was used to aid in the diagnosis of hemoperitoneum and ectopic pregnancy. Although a positive result is highly predictive of hemoperitoneum, the advent of pelvic ultrasonography and rapid quantitative beta-hCG tests limits its value in the diagnosis of ectopic pregnancy.

Obstetric Management

Management options for ectopic pregnancy are expectant, medical, and surgical. Management choice depends on the symptoms and diagnostic findings.

Expectant management may be used for selected asymptomatic patients with early tubal ectopic pregnancies and stable or decreasing beta-hCG levels. Successful resolution has been reported in approximately 50% of these selected patients.[4] If expectant management is unsuccessful, a medical or surgical approach is required.

The American College of Obstetricians and Gynecologists (ACOG) as well as the American Society of Reproductive Medicine have published guidelines for the **medical management** of ectopic pregnancy.[20,21] Systemic, intramuscular, oral, and intragestational forms of chemotherapy have been used successfully in the medical management of ectopic pregnancy. **Methotrexate,** a folate antagonist that interrupts DNA synthesis and thus cell replication, inhibits growth of trophoblastic cells of the placenta and is commonly used to treat ectopic pregnancy. Because methotrexate is toxic to all rapidly-dividing tissues of the body, there are many contraindications to medical treatment of ectopic pregnancy, including immunodeficiency and pulmonary, liver, renal, or hematologic disease. Further, the ACOG has recommended that only early tubal pregnancies (i.e., no cardiac activity, a gestational sac with a diameter < 3.5 to 4.0 cm, and no evidence of tubal rupture or hemoperitoneum) be treated with methotrexate.

Methotrexate treatment protocols include a single-dose regimen, a two-dose regimen, and a fixed multidose regimen; the multidose regimen is reserved for patients with high beta-hCG levels (i.e., > 5000 mIU/mL). From day 4 to day 7 after methotrexate treatment, a decrease in beta-hCG level of 15% must be present to consider the treatment successful. Otherwise, repeat methotrexate treatment or surgical intervention is required. Follow up and close monitoring until beta-hCG level reaches nonpregnant values is imperative because of the risk for rupture and hemorrhage. Side effects of methotrexate can be severe and include abdominal pain, vomiting, stomatitis, severe neutropenia, and pneumonitis. Compared with surgical management, medical management of ectopic pregnancy provides no difference in overall tubal preservation, tubal patency, risk for repeat ectopic pregnancy, or success of future pregnancies.

Surgical management depends on the location of the pregnancy, the hemodynamic stability of the patient, the available equipment, and the surgeon's expertise. Most often, diagnostic laparoscopy is performed to confirm the diagnosis and locate the ectopic pregnancy. For tubal ectopic pregnancies, a salpingostomy, salpingotomy, or salpingectomy (usually partial) is performed by means of laparoscopy or laparotomy. To aid hemostasis during laparoscopic removal of the ectopic pregnancy, some obstetricians inject dilute vasopressin into the surface of the fallopian tube. This agent causes marked blanching of the tube and results in a relatively bloodless surgical field. If the vasopressin is accidentally injected intravenously, a marked increase in maternal blood pressure may occur.

A laparotomy is indicated if the surgeon is not trained in operative laparoscopy, laparoscopic removal is anticipated to be difficult (e.g., tube diameter > 6 cm or an interstitial location of the ectopic pregnancy), or there is uncontrollable bleeding. Laparotomy should be performed immediately if there is hemodynamic instability; these cases often require a partial or total salpingectomy. If a partial salpingectomy is performed, tubal repair may be performed primarily or during a second operation. Although some experts have noted that outcomes from randomized trials comparing salpingostomy and salpingectomy are lacking,[22] the risk for persistent ectopic pregnancy may be higher after salpingostomy than after salpingectomy.[23]

Interstitial, cervical, cesarean scar, and abdominal ectopic pregnancies as well as early placenta accreta may

present significant diagnostic and therapeutic challenges, resulting in delay of diagnosis and treatment. There is potential for massive hemorrhage because of disruption of organs and adjacent tissues. The desire to preserve fertility may result in greater blood loss as tissue and organ preservation are attempted.

Interstitial pregnancy often goes unrecognized and may manifest as uterine wall rupture, massive hemorrhage, and shock. Conservative surgery (e.g., cornual resection) may be attempted, but hysterectomy may be required if uterine damage is severe.

Cervical pregnancy often results in massive hemorrhage because of the inability of the cervix to contract. In the past, most cervical pregnancies necessitated hysterectomy to control hemorrhage. More current management options that have greater likelihood of maintaining fertility include (1) methotrexate therapy, (2) local excision, (3) cerclage and tamponade, (4) ligation of the hypogastric arteries or the cervical branches of the uterine arteries, and (5) angiographic embolization of the uterine arteries followed by a dilation and evacuation (D and E) procedure (see later discussion).[24]

Cesarean scar pregnancy occurs when a gestational sac implants in the uterine scar defect (niche) at the site of a previous cesarean delivery. Cesarean scar pregnancy has a high complication rate. Although relatively rare, its incidence is rising with increasing cesarean delivery rates and currently may be as high as 1 in 1800 pregnancies.[25,26] Jurkovic et al.[26] described two types of cesarean scar pregnancies: (1) implantation on the scar with enlargement into the uterine cavity, and (2) implantation into a scar defect with growth into the myometrium. Depending on its progression, the former type may grow normally or may be treated medically. Scar implantation results in an increased risk for hemorrhage at delivery. Growth into the myometrium may lead to eventual rupture and bleeding in the first trimester; prompt surgical intervention is preferred over medical management in this situation.

In a review of 112 cases of cesarean scar pregnancies, Rotas et al.[25] found that approximately half occurred in women with only one previous cesarean delivery. Many patients have vaginal bleeding, abdominal cramps, and/or lower abdominal pain. Up to one third of cases may be asymptomatic and are diagnosed during routine ultrasonography. A review of 751 published cases of cesarean scar pregnancy found that the diagnosis was missed in 107 of 751 cases (13.6%).[27] Transvaginal ultrasonography was the best diagnostic tool. There were a total of 31 different primary treatment approaches, which included hysterectomy, dilation and curettage (D and C), hysteroscopic excision, uterine artery embolization, and intragestational aspiration or injection of methotrexate or potassium. Complications occurred in 331 of the 751 cases (44.1%), of which the most common was hemorrhage. The authors noted that local methotrexate and hysteroscopic-directed procedures had the lowest complication rates and that curettage, systemic methotrexate therapy, or embolization as single treatments should be avoided.

The incidence of **early placenta accreta** is also rising as a result of increasing cesarean delivery rates. It is defined as penetration of the placenta into the myometrium, which is discovered in the first or early second trimester. Because of similarities in pathogenesis, it is thought—although not confirmed—that early placenta accreta may develop from cesarean scar pregnancy. A recent review found that 15 of 47 (32%) patients with early placenta accreta had spontaneous uterine rupture, in most cases followed by bleeding and shock, which resulted in laparotomy, hysterectomy, or uterine artery embolization.[27] Although the gestational age is early, it is imperative that the anesthesia team is aware of the risk for hemorrhage during surgical intervention for cesarean scar pregnancy and early placenta accreta.

Abdominal pregnancy is defined as implantation in the peritoneal cavity, not including the fallopian tubes, ovaries, or ligaments, and is associated with a high incidence of maternal morbidity and fetal demise.[28] In a recently published series of advanced extrauterine pregnancies, Worley et al.[29] identified ten women who presented with extrauterine pregnancies beyond 18 weeks' gestation, of whom three met the diagnostic criteria for abdominal pregnancy. All patients had difficult surgery, nine patients required blood transfusion, and only five fetuses survived after complicated courses.

Diagnosis of abdominal pregnancy can be difficult, historically being missed in as many as one of nine cases.[28] The diagnosis was missed prior to delivery in four of the ten cases in the series of Worley et al.[29] Abdominal pain, vaginal bleeding, symptoms consistent with partial bowel obstruction, shock, or death may be the first indication of this unusual type of pregnancy. Ultrasonography is useful but may miss the diagnosis in more than 50% of cases. Magnetic resonance imaging may prove to be a more sensitive diagnostic tool.

If an extrauterine pregnancy is suspected in early gestation, laparoscopy can be used to diagnose and remove gestational products. If the extrauterine pregnancy is not identified until late gestation, it is associated with decreased placental perfusion (which typically results in fetal growth restriction) and oligohydramnios (which often results in pulmonary hypoplasia and anatomic deformities). In 1993, Stevens[30] reviewed published cases of abdominal pregnancy since 1809 and found that 63% of infants survived when born after 30 weeks' gestation.

Management of an advanced extrauterine pregnancy consists of laparotomy and delivery of the fetus. Once the fetus is delivered, management of the placenta is controversial and fraught with hazard. Removal of the placenta is associated with massive hemorrhage, prolonged and complicated surgery (e.g., bowel resection), and an increased risk for maternal mortality. A decision to leave the placenta *in situ* results in a higher risk for infectious morbidity as well as a potential greater need for additional surgery.[30,31] In the series of Worley et al.,[29] the placenta was left *in situ* in two patients, both of whom developed serious complications. The site of placental implantation and the ability to adequately ligate the blood supply often dictates the obstetrician's decision about management of the placenta.

Heterotopic pregnancy describes the simultaneous occurrence of an ectopic and an intrauterine pregnancy.

Historically, it was thought to occur in 1 in 30,000 spontaneous pregnancies.[32] However, in patients undergoing ART, 0.2% to 3% of pregnancies may be heterotopic.[14,33] Difficulty visualizing the entire fallopian tube on ultrasonography, combined with normal or slightly elevated beta-hCG measurements (i.e., low serum levels from the ectopic pregnancy combined with normal levels from the intrauterine pregnancy), make the early diagnosis of heterotopic pregnancy difficult.[34] This diagnosis should be suspected in cases in which clinical signs of an ectopic pregnancy and a confirmed intrauterine pregnancy coexist. In most cases, the ectopic pregnancy is removed surgically, which can be difficult when trying to maintain the intrauterine pregnancy. Alternatively, transvaginal ultrasonography–guided injection of potassium chloride into the ectopic pregnancy has been performed successfully; however, as many as 55% of patients may require subsequent surgery.[35] The patient often sustains the normal intrauterine pregnancy to term.

Patients with ectopic pregnancies who are Rh-negative should receive Rh_0(D) immune globulin.[36]

Anesthetic Management

Patients with an unruptured tubal pregnancy usually have normal intravascular volume, minimal bleeding before and during surgery, and low anesthetic and surgical risk. Anesthetic considerations for laparoscopy or laparotomy are summarized in Box 16-1. Although most patients may prefer general anesthesia, neuraxial anesthesia with an upper sensory level to at least T4 may be an alternative in selected patients. Shoulder pain from diaphragmatic irritation may occur and can be treated with intravenous analgesics (e.g., fentanyl 1 to 2 μg/kg).

A ruptured ectopic pregnancy may be associated with significant preoperative blood loss, but estimation of the extent of this is difficult because young women may have normal blood pressure despite a markedly reduced circulating blood volume. General anesthesia, with preparation for hemorrhage, is preferred if significant bleeding has occurred (e.g., ruptured tubal pregnancy) or is likely to occur (e.g., cervical, interstitial, cornual, cesarean scar, or abdominal ectopic pregnancy, or early placenta accreta). Intraoperative autologous blood transfusion can be used, and it may be useful especially in developing countries, where blood bank supplies are limited and women typically present late with significant hemoperitoneum and/or hypovolemic shock.[37] The desire to preserve fertility often results in greater blood loss as tissue and organ preservation are attempted.

BOX 16-1 Suggested Anesthetic Techniques for Laparoscopy or Laparotomy for Patients with Ectopic Pregnancy

General Considerations

- Blood typing and antibody screening
- Aspiration prophylaxis if patient has a full stomach
- Routine noninvasive monitors
- Large-bore peripheral intravenous catheter
- Urinary catheter
- If major bleeding has occurred or is expected to occur (e.g., ruptured tubal, interstitial, cervical, uterine scar, or abdominal ectopic pregnancy):
  - Two or more intravenous catheters
  - Typing and crossmatching of blood
  - Consideration of invasive hemodynamic monitoring (e.g., arterial catheter, central venous pressure catheter)
  - Consideration of intraoperative cell salvage
- Although general anesthesia is usually preferred, neuraxial (spinal or epidural) anesthesia may be considered for hemodynamically stable patients with a low likelihood of significant hemorrhage (i.e., unruptured tubal pregnancy):
  - Intravenous fluids, vasopressors, supplemental oxygen, and minimal sedation given as clinically indicated.

General Anesthesia

- Rapid-sequence induction with cricoid pressure if the patient has a full stomach
- Induction: propofol or thiopental (ketamine or etomidate should be considered if patient is hemodynamically unstable)
- Muscle relaxant
- Tracheal intubation
- Maintenance: volatile or intravenous anesthetic agents
- Placement of an oral gastric tube, performance of suctioning, and removal of the tube
- Reversal of neuromuscular blockade and extubation when the patient is awake and responds to verbal commands

Spinal Anesthesia

- Single injection with a small-gauge spinal needle: hyperbaric bupivacaine 12 mg with fentanyl 10 to 25 μg to achieve T4 sensory blockade

Epidural Anesthesia

- Placement of midlumbar epidural needle and catheter
- Lidocaine 2% with epinephrine 5 μg/mL (1:200,000), approximately 20 mL, and fentanyl 100 μg, injected incrementally, to achieve T4 sensory blockade

Modified from Chantigian RC, Chantigian PDM. Problems in early pregnancy. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

ABORTION AND INTRAUTERINE FETAL DEMISE

Abortion refers to a pregnancy loss or termination, either before 20 weeks' gestation or when the fetus weighs less than 500 g. It can occur spontaneously or may be performed electively for personal or medical reasons. A total of 825,564 elective abortions were reported in the United States in 2008, a rate of 16 abortions per 1000 women and a ratio of approximately 234 abortions per 1000 live births.[38] The total number of abortions and rate of abortions (number of abortions per 1000 women) in the United States steadily declined from 1999 through 2007 and then remained static from 2007 to 2008.[38] Between

1999 and 2008, the number, rate, and ratio (number per 1000 live births) of elective abortions in the United States declined by 3%, 4%, and 10%, respectively.[38]

In 2008, 62.8% of elective abortions were performed before 8 weeks' gestation, 91.4% were performed before 13 weeks' gestation, and 1.3% were performed after 21 weeks' gestation.[38] Most (75.9%) were performed by D and C at less than 13 weeks' gestation, although some (14.6%) were induced medically, most commonly using methotrexate and misoprostol, or mifepristone and misoprostol before 8 weeks' gestation.[38]

Of the 4693 reported pregnancy-related maternal deaths from 1998 to 2005 in the United States, 3% were the result of induced or spontaneous abortion.[39] Deaths are usually the result of sepsis, hemorrhage, or embolism.[40] Of the 20 abortion-related maternal deaths in the United States in 2003, 10 were related to spontaneous abortion and 10 women died after legal elective abortion (6 after surgical procedures and 4 after medical or nonsurgical procedures).

From a global perspective, abortion is a significant cause of maternal death. A review of causes of maternal death from 1997 to 2002 by the World Health Organization (WHO) reported that in some areas of Latin America and the Caribbean as many as 30% of maternal deaths are caused by abortion.[41] In 2006, the WHO estimated that 12, 23, and 37 maternal deaths per 100,000 live births occur as a result of induced abortion in South Asia, Latin America/Caribbean, and sub-Saharan Africa, respectively.[41] It is likely that many of these abortions are performed by unskilled individuals in a nonsterile environment that does not meet minimal medical standards. The exact number of maternal deaths that result from induced abortion is unknown and likely underreported.[41,42]

Spontaneous abortion occurs in 10% to 15% of clinically recognized pregnancies; when subclinical pregnancies are also considered, the incidence of spontaneous pregnancy loss may be as high as 60%.[43] Although most spontaneous abortions manifest clinically at 8 to 14 weeks' gestation, ultrasonography suggests that fetal demise usually occurs before 8 weeks' gestation. If the fetus is viable at 8 weeks' gestation, the incidence of subsequent fetal loss is only 3%.

The etiology of spontaneous abortion varies among patients. Chromosomal abnormalities are responsible for at least 50% to 80% of all spontaneous abortions.[44] Other causes include (1) immunologic mechanisms, (2) maternal infections, (3) endocrine abnormalities (e.g., poorly-controlled diabetes mellitus), (4) uterine anomalies, (5) incompetent cervix, (6) debilitating maternal disease, (7) maternal clotting disorders, (8) trauma, and possibly (9) environmental exposures (e.g., irradiation, smoking, certain drugs).

Although some studies (conducted before scavenging of anesthetic gases was routine) suggested a higher incidence of spontaneous abortion among women who were exposed to trace concentrations of anesthetic agents in operating rooms,[45] reevaluation of these data demonstrated significant flaws in study design, casting doubt on the original conclusions.[46] Later studies have shown no increased incidence of spontaneous abortion in women working in operating rooms.[47]

Clinical Presentation and Obstetric Management

The clinical presentation and management of spontaneous abortion vary. A **threatened abortion** is defined as uterine bleeding without cervical dilation before 20 weeks' gestation. Bleeding may be accompanied by cramping or backache. Once the diagnosis is confirmed, the patient's activities are restricted until symptoms resolve. Approximately 25% of pregnancies are complicated by a threatened abortion; approximately half of affected women progress to a spontaneous abortion.[48]

An **inevitable abortion** is defined as cervical dilation or rupture of membranes without expulsion of the fetus or placenta. Spontaneous expulsion of the uterine contents usually occurs, but infection can be a complication.

A **complete abortion** is defined as a total, spontaneous expulsion of the fetus and placenta. Partial expulsion of the uterine contents (i.e., an **incomplete abortion**) is more common after 8 weeks' gestation. Persistent bleeding and cramping after expulsion of tissue are signs of an incomplete abortion. An incomplete abortion usually requires a D and E or a D and C procedure to remove any remaining fetal or placental tissue. A D and C procedure refers to dilation of the cervix followed by curettage, which is typically by suction. A D and E procedure involves greater cervical dilation followed by evacuation of the uterus with surgical instruments. Typically, the latter is required after ossification of the fetal bones, which usually occurs around 13 to 15 weeks' gestation. A D and E procedure is associated with more complications. Oxytocin and/or an ergot alkaloid (e.g., methylergonovine) increases uterine tone and may be administered intraoperatively and/or postoperatively to decrease the amount of uterine bleeding.

Fetal death may go unrecognized for several weeks in a patient with a **missed abortion.** Occasionally, coagulation defects such as disseminated intravascular coagulation (DIC) may complicate intrauterine fetal death; this possibility is more likely when fetal demise occurs at an advanced gestational age. If spontaneous expulsion of the uterine contents does not occur after a brief period of observation, evacuation of the uterus is indicated. Management options include placement of intracervical laminaria or intravaginal or intracervical placement of a prostaglandin E_2 (PGE_2) preparation. This can be followed by induction of labor or a D and C or D and E procedure. Side effects of prostaglandins include nausea, vomiting, diarrhea, and fever. Intra-amniotic instillation of hypertonic saline is not recommended in cases of intrauterine fetal death because coagulation defects may be induced or enhanced.

Recurrent or **habitual abortion** refers to the occurrence of three or more consecutive spontaneous abortions in the same patient.

Obstetric Complications

Complications of D and C and D and E procedures include cervical laceration, uterine perforation, hemorrhage, retained products of conception, and infection. The risk for these complications is increased in

pregnancies that have progressed beyond the first trimester and is greater for D and E procedures than for D and C procedures. Vasovagal events, postabortal syndrome (i.e., intrauterine blood clots with uterine atony, associated with lower abdominal pain, tachycardia, and diaphoresis), DIC, and unrecognized ectopic pregnancy can also occur. Management of uterine perforation may involve simple observation or immediate laparotomy with repair. Management depends on the suspected severity of injury to the uterus and adjacent structures.

Serious infection (e.g., **septic abortion**) complicates approximately 1 in 200,000 spontaneous abortions. It is more common after induced abortion, particularly illegal abortion.[49] Septic abortion causes significant morbidity and is life threatening. Blood cultures should be taken, and broad-spectrum intravenous antibiotics should be administered promptly. Patients with hemodynamic instability may require invasive hemodynamic monitoring to guide fluid, blood, and vasoactive drug therapy. Lower genital tract or bowel injury should be excluded, and the uterus should promptly be re-evacuated. Occasionally, hysterectomy is necessary and may be lifesaving.

Rh_0(D) immune globulin should be administered to prevent Rh sensitization in Rh-negative woman who abort. It should also be given to Rh-negative women with a threatened abortion because a positive Kleihauer-Betke test result (indicating transplacental hemorrhage of fetal blood into the maternal circulation) has been demonstrated in 11% of these patients.[50]

Women who suffer spontaneous abortion are at increased risk for depressive disorders during the 6 months after miscarriage[51] (see Chapter 51).

Anesthetic Management

Several anesthetic techniques are appropriate for D and C and D and E procedures (Box 16-2). The choice depends on several factors (e.g., whether the cervix is dilated; the gestational age and ossification of the fetus; the presence of significant blood loss, sepsis, or a full stomach; and the emotional state and preference of the patient). Dilation of the cervix is relatively painful, whereas suction and curettage are less painful. If the cervix is dilated and the products of conception can be curettaged and suctioned, sedation with or without a paracervical block may suffice. If the cervix is not dilated, paracervical block and sedation, spinal or epidural anesthesia (with sensory blockade from T10 to S4), or general anesthesia should be used. General anesthesia may be most appropriate if the patient is emotionally upset or if the gestational age is 13 to 15 weeks or greater (which requires a greater degree of cervical dilation for a D and E procedure). Selected patients may

BOX 16-2 Suggested Anesthetic Techniques for Dilation and Uterine Suction Curettage (D and C) or Evacuation (D and E) for Spontaneous or Induced Abortion

General Considerations

- Blood typing and antibody screening or typing and crossmatching in patients with a large blood loss or those with advanced gestation
- Aspiration prophylaxis if patient has a full stomach
- Routine noninvasive monitors
- One peripheral intravenous catheter
- Administration of a short-acting benzodiazepine (e.g., midazolam) may be indicated for patients who prefer sedation and/or amnesia
- Neuraxial (spinal or epidural) anesthesia for hemodynamically stable patients without sepsis is an option:
  - Intravenous fluids, vasopressors, supplemental oxygen, and minimal sedation given as clinically indicated
- Oxytocin and/or an ergot alkaloid available
- General anesthesia may be most appropriate for patients with anticipated blood loss or for patients requiring a D and E (e.g., gestation > 15 weeks' with large fetal size and fetal ossification)
- In patients with significant blood loss: observation of the patient on the operating table for evidence of hypotension for at least 5 minutes after the legs have been lowered from the lithotomy to the supine position

Monitored Anesthesia Care (well tolerated when the cervix is dilated and gestational age is first trimester)

- Intravenous analgesia with fentanyl, alfentanil, or remifentanil and sedation with midazolam or propofol
- Paracervical block if needed

Spinal Anesthesia

- Single injection with a small-gauge spinal needle: lidocaine 40 mg or hyperbaric bupivacaine 7.5 mg, with fentanyl 10 to 20 µg, to achieve sensory blockade from T10 to S4

Epidural Anesthesia

- Placement of midlumbar epidural needle and catheter
- Lidocaine 2% with epinephrine 5 µg/mL (12 to 15 mL) and fentanyl 100 µg, injected incrementally, to achieve sensory blockade from T10 to S4

General Anesthesia

- Rapid-sequence induction with cricoid pressure if the patient has a full stomach
- Induction: propofol or thiopental (ketamine or etomidate in cases of severe hemorrhage)
- Mask anesthesia or laryngeal mask airway during early pregnancy if stomach is empty and the patient is hemodynamically stable; otherwise tracheal intubation with a muscle relaxant
- Maintenance: volatile or intravenous anesthetic agents
  - High concentration (> 0.5 MAC) of a volatile anesthetic agent should be avoided if there is significant bleeding or evidence of uterine atony
- Insertion and removal of an oral gastric tube (if trachea is intubated) to evacuate the stomach
- Tracheal extubation when the patient is awake and responds to verbal commands

Modified from Chantigian RC, Chantigian PDM. Problems in early pregnancy. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

benefit from premedication with a short-acting benzodiazepine (e.g., midazolam).

Typically, the cervix is already dilated in patients who have had significant preoperative bleeding; rarely does a patient with a closed cervix have significant bleeding. In the presence of significant bleeding, intravascular volume should be restored first. A paracervical block and sedation may then be adequate. Substantial hemorrhage represents a relative contraindication to the use of spinal or epidural anesthesia, which probably should also be avoided in patients with evidence of sepsis.

General anesthesia may be induced with propofol or thiopental, although ketamine or etomidate may be preferred in patients with significant bleeding. Large doses (1.5 to 2.0 mg/kg) of ketamine increase uterine tone,[52] which may be advantageous in patients who require evacuation of the uterus.

Drugs administered for general anesthesia may influence blood loss during the procedure. Volatile anesthetic agents cause dose-dependent relaxation of uterine smooth muscle[53] and have been associated with increased uterine bleeding.[54,55] In two studies that compared blood loss during general anesthesia for elective first-trimester abortion, blood loss was greater when anesthesia was maintained with isoflurane compared with propofol.[54,55] However, the differences were small considering the blood volume expansion that occurs during pregnancy. Some obstetricians contend that relaxation of the uterus (caused by administration of a volatile anesthetic agent) increases the risk for uterine perforation, and they prefer that administration of a volatile anesthetic agent during a D and C or D and E procedure be avoided.

General anesthesia is commonly maintained with oxygen, nitrous oxide, and an opioid. A propofol infusion or a low concentration (< 0.5 MAC) of a volatile agent may be added. The volatile agent should be avoided or discontinued if there is any evidence of uterine atony. In most cases, oxytocin diluted in crystalloid is administered intravenously to increase uterine tone and decrease blood loss.

The D and C or D and E procedure is performed with the patient in the lithotomy position. After the procedure is completed and the patient's legs are lowered, hypotension may develop in patients who have lost a substantial amount of blood, especially if neuraxial anesthesia has been used.

CERVICAL INSUFFICIENCY OR INCOMPETENCE

An inherent or traumatic deficiency in the structure or function of the uterine cervix results in **cervical insufficiency or incompetence,** which is defined as the inability to sustain a pregnancy to full term. Cervical insufficiency is characterized by recurrent second-trimester pregnancy losses with (1) painless cervical dilation; (2) herniation followed by rupture of the fetal membranes; and (3) a short labor with delivery of a live, immature infant.

The true incidence of cervical insufficiency is difficult to determine owing to a lack of objective clinical findings and definitive diagnostic tests. The reported incidence varies from 1 in 100 to 1 in 2000. The U.S. *National Vital Statistics Report* for 2004 cited a rate of 4.4 cervical cerclages performed per 1000 live births.[56] Lidegaard[57] reported an incidence of cervical incompetence of 4.6 women per 1000 births in Denmark between 1980 and 1990.

Potential causes of cervical insufficiency include cervical trauma, congenital abnormalities, intrauterine infection, endocervical inflammation, deficiencies in cervical collagen and elastin, and hormonal abnormalities.[58] A common cause of cervical insufficiency is trauma, occurring at the time of a previous vaginal delivery or a surgical procedure (e.g., D and C, conization of the cervix, partial amputation or resection of the cervix, cervical cauterization). Congenital abnormalities of the reproductive tract (e.g., unicornuate or bicornuate uterus) may be present in as many as 2% of patients with cervical insufficiency. Some anomalies may result from maternal exposure to diethylstilbestrol *in utero.*

Warren et al.[59] found that more than 25% of women with a diagnosis of cervical insufficiency have a positive family history of cervical insufficiency as well as a greater frequency of two genes associated with abnormalities of connective tissue, collagen, and extracellular matrix. Other recent studies have found high rates of intra-amniotic inflammation (measured by elevated amniotic fluid matrix metalloproteinase-8 concentration) mostly without signs of infection in patients with acute cervical insufficiency or an asymptomatic shortened cervix.[60,61] The presence of this inflammation was a risk factor for impending preterm delivery.[60,61] Further research in this area could determine if there is potential for this observation to translate into therapy to prevent preterm labor.

Diagnosis

Cervical insufficiency remains a clinical diagnosis. A definitive diagnosis is made when herniating fetal membranes are visualized or palpated through a partially dilated cervix during the second trimester. A characteristic history from a previous pregnancy allows the presumptive diagnosis of cervical insufficiency, once other causes of recurrent pregnancy loss have been excluded. History suggestive of the diagnosis of cervical insufficiency consists of two or more second-trimester pregnancy losses, loss of each successive pregnancy at an earlier gestational age, painless cervical dilation to 4 to 6 cm, and cervical trauma or anomaly.[62] Uterine contractions, vaginal bleeding, or chorioamnionitis during a previous pregnancy suggests that other mechanisms are responsible for pregnancy loss.

Symptoms of cervical insufficiency include increased vaginal discharge, lower abdominal or back pressure or discomfort, vaginal fullness, and urinary frequency.

A higher risk for preterm birth has been associated with shortened cervical length at early gestational age.[63,64] Recent trials have indicated that vaginal progesterone treatment in women with a shortened cervix is effective in prevention of preterm birth and neonatal morbidity.[65,66] Physical examination may reveal cervical shortening and/or cervical abnormalities. Historically, it has been

debated whether serial ultrasonographic evaluations of cervical length and dilation should be considered in the early second trimester for pregnant women at high risk for cervical insufficiency.[62,67,68] However, a recent decision and economic analysis concluded that, of four alternatives examined, universal transvaginal ultrasonographic assessment of cervical length at the time of routine anatomic ultrasonography and subsequent treatment with daily vaginal progesterone for women with a short cervix was the most cost-effective strategy and was associated with the greatest reduction in preterm birth less than 34 weeks' gestation.[69]

Obstetric Management

Management of cervical insufficiency remains controversial.[58,70,71] A meta-analysis by Berghella et al.[72] concluded that cerclage does not prevent preterm birth in all women and can actually be detrimental in multifetal pregnancies. Current evidence, however, shows significant benefit in reducing preterm birth in women with singleton gestation who have had a previous preterm birth, have a shortened cervical length, and are less than 24 weeks' gestation.[73] It was estimated that in these patients, 20 cerclages are needed to prevent one perinatal death and more than 6500 infants per year could be saved in the United States by this management.[74]

The most common cerclage procedures are the modified **Shirodkar cerclage** and the **McDonald cerclage,** both of which are performed transvaginally. A ligature (e.g., polyester fiber [Mersilene] tape) is placed around the cervix at or near the level of the internal cervical os. In the more invasive modified Shirodkar procedure, the cervical mucosa is incised anteriorly and posteriorly, the bladder may be advanced, the ligature is placed submucosally and then tied, and the mucosal incisions are closed. The cervical mucosa is left intact with the McDonald cerclage; a purse-string ligature is placed around the cervix and then tied (Figure 16-2). These two procedures result in comparable rates of fetal survival in patients with no history of a previous cerclage.[75] In one study, better outcome (i.e., more advanced gestational age) was obtained when a Shirodkar cerclage was performed in patients who had a previous cerclage.[76]

Transvaginal cerclage can be performed in most patients with an incompetent cervix. However, if no substantial cervical tissue is present (e.g., severe cervical laceration, congenital or traumatic cervical shortening) or if a previous transvaginal cerclage has failed, a **transabdominal cerclage** may be performed, either before or during pregnancy.[77] Although a posterior colpotomy and division of the transabdominal cerclage occasionally are performed in an attempt to allow vaginal delivery, most patients with transabdominal cerclage undergo cesarean delivery. The transabdominal cerclage can remain *in situ* if further pregnancies are desired, or it can be removed at the time of cesarean delivery.

Although the efficacy of perioperative antibiotics and/or tocolytic drugs has not been confirmed, some obstetricians may choose to use them.[62]

Contraindications to cerclage procedures include preterm labor, vaginal bleeding, fetal anomalies, fetal death, rupture of membranes, placental abruption, and chorioamnionitis. Some obstetricians obtain specimens for culture of the amniotic fluid and/or cervix before placement of a cerclage.

Cerclage can be performed (1) prophylactically, before or during pregnancy (interval or primary cerclage); (2) therapeutically, when cervical changes are noted in the current pregnancy (secondary cerclage); or (3) emergently, in patients with marked cervical changes, including membrane exposure to the vaginal milieu (tertiary cerclage).

Interval cerclage may increase the risk for infertility and may prevent easy evacuation of the uterus in the case of a first-trimester spontaneous abortion. Because prophylactic cerclage is more effective than emergency cerclage (historical data show fetal survival is 78% to 87%

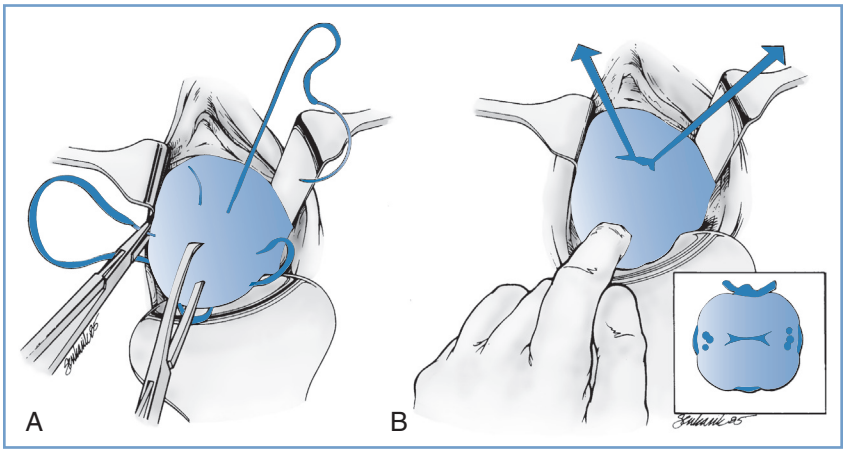

FIGURE 16-2 ■ Placement of sutures for McDonald cervical cerclage. **A,** A double-headed polyester fiber (Mersilene) band with four "bites" is placed in the cervix, avoiding the vessels. **B,** The suture is placed high up on the cervix, close to the cervical-vaginal junction, approximately at the level of the internal os. (Reprinted from Chantigian RC, Chantigian PDM. Problems in early pregnancy. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009. Modified from Iams JD. Preterm birth. In Gabbe SG, Niebyl JR, Simpson JL, editors. Obstetrics: Normal and Problem Pregnancies. 4th edition. New York, Churchill Livingstone, 2002:803.)

versus 42% to 68%, respectively[78,79]), most obstetricians perform prophylactic cerclage in the at-risk patient at 12 to 18 weeks' gestation, once fetal viability is established. A cervical dilation of 2 cm or more is associated with a greater risk of premature rupture of membranes and/or preterm delivery.[76]

The greatest risk during the performance of emergency cerclage is rupture of the membranes. Several techniques have been described to facilitate replacement of the bulging fetal membranes into the uterus. Uterine relaxation is essential, which can be facilitated by administration of a volatile anesthetic agent. Alternatively, a tocolytic drug (e.g., terbutaline) may be administered. The steep Trendelenburg position allows for gravity assistance.

To assist in reduction of herniated membranes, some obstetricians fill the urinary bladder with sterile saline. Insertion of a 16-mm Foley catheter (with the tip removed) into the cervical canal with subsequent inflation of the balloon with 30 to 60 mL of saline has also been described.[80] The balloon is deflated and the catheter is removed at the end of the procedure.

Cervical cerclage is associated with a 0.6% risk for perioperative complications.[81] Immediate complications include rupture of the fetal membranes, hemorrhage, and preterm labor. Delayed complications include infection, suture displacement, cervical stenosis secondary to scarring, and cervical lacerations and uterine rupture if labor proceeds with the cerclage in place. Rarely, sepsis may result in death. Overall, patients who have had a cerclage have a higher rate of cesarean delivery. The Shirodkar procedure is associated with a rate of cesarean delivery almost double that associated with a McDonald cerclage (31% versus 17%, respectively).[76]

Anesthetic Management

Transvaginal cervical cerclage is usually performed under spinal, epidural, or general anesthesia (Box 16-3). The degree of cervical dilation may influence the choice of anesthesia. If the cervix is not dilated, spinal, epidural, or general anesthesia may be administered. Although McCulloch et al.[82] described the use of pudendal nerve block for McDonald cerclage, this may not provide adequate anesthesia for many patients. Spinal anesthesia provides a rapid, predictable onset of sacral anesthesia, which is desirable for these procedures. Sensory blockade from sacral dermatomes to T10 is necessary, because both the cervix (L1 to T10) and vagina and perineum (S2 to S4) require anesthesia.

If the cervix is dilated—and especially if the fetal membranes are bulging—the choice of anesthesia is less straightforward. The advantages and disadvantages of each anesthetic technique must be weighed carefully. It is important to produce adequate analgesia for the mother and to prevent an increase in intra-abdominal and intrauterine pressure that may lead to further bulging and possible rupture of the fetal membranes.

General anesthesia may be preferred in the patient with a dilated cervix and bulging fetal membranes. Administration of a volatile anesthetic agent relaxes uterine smooth muscle and results in a decrease in intrauterine pressure. A decrease in intrauterine pressure facilitates replacement of the bulging membranes and placement of the cerclage. On occasion, an amniocentesis may be performed before or during a cerclage procedure in an attempt to decrease intrauterine pressure and facilitate reduction of the fetal membranes. During induction and maintenance of general anesthesia, it is important to avoid endotracheal tube–induced coughing, which might raise intrauterine pressure. In addition, vomiting significantly raises intrauterine pressure.

Administration of neuraxial anesthesia obviates the need for tracheal intubation and the possibility of coughing on the endotracheal tube. Although some physicians worry that the acute dorsiflexion needed during initiation

BOX 16-3 Suggested Anesthetic Techniques for Transvaginal Cervical Cerclage

General Considerations

- Aspiration prophylaxis if patient has a full stomach
- Routine noninvasive monitors
- One peripheral intravenous catheter
- Neuraxial anesthesia (spinal or epidural):
  - Intravenous fluids, vasopressors, supplemental oxygen, and minimal sedation given as clinically indicated
- Left uterine displacement if the pregnancy is greater than 18 to 20 weeks' gestation
- Consideration of fetal heart rate (FHR) monitoring:
  - Less than 24 weeks' gestation: FHR checked before and after procedure
  - Greater than 24 weeks' gestation: continuous FHR monitoring during and after the procedure

Spinal Anesthesia

- Single injection with a small-gauge spinal needle: lidocaine 40 mg or bupivacaine 7.5 mg, with fentanyl 10 to 20 μg, to achieve sensory blockade from T10 to S4
- If patient is in the Trendelenburg position for emergency cerclage, avoid hyperbaric local anesthetic

Epidural Anesthesia

- Placement of midlumbar epidural needle and catheter
- Lidocaine 2% with epinephrine 5 μg/mL (12 to 15 mL) and fentanyl 100 μg, injected incrementally, to achieve sensory blockade from T10 to S4

General Anesthesia (if cervix is dilated and uterine relaxation is needed)

- Induction: propofol or thiopental
- Tracheal intubation is preferable in patients with a full stomach or at greater than 18 to 20 weeks' gestation; otherwise, mask anesthesia or laryngeal mask airway acceptable
- Maintenance: volatile or intravenous (a volatile anesthetic agent may be useful to provide uterine relaxation)
- Avoidance of large increases in intra-abdominal and intrauterine pressures (e.g., patient coughing on endotracheal tube, vomiting)

Modified from Chantigian RC, Chantigian PDM. Problems in early pregnancy. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

of the neuraxial blockade may raise intrauterine pressure, many prefer the avoidance of general anesthesia during pregnancy whenever possible.

Few clinical studies have compared obstetric outcomes after administration of neuraxial anesthesia and general anesthesia for cerclage. One retrospective study observed no difference in fetal outcome after administration of either general anesthesia (375 cases) or epidural anesthesia (114 cases).[83] Another study found no significant difference in plasma oxytocin levels or postoperative uterine activity between women who received either spinal or general anesthesia for a Shirodkar cerclage.[84]

Fetal heart rate monitoring should be considered during the procedure if the pregnancy is sufficiently advanced to allow monitoring to be performed easily. In theory, it is possible that replacement of bulging membranes and closure of the cervix may raise intrauterine pressure with a subsequent reduction in placental blood flow. In this case, it would be reasonable to give a tocolytic agent to help reduce intrauterine pressure.

The transvaginal cerclage is removed at 37 to 38 weeks' gestation, or earlier if rupture of membranes or onset of labor occurs. Removal of a McDonald cerclage often requires no anesthesia. Anesthesia (e.g., paracervical block, spinal anesthesia, epidural anesthesia) is usually necessary for removal of a Shirodkar cerclage. If the Shirodkar cerclage is epithelialized, some obstetricians elect to leave it intact and perform an elective cesarean delivery.

Labor often begins within a few hours or days after suture removal. If an epidural catheter was placed for cerclage removal, the epidural anesthetic can be allowed to regress while the patient is observed for evidence of cervical dilation and the onset of labor. When labor begins, epidural labor analgesia can be initiated by injection of drugs through the *in situ* catheter.

GESTATIONAL TROPHOBLASTIC DISEASE

In normal pregnancy, trophoblastic tissue forms the placenta. Abnormal trophoblastic proliferation results in **gestational trophoblastic disease** (GTD). When GTD persists after the pregnancy is concluded (diagnosed by persistent elevation of beta-hCG), it is called persistent gestational trophoblastic disease (PGTD).

Prior to 1970, most cases of PGTD were fatal. Early diagnosis and effective chemotherapy have reduced the mortality rate to 0.1% in Great Britain and the Netherlands and to 1% in the United States.[85,86] This improvement may be related to the fact that trophoblastic cells produce beta-hCG, which provides an easily assayed biochemical marker to aid in detection and to monitor treatment. Further, it is thought that cytotoxic chemotherapeutic drugs are particularly effective against PGTD because the latter arises from a genotype that is not entirely that of the patient, thus facilitating rejection of the trophoblastic cells and leaving them vulnerable to this therapy.[87]

However, some women still die of GTD, often as a result of late presentation and drug resistance or concomitant human immunodeficiency virus infection.[88] GTD caused 0.3% of all pregnancy-related maternal deaths in the United States between 1991 and 1999.[8] Risk factors for GTD include advanced or very young maternal age, previous molar pregnancy, and, possibly, nutritional factors.

Categorization and Etiology

The classification and terminology applied to GTD are varied and can be confusing because GTD encompasses a heterogeneous group of diseases. GTD is also called **gestational trophoblastic tumor** or **gestational trophoblastic neoplasia,** although in this context neoplasia simply means "new grown" and does not necessarily differentiate benign from malignant forms of GTD.

In 2003, the WHO classified GTD into eight categories (Box 16-4). The pathologic and clinical features of GTD are summarized in Table 16-1.[89] Discussion of placental site trophoblastic tumor, exaggerated placental site, placental site nodules and plaques, as well as miscellaneous and unclassified trophoblastic lesions, is beyond the scope of this chapter. Here the focus is mainly on molar pregnancies. Overall, it is helpful to simply remember that GTD always involves trophoblastic cells that have abnormally proliferated and/or invaded and/or metastasized to distant sites in the body.

GTD can be categorized according to **pathologic features** of the trophoblastic cells, **malignant potential** of the trophoblastic cells, or the **genetic makeup** of the trophoblastic cells.

Pathologically, although all GTD arises from trophoblast, hydatidiform moles and gestational choriocarcinoma arise from **villous trophoblast,** whereas exaggerated placental site, placental site nodule, placental site trophoblastic tumor, and epithelioid trophoblastic tumor arise from **intermediate trophoblast.** Further differentiation of the pathologic features of GTD is outlined in Table 16-1. **Gestational choriocarcinoma** typically results from a single trophoblastic cell line that has become malignant and metastasized to distant sites in the body. It can occur after a molar pregnancy, a normal pregnancy, or even a pregnancy loss.

The spectrum from the most benign to the most malignant form of GTD is as follows: (1) **partial hydatidiform mole,** (2) **complete hydatidiform mole,** (3) **invasive mole,** and (4) **gestational choriocarcinoma.** Benign

BOX 16-4 World Health Organization Classification of Gestational Trophoblastic Disease

- Hydatidiform mole:
  - Complete mole
  - Partial mole
- Invasive hydatidiform mole
- Choriocarcinoma
- Placental site trophoblastic tumor
- Trophoblastic lesions, miscellaneous
- Exaggerated placental site
- Placental site nodules and plaques
- Unclassified trophoblastic lesion

TABLE 16-1 **Pathologic and Clinical Features of Gestational Trophoblastic Disease**

Gestational Trophoblastic Disease	Pathologic Features	Clinical Features
Hydatidiform mole, complete	46,XX (mainly); 46,XY Absent fetus/embryo Diffuse swelling of villi Diffuse trophoblastic hyperplasia	15%-20% trophoblastic sequelae Beta-hCG often > 100,000 mIU/mL Medical complications
Hydatidiform mole, partial	Triploid (69,XXY; 69,XYY; 69,XXX) Abnormal fetus/embryo Focal swelling of villi Focal trophoblastic hyperplasia	< 5% trophoblastic sequelae Beta-hCG usually < 100,000 mIU/mL Rare medical complications
Invasive mole	Myometrial invasion Swollen villi Hyperplastic trophoblast	15% metastatic, to lung/vagina Most often diagnosed clinically, rather than pathologically
Choriocarcinoma	Abnormal trophoblastic hyperplasia and anaplasia Absent villi Hemorrhage, necrosis	Vascular spread to distant sites: lung/brain/liver Malignant disease
Placental site trophoblastic tumor	Tumor cells infiltrate myometrium with vascular/lymphatic invasion Intermediate cells/absent villi Less hemorrhage and necrosis Tumor cells stain positive for hPL	Extremely rare Beta-hCG levels less reliable indicator Relatively chemoresistant Mainly surgical treatment

hCG, human chorionic gonadotropin; *hPL,* human placental lactogen.
(From Lurain JR. Gestational trophoblastic disease. I. Epidemiology, pathology, clinical presentation and diagnosis of gestational trophoblastic disease, and management of hydatidiform mole. Am J Obstet Gynecol 2010; 203:531-9.)

forms of GTD include complete or partial molar pregnancies that have not demonstrated myometrial invasion. Malignant forms of GTD include invasive mole (complete or partial molar pregnancies that have demonstrated myometrial invasion), gestational choriocarcinoma, and placental site trophoblastic tumor. The latter diseases metastasize, most often to the lungs and brain, and are fatal if not treated. Complete molar pregnancies have a higher rate of associated complications and a higher rate of subsequent PGTD than partial molar pregnancies. Approximately 20% of patients with complete molar pregnancy have postmolar nonmetastatic PGTD (70% to 90%) or malignant PGTD (10% to 30%) and require chemotherapy; in contrast, only 5% of patients with partial molar pregnancy require chemotherapy.[90]

GTD can also be classified according to the genetic makeup of the trophoblastic cells. The various means by which the unusual genetic events occur in GTD are outlined here; further details are available elsewhere.[87] Typically, the genetic makeup of trophoblastic cells in complete hydatidiform molar pregnancy is **androgenic,** meaning nearly all of the genome of the trophoblastic cell arises from the sperm. It can be either **diploid** (two sets of 23 chromosomes [e.g., 46,XY]) or **triploid** (three sets of 23 chromosomes [e.g., 69,XXY]). An ovum lacking chromosomes is fertilized most commonly by one sperm cell with reduplication (46,XX androgenic) or by two sperm cells (dispermy, 46,XX or 46,XY androgenic). No fetus develops. Approximately 90% of hydatidiform moles are complete.[91]

Typically, the genetic makeup of a partial hydatidiform molar pregnancy is **diandric,** meaning the chromosomes arise from both the egg and the sperm but is complicated by triploid conception (69,XXX or 69,XXY). One set of haploid chromosomes is maternal, and there is either reduplication of the paternal donation after fertilization by a single sperm or the egg is fertilized by two separate sperm. Because both maternal and paternal chromosomes are present, it is possible for a fetus to form with a partial mole. As a result, patients with partial mole may have a preoperative diagnosis of incomplete or missed abortion.

Invasive mole is also called *chorioadenoma destruens.* Because this describes any mole (complete or partial) that has invaded into the myometrium, it can have the genetic makeup of either a complete or partial mole. However, most invasive moles result from complete moles.

Complete and Partial Hydatidiform Mole

The reported incidence of hydatidiform mole varies. In the United States, it is detected in 1 in 600 elective abortions and 1 in 1500 pregnancies. Rates of 1 in 400 pregnancies are reported in Korea and Indonesia and among Native Americans.[85,92,93] Coexistence of an intact fetus with molar components is extremely rare, occurring in 1 in 22,000 to 1 in 100,000 pregnancies.[92]

Patients may have a complete molar pregnancy diagnosed during first trimester ultrasonography, or they may have vaginal bleeding after delayed menses, suggestive of a threatened, missed, or incomplete abortion. They may spontaneously pass hydropic vesicles. The absence of fetal cardiac activity, a uterus large for gestational age, and a marked elevation of beta-hCG strongly suggest the diagnosis of hydatidiform mole. Diagnosis may be made after a D and C for an incomplete abortion[92]; baseline chest radiography and quantitative beta-hCG levels should be obtained promptly after surgery in such cases.

Molar pregnancies produce hCG in amounts proportional to the neoplastic volume. Excessive uterine size is associated with a marked elevation of serum beta-hCG concentration (> 100,000 mIU/mL) secondary to a large tumor volume. Large ovarian cysts, hyperemesis

gravidarum, and early onset of gestational hypertension are also strongly suggestive of GTD. Ultrasonography may show characteristic multi-echogenic regions that represent hydropic villi or hemorrhagic foci.

Persistent and Malignant Gestational Trophoblastic Disease

Persistent or malignant GTD can develop after any gestational event, including normal pregnancy, spontaneous or elective abortion, ectopic pregnancy, and molar pregnancy. Histologic forms of postmolar PGTD include noninvasive trophoblastic proliferation, invasive mole, gestational choriocarcinoma, and placental site trophoblastic tumor. Diagnosis of postmolar PGTD is made when beta-hCG levels plateau or rise.[92,93]

Signs and symptoms of malignant GTD after a nonmolar gestational event are very subtle and diagnosis may be delayed. A quantitative beta-hCG measurement should be performed in any patient with continued or abnormal vaginal bleeding 6 weeks after the end of gestation. In any woman of reproductive age with metastatic disease from an unknown primary tumor, the diagnosis of gestational choriocarcinoma should be considered, given the fact that metastases of gestational choriocarcinoma can occur anywhere. The vagina, liver, lung, and brain are the most frequently involved sites. Signs and symptoms are related to the affected site. Biopsy of metastases is rarely needed and can result in profuse bleeding. The diagnosis of metastatic GTD is suggested with a positive beta-hCG result and no pregnancy.[85,92,93]

Details on staging and risk-factor scoring of GTD and their implications for therapy and prognosis are available elsewhere.[90,94,95]

Medical Complications

Routine use of ultrasonography has led to earlier diagnosis of molar pregnancy, which has reduced the incidence of medical complications. However, excessive uterine size occurs in up to half of patients with complete molar pregnancy and is associated with a higher incidence of medical complications. Medical complications occur in about 25% of patients with uterine size of more than 14 to 16 weeks' gestation; they include ovarian theca-lutein cysts, hyperemesis gravidarum, gestational hypertension, anemia, hyperthyroidism, DIC, and sepsis (Table 16-2).[90,92-94,96-99]

Ovarian theca-lutein cysts occur primarily in patients with extremely high serum beta-hCG concentration (>100,000 mIU/mL).[97] They typically regress over 2 to 3 months; rarely, torsion, rupture, or infarction may necessitate oophorectomy. Patients with theca-lutein cysts and a uterus more than 4 weeks larger than expected (for dates) have a 50% likelihood of development of postmolar GTN.[85]

Hyperemesis gravidarum can lead to significant electrolyte disturbances and volume depletion, all of which should be corrected before surgery.

Gestational hypertension occurs in up to 27% of women with molar pregnancy, typically in patients with an excessively large uterus.[98] **Preeclampsia** may be diagnosed if proteinuria accompanies hypertension, although early presentation does not fit usual definitions (see Chapter 36). Although it is thought that convulsions rarely occur in these patients,[97] prophylactic use of magnesium sulfate should be considered. An antihypertensive agent (e.g., hydralazine, labetalol) should be given as required to reduce blood pressure. GTD should be strongly suspected in any patient who develops hypertension during early pregnancy.

Anemia frequently complicates a complete molar pregnancy. The visible vaginal bleeding may underrepresent the total amount of hemorrhage. Occult bleeding into and around the tumor results in multiple hemorrhagic foci. Because blood loss may occur gradually, the patient may have a normal intravascular volume despite the presence of severe anemia. In the 1970s and 1980s, blood transfusion was required in as many as 32% to 45% of patients.[96,99] With earlier diagnosis using ultrasonography, the incidence of transfusion may be less than in the past. Nonetheless, blood typing and antibody screening should be performed preoperatively.

Although it occurs infrequently, **hyperthyroidism** may result from a marked elevation of hCG,[100] which can have a thyrotropin-like effect. Alternatively, hyperthyroidism may result from some other thyrotropic substance produced by the neoplasm.[100] Anesthesia or surgery can precipitate thyroid storm (i.e., sinus tachycardia, atrial fibrillation, hyperthermia, cardiovascular collapse), which is treated using a beta-adrenergic antagonist.

Historically, **acute cardiopulmonary distress** was observed after evacuation of molar pregnancy in as many as 27% of patients.[97,101-103] A higher risk for cardiopulmonary complications occurs in patients with a uterine size of 16 weeks or greater.[101,104] Signs and symptoms include chest pain, cough, tachycardia, tachypnea, hypoxemia, diffuse rales, and chest radiographic evidence of bilateral pulmonary infiltrates. It is thought that **trophoblastic embolization** may be the etiology of cardiopulmonary distress in more than half of cases.[103,104] Other causes include (1) high-output cardiac failure from thyrotoxicosis, (2) pulmonary congestion from severe

TABLE 16-2 Complications of Complete Molar Pregnancies

Complication	Incidence (%)
Excessive uterine size	30-53
Ovarian theca-lutein cysts (> 6 cm)	4-50
Hyperemesis gravidarum	14-29
Gestational hypertension	11-27
Anemia (hemoglobin < 10 g/dL)	10-54
Hyperthyroidism	1-7
Trophoblastic emboli	2-7
Acute cardiopulmonary distress	6-27
Malignant sequelae (metastasis)	4-36
Other (renal, disseminated intravascular coagulation, infection)	Rare

Data from references 88, 90, 94, 96-98, and 100-102. Reprinted from Chantigian RC, Chantigian PDM. Problems in early pregnancy. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

anemia, (3) gestational hypertension or preeclampsia, (4) aspiration pneumonitis, and (5) iatrogenic fluid overload.[103,104] Symptoms usually develop within 12 hours of uterine evacuation.[103] Some patients require tracheal intubation, mechanical ventilation, and invasive hemodynamic monitoring. Symptoms usually subside within 72 hours; however, massive embolization or adult respiratory distress syndrome may result in death. If the patient survives trophoblastic embolization, malignant sequelae often develop.[94,103,105]

Obstetric Management

The following preoperative tests are recommended for patients with suspected hydatidiform mole: (1) complete blood count including platelet count, (2) coagulation studies, (3) renal and liver function studies, (3) blood typing and antibody screening, (4) quantitative beta-hCG level, and (5) chest radiography.[92,93] Prompt molar evacuation should be instituted, because a delay in uterine evacuation may raise the risk for complications. Once the patient is stabilized, suction curettage is performed to evacuate the uterus in patients who want to preserve fertility. Real-time ultrasonography may help the obstetrician perform a complete evacuation of the uterus in patients with excessive uterine size.[106] Hysterectomy is performed in patients who have completed childbearing. Hysterotomy and medical induction of labor are not recommended because they are associated with increased blood loss and a higher incidence of postmolar PGTD.[93] Rh_0(D) immune globulin should be administered to Rh-negative patients.

After uterine evacuation, the beta-hCG level should be measured weekly until it is undetectable for 3 weeks, then monthly for 6 months and every 2 months for another 6 months. Frequent pelvic examinations are performed while beta-hCG levels remain high. Thorough evaluation of the patient with GTD includes screening for evidence of metastasis (e.g., vagina, liver, lung, brain) and other potential complications. Prevention of pregnancy for 12 months is recommended.[85]

Malignant GTD should be managed by an experienced team in a trophoblastic center to minimize mortality.[85,92-94] Chemotherapy is indicated in patients with (1) histologic evidence of invasive mole or choriocarcinoma, (2) an increase in beta-hCG levels of 10% or greater in three or more samples taken over at least 2 weeks, (3) a plateau of beta-hCG levels in four or more samples taken over 3 consecutive weeks, (4) persistence of measurable beta-hCG levels 6 months after molar evacuation, or (5) evidence of metastasis.[95] Some patients may require delayed hysterectomy, thoracotomy for resection of pulmonary metastasis, and/or liver or brain irradiation.

Anesthetic Management

Preoperative assessment of the patient with a molar pregnancy consists of evaluation for specific complications of molar pregnancy, including hyperemesis gravidarum, gestational hypertension and preeclampsia, anemia, and thyrotoxicosis. The main anesthetic considerations are the potential for rapid and significant blood loss and the risk for cardiopulmonary distress with uterine evacuation. The anesthesia provider should establish adequate intravenous access, and blood products should be immediately available. Invasive arterial pressure and/or central venous pressure monitoring may be indicated in the patient with hypoxemia, severe anemia, hemorrhage, severe gestational hypertension or preeclampsia, hyperthyroidism, or a uterus of more than 16 weeks' size.[107]

Although neuraxial anesthesia has been described, general anesthesia is often preferred because of the potential for rapid, substantial blood loss and cardiopulmonary distress during evacuation of the uterus (Box 16-5). For patients with acute hemorrhage and hypovolemia, induction with thiopental or propofol may cause marked hypotension. In hyperthyroid patients, ketamine may result in marked tachycardia.[108] Etomidate is an excellent choice for patients with preoperative bleeding and preoperative evidence of hyperthyroidism. Anesthesia can be maintained using either an inhalational or intravenous technique, although it may be necessary to avoid volatile anesthetic agents in some patients to optimize uterine contractility,[109] and care should be exercised with the use of a propofol infusion in hemodynamically unstable patients.

An intravenous oxytocin infusion (20 IU/L of crystalloid) is begun either before[97,101] or during[94] uterine evacuation. Oxytocin helps the uterus contract, facilitating safe curettage and reducing blood loss. Some obstetricians have speculated that oxytocin may decrease trophoblastic embolization by constricting the uterine veins.[101] Postoperatively, the patient should be monitored closely for any evidence of uterine hemorrhage or cardiopulmonary distress.

BOX 16-5 Suggested Anesthetic Technique for Patients with Gestational Trophoblastic Neoplasm

Preoperative Evaluation

- Evaluation for complications of molar pregnancy
- Measurement of baseline arterial blood gas levels

General Anesthesia

- Routine noninvasive monitors
- Consideration of invasive hemodynamic monitoring in patients with hypoxemia, gestational hypertension or preeclampsia, severe anemia, hyperthyroidism, or a uterine size greater than 16 weeks' gestation
- Two large-gauge peripheral intravenous catheters
- Immediate availability of blood
- Induction: etomidate if evidence of hemorrhage or hemodynamically unstable
- Tracheal intubation with a muscle relaxant
- Maintenance: inhalation or intravenous technique Avoid volatile agents if optimization of uterine contractility is required, and exercise caution with the use of a propofol infusion in hemodynamically unstable patients
- Oxytocin infusion (20 IU/L) after cervical dilation or after partial uterine evacuation

Modified from Chantigian RC, Chantigian PDM. Problems in early pregnancy. In Chestnut DH, Polley LS, Tsen LC, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

HYPEREMESIS GRAVIDARUM

As many as 50% to 80% of women experience nausea and vomiting during pregnancy; this is the most common indication for admission to the hospital during the first trimester of pregnancy. Symptoms are often worse during the morning hours, thus the term *morning sickness*. Symptoms typically improve or resolve by the end of the first trimester.

On rare occasions, pregnant women experience a persistent and severe form of nausea and vomiting called **hyperemesis gravidarum.** This is believed to be an extreme form of normal nausea and vomiting of pregnancy, although there is no single accepted definition. These women may develop dehydration, ketonuria, nutritional compromise, weight loss, electrolyte abnormalities, and/or transient hepatic and renal dysfunction. Intravenous rehydration, correction of electrolyte abnormalities, antiemetics, and, rarely, hyperalimentation are indicated.

Hyperemesis gravidarum may be associated with multiple gestation, thyrotoxicosis, and/or GTD. Diagnosis is by exclusion, and many other underlying diseases should be ruled out, including gastrointestinal diseases (e.g., hepatitis, cholecystitis, pancreatitis, partial bowel obstruction), genitourinary diseases (e.g., pyelonephritis, uremia, ovarian torsion, kidney stones), metabolic disorders, neurologic or psychiatric disorders, acute fatty liver of pregnancy, drug toxicity, and preeclampsia.

CORPUS LUTEUM CYSTS

Symptomatic corpus luteum cysts occasionally occur during early pregnancy. Typically, they resolve over several weeks. In some cases, hemorrhage or ovarian torsion necessitates ovarian cystectomy or oophorectomy. After the cyst is removed, the fetus usually is not affected, provided that supplemental progesterone is administered until 10 to 12 weeks' gestation.

KEY POINTS

- Aortocaval compression does not develop until the uterine fundus reaches the umbilicus (i.e., 18 to 20 weeks' gestation in a normal singleton pregnancy, or earlier in conditions with an enlarged uterus). Left uterine tilt should be initiated when the potential for aortocaval compression exists.
- General anesthesia may be administered by mask or laryngeal mask airway (LMA) for selected extra-abdominal procedures during the first 18 to 20 weeks of pregnancy, provided that the patient fulfills the criteria for an empty stomach and there is no difficulty with mask ventilation. Some anesthesia providers prefer to limit the use of mask anesthesia or the LMA to the first 12 to 14 weeks of pregnancy.
- During pregnancy, the nervous system is more sensitive to local anesthetics and perhaps general anesthetic agents. Lower doses of these drugs should be considered, although it is important to be aware of the greater risk for intraoperative awareness during cesarean delivery.
- Most ectopic pregnancies are located in one of the fallopian tubes. Ruptured tubal pregnancies, as well as interstitial, cervical, cesarean scar, and abdominal ectopic pregnancies as well as pregnancies with early placenta accreta, may result in substantial hemorrhage.
- The most painful part of a dilation and uterine evacuation procedure is the dilation of the cervix. If the cervix is already dilated and the fetal size is first trimester, sedation (with or without paracervical block) often suffices. If the cervix is closed, either a paracervical block with sedation or neuraxial or general anesthesia may be necessary. If the fetal size is advanced (>13 to 15 weeks' gestation), many anesthesia providers prefer general anesthesia because of the greater surgical stimulation and risk for bleeding complications.
- Neuraxial anesthesia is an excellent choice for prophylactic cervical cerclage. In a patient who requires emergency cervical cerclage, it is important to prevent a marked increase in intra-abdominal and intrauterine pressures, which might cause rupture of bulging fetal membranes.
- The patient with a molar pregnancy may have hyperemesis gravidarum, gestational hypertension, severe anemia, and/or hyperthyroidism. These complications are more common in patients with excessive uterine size.
- Rapid and profound blood loss is possible with uterine evacuation of a molar pregnancy, and acute cardiopulmonary distress can develop after uterine evacuation.

CHAPTER 17

Nonobstetric Surgery during Pregnancy

Marc Van de Velde, MD, PhD

CHAPTER OUTLINE

Estimates of the frequency of nonobstetric surgery performed during pregnancy range from 0.3% to 2.2%.[1,2] Thus, as many as 93,000 and 110,000 pregnant women in the United States and the European Union, respectively, may require a surgical or anesthetic intervention each year. These numbers are likely to be an underestimation, because pregnancy may be unrecognized at the time of operation. The reported incidence of positive pregnancy tests in women of childbearing age ranged from 0.002% in women presenting for orthopedic surgery[3] to 0.3% in women presenting to an ambulatory surgery center[4] to 2.6% in women scheduled to undergo elective sterilization procedures.[5]

The practice of routine pregnancy testing for all women of childbearing age presenting for elective surgery and anesthesia is controversial. The American Society of Anesthesiologists Task Force on Preanesthesia Evaluation states "…the literature is inadequate to inform patients or physicians on whether anesthesia causes harmful effect in early pregnancy. Pregnancy testing may be offered to female patients of childbearing age and for whom the result would change the patient's management."[6] In 2000, the U.K. National Institute for Health and Clinical Excellence (NICE) issued preoperative screening guidelines recommending routine pregnancy testing for "female patients who say that it is possible they may be pregnant."[7] There was uncertainty among the Guideline Development Group as to whether women should undergo pregnancy testing if the last menstrual period was documented or if women stated that it was not possible that they were pregnant.[7] This guideline was poorly followed, resulting in 42 serious incidents, 3 pregnancy losses, and several cases of litigation between 2003 and 2009.[8] In 2010, the U.K. National Patient Safety Agency stated that women should be offered a pregnancy test "if there is any possibility that a woman could be pregnant."[8] In certain populations, medical history alone may be an unreliable means of excluding the possibility of pregnancy.[6,7] Thus, some institutions routinely perform pregnancy tests on all women of childbearing age who present for elective surgery.[3]

Surgery may be necessary during any stage of pregnancy. Among 5405 Swedish women who had operations during pregnancy, 42% occurred during the first trimester, 35% during the second trimester, and 23% during the third trimester.[1] Laparoscopy for gynecologic indications was the most common first-trimester procedure (34%), whereas appendectomy was the most common procedure during the remainder of pregnancy. Indications for pregnancy-related surgery include cervical incompetence, the presence of ovarian cysts, and conditions amenable to fetal surgery (see Chapter 7). Indications for non–pregnancy-related surgery include the presence of acute abdominal disease (most commonly appendicitis and cholecystitis), malignancies, and trauma.

When caring for pregnant women undergoing nonobstetric surgery, anesthesia providers must consider both the mother and the fetus. Standard anesthetic procedures

may have to be modified to accommodate pregnancy-induced maternal physiologic changes and the presence of the fetus. The Confidential Enquiries into Maternal and Child Health in the United Kingdom demonstrate that, even in early pregnancy, mothers die of hemorrhage, sepsis, thromboembolism, and anesthesia; substandard care is often present.[9] Erekson et al.[10] analyzed 2005 to 2009 data from the American College of Surgeons National Surgical Quality Improvement Program database. The rate of major complications (e.g., infections, reoperation, wound problems, respiratory complications, venous thromboembolism, blood transfusion, maternal death) for antenatal nonobstetric surgery was approximately 6%.[10]

Possible risks to the fetus of antenatal surgery include (1) the effects of the disease process itself, or related therapy; (2) the teratogenicity of anesthetic agents or other drugs administered during the perioperative period; (3) intraoperative perturbations of uteroplacental perfusion and/or fetal oxygenation; and (4) the risk for abortion or preterm delivery.

MATERNAL SAFETY: ALTERED MATERNAL PHYSIOLOGY

During pregnancy, profound changes in maternal physiology result from increased concentrations of various hormones, mechanical effects of the gravid uterus, greater metabolic demand, and the hemodynamic consequences of the low-pressure placental circulation. Hormonal changes are likely responsible for most of the changes that occur during the first trimester. Mechanical effects become apparent when the uterus emerges from the pelvis during the second half of gestation (see Chapter 2).

Respiratory System and Acid-Base Balance Changes

Alveolar ventilation increases by 30% or more by mid pregnancy. This increase results in chronic respiratory alkalosis with a $Paco_2$ of 28 to 32 mm Hg, a slightly alkaline pH (approximately 7.44), and decreased levels of bicarbonate and buffer base. Although oxygen consumption is increased, Pao_2 usually increases only slightly or remains within the normal range. Functional residual capacity (FRC) diminishes by approximately 20% as the uterus expands, resulting in decreased oxygen reserve and the potential for airway closure. When FRC is decreased further (e.g., from morbid obesity; perioperative intra-abdominal distention; placement of the patient in the supine, Trendelenburg, or lithotomy position; or induction of anesthesia), airway closure may be sufficient to cause hypoxemia.

Weight gain during pregnancy and capillary engorgement of the respiratory tract mucosa lead to more frequent problems with mask ventilation and tracheal intubation (see Chapter 30). Failed intubation (a leading cause of anesthesia-related maternal death) is as much a risk during early pregnancy with nonobstetric surgery as it is during cesarean delivery.[9]

Decreased FRC, increased oxygen consumption, and diminished buffering capacity result in the rapid development of hypoxemia and acidosis during periods of hypoventilation or apnea. Moreover, induction of inhalation anesthesia occurs more rapidly during pregnancy because alveolar hyperventilation and decreased FRC allow faster equilibration of inhaled agents. In addition, induction of anesthesia is accelerated owing to the 30% to 40% decrease in the minimum alveolar concentration (MAC) for volatile anesthetic agents that occurs even during early gestation.[11] The anesthesia provider must be especially vigilant when administering subanesthetic concentrations of analgesic and anesthetic agents to the pregnant patient, in whom unconsciousness can occur quickly and unexpectedly.

Cardiovascular System Changes

Cardiac output increases by up to 50% during pregnancy because of increases in heart rate and stroke volume; both systemic and pulmonary vascular resistances decrease, but myocardial contractility is unaffected. Early in pregnancy (i.e., by 6 weeks' gestation), significant cardiovascular alterations are present.[12] By 8 weeks' gestation, 57% of the increase in cardiac output, 78% of the increase in stroke volume, and 90% of the decrease in systemic vascular resistance that are typically achieved by 24 weeks' gestation have occurred.[13]

During the second half of gestation, the uterus compresses the inferior vena cava when the mother lies supine; the compression reduces venous return and cardiac output by approximately 30%. Although upper extremity blood pressure may be maintained by compensatory vasoconstriction and tachycardia, uteroplacental perfusion is jeopardized whenever the mother lies supine. In some women, frank hypotension may occur in the supine position, especially when neuraxial or general anesthesia attenuates or abolishes normal compensatory mechanisms. For these reasons, it is essential to displace the uterus laterally during any operation performed after 18 to 20 weeks' gestation. Vena caval compression also results in distention of the epidural venous plexus, which increases the likelihood of intravascular injection of local anesthetic during the administration of epidural anesthesia. The reduced capacity of the epidural space most likely contributes to the enhanced spread of epidural local anesthetic solution that is observed during pregnancy.

Changes in Blood Volume and Blood Constituents

Blood volume expands in the first trimester and increases 30% to 45% by term. Dilutional anemia occurs as a result of the smaller increase in red blood cell volume than in plasma volume. Although moderate blood loss is well tolerated during pregnancy, preexisting anemia decreases the patient's reserve when significant hemorrhage occurs. Pregnancy is associated with benign leukocytosis; consequently, the white blood cell count is an unreliable indicator of infection. In general, pregnancy induces a hypercoagulable state, with increases in fibrinogen; factors VII, VIII, X, and XII; and fibrin degradation

products. Pregnancy is associated with enhancement of platelet turnover, clotting, and fibrinolysis; there is a wide range in the normal platelet count. Thus, pregnancy represents a state of accelerated but compensated intravascular coagulation. Although thrombocytopenia may be present in some pregnant women, these patients may still be hypercoagulable. During the postoperative period, pregnant surgical patients are at high risk for thromboembolic complications; thus, thromboembolism prophylaxis is recommended.[14]

Gastrointestinal System Changes

Incompetence of the lower esophageal sphincter and distortion of gastric and pyloric anatomy during pregnancy increase the risk for gastroesophageal reflux, despite similar gastric emptying rates in pregnant and nonpregnant patients[15]; thus the pregnant woman is at risk for regurgitation of gastric contents and aspiration pneumonitis. It is unclear at what stage during pregnancy this risk becomes significant. Although lower esophageal sphincter tone is impaired early in pregnancy (especially in patients with heartburn),[16] the mechanically induced factors do not become relevant until later in pregnancy. It seems prudent to consider any pregnant patient as having a higher risk for aspiration after mid gestation; some anesthesia providers contend that pregnant women are at increased risk for aspiration from the beginning of the second trimester onward.[16]

Altered Responses to Anesthesia

In addition to the decrease in MAC for inhaled anesthetic agents, thiopental requirements begin to decrease early in pregnancy.[17] The effects of pregnancy on propofol requirements are conflicting.[18,19] Higuchi et al.[18] found that the median effective dose for loss of consciousness (ED_{50}) was unchanged in pregnancy, whereas Mongardon et al.[19] reported that lower propofol doses were required to achieve loss of consciousness in early pregnancy compared with the nonpregnant state. This effect appeared unrelated to increased progesterone levels. More extensive neural blockade is attained with epidural and spinal anesthesia in pregnant patients than in nonpregnant patients (see Chapter 12). Pregnancy also enhances the response to peripheral neural blockade.

Plasma cholinesterase levels decrease by approximately 25% from early in pregnancy until the seventh postpartum day. Fortunately, prolonged neuromuscular blockade with succinylcholine is uncommon, because the larger volume available for drug distribution offsets the impact of decreased drug hydrolysis.[20] Nonetheless, the dose of succinylcholine should be controlled carefully in the pregnant patient, and the anesthesia provider should monitor neuromuscular blockade with a nerve stimulator to ensure adequate reversal before extubation.
