CHAPTER 31

Postpartum Headache

Alison Macarthur, BMSc, MD, FRCPC, MSc

CHAPTER OUTLINE

Postpartum headache is the complaint of cephalic, neck, or shoulder pain occurring during the first 6 weeks after delivery. The incidence of postpartum headache throughout the 6-week postpartum period has not been followed in a prospective manner. However, information is available from an evaluation of women during the first week postpartum,[1] from a database that recorded symptoms during pregnancy and in the first week after delivery,[2] and from a survey of women at 5 months and 1 year postpartum.[3] Goldszmidt et al.[1] evaluated 985 women during the first week postpartum and found a 38.7% incidence of headache. The median time to onset of symptoms was 2 days, and the median duration of headache was 4 hours. Benhamou et al.[2] examined information collected on pregnant women who delivered at their institution during a 2-year period; exclusion criteria included recognized dural punctures, preterm deliveries, multiple gestation, and/or elective cesarean delivery. Headache was reported by 12% of 1058 patients who had epidural anesthesia without dural puncture and by 15% of 140 patients who delivered without epidural anesthesia. Saurel-Cubizolles et al.[3] surveyed 1,286 postpartum women and found the incidence of headache was 22% and 42% at 5 and 12 months, respectively.

Post–dural puncture headache (PDPH) is one of the most common postpartum complications of neuraxial anesthesia. However, physicians and nurses should be aware that a dural puncture is only one of many causes of postpartum headache (Table 31-1). Most headaches are benign or do not require immediate attention; however, the timely diagnosis of some headaches (e.g., cortical vein thrombosis, subdural hematoma) is critical to good outcomes. Knowledge of both benign and nonbenign headaches is important for the anesthesiologist who is frequently the first physician to evaluate the patient with postpartum headache. Difficult diagnostic problems may require the opinion of a neurologist. The purpose of this chapter is to discuss the differential diagnosis of postpartum headache and PDPH in particular.

DIFFERENTIAL DIAGNOSIS OF POSTPARTUM HEADACHE

The classification of headaches follows the International Classification of Headache Disorders (ICHD), created in 1988 by the Headache Classification Subcommittee of the International Headache Society. This classification system, which has been updated (ICHD-II), identifies two broad categories of headaches: primary and secondary (Box 31-1).[4] Primary headaches are classified as migraine, tension-type headache, cluster headache and trigeminal autonomic cephalalgia, or other. Secondary headaches are attributable to a specific underlying pathologic process. Primary headaches are 20 times more common than secondary headaches among women in the first week postpartum.[1]

After delivery, women frequently suffer from headache. Stella et al.[5] retrospectively reviewed 5 years of hospital records to identify women who had postpartum headaches between 24 hours and 6 weeks after delivery. Ninety-five women met these criteria, and although the incidence of postpartum headache could not be calculated, the study did identify some important features of postpartum headache. Most women (82%) were still in the hospital at time of onset of the headache. Additionally, the demographics of the study population largely reflected the general obstetric population; the mean age was 25 years, 87% of the women had received some type of neuraxial analgesia/anesthesia, and 29% had a cesarean delivery.

TABLE 31-1 **Differential Diagnosis of Postpartum Headache**

Headache Etiology	Primary Symptoms/Signs	Diagnostic Modality
Tension headache	Mild to moderate headache, lasting 30 minutes to 7 days Often bilateral, nonpulsating, and not aggravated by physical activity	History and physical examination
Migraine	Recurrent moderate to severe headache, lasting 4 to 72 hours Often unilateral, pulsating, and aggravated by physical activity Associated with nausea, photophobia, and phonophobia	History and physical examination
Musculoskeletal	Mild to moderate headache accompanied by neck and/or shoulder pain	History and physical examination
Preeclampsia/eclampsia	Hypertension and/or HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome Headache often bilateral, pulsating, and aggravated by physical activity	History and physical examination Laboratory evaluation (alanine aminotransferase [ALT], aspartate transaminase [AST], uric acid, platelet count, urine protein)
Post–dural puncture headache	Headache within 5 days of dural puncture Worsens within 15 minutes of sitting or standing Associated with neck stiffness, tinnitus, photophobia, and nausea	History and physical examination Possible MRI
Cortical vein thrombosis	Nonspecific headache that may have a postural component. Often accompanied by focal neurologic signs and seizures	History and physical examination CT or MRI Possible angiography
Subarachnoid hemorrhage	Abrupt onset of an intense and incapacitating headache Often unilateral Accompanied by nausea, nuchal rigidity, and altered consciousness	History and physical examination CT without contrast or MRI (FLAIR sequence)
Posterior reversible (leuko) encephalopathy syndrome (PRES)	Severe and diffuse headache with an acute or gradual onset Possible focal neurologic deficits and seizures	History and physical examination, MRI
Brain tumor	Progressive and often localized headache Often worse in the morning Aggravated by coughing/straining	History and physical examination CT or MRI
Subdural hematoma	Headache usually without typical features Often overshadowed by focal neurologic signs and/or altered consciousness	History and physical examination CT or MRI
Carotid artery dissection	Late developing headache that is constant in nature Bilateral or unilateral location	History and physical examination. Carotid ultrasonography or MRA
Cerebral infarction/ischemia	Moderate headache accompanied by focal neurologic signs and/or altered consciousness	History and physical examination CT or MRI (showing angiographic "string of beads" appearance)
Idiopathic intracranial hypertension (pseudotumor cerebri/benign intracranial hypertension)	Progressive nonpulsating headache Aggravated by coughing/straining Associated with increased CSF pressure and normal CSF chemistry	History and physical examination Lumbar puncture
Spontaneous intracranial hypotension	No history of dural trauma Diffuse, dull headache worsening within 15 minutes of sitting or standing Associated with neck stiffness, nausea, tinnitus, and photophobia CSF opening pressure < 60 mm H_2O in the sitting position	History and physical examination Lumbar puncture Radioisotope cisternography CT myelography
Sinusitis	Frontal headache with accompanying facial pain Development of headache coincides with nasal obstruction Purulent nasal discharge, anosmia, and fever	History and physical examination Nasal endoscopy CT or MRI
Meningitis	Headache is most frequent symptom Often diffuse Intensity increases with time Associated with nausea, photophobia, phonophobia, general malaise, and fever	History and physical examination Lumbar puncture

TABLE 31-1 **Differential Diagnosis of Postpartum Headache—cont'd**

Headache Etiology	Primary Symptoms/Signs	Diagnostic Modality
Pneumocephalus	Frontal headache Often an abrupt onset immediately after dural puncture Symptoms can worsen with upright posture	History and physical examination CT or MRI
Caffeine withdrawal	Onset of headache within 24 hours of cessation of regular caffeine consumption* Often bilateral and pulsating Relieved within 1 hour of ingestion of caffeine 100 mg	History and physical examination
Lactation headache	Mild to moderate headache associated temporally with onset of breast-feeding or with breast engorgement	History and physical examination
Ondansetron headache	Mild to moderate headache associated with ondansetron intake	History and physical examination

CSF, cerebrospinal fluid; *CT,* computed tomography; *FLAIR,* fluid-attenuated inversion recovery; *MRA,* magnetic resonance angiogram; *MRI,* magnetic resonance imaging.

*The International Classification of Headache Disorders-II criteria state that caffeine-withdrawal headache occurs on cessation of ≥ 200 mg daily caffeine consumption for more than 2 weeks.[4] However, others have suggested that caffeine-withdrawal headache may occur after as little as 3 days' exposure to 300 mg/day or 7 days' exposure to 100 mg/day.[35]

BOX 31-1 International Classification of Headache Disorders (ICHD-II) Classification

Primary

- Migraine
- Tension-type headache
- Cluster headache and other trigeminal autonomic cephalgias
- Other primary headaches

Secondary

- Headache attributed to:
  - Head and/or neck trauma
  - Cranial or cervical vascular disorder
  - Nonvascular intracranial disorder
  - A substance or its withdrawal
  - Infection
  - Disorder of homeostasis
  - Disorder of the cranial structures (e.g., eyes, ears, nose, sinuses, teeth, mouth)
  - Psychiatric disorder
- Cranial neuralgias and central causes of facial pain
- Other headache, cranial neuralgia, central or primary facial pain

Modified from Headache Classification Subcommittee of the International Headache Society. The International Classification of Headache Disorders: 2nd edition. Cephalalgia 2004; 24(Suppl 1):9-160.

Primary Headaches

The postpartum patient can present with a recurrence of her known primary disorder or with the first manifestation of a primary condition. Patients with a history of headache disorders typically are diagnosed with one of the four major types of primary headaches. The most common postpartum headaches are tension-type and migrainous headaches, which account for almost two thirds of headaches during this period.[1,2] **Tension-type headaches** are often circumferential and constricting, can be associated with scalp tenderness, and are usually of mild to moderate severity.

Migraine

Migrainous headaches (or migraines) are defined as recurring cranial pain lasting 4 to 72 hours, often with typical features such as pulsating pain in a unilateral location, nausea, and photophobia.[4] Headache with aura is a subtype of migraine that is characterized by focal neurologic symptoms preceding the headache. The prevalence of migraine is approximately 17% in the female population (three times more common than in men) and is more common in patients between 30 and 50 years or age.[6] Pregnancy has an ameliorating effect on migraine frequency in the majority of sufferers. However, symptoms may recur soon after delivery, with reports of 34% within the first week postpartum and 55% within the first month.[7] Generally, the symptoms are similar to their typical pattern, although often milder and less often unilateral. It is rare for a migraine to manifest for the first time during the postpartum period. There appears to be an association between migraines and preeclampsia, which may reflect an underlying predisposition to cerebral ischemic injury.[8]

Secondary Headaches

A common secondary headache in the postpartum period is the **musculoskeletal headache**, exacerbated by the maternal physical exertion of labor and associated sleep deprivation. This headache has accompanying neck and shoulder pain without a history of dural puncture. Approximately 11% to 14% of postpartum headaches are diagnosed as musculoskeletal.[1] Other causes of secondary headache are discussed in the following paragraphs.

Hypertension

Hypertensive disorders of pregnancy, including preeclampsia, are commonly associated with headaches.

Eclampsia is a form of hypertensive encephalopathy that includes headache, visual disturbances, nausea, vomiting, seizures, stupor, and sometimes coma. Seizures may occur in the absence of severe hypertension. Headache is a serious premonitory sign, being present in over 50% of women in whom eclampsia develops.[9] Other hypertensive disorders, with or without superimposed preeclampsia, are also associated with headaches both antepartum and postpartum and may lead to encephalopathy. The diagnosis can be complex if the parturient's labor and delivery course is complicated by a dural puncture.[10]

Posterior Reversible Leukoencephalopathy Syndrome

Posterior reversible (leuko)encephalopathy syndrome (PRES) was described in 1996 after recognition of consistent symptom presentation and brain magnetic resonance imaging (MRI) findings in a diverse group of patients. Conditions associated with PRES include preeclampsia, uremia, hemolytic-uremic syndrome, and exposure to immunosuppressant drugs.[11] Approximately 25% of cases of PRES occur during pregnancy or in the immediate postpartum period. PRES symptoms include headache, seizures, altered mental status, visual changes, and, occasionally, focal neurologic deficits.[12]

The neuroradiologic features of PRES include symmetric areas of cerebral edema, predominantly involving the white matter regions of the posterior circulation (occipital lobes, posterior parietal and temporal lobes) (Figure 31-1). The pathophysiology of PRES is similar to that of hypertensive encephalopathy in that altered cerebrovascular regulation causes loss of blood-brain barrier integrity. The accompanying vasogenic edema can be reversed by prompt recognition and supportive therapy (e.g., cessation of provocative medications, aggressive treatment of hypertension, seizure prophylaxis). However, irreversible cytotoxic edema with permanent neurologic damage can occur if the initial disorder is not diagnosed early. This syndrome often manifests in the postpartum period, frequently in conjunction with preeclampsia. Distinguishing PRES from preeclampsia or eclampsia is complex because headache, seizures, and focal neurologic deficits, such as temporary loss of vision, are common symptoms of both disorders.[13,14] Typical features that distinguish PRES from other postpartum headaches include seizures and focal neurologic deficits, such as temporary loss of vision. Definitive diagnosis is made with MRI.

Cortical Vein Thrombosis

The incidence of cerebral cortical vein thrombosis is increased during pregnancy and in the puerperium, and is estimated to be 10 to 20 per 100,000 deliveries in developed countries. The incidence appears higher in developing countries (e.g., 450 per 100,000 deliveries in India).[15] Often it is difficult to distinguish cortical vein thrombosis from PDPH, because the headache of cortical vein thrombosis may have a postural component. Preceding dural punctures have been reported, and it has been hypothesized that the reductions in cerebrospinal fluid (CSF) pressure and cerebral vasodilation that accompany dural puncture predispose to thrombosis development.[16] Associated features may include focal neurologic signs, seizures, and coma. Cerebral infarction may ensue if diagnosis is delayed. Diagnosis is best confirmed by MRI, because computed tomography (CT) appears to identify only one third of cases.[17] Treatment of cortical vein thrombosis largely is symptomatic, with the aim of preventing seizures. Anticoagulation therapy is commonly used to treat these patients, with observational and randomized trial studies indicating better outcomes.[18]

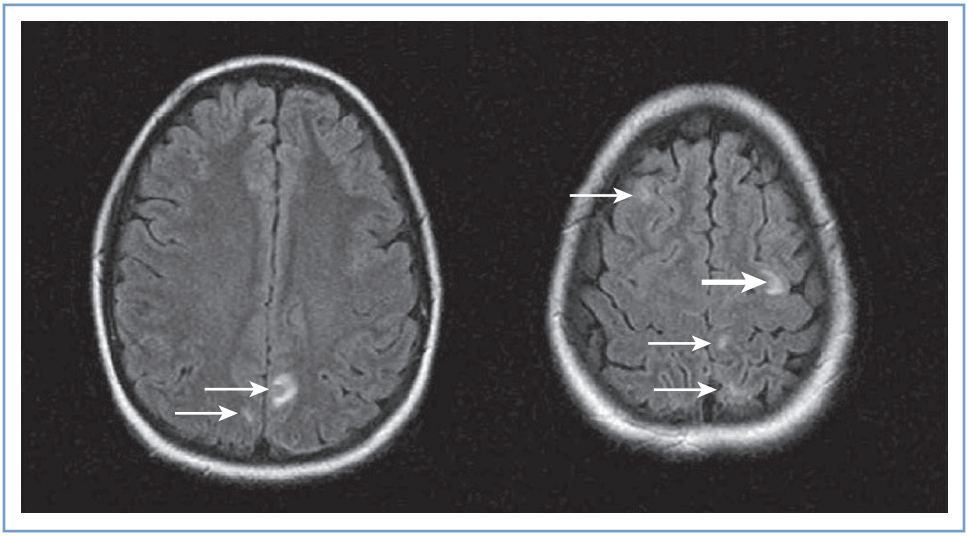

FIGURE 31-1 ■ Posterior reversible (leuko)encephalopathy syndrome (PRES). Axial fluid-attenuated inversion-recovery (FLAIR) images demonstrate foci of abnormally increased T2 signal (*arrows*) in the subcortical white matter and cortex of the frontal and parietal lobes involving both anterior and posterior circulations. (From Long TR, Hein BD, Brown MJ, et al. Posterior reversible encephalopathy syndrome during pregnancy: seizures in a previously healthy parturient. J Clin Anesth 2007; 19:145-8.)

Cerebral Infarction/Ischemia

Cerebral arterial insufficiency is one cause of stroke in pregnancy with an estimated incidence of 4 to 11 per 100,000 deliveries.[19] Approximately half of the events occur in the peripartum period, and the clinical presentation often comprises a sudden onset of a nonpostural thunderclap headache, vomiting, seizures, and focal neurologic deficits. Postpartum cerebral angiopathy has been detected with the aid of cerebral angiography, in which a characteristic "arterial beading" pattern indicative of arterial spasm is evident.[20] Initial CT and MRI findings are often normal, and intracranial Doppler or angiographic investigations may be necessary to diagnose the arterial ischemia or infarct. Treatment is supportive and may include vasodilator therapy.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) occurs secondary to aneurysmal or nonaneurysmal causes. The risk for SAH due to nonaneurysmal causes appears to be increased during pregnancy. A 2012 U.S. population–based study estimated an overall incidence of peripartum SAH at 5.8 per 100,000 deliveries.[21] The classic presentation consists of the sudden onset of a severe headache that is unlike any previous headache. Associated symptoms may be present, such as decreased level of consciousness and focal deficits. Pregnancy may increase the risk for bleeding because of increased blood volume and hormonal changes that affect arterial integrity. Two thirds of all cases in pregnancy occur in the postpartum period, but maternal mortality appears to be less than in nonpregnant patients.[21] Other factors associated with SAH during pregnancy include advanced maternal age, African American race, hypertensive disorders, smoking history, alcohol abuse, and intracranial venous thrombosis. Suspicion of SAH necessitates urgent investigation by CT scan, because nonsurgical therapies (e.g., endovascular ablation) are available and long-term sequelae can be minimized.

Subdural Hematoma

In rare instances, dural puncture is associated with the subsequent development of a subdural hematoma (see later discussion). In several case reports, the identification of the subdural hematoma was preceded by symptoms of a PDPH.[22] Dural puncture results in leakage of CSF and decreased intracranial pressure (ICP). Presumably, the reduction in ICP causes stress on bridging cerebral vessels, which may precipitate bleeding. Neurologic signs of subdural hematoma are variable but include evidence of increased ICP (e.g., headache, somnolence, vomiting, confusion) and focal abnormalities.

Carotid Artery Dissection

A rare, vascular cause of postpartum headache is spontaneous carotid artery dissection. Borelli et al.[23] reviewed the 19 known published cases of postpartum carotid artery dissection. The mean interval from delivery to headache onset was 9.3 days. The headaches were constant in character and both unilateral and bilateral. Stricken woman appeared older (mean age, 35 years) than the average parturient. Diagnosis was made after carotid vessel ultrasonography or magnetic resonance angiography.

Brain Tumor

Intracranial tumors may manifest as postpartum headache. Headache that is dull rather than throbbing may be an early feature of a brain tumor. Nausea, vomiting, seizures, and/or focal neurologic signs may be present. Neurologic examination may reveal evidence of increased ICP. Case reports suggest that atypical presentation of the headache, either with persisting headache symptoms in the supine position or exacerbation after epidural blood patch, should prompt further neuroradiologic investigations.[24,25]

Idiopathic Intracranial Hypertension

Parturients with idiopathic intracranial hypertension (i.e., increased ICP in the absence of a mass lesion, also known as pseudotumor cerebri or benign intracranial hypertension) have headache and visual disturbances, usually in the antepartum period. The features of the postpartum headache of pseudotumor cerebri mimic the usual chronic headache symptoms experienced by the patient. The diagnosis largely is one of exclusion (see Chapter 49). Treatment involves reduction of CSF pressure, either with glucocorticoids, carbonic anhydrase inhibitors, diuretics, or serial lumbar punctures. Case reports describe the use of an intrathecal catheter for labor analgesia[26] and administration of epidural blood patch for PDPH in patients with idiopathic intracranial hypertension.[27]

Spontaneous Intracranial Hypotension

Spontaneous intracranial hypotension develops because of CSF leakage secondary to dural tears. The tears usually occur at the thoracic spinal level and are not associated with prior spinal intervention.[28] Diagnosis requires radioisotope cisternography and CT myelography, which may also identify the level of the leak. Presentation of this disorder is identical to that of PDPH, because the pathophysiology is the same. The only difference is the lack of a prior neuraxial procedure in spontaneous intracranial hypotension. One case report has described the development of a postural headache 4 days after a spontaneous vaginal delivery without neuraxial anesthesia.[29] The patient was found to have a cervicothoracic dural leak.

Pneumocephalus

The subdural or subarachnoid injection of air used for identification of the epidural space may be associated with the sudden onset of severe headache, sometimes accompanied by neck pain, back pain, or changes in mental status.[30] Headache symptoms can mimic PDPH in that they are worse in the sitting position and may be relieved by lying down. Radiologic studies confirm the

presence of intracranial air; the headache typically resolves over the first week. Administration of oxygen by nasal cannula or face mask may hasten resorption of the air and speed recovery, although this has yet to be proven with pneumocephalus after neuraxial anesthesia.[31]

Meningitis

The severe headache of meningitis typically manifests within the first several postpartum days (see Chapter 32). It is accompanied by fever, nuchal rigidity, and the presence of Kernig and Brudzinski signs. Lethargy, confusion, vomiting, seizures, and a rash also may occur. The most common pathogen is *Streptococcus viridans*.[32,33] These organisms are found in the upper airway and vagina; the causative organism has been linked to the oropharyngeal flora of the proceduralist in a number of reports of iatrogenic meningitis after dural puncture procedures. Aseptic technique during the neuraxial procedure, including donning of a mask by the proceduralist, is of paramount importance. The diagnosis is confirmed by examination and CSF culture.

Sinusitis

Headache caused by inflamed paranasal sinuses is associated with purulent nasal discharge and, occasionally, fever. Pain may be unilateral or bilateral, depending on the extent of the disease, and the skin over the affected sinus may be tender. Frontal sinus infection causes headache in the frontal region. Ethmoidal and sphenoidal sinus infections cause periorbital pain, and maxillary sinus infection may cause diffuse facial discomfort. The sinuses fill overnight, and pain typically is worse on awakening. Pain improves in the upright position, which assists drainage.[34]

Caffeine Withdrawal

The withdrawal of caffeine may lead to headache, increased fatigue, and anxiety. Caffeine withdrawal headaches may occur after just 3 days' exposure to 300 mg/day or 7 days' exposure to 100 mg/day of caffeine.[35] Normal-sized caffeinated drinks usually contain 50 to 100 mg of caffeine per serving. Although caffeine withdrawal headache has not been documented as a cause of postpartum headache, if the parturient has been drinking beverages with caffeine during the pregnancy the diagnosis should be considered.

Lactation Headache

Askmark and Lundberg[36] reported episodes of intense headache during periods of breast-feeding in a woman known to suffer from migraine. Onset of headaches occurred within the first few minutes of breast-feeding, and the headaches resolved after cessation of nursing. The headaches were associated with an increase in plasma vasopressin concentration. Headaches have also been described in women with breast engorgement who either have elected not to breast-feed or have reduced the frequency of breast-feeding.[37]

Ondansetron

Sharma and Panda[38] reported a case in which a woman received ondansetron for nausea and vomiting after uneventful spinal anesthesia for cesarean delivery. Several hours later she developed a severe frontal headache that was worse in the upright position and in the morning and evening hours. The symptoms abruptly stopped after the discontinuation of ondansetron.[38] Headache is a common side effect of ondansetron (incidence, 3% to 17%), owing to its antagonism of serotonin 5-HT_3 receptors, and should be considered in the differential diagnosis of postpartum headache.

POST–DURAL PUNCTURE HEADACHE

Incidence

PDPH may occur after intentional dural puncture with a spinal needle or unintentional dural puncture with an epidural or other needle. A meta-analysis of studies of PDPH in obstetric patients (n = 328,769) calculated a pooled risk for unintentional dural puncture with any epidural needle of 1.5% (95% confidence interval [CI], 1.5% to 1.5%).[39] After a dural puncture with an epidural needle, the risk for PDPH was 52.1% (95% CI, 51.4% to 52.8%) (Figure 31-2). The rate of PDPH after dural puncture with spinal needles ranged between 1.5% and 11.2%, depending on the needle size and type of needle (see later discussion) (Table 31-2).[39-43] Although PDPH is often considered a "minor" complication of dural puncture, it was the cause of 14% of obstetric claims in the American Society of Anesthesiologists (ASA) Closed-Claims Project database (see Chapter 33).

Symptoms

Patients typically experience headache pain in the frontal and occipital regions, but location is not diagnostic. Pain often radiates to the neck, which may be stiff. Some women have a mild headache that permits full ambulation. In others, pain is severe and incapacitating. Symptoms are worse in the upright position and are usually relieved in the horizontal position. Abdominal compression may relieve pain in some patients. The ICHD-II defines PDPH as occurring within 15 minutes of moving to an upright position (sitting or standing) and resolving within 15 minutes of moving to the supine position, and requires one of the following symptoms to be present: headache, neck stiffness, tinnitus, hypacusis, photophobia, or nausea.[4]

Lybecker et al.[44] reported the incidence of these symptoms in a prospective study of 75 nonobstetric patients with PDPH (Table 31-3). Cranial nerve palsy, thought to be secondary to nerve traction due to low CSF volume, is occasionally associated with PDPH. The sixth cranial nerve is most susceptible to traction during its long intracranial course. The traction results in failure of the involved eye to abduct, and patients may have diplopia. Hearing loss is usually in the low-frequency range and may be secondary to endolymph and perilymph

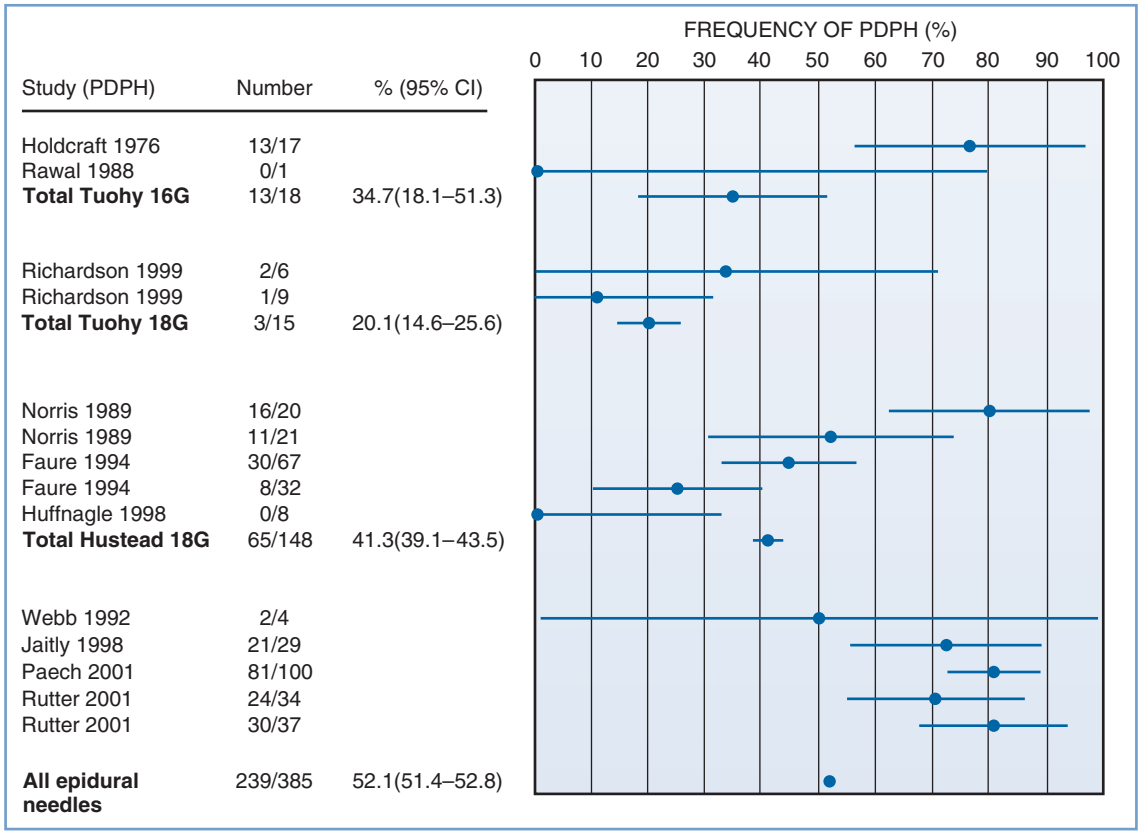

FIGURE 31-2 ■ Meta-analysis of post–dural puncture headache (*PDPH*) frequency for epidural needles in the obstetric population. The *dots* represent the percentages of patients experiencing the event. The *horizontal lines* represent the 95% confidence interval (*CI*). (From Choi PT, Galinski SE, Takeuchi L, et al. *Ocular symptoms include photophobia, diplopia, and difficulty in accommodation.
†Auditory symptoms include hearing loss, hypacusis, and tinnitus.
Data from Lybecker H, Djernes M, Schmidt JF. Postdural puncture headache (PDPH): onset, duration, severity, and associated symptoms. An analysis of 75 consecutive patients with PDPH. Acta Anaesthesiol Scand 1995; 39:605-12.

imbalance and alteration of hair cell position in the inner ear.[45] The risk for hearing loss appears to be increased with advanced age (> 40 years) and dural puncture with larger-gauge needles. Other rare symptoms associated with PDPH include seizures,[46,47] vertigo,[48] bilateral forearm pain,[49] abdominal pain, and diarrhea.[50] In all these case reports the headache and associated symptoms cleared after therapy with an epidural blood patch.

Onset and Duration

Headache typically occurs on the first or second day after dural puncture; by ICHD-II criteria, it must appear within 5 days of dural puncture.[4] However, Choi et al.[39] found that PDPH can occur up to 7 days after dural puncture, and one case report identified a woman who developed a PDPH 12 days after labor neuraxial analgesia.[51] Ninety-five percent of PDPH headaches last less than a week. The National Obstetric Anaesthesia Database project of the Obstetric Anaesthetists' Association demonstrated that 75% of 975 women with PDPH had difficulty with performing activities of daily living.[52] Rarely, symptoms may persist for months or even years.[53] Webb et al.[54] found that 18% of women who sustained a dural puncture with a 17-gauge Tuohy needle suffered from chronic headaches compared with 5% of women in a matched cohort who did not sustain dural puncture with an epidural needle. These findings require confirmation, but they suggest that there may be long-term sequelae from dural puncture with a large-gauge needle.

Imaging

Imaging investigations are not routinely recommended for the postpartum patient with a PDPH unless the symptoms suggest other diagnoses or the diagnosis of PDPH is in doubt. Contrast-enhanced MRI is the method of choice to study the meninges and has revealed characteristic findings of PDPH.[55,56] These findings include (1) marked, diffuse pachymeningeal thickening and enhancement; (2) compression of the ventricles; (3) caudal displacement of the brain, brainstem, and optic chiasm; (4) cerebellar ectopia; (5) pituitary enlargement and enhancement; (6) and expansion of the superior sagittal sinus. The enlarged venous sinus may represent compensatory venous expansion in response to low CSF pressure. The presence of intracranial air on CT imaging (after using a loss-of-resistance to air technique to identify the epidural space) may help differentiate headache due to pneumocephalus from a low-CSF pressure headache.[57]

Pathophysiology

Debate continues regarding the precise etiology of PDPH symptoms. The original theory was that pain-sensitive nerve fibers were stimulated by a downward shift of the brain secondary to a loss of CSF volume. German surgeon August Bier[58] is credited with the first description of successful spinal anesthesia and PDPH after his pioneering work on spinal anesthesia with cocaine. Bier and his assistant, Hildebrandt, performed spinal anesthesia on each other; using blows to the shin with an iron hammer and application of a burning cigar to the skin they demonstrated adequate sensory blockade.[58] Both experienced severe PDPH. The assistant forced himself to work the next day, but Bier stayed home for 9 days. Bier suggested the PDPH might be caused by CSF loss. Today there is no doubt that leakage of CSF initiates the syndrome. Kunkle et al.[59] consistently produced PDPH by draining 20 mL of CSF from volunteers. Symptoms were immediately relieved by subarachnoid injection of saline to restore initial CSF pressure.

Total CSF volume is estimated to be 150 mL, and the production rate is approximately 0.35 mL/min or a daily rate of 500 mL. The rate of CSF leakage through a dural hole may exceed the rate of CSF production. If this occurs, low CSF pressure results in a loss of the cushioning effect provided by intracranial fluid.

CSF pressure during labor is normal between contractions but increases significantly during painful contractions and expulsive efforts. Effective epidural analgesia attenuates this increase in CSF pressure.[60] In a study of five women with unintentional dural puncture, epidural pressures were normal preceding the development of headache.[61] However, with development of headache symptoms, the mean epidural pressure measurements were found to decrease significantly.

Not all patients with PDPH symptoms have decreased CSF pressure, and not all patients with a significant CSF leak experience symptoms. The pain of PDPH may be caused, in part, by an increase in cerebral blood flow (and cerebral vasodilation) as a consequence of low CSF pressure or volume. This phenomenon has been observed in animals.[62,63] The inverse relationship between intracranial blood volume and CSF volume reflects the body's effort to maintain a constant intracranial volume.[64] The lumbar CSF compartment is a dynamic structure and acts as a reservoir for intracranial CSF volume adjustment.[65] The occurrence of cerebral vasodilation may explain the relief of headache symptoms with vasoconstrictors such as caffeine, theophylline, and sumatriptan.

Risk Factors

In a classic study of 10,098 spinal anesthetics published in 1956, Vandam and Dripps[66] noted that three patient factors influenced the incidence of PDPH: age, gender, and pregnancy. The analysis did not allow determination as to whether these factors were independent risk factors. Subsequently, other risk factors for development of PDPH have been identified.

Age

Extensive evidence supports the observation that PDPH is uncommon in patients older than 60 years of age and is most common in patients who are younger than 40 years of age.[67] In the elderly, the dura may be inelastic and less likely to gape after puncture. CSF leakage may be impeded by adhesions and calcification. The cerebrovascular system also may be less reactive in older patients. Further, this group is less active physically and older patients may be less likely to complain.

Gender

Vandam and Dripps[66] observed a twofold higher incidence of PDPH after spinal anesthesia in women than in men (14% versus 7%, respectively). This difference may be related to differences in cerebrovascular reactivity, because it is well known that migraine headaches occur predominantly in females and are influenced by

hormonal changes. Women may have enhanced vascular reactivity, or perhaps changes in cerebral blood flow are more likely to produce pain in women than in men. A meta-analysis of randomized clinical trials identified a twofold higher risk for PDPH in nonpregnant females than in males.[68]

Vaginal Delivery

Vandam and Dripps[66] also observed a high incidence of PDPH (22%) in women who received spinal anesthesia for vaginal delivery. This high incidence may be a result of the mechanical consequences of expulsive efforts during the second stage of labor and/or postpartum hormonal changes in cerebrovascular reactivity. Expulsive efforts in the second stage may increase CSF leakage. This possibility has prompted some physicians to restrict maternal pushing after dural puncture and to use forceps to shorten the second stage of labor. In a 20-year retrospective review of 460 parturients who experienced unintentional dural puncture during labor at the Birmingham Maternity Hospital in the United Kingdom, Stride and Cooper[69] did not identify a lower incidence of PDPH in women who underwent prophylactic forceps delivery than in those who had spontaneous vaginal delivery. In contrast, in a retrospective review of the records of 33 laboring women who had experienced unintentional dural puncture, Angle et al.[70] found that women who were allowed to push were much more likely to develop PDPH (relative risk [RR], 7.4; 95% CI, 1.1 to 48.2) and also were more likely to require an epidural blood patch.

Morbid Obesity

In a retrospective study, Faure et al.[71] found that morbidly obese patients are less susceptible to PDPH and are also less likely to receive an epidural blood patch for treatment of PDPH, suggesting either a reduced severity of PDPH or anesthesia provider reticence to perform an epidural blood patch in this patient population. Possible but unproven explanations of a lower incidence and severity of PDPH in obese patients include increased abdominal pressure (which may reduce the extent of CSF leakage) and/or reduced physical activity in these patients. Other confounding factors, such as differences in the mode of delivery (higher rate of cesarean delivery) and neuraxial opioid administration, may also play a role. In contrast to these findings, Webb et al.[54] found that the median body mass index was greater in women who developed PDPH after unintentional dural puncture with a Tuohy needle than in women who did not develop PDPH.

History of Previous Post–Dural Puncture Headache

A history of PDPH after previous spinal anesthesia is associated with the development of PDPH with subsequent spinal anesthesia.[72] A cohort of nonobstetric women with a history of previous spinal anesthesia was monitored prospectively after a second spinal anesthesia procedure. Those with a previous history of PDPH were 2.3 times more likely (95% CI, 1.0 to 5.1) to have a second PDPH than women without a history of headache (24.2% versus 10.6%, respectively). This finding suggests that certain individuals are predisposed to the development of PDPH.

Multiple Dural Punctures

Seeberger et al.[73] found that multiple dural punctures significantly increased the risk for PDPH. Surgical patients who received a second spinal injection owing to failure of the initial spinal puncture had a 4.2% incidence of PDPH compared with a 1.6% incidence among patients who had a single dural puncture.

Neuraxial Anesthetic Technique

Technical factors related to the neuraxial technique influence the incidence of PDPH.

Epidural Needle Size/Design. The high rate of PDPH after unintentional dural puncture with an epidural needle has led investigators to alter the epidural needle design or size in an attempt to reduce headache incidence or severity. Data on the success of this endeavor are conflicting. In an *in vitro* study using cadaver dura, no differences were found in fluid leak rate among punctures made with Hustead, Tuohy, Crawford, and Sprotte epidural needles.[74] In contrast, in an *in vivo* study, Morley-Forster et al.[75] observed a lower incidence of PDPH with the use of an 18-gauge Sprotte needle than with the use of the standard 17-gauge Tuohy needle, despite no difference in the unintentional dural puncture rate. A pilot study has examined the use of a 19-gauge Tuohy needle with 23-gauge epidural catheter.[76]

Spinal Needle Design. Historically, the beveled Quincke needle (Figure 31-3) has been the most widely used needle for dural puncture for both diagnostic and anesthetic purposes (see Chapter 12). A modification of the Quincke needle, the Atraucan needle, has a cutting tip and a double bevel, which is intended to cut a small

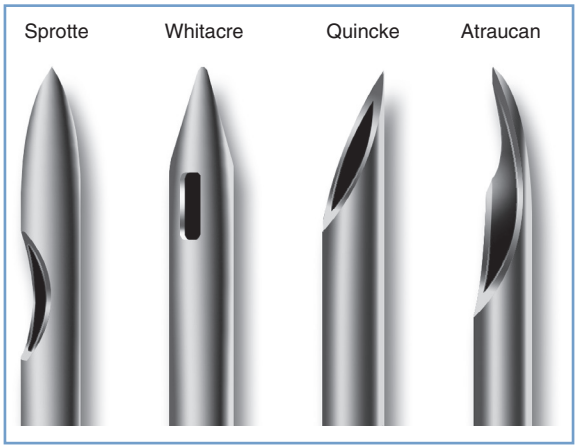

FIGURE 31-3 ■ Designs of spinal needle tips (not to scale). (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

dural hole and then dilate it.[40] Clinical experience with the Atraucan needle has been generally good,[40,41] although studies appear to suggest that the use of this needle is associated with a higher risk for PDPH than the use of a non-cutting, pencil-point needle (see Table 31-2).[42]

In 1951, Hart and Whitacre[77] introduced a solid-tipped, pencil-point spinal needle with a lateral injection port, which is now known as the Whitacre design (see Figure 31-3). They believed that their new needle would stretch and separate rather than cut the dural fibers and result in a lower incidence of PDPH. Currently, both 25- and 27-gauge Whitacre needles are very popular, and studies have confirmed the anticipated low incidence of PDPH.[39] A randomized comparison of 27-gauge Quincke and Whitacre needles in outpatients undergoing spinal anesthesia found a lower incidence of PDPH in the Whitacre needle group.[78] *In vitro* evidence suggests that fluid leak through the dural puncture site is lower after use of a pencil-point needle than after use of a beveled needle.[79] With the recognition that pencil-point spinal needle tips reduce the incidence of PDPH, other tip designs have appeared. In 1987, Sprotte et al.[80] reported experience with the use of a new needle that was designed to reduce the risk for neural and dural trauma (see Figure 31-3). The Sprotte needle has a solid oval tip and a longer orifice than the Whitacre needle. The incidence of PDPH was 0.02% with its use in a heterogeneous patient population of almost 35,000 patients.[80] Subsequent studies have shown the incidence of PDPH with the Sprotte needle is lower than that with Quincke needles of smaller gauge (see Table 31-2).[39] There are currently many other non-cutting spinal needle products available and all are associated with a low PDPH rate.

Spinal Needle Size. With the Quincke needle, the incidence and severity of PDPH are directly related to the size of the needle. The incidence of PDPH appears to be lower with a 27-gauge needle than with 25- and 26-gauge needles (see Table 31-2). A similar relationship may exist with pencil-point needles. When needles smaller than 27-gauge are used, the incidence of PDPH is very low, but technical problems with needle insertion and failure to produce adequate anesthesia are more common.[81] Locating the epidural space before insertion of the spinal needle (e.g., using the epidural needle as an introducer needle) may improve the success rate with these fine-gauge needles.

The current popularity of spinal anesthesia in obstetric patients is largely a result of new needle technology, which has led to a reduction in the incidence of PDPH. Because of the morbidity associated with PDPH, every effort should be made to use a needle associated with a low incidence of PDPH (e.g., a small-gauge, non-cutting needle).[82] There are times when urgency or body habitus will dictate the use of a larger needle, but there is seldom justification for using a Quincke needle larger than 27-gauge.

Direction of Bevel of the Quincke Needle. Studies have confirmed that puncturing the dura mater with a Quincke needle bevel parallel to the long axis of the spine reduces the incidence of PDPH by 70% compared with a perpendicular orientation.[83] An early study by Franksson and Gordh[84] demonstrated that orientation of the bevel of a Quincke spinal needle parallel to the long axis of the spine produced less dural trauma than occurred when the bevel was inserted perpendicularly. These investigators thought that the dural fibers were predominantly longitudinal in direction. Electron microscopy has revealed that the dural structure is far more complex than originally proposed. Fink and Walker[85] noted that the dura consists of multidirectional interlacing collagen fibers with both transverse and longitudinal elastic fibers. They suggested that the insertion of the needle with the bevel parallel to the long axis of the spine most likely results in less tension on the dural hole and, therefore, a smaller aperture with less CSF leak. *In vitro* studies of bevel orientation and fluid leak have provided conflicting results.[86-88] Despite confusing anatomic evidence, clinical experience strongly supports insertion of the Quincke needle with the bevel parallel to the long axis of the spine.[83]

Direction of the Bevel of the Tuohy Needle. Norris et al.[89] examined two groups of women who received epidural anesthesia with a Tuohy needle. In one group the bevel was kept perpendicular to the long axis of the spine. In the other group the needle entered the epidural space with the bevel parallel to the long axis and the needle was then rotated 90 degrees before insertion of the catheter. The authors observed a decreased incidence of PDPH in the latter group. However, some anesthesiologists argue that rotation of the needle within the epidural space may increase the risk for unintentional dural puncture. Richardson and Wissler[90] randomized laboring women to a cephalad or lateral orientation of the Tuohy bevel during epidural needle insertion. The needle was not rotated before insertion of the epidural catheter. There was no difference in dural puncture or PDPH rates, but catheter insertion was easier with a cephalad orientation of the bevel.

Midline or Paramedian Approach. There is conflicting evidence as to whether the spinal needle approach affects the incidence of PDPH. Haftalvi[91] reported no cases of PDPH in a retrospective survey of 4465 spinal anesthesia procedures. This investigator used a paramedian approach with a 20-gauge Quincke needle, and the skin was punctured 3 cm from the midline. He suggested that tangential dural puncture creates a dural flap and prevents PDPH. In contrast, Viitanen et al.,[92] prospectively monitoring obstetric patients after administration of single-shot spinal analgesia for labor (27-gauge Quincke needle), observed PDPH in 3 of 85 (3.5%) patients in whom the midline approach was used, compared with 15 of 127 (11.8%) patients in whom the paramedian approach was used. Using a rigid paper cylinder model of the dura, Kempen and Mocek[93] studied median and paramedian punctures with a 22-gauge Quincke needle in different orientations. With midline punctures, all entry and exit holes were of uniform size regardless of bevel orientation and no dural flaps were seen. After paramedian punctures, flaps formed when the needle bevel faced the cylinder surface with a near-tangential

angle of perforation, suggesting it may be beneficial to insert the needle via the paramedian approach to reduce the incidence of PDPH. Currently, data are insufficient to recommend either the median or paramedian approach in regard to subsequent PDPH.

Skin Preparation. In a nonrandomized, nonblinded study reported in a letter, Gurmarnik[94] found that the removal of dried povidone-iodine solution from the skin before placement of the spinal needle was associated with a lower incidence of PDPH (6% versus 0%). This investigator recommended removal of the povidone-iodine solution before insertion of the spinal needle and suggested that chemical meningismus resulting from povidone-iodine introduced into the intrathecal space by the spinal needle contributed to PDPH. This finding has not been confirmed by other investigators. Simsa[95] suggested that using an introducer needle so the spinal needle does not touch the povidone-iodine solution may be preferable and accomplish the same goal. (*Editors' note:* We do not recommend removal of povidone-iodine [or other solutions used for skin antisepsis] before initiating neuraxial analgesia, because povidone-iodine works by desiccating bacteria, and removing the povidone-iodine reduces its antibacterial effect. Rather, the solution should be allowed to dry on the skin.)

Air versus Saline Method of Locating the Epidural Space. The medium (air or saline) used for the loss-of-resistance technique to identify the epidural space has not clearly been shown to influence the incidence of PDPH. Many anesthesia providers have adopted the loss-of-resistance-to-saline technique in the belief that it is associated with a lower incidence of unintentional dural puncture and PDPH than the use of air.[96] However, the data are inconsistent, and not all studies have found a difference.[97,98] In a meta-analysis of prospective randomized studies comparing air to saline and the incidence of both unintentional dural puncture and PDPH, no difference in either outcome was found.[99] Segal and Arendt[100] suggested that a randomized study of air versus saline may not be the best approach to study headache rate; the study design may lead to overestimation of the difference between air and saline, should one exist, because it is impossible to blind the anesthesia provider to technique and it forces the provider to use a less preferred technique. They performed a retrospective study comparing air with saline; the rate of unintentional dural puncture was not different between groups. However, among anesthesia care providers who had a preference for one technique, use of their preferred technique was associated with fewer unintentional dural punctures. Thus, current data do not support a difference in the incidence of PDPH between air and saline used for the loss-of-resistance technique to identify the epidural space, and one should certainly not change techniques hoping it may decrease headache rates.

Choice of Local Anesthetic Drug for Spinal Anesthesia. Naulty et al.[101] reported that the use of bupivacaine-glucose or lidocaine-glucose for spinal anesthesia was associated with a higher incidence of PDPH than the use of tetracaine-procaine. They postulated that osmotic, cerebral irritant, and/or cerebrovascular effects of the glucose could be responsible for these findings. Whether this finding is applicable to other non–glucose-containing local anesthetic preparations, such as plain bupivacaine, is unknown.

Continuous Spinal Anesthesia. A multicenter trial published in 2008 reexamined the safety and use of 28-gauge microcatheters for spinal labor analgesia.[102] There was no difference in the incidence of PDPH (9% versus 4%, respectively) or epidural blood patch (5% versus 2%, respectively) between women randomly assigned to receive an intrathecal catheter and those who received an epidural catheter; however, the study was insufficiently powered to assess these outcomes. Spinal microcatheters are not currently commercially available in North America.

A 23-gauge spinal catheter inserted using a catheter-over-needle technique is available in North America. Three case series have evaluated this catheter for labor analgesia or cesarean delivery.[103-105] The headache rate ranged from 9% to 29% in these series. This rate is greater than that reported in other studies using traditional epidural or combined spinal-epidural techniques.

Combined Spinal-Epidural Anesthesia. The combined spinal-epidural (CSE) technique is widely used for both labor analgesia and cesarean delivery. Intuitively, it seems that the incidence of PDPH should be identical to, or greater than, that observed after single-shot spinal anesthesia with the same size and type of needle. However, the available evidence, primarily from observational studies, suggests that the risk for PDPH is not increased with the CSE technique.[106-108] PDPH rates with the CSE technique in these three studies were 1.7%, 0.43%, and 1.4%, respectively, compared with 1.6%, 0.45%, and 0.8% for the epidural technique. Initial placement of the epidural needle facilitates precise dural puncture, and the subsequent increase in epidural space pressure after the epidural injection of local anesthetic may reduce CSF leakage. If the anesthesia provider is in doubt about correct epidural needle placement, a needle-through-needle dural puncture might resolve the issue and prevent unintentional dural puncture with a large-gauge epidural needle.

Complications

The immediate problems associated with post–dural puncture headaches include (1) the inability to perform activities of daily living, such as providing care for the newborn; (2) an extended duration (almost one full day) of hospitalization; and (3) a higher number of emergency department visits, with almost 40% of patients returning for more than one visit.[109] Although these complications are very bothersome to the patient, they are short-lived and do not result in long-term morbidity. However, rare but serious complications may occur after dural puncture and PDPH.

Zeidan et al.[110] reviewed the published reports of subdural hematoma after dural puncture. They found that **subdural hematoma** was associated with new neurologic

symptoms in addition to changing headache characteristics. The proposed mechanism of subdural hematoma development is ongoing intracranial hypotension leading to caudal movement of the brain and rupture of fragile, bridging subdural veins. These cases have been managed expectantly, with an epidural blood patch, as well as with neurosurgical decompression.

Dural sinus thrombosis has been documented after unintentional dural puncture and treatment of PDPH with an epidural blood patch.[111] Responsible factors may be cerebral venous dilation (associated with decreased ICP) and the hypercoagulability that occurs during pregnancy. Therapy may include anticoagulation.[18]

Diplopia or **hearing loss** after dural puncture, secondary to cranial nerve dysfunction, may be permanent, even after successful treatment of the PDPH with an epidural blood patch.[112] A review of 95 cases of neurapraxia or axonotmesis of the ocular cranial nerves (oculomotor, trochlear, and abducens nerves) concluded that symptoms may last from 2 weeks to 8 months but that almost 90% of patients recover.[113]

Three studies have focused on the long-term morbidity arising from unintentional dural puncture or spinal anesthesia in obstetric patients.[54,114,115] Women delivering between 1978 and 1985,[114] between 1991 to 1996,[115] and between 2009 to 2010[54] were asked to recall symptoms beginning after their deliveries, including back pain and headache. The responses of women with unintentional dural punctures or spinal anesthesia were compared with women who had uneventful procedures. The first study found that 18% of women with unintentional dural puncture had complaints of frequent headaches or neck ache compared with only 7% of women experiencing uneventful neuraxial procedures.[114] The second study, from the same labor and delivery unit in Birmingham, England, did not confirm an increased risk for headache with prior unintentional dural puncture but instead found a higher rate of backache symptoms.[115] The third and most recent study compared patients with unintentional dural puncture (identified from a database and contacted at 12 to 24 months after delivery) with 40 women who received neuraxial techniques without an unintentional dural puncture.[54] Using validated pain questionnaires, the investigators found that 11 of 40 (28%) women with an unintentional dural puncture had chronic headaches compared with 2 of the 40 (5%) women in the control group.

Prevention

Many practices and maneuvers have been used in an attempt to reduce the incidence of PDPH after unintentional dural puncture, most with limited success. A 2005 survey of British obstetric anesthesiologists quantified the frequency of such practices.[116] These include encouraging postpartum fluid intake (91%), regular analgesia (83%), caffeine administration (30%), and using an intrathecal catheter (15%) at the time of unintentional dural puncture. Older practices, such as avoiding pushing during the second stage, restricting postpartum mobility, abdominal binders, and prophylactic epidural administration of saline or autologous blood, appear to be declining in use. Panadero et al.[117] suggest it may be prudent to restrict air travel after discharge from the hospital. Presumably, the headache can be precipitated by a change in the gradient between the subarachnoid space and the epidural space due to decreased atmospheric pressure. A 2010 systematic review of prevention strategies summarized the evidence from comparative studies and concluded that studies were heterogeneous and that "no clinical recommendation can be made until the superiority of one preventative intervention over another has been unequivocally proven in a definitive multicenter RCT [randomized controlled trial]."[118]

Posture

In a systematic review, Sudlow and Warlow[119] reviewed the evidence for reducing PDPH by use of bed rest rather than early mobilization (usually within 6 hours of dural puncture). The review included eleven trials with 1723 patients, and the results were consistent across all patient types; there was no benefit to bed rest compared with early mobilization (PDPH incidence 31% versus 27%, respectively). It is important to encourage early ambulation during the puerperium. Pregnant women are hypercoagulable and at increased risk for deep vein thrombosis and pulmonary embolism, and immobility increases this risk (see Chapter 39).

Hydration

Despite the widespread practice of encouraging women to increase oral fluid intake after unintentional dural puncture, there is little evidence that greater hydration prevents PDPH. A 2002 systematic review identified only one randomized trial in 100 nonobstetric patients. There was no difference in the incidence of PDPH in patients randomly assigned to receive 3 L or 1.5 L of fluid per day.[119]

Caffeine

Two clinical trials in nonobstetric patients have evaluated the efficacy of oral caffeine to prevent PDPH, but neither study showed a reduction in the incidence of headache.[120,121] Based on these results, prophylactic caffeine is not advocated for prevention of PDPH.

Cosyntropin

Hakim[122] evaluated whether cosyntropin, an adrenocorticotropic hormone (ACTH) analogue, was effective in reducing the incidence of PDPH after unintentional dural puncture in parturients. Patients were randomized to receive intravenous cosyntropin 1 mg or placebo 30 minutes after delivery. The incidence of PDPH was significantly lower in the cosyntropin group (33% versus 69%). The mechanism is unknown but may be related to an aldosterone-stimulating effect on volume expansion, modulation of pain perception via central endorphin-like action, or increased CSF production by enhanced sodium ion transport. Adequate dose-response and safety studies have yet to be performed.

Neuraxial Opioids

Earlier studies suggested that prophylactic neuraxial administration of a hydrophilic or lipophilic opioid does not reduce the incidence of PDPH after spinal anesthesia or unintentional dural puncture.[123,124] However, in a randomized, blinded trial published in 2008, 50 parturients with unintentional dural puncture and subsequent epidural analgesia were randomized to receive epidural morphine 3 mg or saline-placebo after delivery and again 24 hours later, before removal of the epidural catheter.[125] The incidence of PDPH was 48% in the saline-placebo group and 12% in the morphine group. Although no complications were reported, we would caution against routine administration of epidural morphine in these circumstances until this finding is confirmed and further safety studies are undertaken. The movement of morphine across the dura is increased by the presence of a large-gauge needle puncture, possibly increasing the risk for respiratory depression.[126]

Intrathecal Catheters

Placing a 19- or 20-gauge epidural catheter into the intrathecal space after an unintentional dural puncture with an epidural needle has become an increasingly popular technique.[127-129] The immediate benefits of an intrathecal catheter are reliable, low-dose local anesthetic labor analgesia and rapid-onset surgical anesthesia should it be required. Some experts have speculated that the intrathecal catheter might reduce the immediate CSF leak into the epidural space by a mechanical obstruction and induce an inflammatory fibrous reaction in the dura, thus facilitating closure of the puncture after removal of the catheter. Most studies are retrospective and observational and lack rigorous outcome definitions and follow-up. Data from these studies are conflicting but suggest that intrathecal catheters do not significantly reduce the incidence of PDPH unless they are left in place for at least 24 hours after delivery (Table 31-4).[127-133]

Russell[130] conducted a prospective, nonblinded, quasi-randomized multicenter study of parturients who had an unintentional dural puncture during epidural needle placement. Women were randomized in 6-month blocks to a repeat epidural procedure or placement of a spinal catheter through the dural puncture and leaving the catheter *in situ* for 24 to 36 hours. The incidence of PDPH was not significantly different between the epidural (62%) and spinal (72%) catheter groups. Given the current evidence, intrathecal catheters do *not* appear to reduce the incidence of PDPH, but further study is required before a definitive conclusion can be reached.

Prophylactic Epidural/Intrathecal Saline

Trivedi et al.[134] randomly assigned patients with unintentional dural puncture to receive either a prophylactic epidural saline bolus (40 to 60 mL) or blood patch (15 mL) given just before epidural catheter removal or conservative therapy without a saline bolus or blood patch. The incidence of PDPH was not different between the saline and control groups (88% versus 67%, respectively). Shah[61] studied 17 patients who received an epidural saline infusion (at a rate of approximately 40 mL/h) for 24 to 36 hours after unintentional dural puncture. Four patients complained of severe intrascapular pain, which resolved when the infusion rate was reduced. Severe PDPH developed in 47% of patients after the infusion was stopped. In contrast, in a nonrandomized, nonblinded study of patients with unintentional dural puncture, Charsley and Abram[135] reported that *intrathecal* injection of 10 mL of saline immediately before needle or catheter withdrawal resulted in a lower incidence of PDPH (32%) than in a control group who did not receive the saline (62%), as well as a less frequent need for an epidural blood patch. The intrathecal injection of saline after unintentional dural puncture deserves further study. Intrathecal saline should not be administered until residual local anesthetic effects have resolved.

TABLE 31-4 Rate of Post–Dural Puncture Headache after Unintentional Dural Puncture and Prophylactic Intrathecal Catheter Placement

Study*	Study Design	Spinal Catheter, n/N (%)	No Spinal Catheter, n/N (%)
Norris and Leighton[131]	Retrospective cohort; catheter left in place for 2 h	19/35 (54)	11/21 (52)
Cohen et al.[132]	Retrospective cohort:		5/15 (33)
	Catheter discontinued immediately after delivery	8/17 (47)	
	Catheter left in place for 24 h	0/13 (0)†	
Dennehy and Rosaeg[221]	Case series; catheter left in place for 13-19 h	0/3 (0)	
Paech et al.[129]	Prospective cohort; catheter discontinued immediately after delivery	21/24 (87)	60/76 (79)
Rutter et al.[128]	Retrospective cohort; catheter left in place for unknown duration	24/34 (71)	30/37 (81)
Ayad et al.[127]	Retrospective cohort:		34/37 (92)
	Catheter discontinued immediately after delivery	18/35 (51)†	
	Catheter left in place for 24 h	2/31 (6)†	
Russell IF[130]	Prospective, randomized in 6 month blocks, nonblinded intrathecal catheter for 24-36 h	36/50 (72)	29/47 (62)

*Superscript numbers indicate reference citations at the end of the chapter.
†Different than no catheter, $P < .05$.

Prophylactic Blood Patch

Interest in the use of prophylactic epidural blood patch prior to the removal of a labor epidural catheter arose after early observational studies suggested that the incidence of PDPH was lower with such treatment.[136] A 2010 systematic review[137] identified five studies of obstetric patients involving 221 women; four studies found a reduction in the headache rate and one did not.[138] Scavone et al.,[138] in the largest study included in the review, reported a double-blind trial in which 64 parturients with unintentional dural puncture were randomly assigned to receive 20 mL of autologous blood (prophylactic epidural blood patch) or a sham procedure. Both groups had a 56% incidence of PDPH; however, the duration of headache was shorter in the prophylactic blood patch group. The systematic review highlighted the difficulty in estimating the risks and benefits of prophylactic epidural blood patch. Because of the low incidence of unintentional dural puncture, studies are small; therefore, reliable conclusions about the technique cannot be made based on current evidence.[137]

Because unintentional dural puncture with a 16- or 18-gauge epidural needle results in a high incidence of PDPH, some anesthesiologists believe that prophylactic blood patch is always justified. Others argue that with such an approach, a significant number of patients would receive unnecessary treatment and that a blood patch is not devoid of complications. These latter anesthesia providers call attention to the potential for epidural catheters to become contaminated after prolonged use. The injection of blood through a contaminated epidural catheter may be associated with a higher risk for infection than injection through an epidural needle placed *de novo* for a therapeutic blood patch. A case report of a parturient who received a prophylactic epidural blood patch and was subsequently diagnosed with streptococcal septicemia highlights the potential risk for maternal infection during the puerperium.[139]

If performed, a prophylactic blood patch should be delayed until resolution of residual neuroblockade. The occurrence of pain during injection is a signal for the anesthesia provider to stop the injection of blood. If the patient has sensory blockade, she will not perceive pain. Additionally, evidence suggests that lidocaine may inhibit coagulation.[140] Finally, Leivers[141] reported a case of total spinal anesthesia after the epidural injection of 15 mL of blood before epidural anesthesia had regressed. The investigator speculated that residual lidocaine in the lumbar CSF was transferred to the brain as a consequence of an increase in lumbar CSF pressure and reduced volume produced by the patch. (*Editors' note:* One of us [DHC] has observed one case of transient, total blindness after the rapid, bolus injection of 30 mL of epidural saline after vaginal delivery in a patient who had experienced unintentional dural puncture during labor. The blindness resolved after 15 to 20 minutes, and subsequent ophthalmologic and neurologic examinations were normal. The etiology of the transient blindness was unclear. Nonetheless, it seems prudent to delay administration of prophylactic epidural saline or blood until the block has regressed and to avoid rapid epidural administration of blood or saline at any time.)

It is important to avoid the direct intrathecal injection of blood. Aldrete and Brown[142] reported a case of intrathecal hematoma and arachnoiditis with prolonged neurologic sequelae after prophylactic blood patch. Nineteen milliliters of blood were injected through an epidural catheter that, in retrospect, was positioned in the subarachnoid space. There was considerable resistance to injection of the blood, and severe lower back pain with tinnitus accompanied the procedure.

Prophylactic Dextran Patch

Salvador et al.[143] reported the prophylactic epidural injection of 20 mL of dextran-40 in 17 patients who had experienced unintentional dural puncture with a 17- or 18-gauge needle. Three of the patients were parturients, and none of the 17 patients experienced PDPH. This injection was performed before regression of the local anesthetic effect. No additional studies of this technique have been reported; its safety and efficacy remain unclear.

Treatment

Early treatment of PDPH is indicated. Not only does this avert the vicious cycle of immobility, weakness, and depression, but it also may help prevent the rare case of subdural hematoma or cranial nerve palsy in the patient with persistent PDPH.

Psychologic Support

The patient is aware that PDPH is an iatrogenic problem, and she may be angry and resentful as well as depressed and tearful. It is imperative to include disclosure of the risk during the preoperative interview. Headache makes it more difficult to care for the newborn and to interact with other family members. Severe PDPH may delay discharge from the hospital and have economic consequences.[109] Unlike patients who have PDPH after nonobstetric surgery, these patients typically are healthy and do not expect to feel ill. Two patients have eloquently described their own miserable experiences with postpartum PDPH.[144,145] Not surprisingly, a retrospective study of 43 obstetric patients with PDPH showed that this complication leads to a negative attitude toward epidural anesthesia.[146]

It is essential that anesthesia providers visit the patient at least once daily to explain symptoms and prognosis, give support, and offer therapeutic options. If feasible, the patient's partner should attend these discussions. Nurses can help the patient by ensuring adequate analgesics are given on a regular schedule and by teaching alternative breast-feeding techniques, such as the lateral horizontal position.

The anesthesia provider and nurses should write detailed notes in the patient's record. After discharge, follow-up telephone conversations should be documented. Headache associated with neuraxial anesthesia was the third most common reason for litigation among obstetric cases in the American Society of Anesthesiologists

(ASA) Closed-Claims database (see Chapter 33), after maternal death and neonatal brain damage.[147] This fact should dispel any notion that postpartum PDPH is a trivial complaint.

Posture

The diagnosis of PDPH requires demonstration of a postural component. Significant relief should occur when the patient assumes the horizontal position. However, there is no evidence that remaining supine for a prolonged period of time treats or shortens the duration of the headache.[119] The prone position relieves PDPH in some patients, presumably because increased intra-abdominal pressure results in an increase in CSF pressure. Unfortunately, this position is not comfortable for many patients, especially those who had a cesarean delivery.

Hydration

Enhanced oral hydration remains a popular therapy initiated by most anesthesiologists for parturients with PDPH, but there is no evidence that vigorous hydration has any therapeutic benefit in a patient with normal fluid intake. However, no patient with PDPH should be allowed to become dehydrated, because of the increased fluid demands of breast milk formation and CSF production.[119]

Pharmacologic Treatment

In the past, a variety of drugs have been used to treat PDPH, including steroids, vasopressin, alcohol, and ergotamine. A safe and effective oral drug therapy for PDPH would be very useful, even if relief is transient. Blood patch therapy is not appropriate or effective in all patients.

Caffeine. Caffeine has been used to treat PDPH for many years, despite lack of clear evidence of its efficacy. A systematic review of the literature[148] identified a single randomized trial performed by Camann et al.[149] Forty postpartum women with PDPH received a one-time dose of oral caffeine or placebo. Headache pain scores (visual analog scale [VAS], 0 to 100 mm) were lower in the caffeine group at 4 hours than the control group (33 ± 6 versus 49 ± 7 mm, respectively), but there was no difference at 24 hours. It appears that the beneficial effect of caffeine is transient.

The caffeine content of a 150-mL cup of drip coffee is approximately 150 mg. Caffeine is a cerebral vasoconstrictor, and one study has demonstrated a reduction of cerebral blood flow after intravenous administration of caffeine sodium benzoate for the treatment of PDPH.[150] Caffeine is also a potent central nervous system stimulant. There are published case reports of seizures after intravenous[151] and oral administration[152] of caffeine for the treatment of PDPH in postpartum patients.

Caffeine appears in breast milk in very small amounts.[153] To our knowledge, there are no reports of adverse effects on the infant after maternal administration of one or two doses of caffeine for the treatment of PDPH. The risk-to-benefit ratio to mother and newborn of multiple doses of caffeine has not been addressed. Until such studies are available it seems wise to restrict the prescription of oral caffeine to 600 mg in 24 hours, given as 300-mg doses at least 8 hours apart. Long-term caffeine therapy cannot be recommended. Another methylxanthine, theophylline, is also a cerebral vasoconstrictor, and is available in long-acting preparations. Some investigators have found that intravenous theophylline is more effective than placebo in the treatment of PDPH, but it has not become a popular therapy.[154]

Sumatriptan. Sumatriptan is a serotonin receptor agonist that affects predominantly type 1D receptors. Possessing cerebral vasoconstrictor properties, this agent is used in the treatment of migraine headaches. It is given by subcutaneous injection. Side effects include pain at the injection site and, uncommonly, chest tightness. Sumatriptan may cause coronary artery vasospasm and should not be used in those with Prinzmetal's angina or known coronary artery disease. Carp et al.[155] reported that the administration of sumatriptan 6 mg resulted in complete resolution of PDPH in four of six patients, and Paech et al.[129] reported relief of PDPH in one of seven patients treated with sumatriptan. Connelly et al.[156] studied 10 patients with severe PDPH scheduled for epidural blood patch who were randomized to receive either sumatriptan 6 mg or placebo. After 1 hour, only one patient in each group had significant relief, and the authors concluded that sumatriptan was of no value.

Adrenocorticotrophic Hormone. The use of ACTH for the treatment of PDPH was first reported in a 1994 letter to the editor.[157] Subsequently, anecdotal reports have described different regimens of either intramuscular or intravenously administered ACTH or the synthetic drugs cosyntropin or tetracosactrin acetate. Mood elevation, anti-inflammatory effects, increased endorphin levels, and augmented intravascular volume are postulated as possible modes of action in the relief of headache with ACTH. Kshatri and Foster[158] described a curative response to ACTH in two patients with PDPH. The ACTH dose was 1.5 units/kg in 250 mL of normal saline, infused intravenously over 30 minutes. Gupta and Agrawal[159] assessed the effect of ACTH 60 units intramuscularly in 48 patients with PDPH. Complete and permanent relief was obtained in 40 patients, without any side effects. Carter and Pasupuleti[160] reported the management of a patient with intractable PDPH who had already received three epidural blood patches; cosyntropin 0.5 mg in 1 L lactated Ringer's solution was infused over 8 hours, and the headache was completely and permanently relieved.

To date, the only randomized clinical trial of ACTH treatment involved 18 postpartum women who had PDPH after spinal anesthesia or unintentional dural punctures.[161] There was no difference in the severity of headache or the requirement for epidural blood patch between women receiving tetracosactrin acetate 1 mg intramuscularly and those who received saline-placebo.

Oliver and White[162] described three patients who experienced PDPH after administration of epidural

analgesia during labor and who subsequently had seizures. All had received two or three doses of tetracosactrin acetate (1 mg intramuscularly), and one had also received sumatriptan. No epidural blood patch procedures were performed. CT scans showed or suggested infarction in two of these subjects. The investigators stated that before the occurrence of these three cases ACTH had been used regularly to treat PDPH in their institution but that subsequently they had discontinued the administration of ACTH as a therapy for PDPH. No conclusion can be drawn about the possible contribution of ACTH therapy to the observed seizure activity. With the evidence to date, it appears that ACTH therapy cannot be recommended for first-line treatment of PDPH but may be considered for cases that are not amenable to epidural blood patch therapy.

Miscellaneous Medications. Other agents evaluated for their effectiveness in reducing PDPH symptoms include pregabalin, methylergonovine, gabapentin, and hydrocortisone. Randomized clinical trials have been conducted with intravenous hydrocortisone[163] and oral pregabalin.[164] Noyan Ashraf et al.[163] evaluated 60 parturients who developed PDPH after spinal anesthesia and were randomly assigned to receive intravenous hydrocortisone (200 mg loading dose followed by 100 mg three times daily for 2 days) or conventional therapy (bed rest, hydration, and scheduled acetaminophen with meperidine). Patients who received hydrocortisone had a 50% reduction in headache severity as assessed by VAS scores at 6 to 48 hours. A criticism of this study is the lack of blinding on the part of the study participants, which may have influenced their perception of headache pain. Huseyinoglu et al.[164] randomized 40 patients after lumbar puncture and PDPH to receive pregabalin (150 mg daily for 2 days followed by 300 mg for 3 days) or placebo; pain scores and oral analgesic requirements were lower in the treatment group.

Use of gabapentin or methylergonovine has been reported only in case series.[165] Efficacy and side effects (maternal and neonatal) are unclear. All four drugs require further study before they can be recommended for therapy for PDPH.

Epidural Morphine

Eldor et al.[166] reported six nonobstetric patients whose PDPH headaches were successfully treated with epidural morphine 3.5 to 4.5 mg. Further study is required before conclusions can be reached. However, this therapy should be used with caution because epidural morphine injected in the presence of a large dural puncture site may pass readily into the CSF and predispose to respiratory depression.

Epidural/Intrathecal Saline

The use of epidural or intrathecal fluids to treat PDPH preceded the use of epidural blood patches. Intrathecal injection of fluid was first described by Jacobeus et al.[167] in 1923, and epidural injection of saline was reported by Rice and Dabbs in 1950.[168] These first reports were in conjunction with research attempting to understand the pathophysiology of PDPH, and they demonstrated transient elevations of CSF pressure after fluid injection. Subsequently there has been sporadic interest in using injection of fluids (other than blood) into the neuraxial space to treat PDPH.

Usubiaga et al.[169] injected 10 to 30 mL of saline through a lumbar epidural catheter in 11 nonobstetric patients with a PDPH after spinal anesthesia in whom 48 hours of conservative therapy had failed. Immediate relief of headache was observed in 10 patients, and the relief was permanent in 8 patients. However, the investigators did not comment whether other therapies (e.g., supine posture, abdominal binder, analgesics) were continued. In a quasi-randomized trial, 43 parturients with PDPH after unintentional dural puncture during an epidural procedure or after spinal anesthesia with a 25-gauge needle were assigned to receive a 30-mL epidural saline bolus in the lumbar region or a 10-mL lumbar epidural blood patch.[170] Forty-two patients had dramatic relief of their symptoms in the first hour after the intervention; however, 12 of the 21 (57%) patients who had received saline had return of the PDPH in the next 24 hours.

Prolonged epidural saline infusion may provide better therapy for PDPH symptoms than therapy with a single bolus.[171,172] Two case reports described the use of epidural saline infusion for parturients with an unintentional dural puncture, whose PDPH symptoms returned after epidural blood patch therapy. The rate of infusion (15 to 25 mL/h) was limited by the onset of pain in the back, legs, and eyes. A comparative study of epidural saline bolus versus infusion to treat PDPH is needed to determine whether either modality continued over 24 hours would provide better results than conservative therapy. Although both saline techniques seem to only offer temporary relief, these options might be considered for patients who have a contraindication to epidural blood patch therapy.

Epidural Blood Patch

Efficacy. The epidural blood patch is regarded by many as the gold standard therapy for PDPH. Although reported in third person, Gormley, in 1960, is credited with performing the first successful epidural blood patch.[173] He described relief of PDPH symptoms in seven patients after epidural administration of only 2 to 3 mL of blood. However, this report was largely ignored until 1970, when DiGiovanni and Dunbar[174] described the immediate and permanent cure of PDPH in 41 of 45 patients in whom 10 mL of autologous blood was injected into the epidural space. Their success led to the widespread adoption of this technique for the relief of PDPH. An excellent review of the history of PDPH and development of the blood patch was written by Harrington.[175]

In early case series, the reported success rate of epidural blood patch therapy for PDPH series was between 89% and 91%.[174,176] Subsequent studies have not confirmed this high rate of success. Taivainen et al.[177] studied 81 patients with PDPH after spinal needle dural puncture. Initially, symptoms were relieved in 88% to 96% of patients; however, a permanent cure was achieved in only

61%. Safa-Tisseront et al.[178] reviewed their experience with epidural blood patch therapy over a 12-year period (n = 504 patients, including 78 obstetric patients). Complete relief of PDPH was obtained in 75%, partial relief occurred in 18%, and treatment failed in 7% of patients. The investigators noted a significantly higher failure rate of epidural blood patch after large-gauge needle puncture of the dura. The difference in early reports and more modern audits of PDPH and epidural blood patch success may be related to differences in the duration of follow-up or perhaps to other differences in management after blood patch therapy, such as delayed mobilization.

In studies limited to obstetric patients, the published success rates of epidural blood patch have been even less encouraging. Stride and Cooper[69] noted complete and permanent relief of PDPH in 64% of patients after one blood patch procedure. Williams et al.[179] reported only 33% of their patients obtained complete and permanent relief from the first blood patch. The authors suggested that this high failure rate might be related, in part, to their frequent performance of the blood patch procedure within 24 hours of dural puncture. Banks et al.[180] prospectively monitored 100 patients with unintentional dural puncture. Fifty-eight received a therapeutic blood patch; the treatment completely failed in 3 patients, and 17 patients had recurrence of moderate or severe headache requiring further therapy. These observational studies also describe the use of repeat epidural blood patch procedures for parturients with a recurrence of PDPH.

A 2010 systematic review[137] identified three randomized trials comparing epidural blood patch to either a sham procedure or conservative treatment. All three studies found a reduction in headache rate in the treatment group. Seebacher et al.[181] randomized 12 heterogeneous patients with PDPH to receive an epidural blood patch with 10 to 20 mL of blood or a sham patch procedure. Five of six patients receiving a blood patch had complete relief of headache symptoms at 24 hours, and none of the sham procedure patients did. Sandesc et al.[182] described a randomized trial of 32 obstetric and nonobstetric patients with PDPH symptoms for a minimum of 24 hours; subjects were randomly assigned to receive conservative therapy or an epidural blood patch. The primary outcome was headache VAS scores at 2 and 24 hours. At 2 hours the mean VAS score for the conservative therapy group was 8.2 ± 1.4 cm compared with 1.0 ± 0.2 cm for the group receiving a blood patch ($P < .001$). This difference remained at 24 hours. In the largest trial to date, van Kooten et al.[183] randomized 40 subjects with PDPH for 1 to 7 days to receive either conservative therapy or an epidural blood patch using 15 to 20 mL of autologous blood. The primary outcome was headache 24 hours after intervention, but patients were observed for 1 week after therapy. The incidence of headache at 24 hours was 58% in the blood patch group compared with 90% in the conservative therapy group (RR, 0.64; 95% CI, 0.43 to 0.96). At 1 week the difference widened, with 16% incidence of headache in the blood patch group compared with 86% in the conservative group. In summary, administration of an autologous epidural blood patch, although not perfect, often dramatically relieves this debilitating condition and, at present, it is the therapy with the greatest likelihood of success.

Volume. The optimal volume of injected blood remains controversial. Szeinfeld et al.[184] used a gamma camera to observe the epidural spread of technetium-labeled red blood cells during and after epidural blood patch. They injected blood until pain occurred in the back, buttocks, or legs. The mean ± SD volume injected was 14.8 ± 1.7 mL of blood, and the mean ± SD spread was 9.0 ± 2.0 spinal segments. Blood spread more readily in the cephalad than in the caudad direction. The blood patch relieved the headache in all 10 patients. The investigators concluded that 12 to 15 mL of blood should be a sufficient patch volume for most patients.

The best evidence to date is an international, multicenter study by Paech et al.,[185] who randomized 121 women after unintentional dural puncture with a Tuohy needle (16- or 18-gauge) to receive an epidural blood patch with 15, 20, or 30 mL of blood. Partial or complete relief of headache (the primary outcome) occurred in 61%, 73%, and 67% of those who received 15, 20, or 30 mL of blood, respectively. However, complete relief of headache was achieved by only 10%, 32%, and 26% of women in these same groups. The rate of complete headache relief was greater in the 20-mL than the 15-mL group; there was no difference between the 20- and 30-mL groups. Thus, the investigators concluded that 20 mL of autologous blood is the optimal volume for an epidural blood patch. A 2011 survey demonstrated that most North American anesthesiologists inject 20 mL of blood.[186]

Beards et al.[187] performed MRI studies after the performance of an epidural blood patch (18 to 20 mL) in five patients. Similar to Szeinfeld et al.,[184] they noted that the injected blood spread over three to five segments in a predominantly cephalad direction. All patients had an extensive hematoma in subcutaneous fat, and some also had displacement of nerve roots and/or evidence of intrathecal blood. A thick layer of mature clot had formed by 7 hours, which had broken up into smaller clots by 18 hours. These findings may help explain the back pain and occasional nerve root pain that occur after blood patch therapy.

In another MRI study, Vakharia et al.[188] noted compression of the thecal sac and a mean spread over 4.6 segments after the lumbar epidural injection of 20 mL of blood (Figure 31-4). Djurhuus et al.[189] employed CT epidurography in four patients immediately and 24 hours after an 18-mL blood patch. Initial images showed adherence of clot to the dura in three patients as well as dural compression in two patients, but there was no evidence of compression at 24 hours.

Using a goat model, DiGiovanni et al.[190] examined the microscopic appearance of the dura as late as 6 months after dural puncture. Some study animals received a 2-mL blood patch in addition to dural puncture. The investigators concluded that the blood patch acted as a gelatinous tampon that produced no harmful tissue reaction.

Mechanism of Action. The mechanism of action of epidural blood patch for relief of PDPH is unclear. Pain

FIGURE 31-4 ■ **A,** Pre–blood patch magnetic resonance imaging using sagittal spin-echo proton density. The dural puncture has been performed at L2 to L3, which local static fluid collection (*arrows*) affirms; *3,* denotes L3 vertebral body. **B,** Post–blood patch magnetic resonance imaging of cerebrospinal fluid flow in systole shows the long length of the compression of the thecal sac posteriorly (*arrows*). (From Vakharia SB, Thomas PS, Rosenbaum AE, et al. Magnetic resonance imaging of cerebrospinal fluid leak and tamponade effect of blood patch in postdural puncture headache. Anesth Analg 1997; 84:585-90.)

relief is often rapid, but CSF volume is not restored immediately. Thus, there must be another explanation for the immediate relief of headache besides "patching" of the dural puncture. Carrie[191] hypothesized that epidural injection of blood increases lumbar CSF pressure, an action that restores intracranial CSF pressure and decreases symptoms. Increased CSF pressure also may result in reflex cerebral vasoconstriction. Coombs and Hooper[192] demonstrated that epidural blood patch resulted in a threefold increase in lumbar CSF pressure. Further, they noted that 15 minutes later, lumbar CSF pressure was sustained at greater than 70% of the peak pressure observed after the injection of blood. Ultrasonographic examination of the optic nerve sheath diameter (a noninvasive measurement that correlates with intracranial pressure) in 10 patients with PDPH demonstrated increased measurements after epidural blood patch.[193] The sheath diameter increased 10 minutes after an epidural blood patch with 17 to 26 mL of blood and was sustained over the 20-hour study period. The only patient whose blood patch failed to successfully relieve the PDPH did not have the same increase in optic nerve sheath diameter.

MRI and CT studies have shown that the epidural blood is largely resorbed or broken up 18 to 24 hours after the procedure.[187,188] It is unlikely that the increase in CSF pressure is sustained or that the blood acts as a mechanical plug to block CSF leak for a prolonged duration. The blood applied to the hole in the dura may initiate an inflammatory reaction that facilitates puncture site repair and closure. It is possible, and even likely, that an epidural blood patch ameliorates PDPH by several mechanisms.

Timing. The optimal timing for administration of a blood patch has not been adequately studied. Observational studies suggest that failure is more likely if the blood patch is performed within 24[178] or 48 hours[185] of the dural puncture. It is unclear, however, whether this finding is a result of selection bias. Early-onset PDPH (often resulting from dural punctures with large-gauge needle) is likely to be more severe and more difficult

to treat. Alternatively, a large CSF leak may displace the clot. Partial healing of the dura may have already occurred if a blood patch is delayed, a possibility that may explain the better outcome of a delayed patch procedure.

Technique. The anesthesia provider should thoroughly explain the risks and benefits of the blood patch procedure to the patient, and the patient should give consent for the procedure. An epidural blood patch can be accomplished on an outpatient basis. Ideally, the environment for the procedure is one conducive to postpartum patients who may have accompanying family and a newborn. Contraindications to the administration of an epidural blood patch are related to complications of placing a needle in the central neuraxis or the injection of blood into the epidural space; they include (1) known coagulopathy, (2) local cutaneous infection or untreated systemic infection, (3) increased ICP due to a space-occupying lesion, and (4) patient refusal. Transient bradycardia has been observed after administration of an epidural blood patch, and some anesthesia providers may choose to establish intravenous access and monitor the electrocardiogram in selected patients.[194]

The blood patch procedure should employ sterile measures equivalent to those used for the administration of any neuraxial procedure. The lateral position is usually more comfortable than the sitting position for patients with severe PDPH. If the anesthesia provider is uncertain about the location of the dural puncture, the more caudad interspace should be chosen. The epidural space is identified in the usual manner. Using meticulous sterile technique (including skin preparation and draping, and donning of a mask and sterile gloves), an assistant withdraws the desired volume of blood (usually 10 to 25 mL) into a syringe. This autologous blood is injected slowly into the epidural space through the Tuohy needle; the injection is terminated if severe back, leg, or neck pain or pressure occurs. Sometimes slowing the injection rate leads to resolution of the back pain. Jehovah's Witness patients may accept a blood patch procedure if a technique is used that keeps blood in continuity with the circulation.[195]

Occasionally a few drops of CSF are encountered on entering the epidural space, leading to doubt about correct needle placement.[196] One can either repeat the epidural needle placement, or a small test dose of a local anesthetic agent can be administered, sufficient to cause a rapid onset of spinal anesthesia. If no block results, the blood patch can be performed. Two case reports have described the use of real-time ultrasound-guided and fluoroscopically guided epidural blood patch.[197,198] The usefulness of these modalities to assist in localizing deposition of epidural blood requires further study.

After the procedure the patient should rest quietly in the supine position for 1 to 2 hours.[199] Subsequently, the patient may resume ambulation, but she should avoid vigorous physical activity for several days. It would be wise for the patient to avoid the Valsalva maneuver and heavy lifting. A stool softener should be considered. Most patients report almost instantaneous relief of headache symptoms, although relief is delayed for 6 to 8 hours in some patients. The patient may continue to have neck and back fullness over the next 24 hours.[185] The back pain can continue up to 5 days after the procedure. Patients should be counseled to immediately report fever, severe back pain, or radiating lower extremity pain. The anesthesia provider should contact the patient after the blood patch procedure.

The blood patch may be repeated if the initial patch fails to relieve pain. Often the second patch is successful. Although not adequately studied, it seems reasonable to wait 24 hours before repeating an epidural blood patch procedure to allow the first procedure adequate time to work. The diagnosis should be reconsidered if headache persists after two failed blood patch procedures. Consultation by a neurologist may be appropriate when a PDPH fails to respond to two blood patches and should definitely be requested if there is any doubt about the diagnosis. Imaging of the head should be considered to exclude other causes of headache.

Complications. Ong et al.[200] reported that the success of neuraxial anesthesia/analgesia was impaired in women with a prior history of unintentional dural puncture with or without epidural blood patch therapy. However, this conclusion has been refuted by follow-up studies in both obstetric[201] and nonobstetric patients.[202] In both of these retrospective studies, a history of blood patch therapy had no apparent effect on the quality of subsequent epidural anesthesia.

Although epidural blood patch therapy is the most reliable method of relieving PDPH symptoms, adverse outcomes are associated with the procedure. These adverse events can be categorized into two broad groups: infectious/hematologic and neurologic.

Infectious/Hematologic Complications. Conventional wisdom holds that the patient should be afebrile at the time of the blood patch procedure. Many anesthesia providers believe that it is wise to avoid the epidural injection of blood in the presence of systemic infection. Meningitis has been reported after a blood patch procedure.[203] After conservative measures have failed, the optimal treatment of a febrile patient with severe, persistent PDPH is controversial. Epidural infusion of saline involves the use of an indwelling epidural catheter for many hours, which also may be undesirable in a febrile patient. A patch using dextran-40 may be an alternative in febrile patients, but further experience is needed in healthy patients before this technique can be recommended. The presence of high fever and/or other evidence of sepsis contraindicate the performance of a blood patch procedure. However, we do not believe that a low-grade fever of known etiology is an absolute contraindication to epidural blood patch, provided the patient is receiving appropriate antibiotic therapy. Management should be individualized, and the known benefits of blood patch should be weighed against the unknown risk for infection.

The risks of epidural blood patch therapy in the presence of human immunodeficiency virus (HIV) infection have been debated (see Chapter 45). However, the central nervous system is infected with HIV at the time of primary infection; therefore, it seems unlikely that the injection of autologous blood into the epidural space would alter progression of the disease. There are

published reports of the successful use of blood patch therapy, without sequelae, in patients with acquired immunodeficiency syndrome (AIDS) or who are HIV positive.[204,205]

The incidence of cancer during pregnancy is increasing, likely secondary to advancing maternal age. The development of PDPH in this population has raised a theoretical concern about seeding the neuraxial space with neoplastic cells if a blood patch procedure is performed. This concern should be discussed with the patient and her oncologist before the procedure. Bucklin et al.[206] reported the conservative management of a woman with acute leukemia and PDPH; the investigators discussed the therapeutic options for this immunocompromised patient. The use of epidural fibrin glue was reported in a nonobstetric patient with metastatic breast cancer and PDPH,[207] whereas a blood patch was performed for PDPH in a young woman with rhabdomyosarcoma.[208]

Neurologic Complications. Serious or permanent problems after epidural blood patch therapy are rare. Diaz and Weed[209] wrote a review of case reports of adverse neurologic complications after epidural blood patch procedures. These authors identified 26 reports published between the years of 1966 and 2004 and stratified the complications into neurologic, neurovascular, or inflammatory events. The events occurring in obstetric patients included lumbovertebral syndrome (defined as low back pain with neurologic impairment of the lower extremities), subdural hematoma, arachnoiditis, radicular back pain, pneumocephalus, seizures, and acute meningeal irritation. Compressive complications (e.g., lumbovertebral syndrome, subdural hematoma, cauda equina syndrome) were associated with a larger blood patch volume (mean of 35 mL) than the noncompressive complications (17 mL). Cranial nerve palsy symptoms that were present before blood patch administration did not uniformly resolve. The delay in performing the blood patch may have been the significant factor. Two patients who were treated within 4 days of the onset of PDPH symptoms recovered within 6 weeks, whereas three patients treated on days 9 to 11 had palsy that persisted for 3 to 4 months. Two obstetric patients experienced new facial nerve palsies, which manifested as facial weakness after administration of an epidural blood patch.

Abouleish et al.[176] reported the results of the long-term evaluation of 118 patients who had received an epidural blood patch. Back pain was the most common complication; it occurred during the first 48 hours in 35% of patients and persisted in 16% of patients, with a mean duration of 27 days. These investigators also noted cases of neck pain, lower extremity radicular pain, and transient temperature elevation.

Epidural space scarring is also a possibility after placement of a blood patch. Although subsequent epidural analgesia is generally successful (see earlier discussion),[201,202] Collier[210] reported two cases of unsuccessful epidural analgesia related to suspected scarring of the epidural space. In both women, the initial epidural catheter placement was complicated by unintentional dural puncture and PDPH treated with epidural blood patch. During a subsequent pregnancy, epidural catheter placement was complicated by inadequate analgesia, and an epidurogram revealed limited spread of the contrast media, suggesting epidural space scarring.

The development of an inflammatory reaction to epidural blood can cause acute arachnoiditis, an entity that can present several days after epidural blood patch.[211] This phenomenon is believed to be secondary to free radical damage to spinal root nerves in the intrathecal space after hemoglobin degradation. There are case reports of obstetric patients with this entity who required analgesic therapy for prolonged periods.[212] The diagnosis is made with a presenting history of severe back pain, often with radicular pain, and characteristic MRI findings such as nerve root clumping in the intrathecal space and adhesions between nerve roots.

The occurrence of new neurologic symptoms appearing after an epidural blood patch should prompt consideration of the presence of other intracranial pathology. Such symptoms may include (1) mental deterioration due to increased ICP from an intracranial tumor[24] and (2) seizures due to late-onset eclampsia.[213]

Diaz[214] described a woman in whom permanent paraparesis and cauda equina syndrome developed after an epidural blood patch with 30 mL of blood injected slowly and without symptoms. Low back pain and leg pain developed after the blood patch procedure, and later the patient also experienced incontinence. Twelve days after the procedure a subdural hematoma at L2-L4 was diagnosed and surgically treated. Six months later the patient still had marked symptoms. Although a larger volume of blood than usual was injected, the technique appears to have been within normal practice standards. Other long-term sequelae reported in obstetric patients include a postpartum cerebral ischemic event after two blood patches that resulted in permanent hemianopsia[215] and a calcified epidural blood patch leading to chronic back pain.[216]

Alternatives to Epidural Blood Patch

Alternatives to an epidural blood patch may be considered if a blood patch is contraindicated or fails. In extreme cases, surgery may be needed to close the dural tear.

Dextran/Gelatin Patch. Dextran-40 and gelatin-based solutions, including Gelfoam and Plasmion, have been substituted for blood in epidural patches.[143,217] These solutions were chosen as alternatives to blood owing to relative contraindications to injection of blood. The use of these agents appears to be more common in countries outside North America. In an observational study of 56 patients, Barrios-Alarcon et al.[218] reported that epidural administration of 20 to 30 mL of dextran-40 was safe and effective for the relief of PDPH; all headaches were relieved permanently. The only side effect was a transient discomfort or burning sensation at the time of injection in 6 patients. Some physicians have treated intractable PDPH successfully by performing a dextran-40 patch followed by epidural infusion of dextran at 3 mL/h for 5 to 12 hours.[219,220]

Information on neurotoxicity of these materials is scant; Chanimov et al.[221] did not observe neurotoxicity after infusion of dextran-40 or polygeline, a gelatin

powder, into the rat intrathecal space. However, further information is needed before these materials can be widely adopted for epidural administration in humans. From MRI studies in patients with an epidural blood patch, we can anticipate that some dextran will enter the subarachnoid space. The small but definite risk for anaphylaxis after the injection of dextran also must be considered, although the risk appears minimal with dextran-40.

Fibrin Sealant Patch. Fibrin sealant is composed of fibrinogen and thrombin. Several commercial products are prepared from human pooled plasma. Products may also contain antifibrinolytics, such as animal aprotinin.[222] When injected, these products form a firm, nonretractable fibrin clot. Epidural injection of fibrin glue in rats produces a sustained rise in CSF pressure comparable to the increase that occurs after injection of blood.[223] Fibrin sealant has been evaluated for its effectiveness in preventing dural leaks after spinal surgery.[224] An epidural fibrin glue patch has been used successfully to treat recurrent PDPH,[225] spontaneous intracranial hypotension,[226] and CSF leak after long-term intrathecal catheterization.[227] In the future, fibrin glue may have a role in patients with intractable PDPH, but further study is required before it can be recommended for routine use.

Surgery. There are rare reports of curative surgical closure of a dural rent for intractable PDPH. In one case, the interval between dural puncture and surgery was 5 years.[228]

Summary of Treatment

The parturient with PDPH should be actively managed with scheduled analgesics and should receive psychological support as she cares for her newborn and manages her symptoms. If the headache is severe, the physician can consider additional agents, such as caffeine or sumatriptan, or proceed directly to an epidural blood patch. Epidural administration of fluids other than blood, such as saline or dextran, typically is not first-line therapy but may be considered when there are contraindications to the epidural injection of autologous blood or if an epidural blood patch procedure fails. The accuracy of PDPH diagnosis must always be considered when atypical symptoms present or when therapy fails.

UNANSWERED QUESTIONS

Important information about PDPH is still lacking. A large, detailed prospective study of PDPH, with and without epidural blood patch, with a long follow-up period (e.g., 1 year) is needed in obstetric patients. What are the long-term effects of both PDPH and blood patch therapy? How common are residual back pain, neurologic symptoms, and auditory/visual symptoms, and do they interfere with everyday life? Answers to these questions are needed to give our patients reliable information, a sound basis for informed consent, and the best possible care. The Obstetric Anaesthetists' Association and the Association of Anaesthetists of Great Britain and Ireland[229] have recommended that each facility providing obstetric anesthesia services should have institution-specific protocols for the management of PDPH to facilitate the identification of parturients with this complication and to provide consistent care.

KEY POINTS

- Dural puncture is only one of many causes of postpartum headache, although many are quick to blame postpartum headaches on dural puncture. A detailed history and physical examination as well as indicated neuroimaging should ensure diagnostic accuracy.
- A patient with post–dural puncture headache experiences an exacerbation of symptoms when she moves from the horizontal to the upright position, possibly owing to decreased intracranial pressure and secondary cerebral vasodilation, which affect pain-sensitive intracranial structures.
- Anesthesia providers should use a small-gauge (24-gauge or smaller), non-cutting (pencil-point) spinal needle whenever possible to decrease the risk for post–dural puncture headache.
- No therapies reliably prevent the development of post–dural puncture headache after unintentional dural puncture with an epidural needle.
- The initial therapy for post–dural puncture headache consists of psychological support, bed rest in the supine position, and scheduled oral analgesics. Although dehydration should be avoided, no evidence supports a role for vigorous hydration for prophylaxis or therapy for post–dural puncture headache.
- The "gold standard" therapy for post–dural puncture headache is an autologous epidural blood patch. A second blood patch may be performed—and typically is successful—if the first one fails. If the second procedure fails, alternative diagnoses should be excluded. Other therapies have not proved as effective and safe as the epidural blood patch for treatment of post–dural puncture headache.

CHAPTER 32

Neurologic Complications of Pregnancy and Neuraxial Anesthesia

Felicity Reynolds, MD, MBBS, FRCA, FRCOG ad eundem

CHAPTER OUTLINE

Neurologic complications of childbirth may be associated with neuraxial analgesia and anesthesia or may result from childbirth itself. Complications of neuraxial anesthesia may be immediate, such as motor blockade, unexpectedly high or prolonged blockade, and seizures after unintentional intravenous injection of local anesthetic, or they may be prolonged or delayed (sequelae). Immediate complications of neuraxial anesthesia are described in Chapter 23; here the discussion is focused on neurologic sequelae.

Although neurologic disorders after childbirth are more likely to have obstetric than anesthetic causes, neuraxial anesthesia is all too often blamed. For example, Tubridy and Redmond[1] described seven women referred with neurologic symptoms after childbirth, all of which had been attributed to epidural analgesia. The women suffered from brachial neuritis, peroneal neuropathy, femoral neuropathy, neck strain, and leg symptoms for which there was no obvious physical cause. In such circumstances, a careful history and neurologic examination, together with diagnostic aids such as electromyography, nerve conduction studies, and imaging techniques, can localize the lesion and differentiate obstetric from anesthetic causes. For example, it should be possible to distinguish by simple clinical means between a mononeuropathy, which is likely to have an obstetric cause, and a radiculopathy resulting from neuraxial blockade. Accurate and prompt diagnosis is essential.

THE INCIDENCE OF NEUROLOGIC SEQUELAE

Patients frequently ask obstetricians and anesthesia providers about the incidence of complications of neuraxial anesthesia, but even if accurate data were available, the question has no true answer. The incidence of neurologic complications varies widely according to local practice and the skill and training of the practitioners. Some old surveys are based on accurate local records, but the data relate to a time when obstetric and anesthetic practices, equipment, and drugs were less safe than they are today. The incidence of serious complications is now too low to be estimated accurately on a local basis. Nonetheless, anesthesia providers have a duty to inform patients of the complications associated with a proposed procedure and are expected to give some figure for the level of risk, however meaningless such an estimate may be.

Obstetric Surveys

In early surveys, the reported incidence of neurologic deficits in obstetric patients ranged from 1 in 2100 to 1 in 6400.[2,3] During this period, long labor and difficult rotational forceps delivery were commonplace and neuraxial anesthesia was relatively unusual. Many surveys have subsequently attempted to assess the incidence of

BOX 32-1 Limitations of Surveys of Neurologic Sequelae of Neuraxial Anesthesia in Obstetrics

- Poor response rate
- Positive reporting bias
- Absence of controls without neuraxial anesthesia
- Greater attention given to those who received neuraxial anesthesia
- Inadequate investigation and lack of accurate diagnosis
- Variable skill and care of obstetric and anesthetic providers
- Older surveys relate to outdated obstetric and anesthetic practices
- Lack of statistical power to assess incidence of rare disorders
- Inaccurate counting of numerator and denominator
- Likelihood of missing cases that arise after hospital discharge

neurologic complications of neuraxial anesthesia, overlooking obstetric problems and other sources of error (Box 32-1).

Some of the more relevant surveys are listed in Table 32-1, those of the 20th century having been ably reviewed by Loo et al.[4] in 2000. Ong et al.[5] reviewed the medical records of all women who delivered in Winnipeg over a 9-year period and interviewed all those who received anesthesia care. All neurologic deficits in this series were transient, with none lasting more than 72 hours. The incidence of neurologic symptoms was similar after epidural and general anesthesia, but symptoms were more likely to be reported by women who received anesthesia than by those who received none. This is not surprising because only women who received anesthesia were interviewed. Indeed, the survey identified 45 cases of neurologic deficit, but only 10 had been noted in the hospital record, suggesting that many deficits may have been missed in the patients who were not interviewed. Moreover, modern statistical methods such as logistic regression analysis were not used to tease out the influence of prolonged labor and traumatic delivery, which the investigators noted as possible causative factors.

In a large retrospective survey of long-term symptoms, women who delivered in one hospital in Birmingham, United Kingdom, were asked to recall events 2 to 9 years after delivery.[6] The response rate was only 39%, and all those (and only those) who received epidural analgesia had been interviewed intensively about their symptoms immediately postpartum, thereby enhancing subsequent recall in this subset of the population. Logistic regression analysis demonstrated a link between epidural analgesia and many symptoms, including tingling and numbness in the arms, calling into question any causative link with neuraxial anesthesia. No major neurologic sequelae were detected.

Scott and Hibbard[7] conducted a retrospective British survey of more than 500,000 epidural procedures administered between 1982 and 1986, which detected a number of serious sequelae, including one epidural abscess, one hematoma, and one anterior spinal artery syndrome, but many of the diagnoses were presumptive.[7] This survey probably failed to detect many minor lesions, but it was followed by a smaller prospective survey by Scott and Tunstall,[8] which included some spinal anesthetics and involved a self-selected group of respondents. The investigators found no major neurologic disorders but a more believable number of what were termed *mononeuropathies*.

A French survey based on a questionnaire covering the years 1988 to 1993, and sent to all hospitals with maternity units, recorded one cranial subdural hematoma but no cases of epidural abscess or hematoma in 288,351 obstetric epidural procedures.[9] Seven deaths were reported. Complications of spinal anesthesia were not included in this survey.

Both the Scott surveys[7,8] and the French inquiry[9] overlooked the need for a control group of laboring patients who did not receive neuraxial analgesia/anesthesia. The study by Holdcroft et al.[10] avoided this pitfall; the denominator consisted of all 48,066 women who delivered in one region over a year, and every effort was made to detect genuine neurologic symptoms in the community. Because the women themselves were not sent questionnaires, however, the response rate could not be estimated. The investigators judged that only one case of paresthesia, without physical signs, could be attributed to epidural analgesia and none to spinal anesthesia. Peripheral nerve damage was more common. The most serious was one case of foot drop in a woman who had a spontaneous delivery of a large baby with inhalation analgesia only.

With the increase in popularity of spinal anesthesia, concern about the growing numbers of reports of paresthesias and possible root trauma led Holloway et al.[11] to conduct a retrospective U.K. national survey of spinal and combined spinal-epidural (CSE) anesthesia in the 1990s. No difference in frequency of neuropathy was detected between Whitacre and Sprotte needles or between single-shot spinal and CSE techniques. Imprecise diagnoses made it difficult to differentiate anesthetic from coincidental causes, but after eliminating obvious obstetric or peripheral nerve palsies while otherwise erring on the pessimistic side, the investigators estimated that the incidence of neurologic sequelae was approximately 1 in 1000, including two cases of conus damage, one of meningitis, and the rest minor root palsies.

Two thorough local audit reports of immediate postpartum symptoms provided somewhat contrasting findings. One from Perth, Australia,[12] involved prospective recording of complications in 10,995 parturients who received epidural analgesia, but it regrettably did not include a control group. The investigators detected only a single lasting neurologic problem. Although they termed the injury a traumatic mononeuropathy, it was apparently a radiculopathy, because it was attributed to a traumatic epidural procedure.

The second report, from Leeds, United Kingdom, involved 3991 women who delivered in one center in 1 year.[13] Twenty-one women presenting with symptoms after neuraxial blockade were matched with 21 asymptomatic control patients who had also received neuraxial blockade and 21 who had not. Only 1 woman who had not had a neuraxial block presented with symptoms, and

TABLE 32-1 Surveys of Neurologic Complications of Childbirth and of Neuraxial Blocks in Obstetrics

Study	Type of Study	Population	No. of Neurologic Deficits (Risk Ratio)
Ong et al., 1987[5]	Medical record review of all patients, interview of those receiving anesthesia in one center (1975-1983)	23,827 deliveries	45, all transient (1/530)
		12,964 inhalational or no analgesia	5 (1/2,593)
		9,403 epidural procedures	34 (1/277)
		1,460 general anesthetics and other	6 (1/243)
Scott & Hibbard, 1990[7]	Retrospective multicenter review (1982-1986), no control group	505,000 epidural procedures	47 (1/10,745) 1 anterior spinal artery syndrome 1 epidural abscess, 1 epidural hematoma (unconfirmed) 38 mononeuropathies, 5 cranial nerve palsies 1 subdural hematoma
MacArthur et al., 1992[6]	Questionnaire sent in 1987 to mothers delivering in one center (1978-1985)	11,701 women (39%) who responded	Tingling/paresthesias:
		4766 epidural procedures	143 upper limb, 23 lower limb
		6935 no epidural procedures	150 upper limb, 3 lower limb
Palot et al., 1994[9]	Questionnaire listing possible complications sent to hospitals with obstetric beds (1988-1993), no control group	288,351 epidural procedures	92 (1/3134) 1 cranial subdural hematoma 88 temporary radiculopathy (1/3277) 3 meningitis (1/96,117) (also reported negligence cases: 1 sciatic nerve palsy, 1 intracranial hematoma)
Scott & Tunstall, 1995[8]	Prospective multicenter review (1990-1991), no control group	467,491 deliveries	46 neuropathies (details for procedures not given)
		108,133 epidural procedures	38 (1/2846)
		14,856 spinal procedures	8 (1/1857)
Holdcroft et al., 1995[10]	Regional community and hospital-based trawl (1991-1992)	48,066 deliveries	10 new neurologic complications (1/4807)
		34,430 no neuraxial block	1 foot drop, 1 cervical nerve lesion (1/17,215)
		13,007 epidural procedures	1 paresthesia of nerve root distribution (1/13,007) (Disorders unrelated to anesthesia: 2 cranial nerve palsies, 1 hypotensive cord damage; 5 peripheral nerve lesions)
		629 spinal procedures	0
Paech et al., 1998[12]	Prospective local audit (1989-1994), no control group	10,995 epidural procedures	1 traumatic "mononeuropathy" (1/10,995)
Holloway et al., 2000[11]	Retrospective multicenter trawl, elastic time frame, no control group	29,698 spinal procedures	4 unrelated to anesthesia (3 meralgia paresthetica, 1 peroneal neuropathy), 10 ?root damage, 1 conus damage, 22 uncertain (overall incidence ?1/986)
		12,254 CSE procedures	5 unrelated to anesthesia (1 femoral neuropathy, 2 foot drop, 2 paresthesia), 6 root damage, 1 meningitis, 1 conus damage, 6 uncertain (overall incidence ?1/901)
Dar et al., 2002[13]	Prospective local audit of immediate symptoms (1998-1999)	1,376 vaginal deliveries without anesthesia (random sample of 21 examined + 1 complaint)	4 peripheral neuropathy, 1 foot drop, 2 vague (1/3)
		2,615 regional blocks (all followed up)	21 had neurologic symptoms:
		1,782 vaginal deliveries	7 peripheral neuropathies, 1 foot drop, 3 vague (1/162)
		833 cesarean deliveries	8 numb areas, 2 vague (1/83)
Auroy et al., 2002[15]	Prospective multicenter survey, no control group	29,732 epidural procedures	0
		5,640 spinal procedures	2 "peripheral neuropathy"
Moen et al., 2004[16]	National postal survey and search of administrative files (1990-1999), no control group	205,000 epidural procedures	1 epidural hematoma (HELLP), 1 epidural abscess, 2 cord damage, 2 intracranial subdural hematoma, 1 abducent nerve palsy (1/29,286)
		50,000 spinal procedures	1 spinal hematoma (HELLP), 1 cord damage (1/25,000)
Cook et al., 2009[18]	National audit of major complications of neuraxial blockade over 1 year (unstated), obstetric and nonobstetric, no control group	329,425 obstetric procedures	1 epidural abscess, 2 nerve injury, 1 unknown Incidence of possible harm per 100,000 (95% CI)
		161,550 epidural procedures	0.6 (0-3.4)
		133,525 spinal procedures	1.5 (1-5.4)
		25,350 CSE procedures	3.9 (1-22)

CSE, combined spinal-epidural.

she was found to have foot drop after a vacuum extraction. Typical peripheral neuropathies occurred among those who delivered vaginally; sacral numbness was most commonly detected after cesarean delivery. All changes were transient, and none could be attributed to neuraxial anesthesia. Similar neurologic deficits were detected among the randomly selected, asymptomatic 21 control patients who had had no anesthetic intervention. In contrast, negligible deficits could be detected among the 21 asymptomatic control women who *had* had an anesthetic intervention. These results demonstrate that minor neurologic deficits are to be found postpartum quite frequently if sought, but only those who have had anesthetic intervention are likely to complain.

A prospective survey among 6057 women who delivered in 1 year in Chicago[14] does not feature in Table 32-1 because the patients were not grouped by type of analgesia, but the findings of this survey corroborate those of the Leeds study.[13] The incidence of lower limb nerve injuries was approximately 1% (24 lateral femoral cutaneous nerve, 22 femoral nerve, 3 peroneal nerve, 3 lumbosacral plexus, 2 sciatic nerve, 3 obturator nerve, and 5 radicular injuries).[14] Significant risk factors identified by logistic regression analysis included nulliparity and a prolonged second stage of labor but not neuraxial anesthesia.

In a nationwide 10-month prospective French survey, only two so-called peripheral neuropathies and no major sequelae were detected among 5,640 spinal and 29,732 epidural procedures in obstetric patients.[15] In contrast, in a retrospective Swedish national survey covering the years 1990 through 1999, Moen et al.[16] reported nine serious sequelae among an estimated 200,000 epidural and 50,000 spinal procedures in parturients.

Ruppen et al.[17] attempted to conflate the findings of various surveys to derive a consensus incidence of neurologic injury after obstetric epidural block. Unfortunately, this study took no account of the now widespread use of spinal and CSE techniques, denominators were calculated inaccurately, and the findings of surveys were not always interpreted correctly. For example, cranial subdural hematoma was counted as a spinal hematoma. Therefore, reliable information cannot be derived from this publication.

A U.K. national audit of neuraxial blocks, without controls, published in 2009, found that the risk for major complications was 6- to 14-fold higher for perioperative than for obstetric procedures. Among the obstetric patients, the risk was highest for CSE, intermediate for spinal, and lowest for epidural procedures.[18]

Several conclusions can be drawn from these surveys. Despite an increased cesarean delivery rate, obstetric palsies (albeit now more short-lived) still occur, and the reported frequency of neurologic sequelae depends on how hard one seeks them. The risk for transient mild deficits after childbirth may be quite high.[13,14] A true figure for anesthetic complications cannot be calculated even from thorough surveys because (1) the diagnosis is rarely accurate; (2) definitions, severity, and duration are often ill defined; and (3) anesthesia provider skills vary. Table 32-1 demonstrates a variation in the incidence of neurologic sequelae from 1 in 3 for mild symptoms with no neuraxial block[13] to 1 in 30,000 for epidural analgesia.[16] Moreover, bias is created when more attention is paid postpartum to patients who have received neuraxial blockade than to those who have not.

Other Surveys

Modern surveys of neurologic complications of spinal and epidural anesthesia among nonobstetric populations may yield more reliable results but still lack sensitivity to detect all potential problems and are commonly conducted in relatively elderly and sick populations. Moreover, the occurrence of case clusters gives the lie to the existence of a "true" incidence of complications.[16] Auroy et al.,[15] Moen et al.,[16] and Cook et al.[18] surveyed mixed populations and found a lower incidence of serious sequelae in obstetric than in other patients. It is therefore invalid to extrapolate findings from one population to the other. The reported risk for neurologic problems varies greatly with the patient population, local practice and skill, completeness of detection, and inclusion criteria. Hence, it is meaningless to attempt to put any firm figure on the risk for neurologic complications after neuraxial anesthesia.

PERIPHERAL NERVE PALSIES

Postpartum nerve injury is often assumed to be due to neuraxial anesthesia, but peripheral nerve palsies, which generally have obstetric causes, are much more common, with a reported incidence between 0.6 and 92 per 10,000.[19] They may arise from compression in the pelvis by the fetal head, or from more distal compression, the signs of which may be overlooked in the presence of neuraxial anesthesia. In contemporary obstetric practice, cesarean delivery is usually preferred to prolonged labor and difficult or forceps delivery. The incidence of pelvic nerve trauma and compression should therefore be lower than in years past. Surveys have shown that although obstetric palsies still occur,[11,13,14] most are short-lived and less disabling than hitherto.[2,3] Foot drop, however, is still reported,[10,13,14,20] primarily in cases in which the effort to avoid cesarean delivery leads to vaginal delivery of a disproportionately large baby.[10,13] Abnormal presentation, persistent occiput posterior position, fetal macrosomia, breakthrough pain during epidural labor analgesia, a prolonged second stage of labor, difficult instrumental delivery, and prolonged use of the lithotomy position may presage postpartum neuropathy.

Reference to the distribution of spinal dermatomes and peripheral nerve sensory innervation clearly demonstrates the distinction between peripheral and central lesions (Figure 32-1). Spinal nerve root lesions are also manifested by weakness that involves several lower extremity joints and movements (Figure 32-2).

Compression of the Lumbosacral Trunk

Compression of the lumbosacral trunk by the fetal head at the pelvic brim (Figure 32-3) preferentially affects the more medial fibers that make up the peroneal rather than the tibial nerve.[19] In addition to weakness that

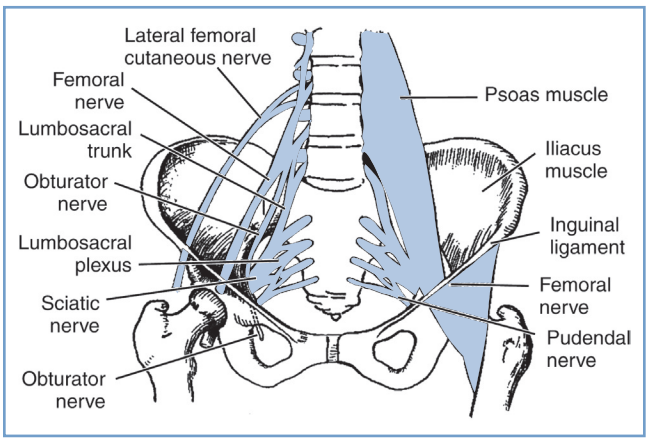

FIGURE 32-3 ■ The principal nerves in the pelvis. The lumbosacral trunk (L4 to L5) and obturator nerve (L2 to L4) are vulnerable to pressure as they cross the pelvic brim, particularly in cases of cephalopelvic disproportion. The femoral (L2 to L4) and lateral femoral cutaneous (L2 to L3) nerves are particularly vulnerable in the lithotomy position, where they pass beneath the inguinal ligament. (Adapted from Cole JT. Maternal obstetric paralysis. Am J Obstet Gynecol 1946; 52:374.)

predominantly affects ankle dorsiflexion (foot drop), compression of the lumbosacral trunk produces sensory disturbance mainly involving the L5 dermatome (see Figure 32-1). This palsy most often results from some cephalopelvic disproportion and is therefore typically seen after prolonged labor and difficult vaginal delivery.[2,3,11-14]

Obturator Nerve Palsy

The obturator nerve is susceptible to compressive injury as it crosses the brim of the pelvis or within the obturator canal (see Figure 32-3). The mother may complain of pain when the damage occurs, followed by weakness of hip adduction and internal rotation, with sensory disturbance over the upper inner thigh (see Figure 32-1). Cases are reported after both labor and cesarean delivery[20-22]; three were detected in a prospective study by Wong et al.[14] Because the nerve would appear to be in a vulnerable position, it may be that injury occurs more often than is reported, but is misdiagnosed.

Femoral Nerve Palsy

Approximately one third of the postpartum palsies detected by Wong et al.[14] were femoral nerve palsies. Dar et al.[13] detected five cases in their small population, although the symptoms were transient. The femoral nerve does not enter the pelvis and is therefore not vulnerable to compression by the fetal head but is vulnerable to stretch injury as it passes beneath the inguinal ligament. Damage may result from prolonged flexion, abduction, and external rotation of the hips during the second stage of labor and also during procedures conducted in an excessive lithotomy position.[23] The hips should therefore never remain continuously flexed during the second stage of labor. In femoral neuropathy, the nerve supply to the iliopsoas muscle is spared, so that

some hip flexion is still possible. The patient with a femoral neuropathy may walk satisfactorily on a level surface but may be unable to climb stairs; the patellar reflex is diminished or absent.

Meralgia Paresthetica

Meralgia paresthetica is a neuropathy of the lateral femoral cutaneous nerve, a purely sensory nerve also known as the lateral cutaneous nerve of the thigh. First described more than 100 years ago, meralgia paresthetica is commonly encountered in pregnancy and childbirth.[13,14] It may arise both during pregnancy, typically at about 30 weeks' gestation, and intrapartum,[14,24] in association with increasing intra-abdominal pressure. It may recur during successive pregnancies. The most likely cause is entrapment of the nerve as it passes around the anterior superior iliac spine beneath or through the inguinal ligament, where its vulnerability is increased by a large intra-abdominal mass or by retractors used during pelvic surgery. The compressive effect of edema may also contribute. Meralgia paresthetica manifests as numbness, tingling, burning, or other paresthesias affecting the anterolateral aspect of the thigh. The distribution is quite unlike that of a nerve root lesion (see Figure 32-1), yet the disturbance is commonly attributed to neuraxial blockade by those ignorant of neuroanatomy. The condition can be expected to resolve after childbirth; transient pain may be relieved by local infiltration analgesia.

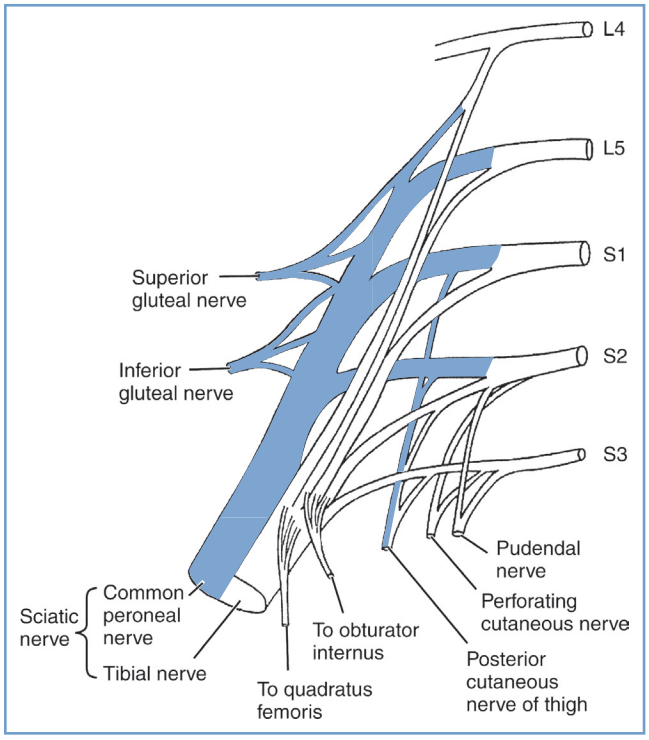

FIGURE 32-4 ■ **The sacral plexus. The dorsal divisions of the anterior primary rami are shaded.** (From Silva M, Mallinson C, Reynolds F. Sciatic nerve palsy following childbirth. Anaesthesia 1996; 51:1144-8.)

Sciatic Nerve Palsy

Sciatic nerve palsy arises from compression of the nerve, usually in the buttock. It is not commonly mentioned in surveys or generally recognized as a complication of childbirth, possibly because it is mistaken for a lesion of the lumbosacral trunk. It gives rise to loss of sensation below the knee with sparing of the medial side and loss of movement below the knee. Posterior cutaneous nerve and gluteal function are preserved, implying damage distal to the lumbosacral plexus, where the gluteal nerves branch off the sciatic nerve (Figure 32-4). It has occurred during childbirth under neuraxial blockade, either from sitting in one position too long[25] or from a hip wedge misplaced during cesarean delivery.[25-27] Hypotension may be contributory. Three cases were detected by Wong et al.[14] Despite the peripheral location of the lesions, neuraxial anesthesia cannot be exonerated, because the symptoms of nerve compression, which otherwise would have prompted a change of position, may be overlooked or wrongly attributed to local anesthetic-induced sensory blockade.

Peroneal Nerve Palsy

The common peroneal nerve is vulnerable to compression as it passes around the head of the fibula below the knee. It is also susceptible to damage while it still forms part of the sciatic nerve as it leaves the pelvis. Peroneal nerve palsy may be caused by prolonged squatting,[28] sometimes popular in "natural childbirth," by excessive knee flexion for any reason, by compression of the lateral side of the knee against any hard object, even the parturient's hand,[29] and by prolonged use of the lithotomy position. These risks are compounded by the presence of neuraxial blockade. When the peroneal nerve is damaged at the knee, there is sensory impairment on the anterolateral calf and the dorsum of the foot; foot drop may be profound, with steppage gait and weak ankle eversion, but plantar flexion and inversion at the ankle are preserved.

Compression as a Risk Factor for Peripheral Neuropathy

During pregnancy, nerve compression due to edema may be a factor in the genesis of several peripheral neuropathies, such as carpal tunnel syndrome, Bell's palsy, and meralgia paresthetica.[24,30,31] Anesthesia providers cannot be wholly absolved from responsibility for peripheral neuropathies, the signs of which may be overlooked or attributed to neuraxial anesthesia.[26,29] Adverse factors can be minimized by attention to simple rules (Box 32-2). One group of patients, those with hereditary neuropathy with liability to pressure palsy, requires particular attention. In these women even relatively brief periods of immobility or pressure on any one site must be avoided.[32,33]

POSTPARTUM BLADDER DYSFUNCTION

There are several mechanisms by which bladder function may be disturbed postpartum (Figure 32-5). In theory,

neuraxial blockade (1) may provoke the need for bladder catheterization with increased risk for infection, (2) may allow bladder distention to go undetected, and (3) on very rare occasions, may be associated with cauda equina syndrome (see later discussion). However, several postpartum studies of bladder function have found no association with neuraxial analgesia[34,35] or only a weak correlation between epidural analgesia and an increased residual volume immediately postpartum.[36] In contrast, a prolonged second stage of labor, instrumental delivery, and perineal damage have been identified as significant factors for postpartum bladder dysfunction.[34-36] In the previously described large survey of long-term symptoms after childbirth conducted in Birmingham, United Kingdom, no association was found between epidural analgesia and stress incontinence or urinary frequency.[8,37] By far the most common cause of bladder dysfunction appears to be non-neurologic. Nevertheless, it must be part of the anesthesia provider's responsibility to ensure that the bladder does not become overdistended either intrapartum or postpartum.

BOX 32-2 Safeguards to Minimize Peripheral Nerve Compression

- Be watchful for patient positioning that contributes to nerve compression, particularly with neuraxial blockade.
- Avoid prolonged use of the lithotomy position; regularly reduce hip flexion and abduction.
- Avoid prolonged positioning that may cause compression of the sciatic or peroneal nerve.
- Place the hip wedge under the bony pelvis rather than the buttock.
- Use low-dose local anesthetic/opioid combinations during labor to minimize numbness and allow maximum mobility.
- Encourage the parturient to change position regularly.
- Ensure that those caring for women receiving low-dose local anesthetic/opioid combinations understand that numbness or weakness may be signs of nerve compression; such symptoms should prompt an immediate change of position.

CENTRAL NERVOUS SYSTEM LESIONS

Lesions of the central nervous system (CNS) after childbirth have complex causes (Figure 32-6), which may be classified as **traumatic** (to nervous tissue, meninges, or blood vessels), **infective, ischemic,** or **chemical** (to nervous tissue or meninges). Anesthesia providers should bear in mind that even central lesions may have causes other than neuraxial block, the most obvious being a prolapsed intervertebral disc. Apart from sequelae of dural puncture, serious iatrogenic complications are remarkably rare.

Neurologic Sequelae of Dural Puncture

The subject of post–dural puncture headache is discussed in detail in Chapter 31. There are several other causes of severe postpartum headache, some of which have serious neurologic implications. Postpartum headache requires diagnosis first and foremost, followed by treatment that is curative rather than palliative.

Postpartum cortical vein and venous sinus thrombosis are more common than expected because of the hypercoagulable state of the blood.[38-40] Cortical vein thrombosis has been associated with dural puncture and post–dural puncture headache. Headaches caused by meningitis, venous sinus thrombosis, preeclampsia, hypertensive encephalopathy, subdural hematoma, internal carotid artery dissection, and posterior reversible encephalopathy syndrome may cause difficulty in diagnosis, particularly if they occur after epidural bolus injection, unintentional dural puncture, or administration of an epidural blood

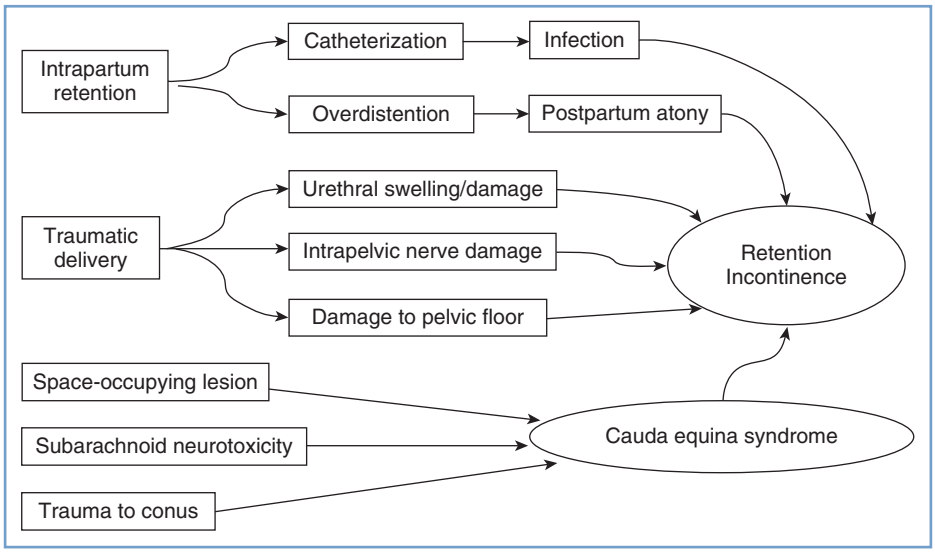

FIGURE 32-5 ■ Mechanisms by which bladder function may be disturbed after parturition.

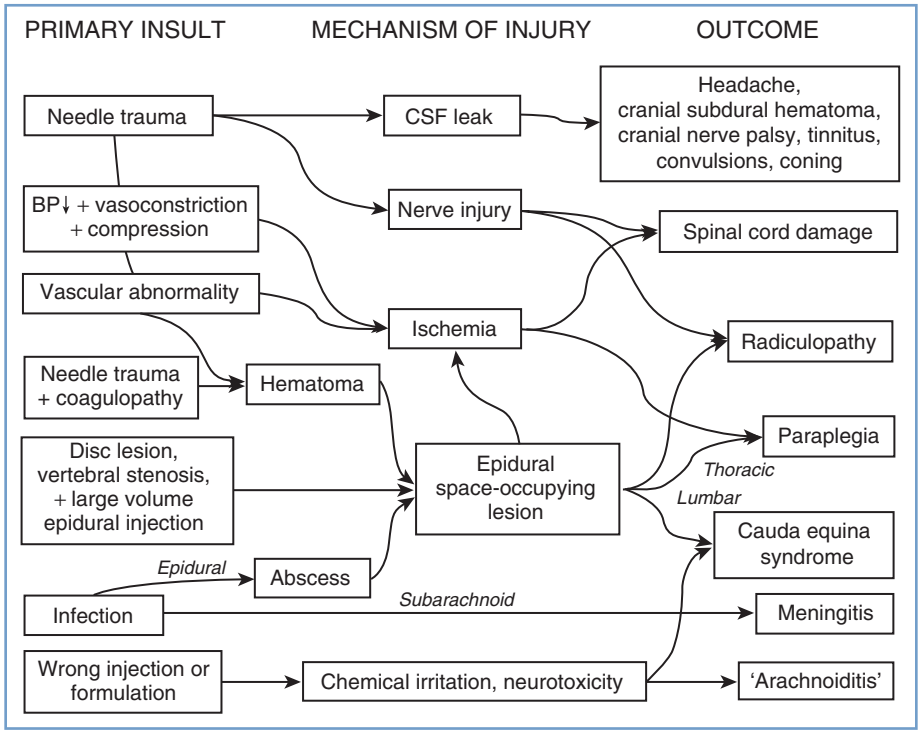

FIGURE 32-6 ■ Mechanisms by which lesions of the central nervous system may arise in parturients.

patch. Seizures may occur in patients with eclampsia, hypertensive encephalopathy, meningitis, or pneumocephalus but may also follow dural puncture or performance of an epidural blood patch.[38-49]

It is commonly assumed that headache after dural puncture will resolve spontaneously over time, but unfortunately a dural leak can persist and may occasionally have more serious consequences, including cranial nerve palsy and subdural hematoma. Neglected cerebrospinal fluid (CSF) leak has also been known to induce medullary and tentorial coning.[50] Although serious problems are more likely to occur from unintentional dural puncture with a large epidural needle and a neglected headache, they may occasionally follow deliberate dural puncture with a small-gauge spinal needle.[50]

Cranial Nerve Palsy

Major loss of CSF, usually following unintentional dural puncture with a large needle, may cause a number of cranial nerve palsies; those affecting cranial nerves VI, VII and VIII are the most frequently reported.[51-57] Because of its long course within the cranium, the **abducens nerve** (VI) is the most vulnerable. All cranial nerve palsies require prompt epidural blood patch, but even after the blood patch, recovery may be delayed. In the case of cranial nerve VIII dysfunction, tinnitus may become permanent.[56,57] Trigeminal nerve dysfunction is usually a transient effect of high spinal blockade.

Cranial Subdural Hematoma

More seriously, reduced CSF pressure may cause rupture of bridge meningeal veins and result in cranial subdural hematoma, a potentially fatal condition that has been reported sporadically over many years.[50] Palot et al.[9] found one case in 288,351 obstetric epidural procedures; in 2000, Loo et al.[4] identified eight obstetric cases, and more have been reported since.[58-62] Although commonly believed to result only from neglect of a dural puncture with a large needle or a cutting spinal needle, subdural hematoma requiring craniotomy has been reported after puncture with a small-gauge, pencil-point spinal needle[60] and after an unintentional dural puncture that had been appropriately treated with an epidural blood patch.[58] Whenever headache persists after treatment with an epidural blood patch (particularly if the headache is accompanied by altered consciousness, seizures, or other focal neurologic findings), magnetic resonance imaging (MRI) is warranted to exclude subdural hematoma, which may be fatal without urgent surgery.

One case of cranial *epidural* hematoma arose after spinal anesthesia for removal of the placenta; the hematoma occurred after a seizure.[63] Nothing was as it seemed, however; the seizure was not eclamptic, but rather epileptic, and the hematoma was not a result of spinal anesthesia.

Trauma to Nerve Roots and the Spinal Cord

Insertion of a spinal needle or epidural catheter is not infrequently accompanied by paresthesia that is sometimes painful. Although a flexible catheter is unlikely to do lasting damage to a nerve root in the epidural space, nerve roots in the subarachnoid space are more vulnerable.

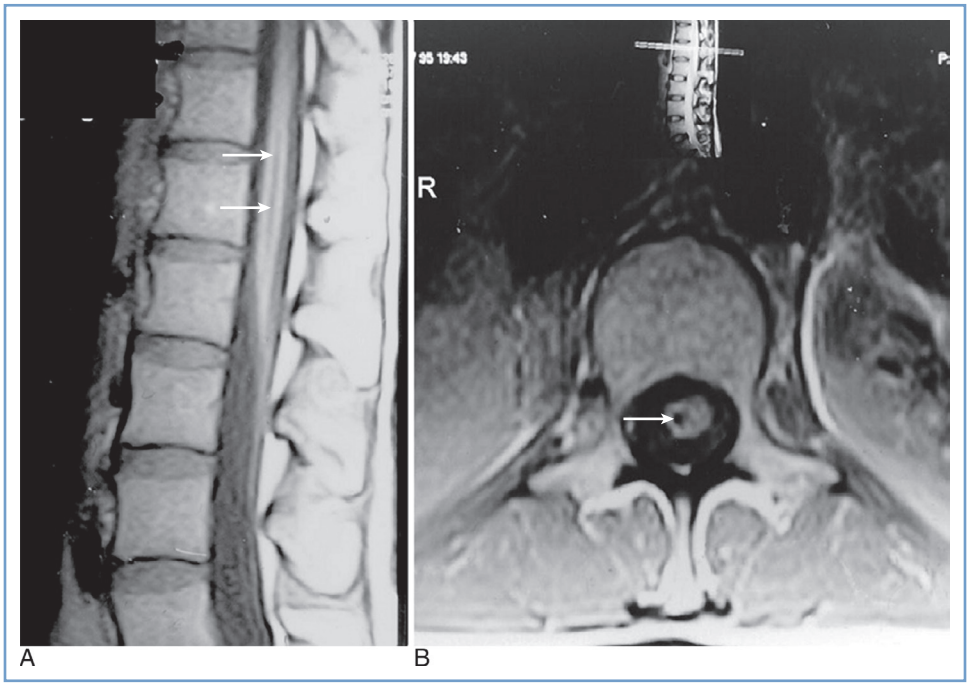

FIGURE 32-7 ■ **A** and **B,** Magnetic resonance images of a conus medullaris lesion (*arrows*). (From Reynolds F. Damage to the conus medullaris following spinal anaesthesia. Anaesthesia 2001; 56:238-47.)

Trauma Associated with Attempted Epidural Catheter Insertion

An epidural catheter may injure nerve roots either because it is inappropriately rigid[64] or because an undue length is threaded and ensnares a root.[65] A catheter seemingly threaded into the epidural space may lodge in an intervertebral foramen or even pass into the paravertebral space. In rare instances the epidural catheter and the artery of Adamkiewicz share the same foramen. If the epidural catheter is stiff enough to compress the artery within the unyielding foramen, the blood supply to the spinal cord may be impaired. This is a possible cause of anterior spinal artery syndrome. Clinical reports indicate that the condition resolves rapidly and completely if the catheter is withdrawn before permanent damage has occurred.[66,67]

Injury to the spinal cord may result from attempted identification of the epidural space in the presence of undetected spina bifida occulta or a tethered cord[68] or as a result of an unsteady grip or uncontrolled advancement of the epidural needle. Insertion of an epidural catheter in an anesthetized patient greatly increases the risk for spinal cord damage, and catastrophic injury may occur with injection of fluid into the substance of the spinal cord.[69]

Trauma Associated with Spinal Anesthesia

Insertion of a spinal needle below the level of the spinal cord sometimes causes brief radiating pain or paresthesia, which may be associated with persistent paresthesia in the same dermatomal distribution. Prolonged symptoms involving more than one spinal segment suggest damage to the spinal cord itself. Damage to the terminal portion of the cord (the conus medullaris) without intracord injection has also been reported in healthy conscious parturients receiving spinal or CSE anesthesia using a pencil-point needle.[11,16,70,71] Typically, the patient complains of pain on needle insertion before any fluid is injected, often followed by the normal appearance of CSF from the needle hub, easy injection of the local anesthetic agent, and a normal onset of neural blockade. On recovery, there is unilateral numbness, which is succeeded by pain and paresthesia in the L5 to S1 distribution and foot drop, and in some cases urinary symptoms; sensory symptoms may last for months or years. The MRI appearance is one of a small syrinx or hematoma within the conus at the level of the body of T12 on the same side as the pain on insertion and subsequent leg symptoms (Figure 32-7).[71] In the majority of cases, the anesthesia provider believed the interspace selected was L2-L3. In one patient who subsequently died of other causes, hematomyelia was confirmed at autopsy.[72] Since a spate of cases of conus damage in the 1990s, the practice of spinal needle insertion may have been modified, but an abnormally long cord may still be damaged with the best of techniques.[73]

These injuries may have occurred for the following reasons:

- Anesthesia providers, accustomed to siting epidural needles and catheters, had forgotten the precautions necessary to avoid contact with the spinal cord during dural puncture. Moreover, the option to use an *upper* lumbar interspace was sanctioned by some reputable textbooks.[74]
- Identification of lumbar interspaces was far from accurate. Studies showed that it was common to select a space that is higher than assumed by one,

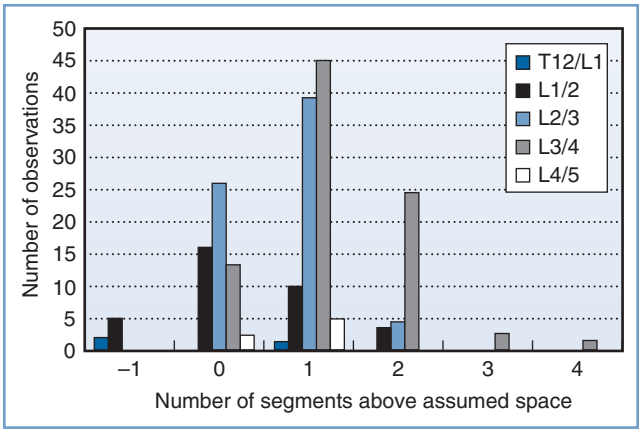

FIGURE 32-8 ■ Identification of lumbar interspaces by Oxford anesthetists. The horizontal axis shows the position of the actual interspace identified on magnetic resonance imaging, relative to the assumed space, in 200 observations. (Data from Broadbent CR, Maxwell WB, Ferrie R, et al. Ability of anaesthetists to identify a marked lumbar interspace. Anaesthesia 2000; 55:1122-6.)

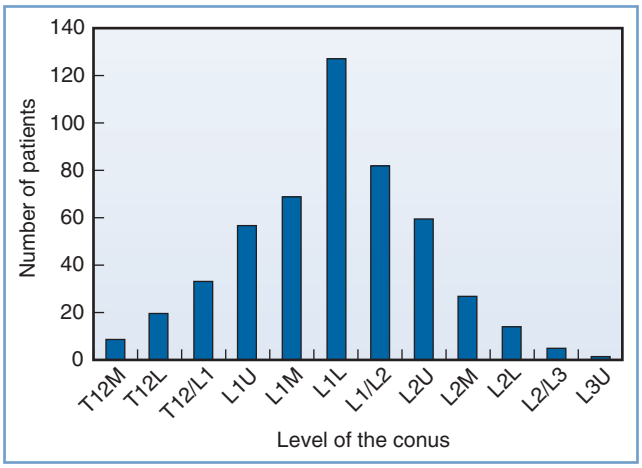

FIGURE 32-9 ■ Variation in the level of the tip of the conus medullaris assessed by magnetic resonance imaging of the lumbar spine among 504 consecutive adults. *L,* lower third of vertebral body listed; *M,* middle third of vertebral body listed; *T12/L1,* interspace between T12 and L1; *U,* upper third of vertebral body listed. (Data derived from Saifuddin A, Burnett SJ, White J. The variation of position of the conus medullaris in an adult population: a magnetic resonance imaging study. Spine 1998; 23:1452-6.)

two, or even more segments (Figure 32-8).[75,76] Anesthesia providers had little opportunity for feedback to improve their skill in interspace identification.

- Although the spinal cord typically ends level with the lower body of L1 or the L1-L2 interspace, the length varies (Figure 32-9).[77] From the L1-L2 interspace, the needle tip can easily reach the conus in 27% of men and 43% of women.[78]
- The standard method of identifying lumbar interspaces involves the use of Tuffier's line, the imaginary line joining the two iliac crests. This method can be inaccurate, however, particularly in obese or pregnant women (Figure 32-10). Moreover, even when accurately assessed, Tuffier's line is an inconstant landmark.[79] Although typically at the level of the L4 spinous process, it may lie anywhere between the L3-L4 and L5-S1 interspaces. Other means of identifying the interspace, such as counting down from C7 or finding the vertebra that is attached to the 12th rib, are tedious and of little help in obese patients.
- Pencil-point spinal needles must be advanced further than cutting needles before the orifice is within the subarachnoid space, at which point the tip may impinge on the spinal cord.

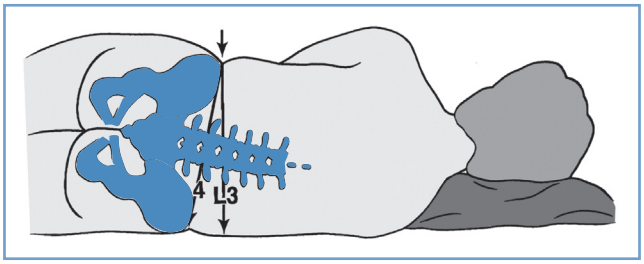

FIGURE 32-10 ■ Error that may arise if Tuffier's line is judged in a pregnant patient in the lateral position, when a line is drawn perpendicularly from the upper iliac crest rather than through both iliac crests. In pregnant patients at term, the hips may have a greater width than the shoulders. The resulting cephalad pelvic tilt may lead to an error in the cephalad direction.

BOX 32-3 Points to Remember to Reduce Risk for Damage to the Conus Medullaris during Spinal Anesthesia

- The conus medullaris reaches L2 in 27% of men but in 43% of women.
- Tuffier's line is not in a constant position relative to the spine.
- The interspace chosen is usually higher than supposed.
- The spinal needle should not knowingly be inserted above the L3 spinous process.
- Pencil-point spinal needles have at least 1 mm of "blind tip" beyond the orifice.
- Spinal needles must be advanced with gentleness and control.
- Advancement of the spinal needle should be halted immediately, and the stylet removed to check for CSF, if entry of the needle tip into the subarachnoid space is suspected.
- The procedure should be abandoned if the patient is unable to cooperate.

Medical students and residents are usually instructed to select the L4-L5 interspace for diagnostic lumbar puncture, but anesthesia providers have been more liberal in their approach. Given the inaccuracy of identification of lumbar interspaces and the variability of the position of the conus, it is both logical and prudent to insert a spinal needle below the spinous process of L3, or at least into a lower lumbar interspace, especially in women. Box 32-3 summarizes the problems and precautions in identifying lumbar interspaces and avoiding damage to the conus medullaris.

Space-Occupying Lesions of the Vertebral Canal

Space-occupying lesions of the vertebral canal include intraspinal hematomas (epidural or subdural), epidural abscess, and intraspinal tumors, any of which, within the rigid confines of the bony spinal canal, can cause dangerous compression of nervous tissue and its blood supply. Urgent laminectomy is required to avoid permanent neurologic damage. Delayed recognition and treatment (> 6 to 12 hours after onset of symptoms) may have a catastrophic outcome and grave medicolegal consequences.

Epidural analgesia in labor does not normally behave like a space-occupying lesion and produces no lasting deformation of the thecal sac on MRI.[80] Nevertheless, in the presence of vertebral stenosis or lumbar disc protrusion, a large volume injected into the epidural space may tip the balance and produce signs of nervous tissue compression that normally resolve in a few hours.[81,82]

The neurologic deficit that may arise from a compressive lesion depends on the vertebral level; lower thoracic lesions are associated with leg weakness or paraplegia, and lumbar lesions with cauda equina syndrome, including urinary retention and incontinence. Back pain (often radiating to the legs) is a common feature.

Spinal Hematoma

Spinal hematomas may be classified as epidural, subdural, or subarachnoid.[83] Keppel et al.[83] found 613 cases of spinal hematoma published in the medical literature between 1826 and 1996, 461 of which were epidural, 25 subdural, and 96 subarachnoid. Spinal hematomas were described at all vertebral levels. Twice as many patients were male as female. Many patients were elderly and only five were pregnant (details unknown). The majority of cases (44%) were spontaneous or followed minor trauma, and 22.5% were related to coagulopathy or anticoagulant treatment; only 63 cases followed lumbar puncture or neuraxial anesthesia. Of these 63 patients, 26 were without coagulopathy.

Similarly, during pregnancy and the puerperium, spontaneous epidural hematoma is reported more frequently than hematoma associated with neuraxial blockade. Loo et al.[4] found three cases (that may have been included in the earlier review[83]) and more have been reported in the 21st century.[84-88] Epidural hematoma in pregnancy associated with coagulopathy but without neuraxial anesthesia is also reported.[89,90] It has been suggested that pregnancy-induced structural changes in vessel walls, together with hemodynamic changes, may predispose to spinal hematoma.[86]

Epidural Hematoma after Neuraxial Blockade.

Incidence. Epidural hematoma after neuraxial blockade typically causes neurologic deficit in elderly patients with arterial disease; it is very rare in obstetric patients, despite the engorgement and possible fragility of epidural veins. Nine surveys, covering 1,331,171 obstetric epidural procedures,* found two cases (see Table 32-1), one without confirmatory details[7] and the other in a patient with HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome.[16] This gives an incidence of 0.150 per 100,000 epidural procedures (95% confidence interval [CI], 0.018 to 0.543). Any estimate of the incidence of epidural hematoma in the surgical population is equally meaningless because, as with obstetric cases, it depends on how assiduously neuraxial blockade is avoided in the presence of coagulopathy and also on the incidence of vessel puncture, which in turn is affected by the skill of the anesthesia provider.

Causation. Risk factors identified from comprehensive reviews of case reports include (1) difficult or traumatic epidural needle/catheter placement, (2) coagulopathy or therapeutic anticoagulation, (3) spinal deformity, and (4) spinal tumor.[4,91,92] Antiplatelet therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) is believed not to increase the incidence of neurologic dysfunction after neuraxial anesthesia,[93] although NSAIDs were involved in three cases in one survey of a mixed population.[91]

Of the five cases of epidural hematoma in obstetric patients found by Loo et al.,[4] four were without details and the other associated with coagulopathy. In the most recent analysis from the American Society of Anesthesiologists' (ASA) Closed-Claims Project database,[94] there were four cases of epidural hematoma, of which only one had coagulopathy; again, details were not provided. Two further case reports are of interest. An eclamptic patient with thrombocytopenia suffered a persistent lower limb deficit after a traumatic epidural catheter insertion using the loss-of-resistance-to-air technique.[95] Laminectomy revealed multiple bubbles and a 4-mL blood clot, the exact site of which was not stated. Such a small volume could have caused neurologic deficit only if it was subdural rather than epidural. An epidural hematoma was reported presenting *nine days* after removal of an epidural catheter that had been sited and used uneventfully for labor analgesia.[96] Apparently the only risk factors were a traumatic insertion and self-medication with ibuprofen postpartum. The coagulation assessment was normal, but the hematoma was extensive and required decompressive surgery. It is of course possible that this was a spontaneous hematoma and neuraxial analgesia was coincidental.

Both vessel damage and coagulopathy (whether inherited, acquired, or due to anticoagulation) are usually necessary to produce a hematoma large enough to cause a neurologic deficit in the parturient. Safe epidural catheter insertion in coagulopathic parturients has often been recorded, but the frequency of vessel trauma is rarely mentioned.[97-100] Vessel trauma can arise not only during insertion but also on removal of the epidural catheter.

Protective Factors. It may be that, in obstetric patients, many epidural hematomas arise but are too small to cause neurologic deficit. One factor may be the hypercoagulable status of blood peripartum. Another is the ease with which a large volume of anticoagulated blood may flow out of the unrestricting intervertebral foramina in young

*References 5,7-10,12,15,16,18

patients. Injected blood is known to disappear from the epidural space rapidly in the parturient.[80,101] During performance of an epidural blood patch, 20 mL of blood is commonly injected with impunity. Although compressive symptoms may be experienced with a volume larger than 20 mL, they do not normally presage any neurologic deficit in obstetric patients.

Subdural and Subarachnoid Hematoma. Spinal subdural hematoma has been reported in obstetric patients, one in association with an ependymoma,[4] one after spinal anesthesia and an epidural blood patch,[102] and another in a woman with preeclampsia, known vessel puncture during epidural catheter insertion, and mild coagulopathy.[103] A subarachnoid hematoma after spinal anesthesia was reported in a patient with HELLP syndrome.[104] More worryingly, one woman suffered a major subarachnoid hematoma after apparently straightforward CSE anesthesia.[105] All four patients developed cauda equina syndrome and laminectomy was required in three.

Dural puncture (with or without arachnoid puncture) is a prerequisite for subdural and subarachnoid hematoma. On the other hand, coagulopathy may *not* be a prerequisite, because the extravasated blood is confined in a small space and may compress adjacent nerve roots more readily than in the capacious epidural space.

Prevention, Diagnosis, and Management. It is clearly important to check coagulation status in an at-risk parturient not only when inserting but also when removing an epidural catheter. If neuraxial blockade is found to have been conducted in the presence of risk factors for spinal hematoma, it is an essential responsibility of the anesthesia provider to examine the lower extremities after delivery, to confirm and document the return of normal motor and sensory function, and to request subsequent checks by the nursing staff. Severe back pain and a significant delay in normal recovery or deterioration of lower extremity or bladder function signal the need for emergency imaging of the spine. If intraspinal compression is confirmed by MRI, a neurosurgical opinion must be urgently sought.

The dangers of neuraxial anesthesia in the presence of coagulopathy and anticoagulant treatment are discussed in Chapters 39 and 44.

Infection

Neuraxial infection (epidural abscess and meningitis) was identified as the most common cause of neuraxial injury in obstetric cases in the ASA Closed-Claims Project database between 1980 and 1999.[106] Infections that have been reported include epidural abscess, paraspinal and other epidural-related infection, and meningitis.

Epidural Abscess

Frequency. Epidural abscess may occur spontaneously in pregnancy and the puerperium as at other times.[4,107] An analysis of 915 reports of spinal epidural abscess published between 1954 and 1997 found that epidural blockade had been performed in only 5.5% of cases.[108] After neuraxial blockade, epidural abscess, like spinal hematoma, appears to be rare in obstetric patients. Three cases were found among 1,331,171 epidural procedures listed in nine surveys summarized in Table 32-1, a frequency of 0.225 per 100,000 (95% CI, 0.047 to 0.659). The incidence among surgical patients has been reported as 10-fold[16] to 100-fold[109] higher, with most cases arising in elderly and immunocompromised patients. A careful 4-year Australian study of 9482 obstetric patients who underwent childbirth in a center where correct sterile procedures were used found 49 epidural catheter–related infections (0.52%): 45 superficial, 2 epidural, and 2 paraspinal, giving an epidural infection rate of 21 per 100,000,[110] which was 100-fold higher than the calculated frequency from larger, but apparently less sensitive, surveys.

Sixteen case reports of well-authenticated epidural abscess after epidural analgesia in obstetric patients[111-126] have been tabulated elsewhere.[127] All cases occurred after epidural catheterization, with three as part of CSE anesthesia. None followed spinal anesthesia alone. One case was reported as meningitis but was actually an epidural abscess.[122]

One additional case report concerned a mother who developed back pain 12 months after uneventful epidural analgesia for labor.[128] After 2 further months she developed leg weakness; diagnostic lumbar puncture provoked further acute neurologic deterioration, and she was found to have an epidural abscess from the cervical to the lumbar region.

Possible risk factors identified from these cases are outlined in Table 32-2. An epidural abscess typically follows prolonged epidural catheterization, usually between 1 and 4 days in obstetric cases. Other possible etiologic factors are traumatic or difficult insertion of the catheter,[112,114,117,120] epidural administration of opioid *without* local anesthetic,[110,112,118,119] and diabetes or immunosuppression from any cause.[109,112,115,121] Inflammation at the epidural catheter entry point may presage epidural space infection.[110,114,119] In light of these reports it may be prudent to avoid prolonged epidural catheterization in the patient with other risk factors for infection.

Some practitioners have suggested that administration of an epidural blood patch necessitates prior blood culture. However, a Medline search carried out in April 2012 for "epidural abscess AND epidural blood patch" did not yield any cases, and the only recorded instance of an infected blood patch is one that appears to have entered the subcutaneous fat (see later discussion).

Clinical Presentation. Symptoms of epidural abscess typically start between 4 and 10 days after removal of the epidural catheter. The interval of 14 months cited earlier is extreme and poses the question whether the epidural catheter was causative. Severe backache (with local tenderness) and fever, with or without radiating or root pain, are the presenting features. The catheter entry point may be inflamed with some fluid leak, and a hematology screen typically reveals leukocytosis and increased C-reactive protein. Fever, neck stiffness, headache, and signs of inflammation serve to differentiate epidural abscess from hematoma. These signs and symptoms should prompt MRI, which may allow early diagnosis

TABLE 32-2 **Possible Etiologic Factors for Epidural Abscess and Meningitis**

	Epidural Abscess	Meningitis
Entry Point	Through the epidural catheter or along its track	Via the dural puncture
Usual Causative Organism	*Staphylococcus aureus*	*Streptococcus salivarius*
Possible Source of Infection	Patient's skin, tracking along the catheter entry point Epidural equipment contaminated by operator's skin Body fluids in the bed Injectate without racemic local anesthetic	Operator's mouth Talking without a mask Blood borne Vagina
Risk Factors	Prolonged catheterization Poor aseptic technique Multiple attempts at insertion, traumatic insertion No bacterial filter Lying in a wet, contaminated bed Polyurethane occlusive dressing Immunocompromise: corticosteroids, diabetes, acquired immunodeficiency syndrome	Dural puncture Labor No face mask Manual removal of the placenta Vaginal infection Bacteremia Immunocompromise?

before the onset of neurologic changes (Figure 32-11).[129] If untreated, symptoms may progress to leg weakness, paresthesias, bladder dysfunction, and other evidence of cauda equina syndrome. Blood culture may identify the organism before or without surgical drainage. Diagnostic lumbar puncture is *contraindicated.*[128]

Etiology. *Staphylococcus aureus* is the most common causative organism in cases of epidural abscess, with the occasional infection with *Streptococcus* and *Pseudomonas* species. The skin appears to be the most likely source of infection.[4]

The skin is commonly colonized by *Staphylococcus epidermidis* and other weakly pathogenic bacteria and occasionally by *S. aureus.* The highest concentration of colonies is found in the hair follicles,[130] where organisms may be protected from briefly applied disinfectants. Infectious organisms from the skin can reach deeper tissue planes via the needle track or an implanted epidural catheter to create a localized abscess in the paraspinal or epidural space. Despite all aseptic precautions, some level of detectable bacterial colonization of the epidural catheter is very common, but robust host defenses normally prevent infection. When defenses are weak and infection containment breaks down, epidural abscess formation begins.

Management. As with spinal hematoma, once neurologic signs are present, early diagnosis with prompt laminectomy is essential to recovery. In the presence of mild symptoms without neurologic changes, successful conservative treatment with antibiotics[116] and successful percutaneous needle drainage[131] of epidural abscesses have also been reported, although only laminectomy can ensure that all loculations are drained under direct vision. Prompt identification of the infectious organism(s) and directed antibiotic therapy are mandatory. Antibiotic treatment should be continued for 2 to 4 weeks.[129]

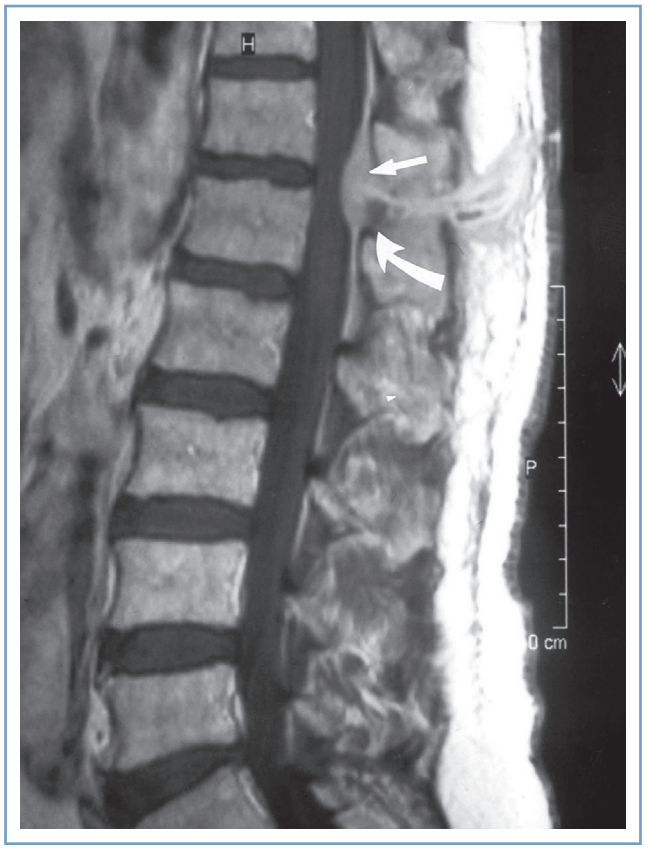

FIGURE 32-11 ■ Epidural abscess. Midsagittal T1-weighted magnetic resonance image of the lumbar and lower thoracic region, after intravenous gadolinium DTPA. Note the dorsal epidural mass located at T12-L1 (*arrows*), convex anteriorly but not compressing the conus. Normal epidural fat is flat anteriorly. (From Royakers AANM, Willigers H, van der Ven AJ, et al. Catheter-related epidural abscesses—don't wait for neurological deficits. Acta Anaesthesiol Scand 2002; 46:611-5.)

Epidural-Related Infection

Paraspinal abscess and osteomyelitis after epidural analgesia[132-137] and discitis after spinal blockade[138] have been reported in obstetric patients. Catheter-site inflammation is relatively common with prolonged postoperative epidural analgesia.[110,139] One report described both a subdural abscess after CSE anesthesia and infection in the subcutaneous tissues after an apparently misplaced epidural blood patch.[140]

TABLE 32-3 **Case Reports of Post–Dural Puncture Meningitis Among Obstetric Patients**

	References: First Author, Year of Publication	No. of Cases	Organism; Comments
Spinal Analgesia for Labor (11 cases)	Gibbons, 1969[142]	3	Case cluster, no growth, "chemical meningitis," CSF findings suggested bacterial etiology
	Phillips, 1970[143]	1	No growth, CSF findings suggested bacterial etiology

	Goldstein, 1996[164]	1	Group B streptococcus
	Choy, 2000[165]	1	Two attempts at epidural analgesia, no growth, CSF findings suggested bacterial etiology, patient died
Total (41 cases)	35 known dural punctures 5 elective cesarean deliveries, all after tsunami 7 deaths		

CSE, combined spinal-epidural anesthesia; *CSF,* cerebrospinal fluid.

A variety of organisms have been associated with epidural-related infections.[127] All such conditions are associated with back pain and signs of inflammation and pose a threat of spread to the epidural space. Moreover, paraspinal abscess may itself cause neurologic deficit.[132,133]

Meningitis

Although not consistently included in surveys, post–spinal meningitis has become a cause for concern[141] and is an important serious neurologic complication of neuraxial labor analgesia. It was suspected in two cases in the prospective survey of 108,133 epidural procedures and 14,865 spinal anesthetic procedures by Scott and Tunstall,[8] although the specific type of anesthesia was not stated. Palot et al.[9] reported three cases of meningitis among 288,351 obstetric epidural procedures but did not state whether they followed dural puncture. One case was identified in a survey of spinal and CSE anesthesia (1/42,000 procedures).[11] A recent review found an incidence derived from surveys of spinal and CSE anesthesia in obstetrics of 1 in 39,000.[127] Table 32-3 summarizes 41 published reports of post–spinal meningitis in obstetric patients.[45,141-165]

Causative Organisms. Community-acquired meningitis may occur in pregnancy as at other times. It is commonly caused by *Neisseria meningitidis*, *Streptococcus pneumoniae*, or *Haemophilus influenzae*, while occasional cases due to tuberculosis, several β-hemolytic streptococci, and viruses are also reported in pregnancy. Post–spinal meningitis, by contrast, is most commonly caused by streptococci of the viridans type (α-hemolytic streptococci such as *S. salivarius*, *S. sanguis*, and *S. uberis*) (see Table 32-3). These organisms are found in the upper airway and the vagina. *Pseudomonas* meningitis has also

been reported.[144] Neither *Pseudomonas* nor α-hemolytic streptococci are normally virulent; they do not, for example, cause wound infection, but they thrive in a watery medium and flourish if introduced into CSF. In several early cases (before the use of the polymerase chain reaction), no organisms were grown on culture and chemical meningitis was diagnosed. In most cases, however, there were features of bacterial meningitis, including low CSF glucose concentration. Of note, streptococci of the viridans type do not grow readily in conventional culture media and may well have been present but not detected.

Risk Factors. Dural puncture is probably a prerequisite for iatrogenic meningitis. A retrospective review of surgical patients in one hospital in Brazil found three cases among 38,128 patients receiving spinal anesthesia (1/12,709) and none among 12,822 patients receiving other types of anesthesia.[166] Among 73 women with β-hemolytic streptococcal infections in the puerperium identified in a survey from Iowa,[167] the only woman who suffered meningitis had received spinal anesthesia. In normal circumstances, the blood-brain barrier (the endothelial lining of the capillaries, which are continuous with tight junctions and no pinocytotic vesicles) protects the CNS against weakly pathogenic bacteria. The dura mater should not be confused with the blood-brain barrier, but dural puncture is commonly associated with vascular trauma,[168] which allows blood to enter the CSF.

Of the 41 published cases of puerperal post–spinal meningitis for which details are available (see Table 32-3), 35 occurred after known dural puncture. Among the six cases that followed apparently uncomplicated epidural analgesia, one was viral and may have been a chance event,[161] one was probably an epidural abscess,[162] and two were blood borne from vaginal infection due to group B streptococcus.[163,164] One case, sadly fatal, followed multiple attempts at epidural catheter insertion.[165] Uncomplicated epidural catheterization itself is unlikely to increase the risk for puerperal meningitis. Although it is used more commonly than spinal analgesia during labor, case reports of meningitis after spinal analgesia far outnumber those after epidural analgesia. A causative relationship between epidural catheterization and meningitis after vaginal delivery may be attributed to unrecognized dural puncture, which may occur during multiple attempts at epidural catheter insertion or even with apparently uncomplicated catheter insertion.

Labor may also be a risk factor for meningitis. The great majority of parturients with nosocomial meningitis had labored (see Table 32-3). In the latest survey from Sweden, where spinal and CSE anesthesia are rarely used during labor, meningitis was found only among surgical patients.[16] Meningitis appears surprisingly rare after elective cesarean delivery, despite the extensive use of spinal anesthesia in this context. The five exceptions were among six unusual cases in Sri Lanka, which resulted from *Aspergillus* contamination of syringes that had been donated after the 2005 tsunami and stored in an unsuitable warehouse at 41°C and 75% humidity.[153]

The possible reasons why meningitis is reported more commonly in laboring women than among those undergoing elective cesarean delivery are as follows:

1. The vagina may be colonized by streptococci, and vaginal delivery is commonly followed by mild bacteremia. Thus labor, with its potential for vaginal trauma, is clearly an important risk factor. Unlike vaginal delivery, elective cesarean delivery is not normally associated with streptococcal bacteremia.
2. For elective cesarean delivery, spinal anesthesia is administered in the operating room, which is a cleaner environment than the labor and delivery room.
3. The anesthesia provider is more likely to wear a mask in the operating room.
4. The nonlaboring patient is not thrashing about in a (possibly) contaminated bed.
5. An antibiotic is usually administered immediately before or after cesarean delivery.

Infection at a remote site may also be a risk factor for meningitis. Bacteremia has been detected in approximately 8% of women with chorioamnionitis,[169] although two small studies found no evidence of spinal infection among 12 women with bacteremia who received epidural blockade without antibiotic treatment.[170,171] Although such negative findings are reassuring, they are not conclusive and do not apply to spinal anesthesia. Human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) should not be regarded as contraindications to neuraxial analgesia, in view of the early presence of the virus within the CNS (see Chapter 45).[172] Performing an epidural blood patch in the presence of bacteremia is also a theoretical risk for both meningitis and abscess, but neither has been reported in this context. Neuraxial analgesia in the presence of maternal fever is discussed in detail in Chapter 37.

Other risk factors for meningitis include faulty technique, in particular failure to wear a mask (see later discussion). Manual removal of the placenta is a postulated risk factor for meningitis, and one such case has been reported,[154] although given the popularity of spinal anesthesia for this indication, one would perhaps expect a higher frequency. It may be postulated that use of the CSE technique, with the presence of a foreign body next to a dural hole, may increase the risk for meningitis.

Clinical Presentation and Management. Fever, headache, photophobia, nausea, vomiting, and neck stiffness are typical symptoms of meningitis; when they are accompanied by confusion, drowsiness, and Kernig's sign (inability to straighten the knee when the hip is flexed), meningitis should be strongly suspected. The onset of nosocomial meningitis may be 12 hours to a few days after delivery. Diagnostic lumbar puncture (best avoided in the presence of raised intracranial pressure or suspicion of epidural abscess) shows increased CSF pressure, increases in protein level and white blood cell count (mainly polymorphonuclear leukocytes in patients with bacterial meningitis), and a CSF glucose concentration that is lower than that in the blood. Because of the nature of the *S. viridans* group, culture on plates rather than in broth may have negative results, particularly if antibiotics have been given, or the growth may be assumed to be a contaminant.[141] Treatment with an appropriate antibiotic should not await the microbiology results and should result in full recovery.[4] Vancomycin and third-generation

BOX 32-4 Procedures to Decrease the Risk for Infection after Neuraxial Anesthesia

- Avoid dural puncture unless indicated:
  - During labor.
  - In the presence of known genital tract infection.
- Wear an effective mask; wear a new mask for each patient.
- Remove hand jewelry and watches, and wash hands with an alcohol-based scrub solution.
- In the United Kingdom, a gown is worn for epidural catheter insertion.
- Don sterile gloves in a sterile manner.
- Paint the patient's skin with chlorhexidine in alcohol solution, following the package instructions, and allow the skin to dry after application.
- Make sure the back is securely draped.
- Avoid contaminating any equipment that is used in the procedure, and minimize touching parts of the equipment that will enter the patient.
- After the procedure, apply a suitable dressing to the catheter entry point.
- Use a bacterial filter with an indwelling epidural or spinal catheter if the catheter will remain in place longer than several days.
- Do not leave an epidural catheter *in situ* after delivery if:
  - The dura has been punctured during labor.
  - Multiple attempts at insertion were made.
  - There is any evidence of sepsis.
  - Immunosuppression is present for any reason.
- If there is concern about sepsis or contamination, administer appropriate antibiotics.

cephalosporins have been recommended as first-line treatment.[166] The treatment regimen should be adjusted according to results of culture and sensitivity testing.

Prevention of Intraspinal Infection after Neuraxial Anesthesia

Measures to prevent intraspinal infection are described in Chapter 12 and summarized in Box 32-4. Means of preventing meningitis and epidural abscess are not identical, because abscess usually follows epidural catheterization and is commonly caused by *S. aureus*, which enters via the skin, whereas meningitis classically follows dural puncture, is caused by vaginal or nasal organisms, may be bloodborne, and is usually caused by streptococcus and never by *S. aureus*.

Because adverse outcomes are rare, the use of sterile precautions can rarely be supported by evidence from randomized trials. The components of good sterile technique should be guided by common sense and the best available indirect evidence. It is notable that in many case reports of neuraxial infection, sterile precautions used in initiating neuraxial blockade receive no mention.

A practice advisory published in 2010 by the ASA Task Force on Infectious Complications Associated with Neuraxial Techniques[173] concerns prevention, diagnosis, and management of infectious complications. Certain key aspects are discussed here.

Mask. Several surveys indicate widespread disregard of surgical masks for infection control during neuraxial block administration.[166,174,175] Among case reports of nosocomial meningitis, a mask was not mentioned[143,154,160-162] or was not worn ("as it is of doubtful value"[149] or because it "contributes little to prevent infection during spinal or epidural anesthesia,"[146] or is not considered part of "full aseptic technique"[163]).

Confusion has arisen because randomized trials have demonstrated that omission of masks in the operating room does not increase the occurrence of *wound* infection.[176] This is not surprising, however, because organisms from the upper airway do not cause wound infection, but they certainly do cause nosocomial meningitis. The effect of wearing a mask in the prevention of such rare complications cannot readily be ascertained by a randomized controlled trial. Nevertheless, the obvious value of masks in reducing the dispersion of bacteria from the mouth and nose has been well demonstrated.[177,178] A mask is an essential part of aseptic precautions that should be taken for neuraxial needle and catheter insertion.[141,173] Masks must be of good quality, preferably fiberglass and not simply woven linen or paper, not allowed to become wet, and changed for each patient.[167]

Sterile Gown. Although undeniably part of "full aseptic precautions" employed by surgeons, a sterile gown is rarely worn for spinal needle placement. For insertion of an epidural catheter, a gown is commonly worn in the United Kingdom, although this is not the typical practice in the United States or France. The value of wearing a gown is not supported by good evidence, but it can only be safer than not doing so. During epidural catheter insertion by a novice who is not wearing a gown, the catheter may inadvertently come into contact with the skin of the provider's upper arm or unsterile clothing. This occurrence may facilitate entry, via the catheter, of skin organisms that may cause epidural abscess.

Sterilizing the Skin. Evidence from laboratory and clinical studies shows that chlorhexidine in 70% alcohol consistently outperforms povidone-iodine for skin disinfection.[130,139,179] The concentration of chlorhexidine used varies from 0.5% to 2%. It is superior in speed of onset and duration of action, it is less likely to provoke a skin reaction, and unlike povidone-iodine it is effective in the presence of blood or pus, it stays sterile in the container, and bacterial resistance to it is unlikely.[127] Alcohol provides the rapid onset, and chlorhexidine provides the longer duration of action.

The one question over its use concerns that of neurotoxicity. Neither chlorhexidine nor iodine is licensed for skin sterilization before neuraxial block administration. The risk for infectious complications, however, far outweighs that for neurotoxicity, and the superiority of chlorhexidine as an antiseptic should be paramount. It is appropriate, nevertheless, to take precautions, such as using the lowest effective concentration and not allowing it to come into contact with solutions or equipment that will enter the patient's neuraxis. Use of a spray can overcome this concern; otherwise the chlorhexidine container must be removed from the cart before equipment for

neuraxial insertion is deployed. The ASA practice advisory states that the aseptic technique for neuraxial procedures should include use of chlorhexidine in alcohol with adequate drying time.[173]

Maintaining Sterility of the Epidural Catheter, Its Contents, and the Entry Point. The entry point of the epidural catheter clearly needs to be protected from contamination by a suitable dressing.[180] For prolonged analgesia, racemic bupivacaine may be safer than an opioid alone or the pure L-isomers of local anesthetics, which may permit bacterial growth in the solution.[127] Although it would seem logical, there is no evidence to support or discourage the use of a bacterial filter during a short-term (1 to 2 days) epidural infusion.[180] Prolonged catheterization is best avoided after dural puncture, whether unintentional or deliberate, and when sepsis or immunocompromise is present or suspected.

Vascular Disorders

Ischemic Injury to the Spinal Cord

Ischemic injury to the spinal cord is typically seen in elderly patients after epidural or spinal anesthesia, often with an epinephrine-containing solution, and indeed after general anesthesia with accompanying hypotension. It is rare in the obstetric population, in whom arterial disease is unusual and hypotension is treated aggressively.

The blood supply to the spinal cord depends on a single anterior spinal artery and bilateral posterior spinal arteries. The arteries arise from the circle of Willis and receive reinforcements during their descent in the spinal canal. The posterior spinal arteries receive regular contributions from radicular arteries, but the single anterior spinal artery, which supplies the anterior two thirds of the spinal cord, receives only sporadic reinforcement. **Anterior spinal artery syndrome**, which may result from arterial compression or hypotension, is characterized by a predominantly motor deficit, with or without loss of pain and temperature sensation, but with sparing of vibration and joint sensations, which are transmitted in the posterior columns. The condition has been reported among obstetric patients with particular risk factors (see later discussion).[4,7,181] One report described a series of accidents.[182] A parous woman received epidural analgesia with lidocaine, then bupivacaine with epinephrine followed by 2-chloroprocaine, when she required urgent cesarean delivery. Hypotension due to blood loss from a placenta previa *and* a ruptured uterus was followed by typical irreversible anterior spinal artery syndrome. Hypotension due to blood loss is likely to cause a greater degree of ischemia than that due to vasodilation, and the use of epinephrine may have contributed to the adverse outcome in this case.

Chemical Injury

The Epidural Space

The epidural space is remarkably tolerant of foreign and potentially neurotoxic substances because of two protective factors. First, vascular uptake and outward flow via the intervertebral foramina remove a large proportion of solutions deposited in the epidural space. Second, nerve roots within the epidural space are protected by a cuff of dura and arachnoid as well as pia mater. Severe neuraxial damage occurs only when these defenses are overwhelmed either by gross overdose or if there is unintentional contamination of the subarachnoid space. There are many case reports of unintentional epidural injection of the wrong substance, including the following:

1. **Vasopressors** (**ephedrine** and **metaraminol**). Epidural administration resulted in severe hypertension.[183]
2. **Potassium chloride**. At least four well-documented cases have been reported.[184,185] All the patients had profound motor and sensory block with pain or depolarizing spasms. Only one, who received the largest epidural dose (15 mL of 11.25% KCl), remained permanently paraplegic.[185]
3. **Other potentially noxious substances**. Administration of an unknown substance, possibly paraldehyde, given in error as an epidural bolus injection during labor, resulted in permanent painful quadriplegia and the largest monetary award for damages in the United Kingdom at that time.[186] Unintentional misconnections of intravenous and epidural infusion systems have led to large-volume epidural infusions of potentially harmful substances, including total parenteral nutrition solutions with a high osmolality[187] and ranitidine in a phenol-containing solution.[188] Fortunately, in most cases of this type of drug error, neurologic sequelae have not been reported.

In summary, with a few exceptions, the epidural space appears to be merely an exotic means of systemic administration of analgesia/anesthesia. Nevertheless, the possibility of occult dural puncture means that unintentional administration of a potentially neurotoxic substance (e.g., traces of alcohol, antioxidant, or preservative) may migrate into the subarachnoid space. Vigilance and systems to avoid these errors are mandatory.

The Subarachnoid Space

The subarachnoid space, with its poorly protected nerve roots and direct communication with intracranial structures, presents a greater risk than the epidural space for adverse outcome after unintentional injection of toxic substances. Intrathecal potassium does not merely maim, it can kill.[189] Irritant solutions may cause neurotoxicity and arachnoiditis (see later discussion). Transient neurologic syndrome (see later discussion) may be a minor and transient form of neurotoxicity. Neurotoxicity may manifest as cauda equina syndrome or, if more extensive, as paraplegia or quadriplegia.

Nerve roots within the subarachnoid space are highly vulnerable to chemical damage, particularly the sacral roots, which are poorly myelinated. Therefore, neurotoxicity associated with a small-volume intrathecal injection classically produces **cauda equina syndrome.** For example, in 1937, 14 cases of severe cauda equina syndrome were reported after spinal anesthesia using a

solution called "heavy duracaine," a mixture (in 15% ethanol) of procaine, glycerin, and gliadin or gum acacia, which presumably was added in an attempt to prolong the action of procaine.[190] In the 1940s and 1950s in the United Kingdom, spinal injection of 10 mL of hypo-osmolar dibucaine was associated with paraplegia, but whether the paraplegia resulted from disturbance of the intrathecal milieu or contamination with phenol is argued.

More recently, there were numerous reports of cauda equina syndrome after intrathecal injection of lidocaine (all types of administration, both intended and unintended, most commonly hyperbaric 5%)[191-193] and occasionally after intrathecal administration of other local anesthetics.[194,195] None of these cases involved obstetric patients. In all cases, other causes of neurologic deficit (trauma, ischemia, infection, compression, contamination, and adverse positioning) were excluded. An upper safe dose limit for intrathecal lidocaine of 60 mg[192,196] has been recommended. Hyperbaric lidocaine is not available in either Australia or the United Kingdom. The various risk factors for neurotoxic damage are summarized in Box 32-5.

Conus damage and **cauda equina syndrome** may appear similar. Although conus damage may involve upper motor neuron signs, these are not always present, and both conditions may have unilateral or bilateral features.[71] However, the causation is different. Whereas conus damage may result from ischemia or trauma, cauda equina syndrome typically results from either compression or chemical damage within the lumbar spinal canal.

Transient Neurologic Syndrome

Transient neurologic syndrome (also called transient radicular irritation) is not associated with any detectable neurologic deficit, but the distribution of pain in the back, buttocks, and thighs mirrors the distribution of nerve damage in cauda equina syndrome sufficiently to support the theory that the nerves are indeed irritated by a noxious intrathecal injection. Like cauda equina syndrome, it follows spinal anesthesia, most commonly with lidocaine. Moreover, other risk factors for cauda equina syndrome and transient neurologic syndrome are similar (see Box 32-5), although transient neurologic syndrome may be less dependent on lidocaine dose or the presence of a vasoconstrictor.[197] Transient neurologic syndrome occurs more than four times more frequently with spinal lidocaine than with other local anesthetics.[198] It is, however, much more common in surgical than obstetric patients, with a median frequency, according to one review, of 22%.[197] Parturients are not exempt from transient neurologic symptoms, with reported frequencies of 0%,[199] 4.2%,[200] 5.3%,[201] and 8.9%.[202]

BOX 32-5 Risk Factors for Chemical Damage to the Cauda Equina

- Poor spread of local anesthetic:
  - Block failure, followed by repeat injection
  - Fine-gauge or pencil-point needle
  - Microspinal catheter
  - Continuous infusion
  - Hyperbaric solution
  - Lithotomy position
- Unintentional intrathecal injection of a large volume intended for the epidural space
- Incorrect formulation, with unsuitable preservative or antioxidant
- Intrathecal injection of lidocaine, particularly 5% (also tetracaine or dibucaine?)

Arachnoiditis

Arachnoiditis is a disastrous condition, usually with a delayed onset of permanent quadriplegia. It is extremely rare, and it has not been detected in any surveys of neurologic sequelae of obstetric neuraxial blockade. Among parturients, chronic adhesive arachnoiditis of chemical origin has arisen after unintentional intrathecal injection of a large dose of 2-chloroprocaine with antioxidant and preservative intended for the epidural space,[203] while seven cases occurred in Miami after epidural analgesia for childbirth with 2% lidocaine, probably with preservative.[204] Six cases were reported among Italian surgical patients after apparently standard epidural anesthesia with bupivacaine and/or mepivacaine, usually with epinephrine.[205] The local anesthetic agents, however, were obtained from multidose vials containing parabens as preservative, and the glass syringes used for loss-of-resistance identification of the epidural space had been washed in detergent. With earlier publications it is not always possible to distinguish the cause of arachnoiditis, but it seemed to appear in clusters, suggesting that there may have been shortcomings in anesthetic technique. In a more recent single case in the United Kingdom, a woman suffered severe arachnoiditis after spinal anesthesia for elective cesarean delivery.[206] Her skin had been cleaned with iodine and then chlorhexidine in alcohol and allowed to dry. It was unclear whether the tray containing antiseptic solutions was removed before the rest of the procedure. Because of pain during attempted insertion of the spinal needle, the skin was infiltrated at least three times with lidocaine before intrathecal bupivacaine was given. Shortly thereafter she became disturbed and experienced a severe headache, so she was given general anesthesia for the operation. Postpartum she developed obstructive hydrocephalus and extensive adhesive arachnoiditis. The judge determined that, on balance of probabilities, there must have been contact in some way between the chlorhexidine and the local anesthetic solution.

Vulnerable Patients

Various conditions may render some women more vulnerable than normal to neurologic injury precipitated by neuraxial anesthesia. The following discussion of conditions is not exhaustive.

Vertebral Abnormality

Skeletal abnormalities involving the spine, including congenital anomaly, trauma, and back surgery, can make

epidural or spinal needle insertion difficult. Patients with spina bifida are at risk for accidental dural puncture and nerve root damage unless the needle is inserted above the defect. Those with tethered cord syndrome are at risk for cord damage if spinal or epidural needle insertion is attempted at a vertebral level that would normally be expected to be below the conus.[68] Occasionally, a low-lying conus may be present without any premonitory signs.[73] Pressure from spinal stenosis or prolapsed intervertebral disc, coupled with a large-volume epidural injection, may result in spinal cord compression and neurologic deficit.[82]

Vascular Abnormalities

Vascular disease and malformation are risk factors for spinal cord ischemia, hematoma, and compression. The major supply to the lumbar enlargement of the spinal cord is the artery of Adamkiewicz, a unilateral structure that typically arises from the lower thoracic or upper lumbar portion of the aorta between T9 and L2. Compression of this single vessel may therefore jeopardize the blood supply to the lower cord in susceptible individuals. In 15% of individuals, a secondary blood supply to the spinal cord that ascends from the internal iliac arteries[207] assumes a major role. These ascending arteries lie close to the lumbosacral trunk and are, in theory, vulnerable to pressure from the fetal head or damage by obstetric instrumentation, thus causing conus ischemia.

An **arteriovenous malformation** is an obvious cause for concern for the obstetric anesthesia provider.[208] Small arterial feeders from a segmental intercostal artery supply dilated serpiginous epidural veins that may extend over many segments of the spinal canal.[209] The resulting hemangioma raises the pressure on epidural veins and reduces spinal cord blood flow. Oxygen delivery to local tissues is reduced, and the risks of spinal hematoma or ischemic damage and compression are increased. Pregnancy and epidural analgesia have been known to precipitate paraplegia in previously asymptomatic patients[210,211]; aortocaval compression, a large blood volume, and a large epidural injection (which may cause severe pain) all increase epidural pressure.

The preanesthesia examination should include inspection of the back for cutaneous angiomas or macular areas of skin discoloration, which may suggest the presence of an underlying spinal angioma at the same segmental level. Because spinal cord capillary flow is compromised in the drainage area of an arteriovenous malformation, systemic arterial pressure should be kept close to normal throughout the peripartum period, regardless of anesthetic technique.

Spinal Tumor

Epidural blockade has been reported to precipitate neurologic symptoms in the presence of previously undiagnosed spinal tumors. Spinal tumors also predispose to spinal hematoma after neuraxial blockade,[4] and epidural analgesia may precipitate extreme pain.[212]

Coagulopathy or Anticoagulation

The risk for neuraxial procedures in patients with a preexisting coagulopathy or anticoagulation therapy is discussed earlier in this chapter and also in Chapters 39 and 44.

Immunocompromise

The majority of cases of epidural infection that have been reported in surveys involve elderly patients with immunocompromise.[16,109] This topic is covered in an excellent review.[213] It is advisable to avoid prolonged epidural catheterization in immunocompromised patients.

Preexisting Neurologic Disorder

Relapse rates in patients with multiple sclerosis are increased after delivery, and the fear is that neuraxial blockade will be blamed.[214] It has been postulated that spinal anesthesia may worsen demyelinating conditions, although surveys are inconclusive.[215] If affected nerve roots are indeed at higher risk for neurotoxicity, epidural anesthesia may be safer than spinal anesthesia. Indeed, some anesthesia providers prefer epidural or even general anesthesia over spinal anesthesia in women with multiple sclerosis. It is clearly important to document neurologic status and to discuss relapse rates with the mother before and after any anesthetic intervention.

Patients with hereditary neuropathy with liability to pressure palsy are particularly sensitive to compression neuropathy during the course of labor and delivery.[32,33,216]

It is postulated that patients with preexisting peripheral neuropathies may be more susceptible to nerve injury when exposed to a second insult, the so-called *double crush phenomenon*.[215] To explore whether neuraxial anesthesia represented such an insult, Hebl et al.[215] reviewed the charts of 567 patients with peripheral neuropathies who had spinal or epidural blockade, including 12 obstetric patients. There were two instances of worsening neurologic status, both in elderly diabetic patients. There were no control patients, but clearly, if there is a risk that neuraxial anesthesia will exacerbate a neuropathy, it is very small.

Diabetes

Diabetic patients are vulnerable to neurologic injury for three reasons. They are susceptible to infection, they may have vascular disease, and they may have a peripheral neuropathy. Diabetic patients are at increased risk for epidural abscess, either catheter-associated or spontaneous.[16,109] Anterior spinal artery syndrome has also been described in diabetic parturients,[181] and worsening neuropathy has been observed in diabetic surgical patients.[215]

RISK MANAGEMENT AND FOLLOW-UP

High-risk women should be referred to the obstetric anesthesia clinic during pregnancy, so that an anesthesia

provider can obtain a thorough history, examine the patient, organize consultations or imaging studies as needed, and plan the anesthetic strategy. The recommended points to explore during the history and physical examination are summarized in Boxes 32-6 and 32-7.

In addition to minimizing risk by adopting good and safe practices, vigilance must be extended postpartum to detect, diagnose, and treat any disorders that may arise. Early hospital discharge presents a problem in the detection of post–dural puncture headache and space-occupying lesions, both of which require urgent assessment and treatment. It is important that those caring for women in the puerperium are taught to look for signs of neurologic pathology and that the women themselves, once home, are taught to recognize postanesthesia symptoms and to contact an anesthesia provider if they experience them.

BOX 32-6 Topics to Explore in the Preanesthesia History

- Allergies or recreational drugs
- Diabetes or cardiovascular disorder
- Previous spinal or epidural anesthetics (What was the outcome?)
- Preexisting neurologic signs or symptoms (e.g., sciatica, leg weakness)
- Skeletal abnormality or back surgery
- History of trauma or automobile accident (Is it under litigation?)
- Anticoagulant medication
- Recent history of bleeding gums after dental hygiene (common in late pregnancy and not relevant as an isolated sign) or bruising
- Recent infection, including vaginal or skin infection involving the back
- Possibility of immunocompromise

BOX 32-7 Preanesthesia Neurologic Examination

- If there is a question of neurologic disorder, examine the lower limbs:
  - Sensation to pinprick or ice, and vibration sense using a tuning fork
  - Knee and ankle tendon reflexes and Babinski reflex
  - Motor power of hips, knees, and ankles
- Examine the back for:
  - Signs of infection (pustules to be avoided)
  - Nevi, suggesting arteriovenous malformation
  - Midline hair tuft or fat pad, suggesting dysraphism (e.g., spina bifida occulta)
  - Scoliosis
  - If the spine looks technically difficult, as in severe scoliosis, is there an easily palpable sacral hiatus as an alternative to the lumbar epidural space?
- Look for signs of bleeding tendency
- Document:
  - The history and physical examination
  - Abnormalities and treatment decisions
  - Differences of opinion
  - The reasons the anesthetic is administered despite a relative contraindication

Diagnosis of Possible Neurologic Injury

Through simple clinical examination coupled with knowledge of basic neuroanatomy outlined in this chapter, it should be possible to distinguish peripheral from central lesions. Preanesthesia history and physical examination may reveal some helpful clues, and any preexisting signs or deficits documented in the record will narrow the search or even provide an immediate answer. The history and physical examination should seek to establish whether the complaint is genuine and to determine its site and cause.

The basic physical examination outlined in Box 32-7 should be repeated, and the results should be compared with the preanesthesia findings. Fever and leukocytosis indicate an infective cause. Severe back pain and localized tenderness suggest epidural abscess, and pain radiating to the legs or buttocks is a late and urgent sign of spinal cord or cauda equina compression. Headache, fever, and neck stiffness suggest meningitis. Viral or other community-acquired types of meningitis may coincide with pregnancy, but the responsible organisms differ from those causing nosocomial infection.

MRI has revolutionized the speed and precision with which intraspinal lesions can be identified, and gadolinium enhancement further improves its sensitivity. MRI cannot distinguish clearly between blood and other fluid, although the distinction can usually be made on other grounds. In the presence of meningitis, MRI with gadolinium enhancement shows swelling of the cord and punctate areas of increased density, reflecting inflammatory cell infiltrates. Arteriovenous malformations of the cord or dura may be visible, and the enlarged veins draining them may be seen as serpiginous signal voids.

KEY POINTS

- Maternal obstetric palsy may arise from (1) the process of childbirth, (2) preexisting maternal disease that predisposes to peripartum palsy, (3) coincidental pathology, or (4) neurologic injury directly attributable to the anesthetic.
- Intrapartum nerve compression may go unnoticed during neuraxial analgesia/anesthesia; therefore, neurologic status should be regularly assessed and the patient should be encouraged to change positions.
- Postpartum neurologic deficit is less likely to have anesthetic than other causes. Transient postpartum peripheral palsy is common. Nevertheless, there is a widespread tendency to attribute neurologic deficits to neuraxial anesthesia.
- Careful examination and knowledge of anatomy can usually suggest whether the lesion is central or peripheral.
- Meticulous technique, vigilance, and frequent observation of the patient are keystones to avoiding complications.

- Proper sterile technique involves wearing a mask, hand washing, donning sterile gloves, and cleaning the skin with chlorhexidine in alcohol and allowing it to dry before initiating neuraxial blockade.
- Good epidural needle insertion technique should minimize the risk for accidental dural puncture. Post–dural puncture headache, should it occur, must never be neglected.
- The CSE technique carries a higher risk for complications than either epidural or spinal anesthesia alone.
- Risk for trauma to the spinal cord may be minimized by choosing a lower lumbar interspace (below L3) for insertion of the spinal needle.
- The risk for meningitis may be decreased by avoiding dural puncture during labor in a patient with systemic or vaginal infection.
- Mistakes in drug administration must be avoided by obsessive and careful reading of drug labels.
- The results of the history and physical examination, the rationale behind the chosen anesthetic procedure, and the details of all procedures should be thoroughly documented.
- Rapid diagnosis and treatment are essential to minimizing permanent neurologic sequelae. Compressive intraspinal lesions with neurologic changes require urgent laminectomy within 6 to 12 hours of the onset of symptoms.
- Early hospital discharge necessitates a safety net to detect neurologic complications arising after return home. Patients should be informed about the presenting symptoms of rare but potentially catastrophic complications of neuraxial anesthesia.

CHAPTER 33

Medicolegal Issues in Obstetric Anesthesia

Mark S. Williams, MD, MBA, JD • Joanna M. Davies, MBBS, FRCA

CHAPTER OUTLINE

Childbirth is a natural process in which unexpected and potentially severe adverse events can occur. Responses to such events require timely and collaborative efforts among all caregivers. Obstetric anesthesia providers have a challenging role. Some women have high expectations about the availability and effectiveness of anesthesia services for labor and vaginal or cesarean delivery; these expectations may be influenced by the experiences and biases of family members and friends. By contrast, other women may view anesthesia for labor as an intrusion upon the natural labor process; yet, some of these women may ultimately need or request anesthesia services. The informed consent and decision-making process is fundamental to securing a woman's understanding and support. The effectiveness of this process is subject to cultural and socioeconomic influences as well as the pain of labor.

The degree to which patients and their families possess a realistic understanding of the benefits and risks associated with childbirth and obstetric anesthesia may influence the decision to pursue legal remedies in the event of a real or perceived adverse outcome. Adverse outcomes may profoundly affect families and health care providers. Patients and their families must adjust to the reality of an unanticipated adverse outcome as well as potentially overwhelming and long-term financial costs. Physicians and other caregivers also may be profoundly affected emotionally by an adverse outcome. Medicolegal claims associated with such events (regardless of the merit of the claim) may compound such emotions, raise the costs of liability coverage, and ultimately impact the availability and overall cost of health care services.

Anesthesia providers should possess an understanding of basic medicolegal issues and should proactively embrace risk management strategies that support optimal patient care and minimize both patient dissatisfaction and the legal consequences of an unanticipated adverse outcome. Insights and opportunities for promoting safer and more effective anesthesia and obstetric care are rapidly evolving and are gaining support among payers, governmental agencies, and others.

LAWSUITS INVOLVING CLAIMS AGAINST HEALTH CARE PROVIDERS

Importance of Effective Communication

The ability to effectively communicate information in a manner that is understood by the patient is fundamental to securing patient understanding and cooperation. Lapses in communication may preclude obtaining truly informed consent and may lead to patient dissatisfaction, lapses in patient safety, and inadequate explanation of an unanticipated adverse outcome.

Communication failures are frequent elements in malpractice claims; these failures include lack of informed consent, poor patient rapport, language barriers, and inadequate discharge instructions, among others.[1] There is an increasing recognition that limited **health literacy** interferes with effective communication.[2] Health literacy is defined as the "degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."[3] Providers should strive to adopt methods and approaches that encourage patient engagement, reduce risk, and improve treatment compliance.[4]

Theories of Liability

Every physician has a duty to provide professional services that are consistent with a minimum level of competence. This is an objective standard based on the physician's qualifications, level of expertise, and the circumstances of the particular case.[5] The failure to meet this objective standard of care may give rise to a cause of action for medical negligence. The standard of care for medical practice is dynamic and changes as the profession adopts new treatments and approaches for patient care. Therefore, changes in accepted medical practice may create additional professional obligations and, in turn, additional legal responsibilities for physicians.

Although the specific medical malpractice laws vary from state to state, several different causes of action may be brought against a physician. Patients may sue for injuries resulting from the provision of health care by using one or more of three different theories (or causes of action): (1) medical malpractice, (2) breach of contractual promise that injury would not occur, and (3) lack of informed consent.[6] Plaintiffs (patients) commonly file lawsuits that allege improper care on the basis of more than one of these theories (e.g., alleging both a violation of the standard of care and a lack of informed consent for the medical treatment rendered). Medical malpractice may involve failure to make the diagnosis, failure to obtain informed consent, surgical errors, drug prescription and administration errors, and other mistakes. For a plaintiff to prevail with regard to a medical malpractice claim, he or she must prove that the injury resulted from the failure of the health care provider to follow the accepted standard of care. The standard of care may be defined as "that degree of care, skill, and learning expected of a reasonably prudent health care provider at that time in the profession or class to which he belongs…acting in the same or similar circumstances."[7] This objective standard is applied to the particular facts of the plaintiff's situation in a malpractice action.

A mistake or a bad result does not necessarily denote negligence. Similarly, unless a physician contracts otherwise with the patient (i.e., makes a promise of a specific outcome), the provision of medical care alone does not warrant or guarantee that an illness or disease will be cured. A physician is liable for a misjudgment or mistake only when it is proved to have occurred through a failure to act in accordance with the care and skill of a reasonably prudent practitioner.

Claims of medical malpractice must be filed within a certain period after the alleged incident of medical malpractice. Most jurisdictions in the United States have enacted **statutes of limitations** that are specifically applicable to malpractice claims. Recognizing that a significant time may elapse before symptoms or injury manifest, many states have established **discovery rules** that apply to situations in which the patient has no way of knowing that the injury was caused by wrongdoing or negligence. One example of an unknown injury is sterility that is discovered only when the patient attempts to conceive. Another example is the Rh-negative mother who delivers an Rh-positive child and does not receive Rho(D) immune globulin (RhoGAM). Such an injury would be apparent only when the mother has another child with Rh-positive blood. Other exceptions to—or extensions of—the statutes of limitations might involve situations of fraudulent concealment, an undiscovered foreign object, situations involving long-term continuous treatment, and issues involving infants or minors.

Establishing Medical Malpractice

In most malpractice cases, the following four elements are required for proving medical negligence:

1. **Duty**. It must be shown that a duty to provide care existed (i.e., a health care provider–patient relationship existed). This may apply to situations in which the provider renders medical advice over the telephone to a patient never seen in the office or through a "curbside" consult with another physician.
2. **Breach**. It must be shown that the health care provider failed to meet his or her duty to provide reasonable care (i.e., the health care provider was negligent).
3. **Injury**. It must be shown that the patient experienced an injury that resulted in damages.
4. **Proximate cause**. It must be shown that the negligence of the health care provider proximately caused the patient's injury (i.e., there must be a sufficiently direct connection between the negligence of the health care provider and the injury experienced by the patient).[7]

If any one of these elements is missing, the plaintiff cannot establish medical malpractice. The plaintiff has the burden of proof to establish each of these elements by a "preponderance of the evidence." This quantum of proof means that a proposition is more probably true than not true (i.e., > 50% certainty).

If the malpractice claim involves the issue of whether a physician used a proper method of treatment, the

plaintiff must use expert testimony to establish that the defendant physician violated the standard of care and that such violation probably caused the plaintiff's injury.[7] Expert testimony to establish how a reasonably prudent health care practitioner would act under similar circumstances typically must be provided by an expert with the same educational background and training as the defendant physician.

In certain cases, the plaintiff may not be required to present expert testimony to prove negligence, and the burden of proof may shift to the defendant. This represents the doctrine of *res ipsa loquitur* (i.e., the thing speaks for itself). This doctrine has the following three conditions: (1) the injury ordinarily does not occur in the absence of negligence, (2) the injury must be caused by an agency or instrumentality within the exclusive control of the defendant, and (3) the injury must not have been a result of any voluntary action or contribution on the part of the plaintiff.[5] Claims involving injuries sustained during administration of anesthesia have been made under this doctrine. In one case, a patient complained of pain that he described as a "strong electric shock" after a spinal block was administered. The patient subsequently lost all sensation below that spinal level and became incontinent. Because one would not ordinarily expect a permanent sensory loss from a spinal anesthetic, the verdict was upheld at the appellate level.[8]

Establishing Lack of Informed Consent

Lack of informed consent is a common cause of action in medical malpractice claims. Within the context of the physician-patient relationship, the **doctrine of informed consent** is based in English common law, by which doctors could be charged with the tort of *battery* if they had not gained the consent of their patient before the performance of surgery or another procedure. In the United States, the New York Court of Appeals established the legal principle of informed consent in 1914.[9] In this case, the plaintiff, Mary Schloendorff, was admitted to a New York hospital and consented to examination under ether anesthesia to determine whether a fibroid tumor was malignant, but she withheld consent for its removal. The physician examined the tumor, found it to be malignant, and removed it—in disregard of the patient's wishes. The Court found that this operation constituted medical battery. Writing on behalf of the Court, Justice Benjamin Cardozo wrote, "Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault for which he is liable in damages. This is true except in cases of emergency where the patient is unconscious and where it is necessary to operate before consent can be obtained."[9]

This principle remains embedded in modern medical ethics and has been adopted by most state legislatures in the form of informed consent statutes. To establish negligence for failure to obtain informed consent, a plaintiff must prove (1) the existence of a material and reasonably foreseeable risk unknown to the patient, (2) a failure of the physician to inform the plaintiff of that risk, (3) that disclosure of the risk would have led a reasonable patient in the plaintiff's position to reject the medical procedure or choose a different course of treatment, and (4) a causal connection between the failure to inform the plaintiff of the risk and the injury resulting from the occurrence of the nondisclosed risk.[10]

Expert testimony is typically required to establish at least some of the elements of an informed consent claim, especially the materiality of the risk. However, expert testimony is not essential if an issue falls within the general knowledge of lay persons or if the doctor failed to give the patient *any* information about the risks involved, because a lay person can conclude that in the absence of any information, informed consent is not possible.

The obligation to obtain informed consent lies with the physician.[11] Ordinarily, the hospital or other organization has no independent duty to obtain a patient's informed consent. Likewise, a consultant physician who advises the treating physician has no such duty. A referring physician is not required to obtain informed consent unless he or she actually participates in or controls the subsequent treatment by the other physician.[12]

There are differences of opinion as to the perspective to be embraced when a physician is disclosing the nature and likelihood of a given risk. Specifically, should it arise from the patient's or the physician's point of view? Theoretically, both would desire the same scope of disclosure. Often, the pivotal issue is the determination of which party's viewpoint should dictate the standard for judging the physician's conduct.[13] Most jurisdictions use a "reasonable person" or "prudent patient" standard. Under this rule, a physician is expected to disclose to the patient in lay terms all material information that a prudent or reasonable patient would consider significant to making his or her decision.[14] This approach concerns itself with the patient's needs, rather than the physician's judgment; this approach follows the rationale that the physician should neither impose his or her values on the patient nor substitute his or her level of risk aversion for that of the patient.[15] Under this standard, the jury determines whether a reasonable person in the plaintiff's position would have considered the risk significant in making his or her decision. The issue is not what a particular patient would want to know but rather what a reasonable person in the patient's condition would want to know, taking into account factors such as the individual's medical condition, age, and risk factors.[16] This objective standard protects physicians from potentially self-serving testimony of plaintiffs, who inevitably assert that they would have refused a given procedure if they had been properly informed of the risk.

The materiality of risk is an issue under this "reasonable" or "prudent" patient standard. It is generally accepted that a physician is not required to present every possible risk of a proposed treatment. If the probability of its occurrence is practically nonexistent, then the risk, no matter how severe, is not material. Conversely, even a small risk for occurrence may be significant to a patient's decision if the potential consequences could be severe.[17] Disputes concerning the proper scope of disclosure tend to center on whether the risk was foreseeable or remote.

Some jurisdictions still adhere to the *professional* standard of disclosure. This approach assumes the perspective of the physician and is concerned with what information a reasonable practitioner would share with a patient under the same or similar circumstances.[18]

Even in circumstances in which the health care providers acknowledge their failure to provide important information to the patient or the patient's legally authorized surrogate decision-maker, the jury is still asked to decide whether the patient or the patient's decision-maker would have consented to such a course of treatment despite the risk. For example, in *Barth v. Rock*, a 5-year-old patient suffered a cardiac arrest (and eventual death) after receiving general anesthesia by mask with sodium thiopental, nitrous oxide, and a succinylcholine infusion for open reduction of an arm fracture. Both the surgeon and the nurse anesthetist admitted that they failed to inform the minor patient's parents about the risks of general anesthesia. The appellate court held that the jury should have been instructed that, as a matter of law, there was no informed consent; the jury then should have decided whether the parents would have consented to the anesthesia had they been adequately informed of the risks.[19]

If a plaintiff establishes the four elements for a cause of action based on lack of informed consent, the burden shifts to the physician to establish a defense that justifies why the material information was not provided (e.g., the insignificant nature of the risk) or why disclosure would not have altered the chosen course of treatment. In addition, the health care providers may claim that the case was a medical emergency. State laws generally supply a defense of "implied consent" for provision of necessary emergency treatment when the patient is unable to provide his or her own consent and no legally authorized surrogate decision-maker is immediately available.[20] If the health care providers' treatment was authorized under a medical emergency, the providers should carefully document their determination of same. The documentation in the patient's medical record should contain a description of the patient's presenting condition, its immediacy, its magnitude, and the nature of the immediate threat of harm to the patient. It is advisable for at least two health care providers to document this information, because the documentation would support their actions if a lack-of-informed-consent lawsuit were filed. The "emergency treatment" rule is limited in two respects. First, the patient must require immediate care to preserve life or health. Second, the physician may provide only the care that is reasonable in light of the patient's condition.

THE LITIGATION PROCESS

It is helpful for health care providers to have a basic understanding of sources of law, how lawsuits are initiated, and typical steps in the litigation process.

Sources of Law

Legal authority has multiple sources, including federal and state constitutions, federal and state statutes, federal and state regulations, and federal and state case law. **Constitutions** are the fundamental laws of a nation or state, which establish the role of government in relation to the governed. Constitutions act as philosophical touchstones for the society, from which other ideas may be drawn. One example is the "right to privacy" established in case law, which flows from the constitutional recognition of individual liberty.[21] **Statutes** are the laws written and enacted by elected officials in legislative bodies. **Regulations** are written by government agencies as permitted by statutory delegation. Although regulations have the force and effect of law, they must be consistent with their enabling legislation. **Case law** refers to written opinions or decisions of judges that arise from individual lawsuits. Case law that may be cited as legal authority (precedent) is limited to cases at the appellate court level (i.e., cases appealed from trial court decisions). The vast majority of lawsuits settle before trial, and only a small percentage of trial court decisions result in appeal; thus, case law reflects a very small portion of actual litigation. Like medicine, the practice of law is dynamic and changes as new legislation and regulations are adopted or new case law is created. In addition, any one or several of these sources of law may be relevant to a particular case.

When creating new laws or applying the law in deciding the proper result for a particular case, a legislative body or a court may also consider other information about standards for health care providers' conduct. For example, the court may give strong weight to The Joint Commission standards and find that a provider acting in accordance with The Joint Commission requirements was adhering to his or her professional obligations.[22] In writing legislation or court decisions, lawmakers also may defer to standards and practice guidelines adopted by professional organizations, such as the American Society of Anesthesiologists (ASA). The adoption of professional standards and practice guidelines strengthens the influence of professional organizations in the lawmaking process because lawmakers often are willing to defer to professional organizations' statements on standards of care and professional ethics.

Some experts have suggested that the value of "evidence-based" guidelines within the venue of medical malpractice has been disappointing, primarily because of a lack of scientific evidence supporting the guidelines.[23] A 2009 analysis of guidelines issued by the American College of Cardiology and the American Heart Association determined that "the significant increase in the quantity of scientific literature concerning cardiovascular disease published in recent years (along with the number of technical and medical advances)—if aimed to address unresolved issues confronting guideline writers—should have resulted in guideline recommendations with more certainty and supporting evidence."[24] Recent federal regulation dictates the funding of some comparative effectiveness studies that may provide additional evidence on which to base clinical guidelines.[25] It will be several years before the merit of these investments can be assessed.

Initiation of a Lawsuit

Medical malpractice lawsuits are typically initiated when a plaintiff files a **complaint** with the court. Some states have

enacted statutes that impose certain conditions (including notification of the defendant physician) before a complaint is filed.[26] The physician receives notice of the legal action when he or she is served with a copy of the **summons** and the complaint. In the complaint, the plaintiff alleges the facts giving rise to the cause(s) of action against the physician. The complaint requires a written **answer** to be filed (by the attorney representing the physician) with the court within a specified period. If a timely answer is not filed, a default judgment may be entered against the physician (i.e., a judgment is allowed because *no response* may be treated as *no defense* against the allegations).

In civil actions against health care providers, plaintiffs are frequently motivated to sue for an award of monetary damages. Medical malpractice lawsuits may involve multiple defendants, such as the treating physician, the hospital, manufacturers of health care equipment, and pharmaceutical companies. Defense counsel evaluates its client's potential liability exposure (i.e., any aspect of care arguably not meeting the standard of care). Both plaintiff counsel and defense counsel weigh the perceived risks if the case proceeds to trial and then determine how much they think the case is worth. The valuation of a case may include more than the estimated dollar value; it may also include considerations such as setting a potential precedent or maintaining a business relationship.

Discovery

Discovery refers to the early phase of litigation after a lawsuit is initiated. During this phase, the litigants on both sides research the strengths and weaknesses of their cases by obtaining and examining medical records, reviewing medical literature, and interviewing and deposing witnesses, including the plaintiff(s), the treating health care provider(s), and potential expert witnesses.

During discovery, certain methods of gathering information are generally used. The methods include interrogatories and depositions. **Interrogatories** are written questions that are served on one party from an opposing party. Interrogatories must be answered in writing, under oath, within a prescribed period. Failure to respond as required may result in the court's issuing sanctions against the nonresponding party. **Depositions** involve testimony given under oath that is recorded by a court reporter. In a deposition taken for the purpose of discovery, the attorneys representing all opposing litigants participate and ask questions of the witness. The purposes of discovery depositions are (1) to obtain facts and other evidence, (2) to encourage the other side to commit to a position "on the record" (i.e., in preserved testimony), (3) to discover the names of other potential witnesses, (4) to assess how strong a witness the deposed individual may make, (5) to limit facts and issues for the lawsuit, (6) to encourage the other side to make admissions against its own interests in the lawsuit, and (7) to evaluate the case for its dollar (or other) value and potential for settlement.

Trial

A trial typically consists of (1) jury selection, (2) opening statements, (3) plaintiff's trial testimony, (4) defendant's trial testimony, (5) closing arguments, (6) jury instructions given by the judge, and (7) delivery of the jury's verdict. There also may be post-verdict proceedings and motions. The lawyers for all parties file briefs with the court in advance of the trial to outline the case for the trial judge. The lawyers also prepare and argue over the content of jury instructions, seeking the best language to support their theories of the case. The judge decides which jury instructions will be given and reads them to the jurors immediately prior to jury deliberation. Attorneys commonly file motions about significant trial proceedings, such as the scope of admissible evidence. The trial judge rules on these motions outside the presence of the jury.

A jury verdict does not necessarily end the case. If a verdict in favor of the plaintiff(s) is reached, defense counsel may file a motion (1) asking the court to set aside the verdict and grant a new trial, (2) asking the court to change the verdict and enter a judgment in the defendant's favor, or (3) asking for a reduction in the amount of damages awarded to the plaintiff(s). Defense counsel also may seek to reopen settlement negotiations or may choose to appeal the case. The plaintiff(s) may take similar post-verdict steps if the jury renders a verdict in favor of the defendant(s).

The vast majority of medical malpractice cases never go to trial. A 1991 study showed that only 2% of persons injured by physicians' negligence ever file a lawsuit.[27] Subsequently, only 10% of all medical malpractice claims go to trial. Settlement negotiations result in the disposal of many cases. Other cases are withdrawn by plaintiffs or are dismissed by the court on legal grounds such as **summary judgment,** whereby a judge may rule that a plaintiff's case is legally insufficient. Defendants win approximately 71% of medical malpractice claims.[28]

In seeking alternatives that might speed the litigation process and reduce the overall costs, a number of states have created medical pretrial screening panels. As an alternative to a full trial, a medical screening panel is typically comprised of several physicians and an attorney, who determine whether the defendant met the appropriate standard of care and if the injury was proximately caused by a failure to meet that standard. The findings of the group are then submitted to the court for further adjudication.[29] The effectiveness of this model is subject to considerable debate. Other alternatives include arbitration, mediation, and other types of alternative dispute resolution.

INFORMED CONSENT

Process and Documentation

A patient's right of self-determination lies at the root of informed consent. A patient can make an informed decision only after (1) a discussion of the diagnosis and the indications for the procedure or therapy; (2) disclosure of material risks, benefits, and alternatives; and (3) provision of an opportunity for questions and answers. This process is neither accomplished nor affirmed solely by having the patient's or the patient surrogate's signature

on a document asserting informed consent. Evidence of this process and the physician's involvement in the process may be found among office notes, informational aids shared with patients, hospital notes, and signed forms acknowledging informed consent.

The necessity of having a specific process is not only an ethical obligation but also a requirement of various state and federal agencies. For example, the U.S. Centers for Medicare and Medicaid Services (CMS) have *Conditions of Participation* that define the requirements that facilities must satisfy to participate in the Medicare and Medicaid programs. Specifically, the *Patients' Rights Conditions of Participation* contain the following interpretive guidelines: "Hospitals must utilize an informed consent process that assures patients or their representatives are given the information and disclosure needed to make an informed decision about whether to consent to a procedure, intervention, or type of care that requires consent."[30] Further, the interpretive guidelines for the CMS *Surgical Services Conditions of Participation* specifically state the following[31]:

> *The primary purpose of the informed consent process is to ensure that the patient, or the patient's representative, is provided information necessary to enable him/her to evaluate a proposed surgery before agreeing to the surgery. Typically, this information would include potential short and longer term risks and benefits to the patient of the proposed intervention, including the likelihood of each, based on the available clinical evidence, as informed by the responsible practitioner's professional judgment. Informed consent must be obtained, and the informed consent form must be placed in the patient's medical record, prior to surgery, except in the case of emergency surgery.*

The interpretive guidelines note that there is no specific requirement for informed consent governing anesthesia services but also state that "given that surgical procedures generally entail the use of anesthesia, hospitals may wish to consider specifically extending their informed consent policies to include obtaining informed consent for the anesthesia component of the surgical procedure."[31]

As patients have become more engaged in their health care and are reaching out to nontraditional sources of information, other approaches to ensuring informed consent have been proposed. Studies have demonstrated that standard counseling often results in inadequate decision quality.[32] Some patients may have an incomplete understanding of the risk and benefits of a treatment, and clinicians are often poor judges of patients' values; consequently, there may be overuse of treatments that informed patients would not choose or value.[33] Thus, decision-making aids are used to improve the quality of informed consent and to reduce unnecessary practice variations by (1) providing facts about the condition, options, outcomes, and risks; (2) clarifying patients' evaluations of the outcomes that are most meaningful to them; and (3) guiding patients in the steps of deliberation and communication so that a choice can be made that reflects their informed values. These decision-making aids may be used by practitioners and/or patients in either individual or group settings, and they may be presented in a variety of formats, such as print, video, the Internet, and interactive devices.[33] In essence, this approach attempts to address the weaknesses in both the "reasonable patient" and the "professional standard" approaches to disclosure, and it becomes even more valuable as the diversity of practitioners and patients increases.

Formal documentation of informed consent has other advantages. Adequate documentation helps health care providers defend their actions if patients subsequently challenge their consent for health care. In some jurisdictions, a valid consent form signed by the patient may provide a direct means of defense and actually shift the burden of proof to the plaintiff who wishes to make a claim of lack of informed consent.[34] Some large medical liability insurance providers have strongly recommended that the clinician responsible for providing anesthesia care should obtain a separate written consent.[35] Further, some anesthesia organizations have recommended not only that an anesthesia-specific form should be used but also that practitioners should highlight specific risks that may be present.[36] A separate anesthesia consent form that highlights specific risks demonstrates a meaningful effort to engage patients in a full discussion of relevant issues and may help establish the basis of a potential defense against a medical malpractice claim. It may also reinforce the importance and significance of anesthesia services and choices in the obstetric setting.

In discussing anesthetic options for a given procedure, anesthesia providers should consider several aspects, including the best options given the skill set of the provider, the comorbidities of the patient, and the preferences of the surgeon. In a review of anesthesia consent procedures, O'Leary and McGraw[37] recommended that an explanation of the relevant risks and benefits of alternative techniques as well as the likelihood and details of a backup plan should be included in informed consent. The investigators recommended that anesthesia providers adopt a separate, written consent form for the administration of anesthesia services. A form that clearly delineates common risks but allows documentation of patient-specific risks should be used. Ideally, the anesthesia provider should obtain the patient's consent for anesthesia and should not rely on other professionals who are not competent to explain the risks and benefits of anesthesia options.

Capacity to Consent/Mental Competence

Physicians are bound by ethics and required by law to obtain a patient's informed consent before initiating treatment. This premise assumes that a patient is competent and/or has the capacity to successfully participate in this process. **Competence** generally refers to the patients' legal authority to make decisions about their health care. Adult patients, typically 18 years of age or older, are presumed to be legally competent to make such decisions unless otherwise determined by a court of law. **Capacity** typically focuses on the clinical situation surrounding the informed consent process. For example, an otherwise normal patient who has been given sedation may be legally competent but temporarily incapacitated and

therefore unable to give informed consent.[38] The determination as to whether a patient has the capacity to provide informed consent generally is a professional judgment made by the treating health care provider. However, if a court has made a judgment regarding a patient's capacity to make such decisions, the health care provider(s) should obtain a copy of the court order, because it may delineate whether the patient is considered able to make his or her own health care decisions. For example, a guardianship is a type of court proceeding that may have an impact on the informed consent process. If a patient has a legal guardian with the authority to make health care decisions on behalf of the patient, that guardian should be consulted about the patient's care and is the person legally authorized to provide consent. A failure to recognize a lack of capacity may expose a physician to liability for treating a patient without valid informed consent.

The legal standards for decision-making capacity vary among jurisdictions but generally encompass the following criteria: The patient must be able to (1) understand the relevant information, (2) appreciate the situation and its consequences, (3) reason about treatment options, and (4) communicate a choice.[39] When the patient is unable to do so, surrogate decision-makers may be sought. In emergency situations, physicians can provide necessary care under the presumption that a reasonable person would have consented to the anticipated treatment.[40] Most states have laws that delineate who is legally authorized to provide consent for health care decisions on behalf of an incapacitated individual. State laws vary, but they typically provide a list of persons (in order of priority) who may give consent. These laws assume that legal relatives are the most appropriate surrogate decision-makers. However, the competent patient is free to select any competent adult to act as his or her health care decision-maker by executing a **durable power of attorney for health care,** which appoints that person as his or her agent.

Health care providers are required to make reasonable efforts to locate a person in the highest possible category to provide consent. If there are two or more persons in the same category (e.g., adult children), then the medical treatment decision must be unanimous among those persons. These surrogate decision-makers generally are required to make "substituted judgment" decisions on behalf of the patient (i.e., they are obligated to decide as they believe the patient would, not as they may prefer). If what the patient would want under the circumstances is unknown, then the surrogate must make a decision consistent with the patient's "best interests."[41] The surrogate decision-maker has the authority to provide consent for medical treatment, including nontreatment.

Minor Patients

Existing laws regarding the ability of minors to provide their own consent for medical care may be viewed as a patchwork quilt. Statutes and case law differ from state to state. There are three ways in which a minor may be deemed able to give his or her own consent for medical care: (1) by state law that permits the minor to consent for the specific type of care, (2) by a clinical determination made by the health care providers that the minor is mature and emancipated for consent purposes, and (3) by a judicial determination of emancipation.

Parental involvement in a minor's health care decisions is usually desirable. For most health care decisions, a parent is required to provide consent for medical treatment of a minor patient.[42] However, many minors will not take advantage of some available medical services if they are required to involve their parents.[43] The list of services for which minors can legally give consent has recently expanded to include (1) sexual and reproductive health care, (2) mental health services, and (3) alcohol and drug abuse treatment. The majority of states also permit minor parents to make important health care decisions regarding their own children.

In most states, consent laws apply to minors 12 years of age and older. For example, 26 states and the District of Columbia allow minors (12 years of age and older) to consent to contraceptive services. All states and the District of Columbia allow minors to consent to treatment for sexually transmitted infections. Thirty states and the District of Columbia allow minor parents to consent to medical care for their children. For some medical treatment, including contraception and obstetric care, case law has generally held that minors have rights of privacy and autonomy that are fundamental and equivalent to the rights of adults.[44]

In addition to statutes and case law regarding a minor's ability to provide consent, there also exists a broader legal concept—the **emancipated or mature minor doctrine**.[45] This doctrine allows health care providers to determine whether a minor is emancipated for providing medical consent. Case law may not give a precise definition of an emancipated minor, but it may list criteria that health care providers should consider. Such criteria may include the minor's age, maturity, intelligence, training, experience, economic independence, and freedom from parental control. When a minor is deemed emancipated for medical consent, the health care provider should document the objective facts that support the emancipation decision, consistent with institutional policies and/or other legal guidance.

Some states have adopted emancipation statutes that permit minors to file for emancipation status in court.[46] Typically, a minor is required to be a minimum age to file for emancipation. Once the court grants emancipation status, a minor generally has the right to give informed consent for health care. A signed copy of the court's emancipation order should be placed in the patient's medical record.

Emancipation *per se* does not alter the requirement that a patient provide informed consent for medical treatment, including nontreatment. Emancipation status affords the minor patient rights (for providing consent) that are equal to those of an adult patient. The emancipated minor (like any adult patient) must have the ability to weigh the risks and the benefits of the proposed treatment or nontreatment.

In summary, health care providers typically should obtain consent from the minor's parents before providing nonemergency treatment unless the minor is emancipated (by either a clinical or judicial determination) or

the minor is permitted by statute to give consent to the type of health care sought.

Consent for Labor Analgesia

It is common practice for surgical patients to sign a preoperative consent form, which often includes a statement giving consent for anesthesia. The situation in obstetrics is somewhat different in that not all laboring women require operative delivery. Several years ago, an unpublished survey of obstetric centers in the greater Seattle, Washington, area revealed that approximately half of the institutions did not require a signed consent form for obstetric procedures other than cesarean delivery. At many of these institutions, a separate written consent signed by the patient is not obtained before administration of anesthesia. A 1995 survey of obstetric anesthesiologists in the United States and the United Kingdom indicated that 52% of U.S. anesthesiologists (but only 15% of U.K. anaesthetists) obtained a separate written consent for epidural analgesia during labor.[47] In a survey performed in the United Kingdom in 2007,[48] only 7% of obstetric units routinely obtained written informed consent for epidural analgesia during labor. In a 2004 survey from Australia and New Zealand,[49] less than 20% of anesthesia providers obtained written consent before initiating neuraxial labor analgesia.

Some health care facilities and organizations have begun using a consent form for obstetric and anesthetic procedures that may be desired or necessary during labor and delivery. The process of reviewing and signing the consent form provides a specific opportunity for the patient to ask questions. It also provides additional documentation that consent was obtained. The combined form has the additional advantage of not requiring the patient to sign multiple medicolegal documents. Although a signed consent form is not necessary, it should be standard practice for anesthesia providers to document that verbal informed consent was obtained before administration of anesthesia.

Ideally, the anesthesia provider will discuss anesthetic options before the patient is in severe pain and distress. Unfortunately, the anesthesia provider often first encounters the patient when she is in severe pain. Although the provider may tailor the consent process to the circumstances, the presence of maternal pain and distress does not obviate the need for a frank discussion of the risks of anesthesia as well as the alternatives. A survey of Canadian women revealed their strong preference to be informed of all possible complications of epidural anesthesia, especially serious ones, even when the risk was quite low.[50] This study and others have emphasized that parturients desire to have these discussions as early in labor as possible.

Gerancher et al.[51] performed a study to evaluate the ability of laboring women to recall the details of a preanesthesia discussion and to determine whether verbal consent alone or a combination of verbal and written consent provided better recall. The investigators randomly assigned 113 laboring women to one of two groups, those from whom verbal consent alone was obtained and those from whom verbal consent plus written consent was obtained. The verbal-plus-written consent group had significantly higher median (range) recall scores (90 [80-100]) than the verbal-only group (80 [70-90]). Only two women (both in the verbal group) believed that they were unable (because of either inadequate information or situational stress) to give valid consent. The investigators concluded that "the high recall scores achieved by the women in both groups suggest that the majority of laboring women are at least as mentally and physically competent to give consent as preoperative cardiac patients."

Clark et al.[52] randomly assigned hospital inpatients to receive either an oral anesthesia discussion alone or both an oral anesthesia discussion and a preprinted anesthesia consent form. In contrast to the results of Gerancher et al.,[51] these investigators found that "patients remembered less of the information concerning anesthetic risks discussed during the preoperative interview if they received a preprinted, risk-specific anesthesia consent form at the beginning of the interview." They speculated that "patients who see an anesthesia consent form for the first time during the preoperative interview may try to read and listen simultaneously, and with their attention divided, may remember less of the preoperative discussion."

Anesthesia providers have expressed concern about the adequacy of the informed consent process when women are experiencing the severe pain of active labor. A 2005 study evaluated whether labor pain and neuraxial fentanyl administration affect the intellectual function of laboring women.[53] The Mini-Mental Status Examination (MMSE) was used to evaluate orientation, registration, attention, calculation, recall, and language both before and after initiation of analgesia in 41 laboring women. There was no difference in MMSE scores before and after administration of neuraxial analgesia.

In summary, it seems reasonable for the patient to provide her signature as evidence of her consent, if her condition permits. This consent can be furnished on a separate anesthesia consent form or as part of a consent form for all obstetric care, including anesthesia. A signed consent form is preferable, but it should be standard practice for the anesthesia provider to explain the intended procedure, risks, and alternatives and to document this discussion in the medical record.

REFUSAL OF CARE

Documentation

Competent adult patients may refuse medical treatment, including life-saving care.[42] Health care providers generally determine whether a patient is capable of making medical treatment choices (see earlier discussion). In theory, the health care providers' clinical judgment about a patient's capacity to provide informed consent is the same regardless of whether the patient approves or disapproves the treatment plan. In practice, however, these situations are often handled differently. When a patient consents to the recommended medical treatment, minimal scrutiny of his or her decision-making capacity

is typically made. However, when a patient refuses potentially life-saving treatment, a higher level of scrutiny is applied to the patient's ability to understand and make a choice for nontreatment. Determination of a patient's capacity to give informed consent is typically a clinical judgment. State law may provide some definitions as to when a person may not be competent.

If a patient refuses potentially life-saving treatment, the health care providers should carefully assess the patient's capacity to provide informed consent. It may be advisable to obtain a psychiatric consultation as part of this clinical determination. It is important to document the determination of capacity and the objective facts supporting the decision. If a patient is deemed able to provide consent, he or she is able to either choose or reject the recommended treatment plan. Institutional policies may require the patient (or health care provider if the patient refuses) to sign an "Against Medical Advice" form for a non–medically approved discharge. If a patient is deemed unable to consent, the health care providers should obtain consent from a legally authorized surrogate decision-maker on the patient's behalf. If an incompetent patient needs emergency medical care, it may be provided consistent with an "emergency exception" (see earlier discussion).

Conflicts Arising out of the Maternal-Fetal Relationship

Almost all pregnant women consider the welfare of their unborn child to be of utmost importance. However, there may be situations in which maternal and fetal interests appear divergent or, potentially, in conflict. One example is when a pregnant woman refuses a diagnostic procedure, a medical treatment, or a surgical procedure that is intended to enhance or preserve fetal well-being. Another may arise when the pregnant woman's behavior is considered harmful to the fetus.[54] Physicians who care for pregnant women may confront challenging dilemmas when their patients reject medical recommendations, use illegal drugs, or engage in other behaviors that may adversely affect fetal well-being.

Appellate court decisions typically have held that a pregnant woman's decisions regarding medical treatment take precedence over the presumed fetal consequences of the maternal decisions.[55] One case illustrates the evolution of this judicial approach. Angela Carder was a 26-year-old married woman who had had cancer since age 13 years. At 25 weeks' gestation she was admitted to George Washington University Hospital, where a massive tumor was found in her lung. Her physicians determined that she would die within a short time. Her husband, her mother, and her physician agreed with her expressed wishes to be kept comfortable during her dying process. Ultimately, the hospital sought judicial review of this course of action. The hospital asked whether a surgical delivery should be authorized to save the potentially viable fetus. The situation was presented to a judge, who authorized an emergency cesarean delivery without first ascertaining (using the principle of substituted judgment) the patient's wishes. A cesarean delivery was performed without full consideration of the patient's wishes, the infant died approximately 2 hours after delivery, and the mother died 2 days later.

This case spawned extensive debate as to whether coercive intervention to protect the fetus is ever morally and legally justifiable.[56] With the assistance of the American Civil Liberties Union, Angela's parents sued the hospital, 2 administrators, and 33 physicians for claims including battery, false imprisonment, discrimination, and medical malpractice. These civil lawsuits were settled after several years of litigation, and as part of this process, the hospital adopted a written policy concerning decision-making for pregnant patients.[57] The court later reversed its initial decision authorizing the surgical delivery and ultimately issued an opinion setting forth the legal principles that should govern the doctor–pregnant patient relationship.[58] The court stated, "In virtually all cases the question of what is to be done is to be decided by the patient—the pregnant woman—on behalf of herself and the fetus. If the patient is incompetent…her decision must be ascertained through substituted judgment." In affirming that the patient's wishes, once ascertained, must be followed in "virtually all cases" unless there are "truly extraordinary or compelling reasons to override them," the court did not foreclose the possibility of exceptions to this rule.

Many contemporary medical ethicists agree that a pregnant woman's informed refusal of medical intervention should prevail as long as she has the capacity to make medical decisions.[59] Newer legislation and some high-profile legal cases (some involving criminal prosecution) have challenged this notion and have raised the question of whether there are circumstances in which a pregnant woman's rights to informed consent and bodily integrity may be subordinated to protect her unborn child. In 2004, Amber Rowland, a woman who had given birth vaginally to six children (with birth weights up to 12 pounds), was told by her treating physicians at a Pennsylvania hospital that she should undergo a cesarean delivery on the basis of an ultrasonographic examination that suggested an estimated birth weight of 13 pounds. When she refused, the hospital obtained a court order for a "medically necessary" cesarean delivery. She and her husband left the hospital against medical advice and went to another facility, where she uneventfully delivered a healthy 11-pound daughter.[60]

Other cases have focused on the pregnant woman's potentially harmful behavior. In 1991, Regina McKnight, who was pregnant at the time, began using cocaine after her mother's death. She had a stillbirth, and the state of South Carolina charged her with homicide by child abuse, claiming that her drug use caused the stillbirth. She became the first South Carolina woman to be convicted of this crime, for what both the defense and prosecution agreed was an unintentional stillbirth, and she spent nearly 8 years in jail. In 2008, the South Carolina Supreme Court unanimously reversed her conviction on the grounds that she did not receive a fair trial, primarily on the basis that her attorney failed to challenge the science that was used to convict her.[61]

Also in 2008, the Southern Poverty Law Center, along with 25 medical, public health, and health advocacy groups, filed an *amicus curiae* brief against the prosecution

of pregnant women in Covington County, Alabama, subsequent to the following event. Shekelia Ward delivered an infant on January 8, 2008. Both she and her newborn tested positive for cocaine during their hospital stay, and the facility reported it to authorities for possible child abuse.[62] The following day she was arrested, imprisoned, and charged with a felony—chemical endangerment of a child. The state statute at issue was passed by the Alabama legislature in 2006, for the purpose of prosecuting parents who exposed children to the toxins associated with methamphetamine production; the statute did not mention pregnant women or their fetuses.[63]

These statutes reflect the concept that a fetus can and should be treated as separable and legally, philosophically, and essentially independent from the mother.[55] The refinement of techniques of intrauterine fetal imaging, testing, and treatment prompted the view that fetuses are independent patients who can be treated directly while *in utero*.[64] The prominence of some ethical models that have asserted that physicians have moral obligations to fetal patients separate from their obligations to pregnant women also contributed to these developments.[65] Finally, a number of laws (primarily passed at the state level) were enacted with the aim of defining fetal rights separate from a pregnant woman's rights. In 2011, the American College of Obstetricians and Gynecologists (ACOG) Committee on Health Care for Underserved Women issued a statement addressing the issue of substance abuse reporting and the role of the obstetrician.[66] This document described a "disturbing trend" in legal actions and policies that criminalized drug abuse during pregnancy when such abuse is thought to be associated with fetal harm or adverse outcomes. Noting that women seeking obstetric care should not be exposed to criminal or civil penalties and that few treatment facilities are available to effectively treat drug abuse in pregnancy, the ACOG concluded that the use of the legal system to address alcohol and substance abuse issues is inappropriate and urged that policy makers and legislators instead focus on strategies to address the needs of pregnant women with addictions.

The American Medical Association (AMA) has taken a similar position, stating that (1) drug addiction is a disease amenable to treatment, rather than a criminal activity, and (2) there is a pressing need for maternal drug treatment and supportive child protective services.[67] Any legislation that criminalizes maternal drug addiction or requires physicians to function as agents of law enforcement will be opposed by the AMA.[67]

During the past two decades, practitioners have only infrequently resorted to court-ordered interventions against the wishes of the pregnant woman. In overturning the previous court's decision in the Angela Carder case (mentioned earlier), the Washington, DC, Court of Appeals noted that if a pregnant woman makes an informed decision, "her wishes will control in virtually all cases."[58] The court added, "We do not foreclose the possibility that a conflicting state interest may be so compelling that the patient's wishes must yield, but we anticipate that such cases will be extremely rare and truly exceptional."[58]

Medical ethicists and practitioners agree that clear communication and patient education represent the best means to address maternal-fetal conflict. Failing resolution, a 1999 ACOG opinion offered the following three options: (1) respect the patient's autonomy and not proceed with the recommended intervention regardless of the consequences, (2) offer the patient the option of obtaining medical care from another individual before conditions become emergent, and (3) request that the court issue an order to permit the recommended treatment.[68] In 2004, the ACOG addressed the situation in which health care providers may consider this last option (i.e., legal intervention against a pregnant woman).[54] Specifically, the ACOG stated that the following criteria should be satisfied: (1) "there is a high probability of serious harm to the fetus in respecting the patient's decision"; (2) "there is a high probability that the recommended treatment will prevent or substantially reduce harm to the fetus"; (3) "there are no comparably effective, less intrusive options to prevent harm to the fetus"; and (4) "there is a high probability that the recommended treatment [will] also benefit the pregnant woman or that the risks to the pregnant woman are relatively small."

The ACOG opinions assume the presence of competency and informed consent. Thus, if a pregnant patient is believed to be incompetent and incapable of providing informed consent, the health care providers may not be required to respect the patient's refusal of care. Moreover, if the patient is deemed incompetent and/or a medical emergency exists, care may be provided with consent from a legally authorized surrogate decision-maker or as an "emergency exception."

In summary, two approaches are available to the practitioner dealing with maternal-fetal conflict. One approach is to honor a competent pregnant patient's refusal of care. The other approach (which appears least favored by many medical ethicists and the ACOG) is to seek judicial authorization of treatment, which overrides a competent pregnant woman's refusal of care.[69]

In honoring a competent patient's desires to refuse treatment, the health care providers should carefully document the woman's competency and ability to provide informed consent. Every attempt should be made to counsel her to follow the treatment recommendations. Documentation should include how, when, and what information was provided to the patient and family regarding the significant risks to both the patient and the unborn child if the recommended care were not provided. If time permits, the treatment options should be reevaluated with the patient at frequent intervals, with detailed documentation in the patient's medical record. Additionally, legal counsel for the health care providers and medical facility may wish to prepare an "assumption of risk" form for the patient (and, if possible, her husband) to sign. This form represents another level of documentation (beyond the detailed notes in the patient's medical record) demonstrating that the patient was fully informed about the risks associated with her refusal of treatment and that she voluntarily elected to accept those risks. However, such a release signed by the parents may not protect the physician and medical facility from a claim brought on behalf of the child who suffers an injury as a result of nonintervention. In some cases the court has found that physicians have a duty to provide care to the unborn child.[70]

Patient "assumption of risk" does not release a health care provider from his or her obligations to provide other treatment within the accepted standard of care. For example, in *Shorter v. Drury*,[71] a case that involved a patient's refusal of blood transfusion because of religious preferences, the court upheld the validity of an "assumption of risk" (i.e., release) that relieved the physician from liability for compliance with the patient's refusal of blood transfusion before and after surgery but nonetheless held him partially responsible for her death because of his negligent performance of the surgery.[71]

Before deciding whether to seek court review, health care providers should identify what issue they want the court to resolve. Is it whether the pregnant woman is competent? Is it whether there is a superior state interest in preserving the life of the viable fetus and/or the pregnant woman despite the (competent) patient's desire to refuse recommended care? Health care providers also should consider whether a court is the proper forum for resolving those issues or whether another forum (e.g., an institutional ethics committee) may be a better choice. If a patient care dilemma is put before a judge, the health care providers give up a large amount of control over the disposition of the case. Nonetheless, if a patient's competency is at issue and there is adequate time, court review to settle the patient's competency may be beneficial and is supported by both the ACOG guidelines[54] and the *In re: A.C.* decision.[58] It is beneficial to obtain authorization for the provision of medically recommended care without waiting until the situation becomes an emergency. If the patient is deemed incompetent, the court may either appoint a surrogate decision-maker or directly authorize (by court order) the provision of medically indicated care.

It is not unusual for physicians to disagree with their patients' health care decisions, and such differences are expected. In some cases, physicians conclude that providing the requested care would present a personal moral problem—a conflict of conscience, which prompts them to refuse to provide the requested care. Conscientious refusals have become especially prevalent in the practice of reproductive medicine, an area characterized by deep societal divisions regarding the morality of contraception and pregnancy termination. The ACOG Committee on Ethics[72] has acknowledged that "respect for conscience is one of many values important to the ethical practice of reproductive medicine." The ACOG stated that when conscience implores physicians to refuse to perform abortion, sterilization, and/or provision of contraceptives, "they must provide potential patients with accurate and prior notice of their personal moral commitments." The ACOG committee opinion also emphasized that providers have an obligation to provide medically indicated care in an emergency that threatens the patient's health, in which referral is not possible.[72]

DISCLOSURE OF UNANTICIPATED OUTCOMES AND MEDICAL ERRORS

In 1999, the Institute of Medicine (IOM) estimated that preventable medical errors in the hospital setting kill 44,000 to 98,000 patients each year.[73] In December 2006, the Institute for Healthcare Improvement (IHI) initiated the 5 Million Lives Campaign.[74] At that time, the IHI estimated that 15 million incidents of harm occurred in U.S. hospitals each year (40,000 per day). Since that time, the prevalence of medical errors remains unacceptably high and continues to draw the focus of the public, regulators, and health care providers.[75] Large-scale efforts are underway to improve the safety in health care, and many organizations have achieved remarkable improvements.[76]

Most practitioners strive to provide the highest quality of care, but even with the growing focus on patient safety, unintended consequences—including patient injury and death—do occur. Unfortunately, most physicians remain largely unprepared to engage patients and their families in a timely, truthful, and candid manner in the aftermath of such events. In 1984, David Hilfiker wrote candidly of a life-altering mistake that he had made as a family physician treating a young woman in a small town in Minnesota.[77] Hilfiker was caring for a young woman named Barb Daily whom they both believed to be pregnant. He had delivered Barb and Russ Daily's first child, Heather, 2 years earlier, and he had been a friend of the couple for some years. After several months of care, her serial urine pregnancy test results remained negative and her uterus was only slightly enlarged. Concluding that she may have experienced a missed abortion, Hilfiker scheduled her for a dilation and curettage. The procedure was performed, but it became apparent that the diagnosis was incorrect and the procedure had been carried out with a live fetus. In his reflections on the event, Hilfiker wrote of a physician's expectations of perfection, the lack of training in dealing with unexpected outcomes and mistakes, and the damaging effects of these conditions on physicians.[77]

Disclosure of errors and unanticipated outcomes is a key component in the national patient safety movement. It is also an ethical mandate and a regulatory requirement. The ethical imperative is captured in the following passage from the *Charter on Medical Professionalism*, published by the American Board of Internal Medicine (ABIM) Foundation[78]:

> *Physicians should also acknowledge that in health care, medical errors that injure patients do sometimes occur. Whenever patients are injured as a consequence of medical care, patients should be informed promptly because failure to do so seriously compromises patient and societal trust. Reporting and analyzing medical mistakes provide the basis for appropriate prevention and improvement strategies and for appropriate compensation for injured parties.*

The AMA's *Code of Medical Ethics* contains the following statement: "It is a fundamental ethical requirement that a physician should at all times deal honestly and openly with patients…. Concern regarding legal liability, which might result following truthful disclosure, should not affect the physician's honesty with a patient."[79] The Joint Commission standard RI.2.90 requires that "patients and, when appropriate, their families, are

informed about the outcomes of care, treatment, and services that have been provided, including unanticipated outcomes."[80] Many states require reporting of medical errors, and some have legislated "apology" laws that encourage practitioners to be empathetic and honest with patients by allowing certain statements of sympathy to be made without fear of admitting medical liability.[81]

Physicians and other health care providers should undergo disclosure training to help them provide prompt and honest communication with patients and families and to help manage the risks of legal liability. Many untoward outcomes do not represent malpractice; they may simply reflect risks or complications of procedures that may or may not have been adequately discussed with patients and their families before the procedure or treatment. Adequate informed consent is an essential element of an effective disclosure program. Iatrogenic injuries, obvious mistakes, wrong-site surgeries, medication errors, and similar events that harm the patient should clearly be disclosed. A failure to disclose such an error may lead the patient (or the attorney) to conclude that health care providers made a deliberate effort to "cover up" the error. Furthermore, nondisclosure after such an event can lead to a charge of fraud. In most situations in which a provider conceals an error, the law provides that the statute of limitations "clock" for filing a malpractice claim does not begin to run until the fraudulent concealment is discovered.

In 2006, the Harvard teaching hospitals and their associated Risk Management Foundation developed a document entitled, "When Things Go Wrong: Responding to Adverse Events."[82] This white paper acknowledged the presence of many barriers to disclosure, including the fear of being sued, but the authors insisted that communication with patients and their families must be timely, open, and ongoing. In addition to stressing the imperative of providing support for the patient and/or family involved in the unexpected outcome, the paper emphasized the need to provide support to the health care providers involved. This concern is reflected in a 2008 survey that indicated that as many as 75% of obstetricians felt that caring for a patient with a stillbirth exacted a large toll on them, with almost 10% of those affected considering giving up their obstetric practice.[83]

Organizations that have adopted robust disclosure policies often have early settlement or "offer" programs, with the goals of reducing the overall costs of claims and speeding the resolution process. Recognizing the longstanding gridlock over tort reform, this and other approaches may provide a better balance between the interests of health care providers and their patients. Not only is it an opportunity to reform the process of compensating those who may have been injured, but it can also be linked to improvements in patient safety. A distinguishing feature of "disclosure and offer" models is that information and insights generated from the investigative process can be shared and analyzed for the purposes of implementing interventions that improve patient safety.[84] Physicians have a unique opportunity to lead such efforts, and their participation promotes the buy-in of other staff members.

CONTEMPORARY RISK MANAGEMENT STRATEGIES

Prevention of medical errors and adverse outcomes frequently focuses on the safety culture of the organization, communication and teamwork, and the intelligent use of protocols and checklists (see Chapter 11). The concept of a safety culture originated in organizations outside of health care sometimes referred to as high reliability organizations (e.g., nuclear industry, aircraft carrier operations).[85] A culture of safety is characterized by an institution-wide commitment to minimize adverse events despite the performance of intrinsically complex and hazardous work.[86] The key features of a "culture of safety" are:

- An acknowledgment of the high-risk nature of an organization's activities and the pursuit of consistently safe operations.
- A "blame-free" environment that encourages individuals to report errors or near misses without fear of reprimand or punishment.
- Encouragement of collaboration across levels and disciplines of the organization to seek solutions to the prevention of errors.
- Organizational commitment of resources to address the safety concerns.

Safety culture has been defined and can be measured; poor safety culture has been linked to increased error rates and adverse outcomes. Achieving a culture of safety in health care is daunting, because a culture of individual blame remains dominant and traditional. An issue that often arises is balancing the twin concepts of "no blame" and appropriate accountability. This is a particular struggle with physicians, given that few organizations have implemented meaningful systems of accountability that apply to the physicians.[87]

Communication and teamwork lapses are one of the primary causes of sentinel events identified by The Joint Commission from 2009 to 2011.[88] A 2010 review of obstetric malpractice risks by a major insurer found that 65% of the malpractice cases involved high-severity injuries, including maternal and infant deaths.[89] The most frequent contributing factors were substandard clinical judgment (77% of claims) and miscommunication (36% of claims). The report specifically noted that "at the intersection of individual decision making and team communication, teamwork training fosters development of a culture and structure for effective communication and decisive action. Its hallmarks—development of shared mental models, broad situational awareness, and clear communication among team members—facilitate clinicians' ability to timely identify signs of distress and take appropriate action."[89]

There is also increasing recognition of the value of smart checklists and protocols. Checklists may simplify complex procedures and make them less prone to error. Checklists may reduce the mental flaws inherent in human behavior.[90] The ACOG has issued an opinion noting that "protocols and checklists have been shown to improve patient safety through standardization and communication. Standardization of practice to improve quality

outcomes is an important tool in achieving the shared vision of patients and their health care providers."[91]

Some health care organizations and liability insurers are now adopting strategies to specifically promote these goals (e.g., offering financial incentives to providers for completing disclosure training, participating in multidisciplinary didactic training programs to support accurate interpretation of electronic fetal heart rate tracings, the adoption of other safe practices). Federal agencies, working with health care organizations and liability providers, are also supporting similar initiatives.[92]

LIABILITY PROFILES IN OBSTETRIC ANESTHESIA: THE AMERICAN SOCIETY OF ANESTHESIOLOGISTS CLOSED-CLAIMS PROJECT

In 1985 the ASA Committee on Professional Liability began an ongoing study of insurance company liability claims involving anesthesiologists. Cases that are closed (i.e., no longer active) are reviewed by practicing anesthesiologists, abstracted, double-checked by the ASA Closed-Claims Committee, and entered into a computer database. In 1991 and 1996 comprehensive analyses of obstetric anesthesia claims were published, based on a total database of 1541 and 3533 claims, respectively.[93,94] In 2009, another publication compared obstetric claims from 1990 to 2003 with those before 1990.[95] As of December 2010, some 9536 claims (excluding those for dental injuries) from more than 35 insurance companies across the country have been reviewed and entered into the ASA Closed-Claims Project database. The analysis reported in this chapter focuses specifically on the 640 obstetric claims in the ASA Closed-Claims Project database between 1990 and 2010.

It is important to recognize the limitations of this kind of study. A closed-claims study cannot determine the incidence of a complication, for a number of reasons. First, the denominator is unknown. Neither the total number of anesthetics given each year in each category nor the actual number of injuries per year is known. Second, not all injuries result in a claim of malpractice, and the anesthesiologist may not be named in a claim resulting from an anesthesia-related injury. This latter category may comprise a significant population of patients, which may make the relationship between cause and injury impossible to construct.[96] Conversely, anesthesiologists may be named in claims in which there was no anesthesia-related adverse event.

The claims that have been reviewed are not a random sample of such data. However, given the large number of participating insurance carriers, they are likely to be broadly representative of liability claims involving obstetric anesthesia care in the United States.

Despite the significant limitations of closed-claims studies, such efforts do provide information that cannot be obtained in other ways. For example, claims involving obstetric anesthesia care can be compared with those from other types of anesthesia practice to determine whether different patterns of injury and outcome emerge.

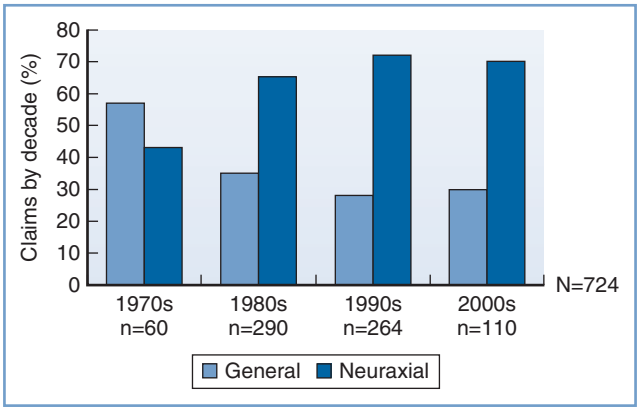

FIGURE 33-1 ■ The percentage of claims in which the anesthetic technique for cesarean delivery was either neuraxial or general. Data are shown as the percentage of the total number of claims for the indicated decade. (Data from the ASA Closed-Claims Project database, N = 9536, December 2010.)

We can ask such questions as: What injuries are most common in obstetric anesthesia claims? What is the relationship between the type of anesthesia and the presumed injury? What are the precipitating events that lead to the injuries? How do payment rates compare between obstetric and nonobstetric claims?

Approximately 12% of the 9536 claims in the ASA Closed-Claims Project database involve anesthesia care for patients undergoing vaginal or cesarean delivery. Of these obstetric claims, 66% involve cesarean delivery. The anesthesia workforce surveys conducted in 1981, 1992, and 2001 revealed a significant increase in the proportion of cesarean deliveries performed under neuraxial anesthesia and a corresponding decrease in those performed with general anesthesia.[97] An analysis of the ASA Closed-Claims Project database illustrates a similar trend in the claims for cases involving neuraxial and general anesthesia for cesarean delivery (Figure 33-1).

Anesthesia-Related Injuries

Table 33-1 lists all injuries or complications that had a frequency of 3% or greater in the obstetric claims that occurred in 1990 or later, as well as the type of anesthesia that resulted in the injury. **Maternal nerve damage** and **neonatal brain damage** were the most common injuries. In contrast to previous analyses, the proportion of nerve damage claims is now greater than maternal death claims. This finding likely reflects the increased use of neuraxial anesthesia (with a corresponding decrease in the use of general anesthesia) in obstetric anesthesia practice over the past two decades. A significantly greater proportion of nerve damage claims were associated with vaginal delivery compared with cesarean delivery. Although nerve damage in obstetric patients is more likely secondary to obstetric causes (e.g., vaginal delivery, fetal position during pelvic descent, maternal position during the second stage of labor [see Chapter 32]) than directly attributable to neuraxial anesthesia, the obstetric claims analysis published in 2009 found that nearly two thirds of the nerve damage claims may be directly linked to a neuraxial procedure.[95] Unfortunately, in many cases it is

TABLE 33-1 Most Common Injuries in Obstetric Anesthesia Claims*

Injury	Obstetric Claims (n = 640)	Type of Anesthesia		Type of Delivery	
		NEURAXIAL ANESTHESIA (n = 489)	GENERAL ANESTHESIA (n = 123)	CESAREAN (n = 387)	VAGINAL (n = 286)
Maternal nerve damage	19% (119)	24% (117)‡	2% (2)	13% (49)‡	29% (69)
Neonatal brain damage	16% (102)	13% (58)‡	29% (33)	21% (74)‡	13% (28)
Maternal death	15% (94)	10% (49)‡	36% (44)	18% (69)‡	7% (17)
Headache	11% (72)	15% (72)‡	0% (0)	7% (27)‡	19% (45)
Back pain	10% (62)	13% (62)‡	0% (0)	5% (20)‡	17% (42)
Neonatal death	9% (60)	6% (26)‡	24% (27)	13% (46)‡	4% (9)
Emotional distress	8% (54)	9% (46)	6% (7)	11% (41)†	5% (13)
Maternal brain damage	7% (44)	7% (34)	7% (8)	9% (36)†	3% (8)
Pain during anesthesia	6% (38)	7% (32)	3% (4)	9% (34)‡	2% (4)
Aspiration pneumonitis	1% (5)	< 1% (2)	2% (3)	1% (4)	< 1% (1)

*The most common injuries in the obstetric group of claims that occurred in 1990 or later are shown as % (n). Percentages are based on the total claims in each group. Some claims indicated more than one injury and are represented more than once. Claims involving brain damage include only patients who were alive when the claim was closed. Claims for which type of anesthesia or form of delivery were unknown are excluded.

†$P \leq .01$; ‡$P < .001$ compared with general anesthesia or vaginal delivery.

Data from the American Society of Anesthesiologists Closed-Claims Project database, N = 9536, December 2010.

almost impossible to differentiate between an anesthetic or obstetric cause for the nerve injury; appropriate neurologic consultation and investigation improves the likelihood of a correct diagnosis in these patients.

Some obstetric patients are reluctant to accept neuraxial anesthesia because of the fear of nerve injury. Because such injuries are uncommon, anesthesia providers often minimize the risks of neurologic injury in their discussions with patients. An ASA Closed-Claims analysis of injuries associated with neuraxial anesthesia in the 1980s and 1990s found that a significantly greater proportion of obstetric neuraxial claims were associated with temporary and low-severity injuries than nonobstetric claims.[98] Epidural abscess accounted for a greater proportion, and epidural hematoma a significantly smaller proportion, of obstetric neuraxial claims than nonobstetric neuraxial claims. Combining both epidural abscess and meningitis claims, infection was the leading cause of obstetric neuraxial complications (46%).[98]

A nonreassuring fetal heart rate tracing and urgent or emergency cesarean delivery were found to be factors in nearly three fourths of neonatal death/brain damage claims in 1990 or later.[95] Determining whether a causal link exists between the anesthetic care (negligent or otherwise) and the injury to the neonate is often difficult. A closer analysis of neonatal brain damage cases in the 1990s found that anesthesia care may have contributed to adverse fetal outcome in less than a fourth of cases; in half of these cases, some delay in anesthesia care was alleged.[95] The payment rate on behalf of the anesthesiologist was 21% in the claims involving neonatal death/brain damage, which was significantly lower than the payment rate of 60% for maternal death/brain damage claims.[95]

Some injuries (e.g., headache, pain during anesthesia, back pain) were almost exclusively associated with neuraxial anesthetic techniques. Most claims involving pain during anesthesia were associated with cesarean delivery (see Table 33-1). This finding suggests that inadequate analgesia for labor and vaginal delivery is rarely a source of liability risk. However, women expect to have satisfactory anesthesia during cesarean delivery, as do patients undergoing other types of surgery. It is also interesting that headache and back pain are relatively more common in the claims involving vaginal delivery. This may result, in part, from factors unique to labor and vaginal delivery (e.g., back strain from assuming unnatural positions during childbirth, increased risk for postdural puncture headache after bearing down during the second stage of labor).[99,100]

TABLE 33-2 Maternal Injuries Compared with Similar Injuries in Nonobstetric Claims*

Type of Injury	Maternal Injury Claims (n = 640)	Nonobstetric Injury Claims (n = 4410)
Maternal/patient nerve damage	19% (119)	20% (868)
Maternal/patient death	15% (94)‡	30% (1325)
Headache	11% (72)‡	1% (44)
Back pain	10% (62)‡	1% (62)
Emotional distress	8% (54)‡	5% (201)
Maternal/patient brain damage	7% (44)†	10% (442)
Pain during anesthesia	6% (38)‡	1% (45)
Aspiration pneumonitis	1% (5)‡	4% (164)

*The most common maternal injuries in the obstetric anesthesia claims occurring 1990 or later are shown as % (n). Percentages are based on the total claims in each group. Some claims had more than one injury and are represented more than once. Claims involving brain damage include only patients who were alive when the claim was closed.

†$P \leq .01$; ‡$P < .001$ compared with nonobstetric claims.

Table 33-2 lists the most common injuries identified after eliminating those involving only the neonate. This allows comparison of the profiles of maternal injury with those among the nonobstetric population. The most

TABLE 33-3 **Most Common Precipitating Events in Obstetric Anesthesia Claims***

Event	Nonobstetric Claims (n = 4410)	Obstetric Claims (n = 640)	Type of Obstetric Anesthesia	
			NEURAXIAL (n = 489)	GENERAL (n = 123)
Respiratory system events	22% (959)§	5% (29)	1% (7)§	16% (20)
Difficult intubation	6% (250)§	2% (15)	< 1% (1)§	11% (14)
Aspiration	3% (149)§	1% (5)	< 1% (1)†	2% (3)
Inadequate ventilation/oxygenation	5% (202)§	1% (7)	1% (5)	1% (1)
Premature extubation	2% (109)§	< 1% (1)	0% (0)	1% (1)
Airway obstruction	2% (72)§	< 1% (1)	0% (0)	1% (1)
Block-related events	11% (473)§	41% (265)	54% (265)§	0% (0)
High spinal/epidural	1% (30)§	6% (41)	8% (41)§	0% (0)
Dural puncture headache	< 1% (20)§	6% (40)	8% (40)§	0% (0)
Inadequate analgesia	< 1% (11)§	5% (35)	7% (35)§	0% (0)
Retained catheter	< 1% (6)§	4% (25)	5% (25)‡	0% (0)
Neuraxial cardiac arrest	1% (43)†	2% (13)	3% (13)	0% (0)
Other block-related**	5% (240)§	16% (101)	21% (101)§	0% (0)
Surgical events/patient condition	9% (416)§	25% (158)	19% (95)§	38% (47)
Cardiovascular system events	15% (682)‡	11% (69)	7% (35)§	26% (32)
Hemorrhage	3% (126)§	6% (38)	3% (15)§	18% (22)
Pulmonary embolism	1% (49)§	4% (23)	3% (15)	7% (8)
Medication events	8% (351)§	4% (27)	4% (18)	6% (7)

*The most common damaging events occurring 1990 or later are shown as % (n). Chronic pain claims are excluded. Percentages are based on the total claims in each group. Specific precipitating events were not identified in all claims. Some claims indicated more than one damaging event, but only the most significant event is listed. Columns do not sum to 100% as minor events are not listed. Statistical comparisons are made between obstetric and equivalent nonobstetric claims as well as between obstetric neuraxial and obstetric general anesthetics.

†$P < .05$; ‡$P < .01$; §$P < .001$ compared with obstetric claims or general anesthesia.

**Of the 101 other block-related claims, 2% (12) were epidural abscess, 1% (5) were epidural hematoma, 2% (13) were other permanent disabling nerve injuries, 7% (43) were temporary or minor nerve injuries, 1% (5) were meningitis, and 4% (23) were other miscellaneous block-related events.

Data from the American Society of Anesthesiologists Closed-Claims Project database, N = 9536, December 2010.

striking finding is that the maternal claims contain a much higher proportion of relatively minor injuries such as headache, pain during anesthesia, back pain, and emotional distress (35%) than do the nonobstetric claims (8%). Obstetric patients may be at greater risk for some of these complications.[98] For example, the popularity of neuraxial anesthetic techniques in obstetric anesthesia combined with the greater risk for post–dural puncture headache in young females may account for the greater number of headache claims in the obstetric group. Pain during anesthesia is almost always associated with cesarean delivery conducted with neuraxial anesthesia. These claims may have resulted from a reluctance by the anesthesiologist to convert to general anesthesia because of the risk for aspiration or anticipated difficult airway management. In some cases claims may have resulted from other factors, such as unrealistic expectations or general dissatisfaction with the care provided.

Precipitating Events Leading to Injuries

Perhaps even more important than the injuries and complications that may result in claims are the precipitating events that lead to the injuries (Table 33-3). Critical events involving the respiratory system were the most common anesthesia-related events in both the obstetric and nonobstetric claims involving general anesthesia. The proportion of difficult intubation and aspiration claims in the obstetric claims was found to be significantly less than that in the nonobstetric claims. Difficult intubation was the precipitating event in 15 (2%) of the obstetric claims, and pulmonary aspiration was the precipitating event in 5 (1%) of the obstetric claims. Among the five aspiration claims, three were related to general anesthesia but only one was associated with a difficult intubation; the other two occurred during the preinduction period. In a fourth case, the patient was sedated with an unprotected airway and aspirated after vomiting. The final case was unrelated to anesthesia.

Several reports have suggested that difficult intubation and pulmonary aspiration are the leading causes of anesthesia-related maternal mortality.[101-103] Interestingly, a study of anesthesia-related maternal deaths in the state of Michigan between 1985 and 2003 found that no deaths occurred during induction of anesthesia; all cases related to airway obstruction or hypoventilation (> 50% of anesthesia-related deaths) occurred postoperatively, often when monitoring and supervision were inadequate.[104]

Despite the reduction in the proportion of claims for respiratory events in the past two decades,[95] these data reemphasize that (1) all obstetric patients are at risk for airway complications (e.g., difficult intubation, aspiration); (2) anesthesia providers should be familiar with protocols such as the ASA difficult airway algorithm; (3) equipment should be immediately available for the management of patients in whom tracheal intubation proves difficult; and (4) obstetric patients require the same standard of postanesthesia care as nonobstetric patients (see ASA "Guidelines for Neuraxial Anesthesia in Obstetrics" [Appendix A]).

Obesity increases the risk for both obstetric[105] and anesthetic[106,107] complications in pregnant women (see

Chapter 50). In the ASA Closed-Claims Project database, damaging events related to the respiratory system were significantly more common among claims involving obese parturients (18%) than in the claims involving nonobese parturients (8%) ($P < .05$). However, the rates of other injuries were not significantly different in obese and nonobese parturients.[93]

With the increasing use of neuraxial anesthesia for both vaginal and cesarean deliveries, it is not surprising that neuraxial blockade–related events are the most common precipitating events in the obstetric population, accounting for a significantly greater proportion of cases than found among the nonobstetric claims. The use of an effective epidural test dose, the incremental injection of the therapeutic dose of local anesthetic, the availability of ropivacaine and levobupivacaine, and the use of pencil-point spinal needles (leading to a greater rate of spinal anesthesia) have undoubtedly contributed to a reduction in the incidence of serious adverse outcomes associated with epidural anesthesia in obstetric patients.[102] However, the database includes several claims for neuraxial anesthesia–associated cardiac arrest (predominantly secondary to unintentional intrathecal injection of drug) and for high spinal or epidural neuroblockade. Ironically, the number of claims for inadequate analgesia during neuroblockade, usually during cesarean delivery, has also increased.

The proportion of cardiovascular events in the obstetric claims has increased over time; maternal hemorrhage was the most common precipitating event (6%). More than half of the cases were associated with abnormal placentation (placenta accreta or percreta); in several cases the abnormal placentation was not diagnosed before delivery. Inability or failure of the anesthesia provider to adequately resuscitate the patient was a factor in the majority of cases. Delayed diagnosis of hemorrhage, poor communication among providers, unavailability of blood products, and inappropriate blood product replacement were other contributing factors. Death secondary to maternal hemorrhage is believed to be the most common preventable cause of maternal mortality.[108] Early diagnosis and intervention (by both surgical and anesthesia providers), and the use of major obstetric hemorrhage protocols to streamline response systems and improve availability of blood products, have been shown to reduce major hemorrhage rates and improve outcomes (see Chapter 38).[109]

An embolic disorder was the second most common cardiovascular event related to maternal death in the ASA Closed-Claims Project database. Of the 23 embolic disorder claims, 20 cases were due to amniotic fluid embolism; only 3 cases were due to venous thromboembolism. This finding may reflect the effectiveness of peripartum thromboprophylaxis measures that have been widely introduced over the past decade.

Payments

The practice of obstetrics is associated with high medicolegal risk. The obstetric anesthesia provider may also be named in a malpractice suit, in an attempt to increase payments beyond policy limits. This belief is reinforced by well-publicized cases involving huge monetary awards. However, the ASA Closed-Claims Project database provides a somewhat different perspective. For the purposes of this discussion, a payment is considered to be any expenditure by the insurance carrier in the form of a settlement or award. Obstetric claims constitute 12% of the ASA Closed-Claims database. Similarly, the obstetric claims account for 11% of the total number of payments made and 14% of the total dollars expended in payments. Clearly, the payments for obstetric claims were not disproportionately frequent or large. Table 33-4 provides additional payment information. For claims in which payments were made, the median payment was greater in the obstetric group. This is not surprising, considering that there are two patients at risk in obstetric anesthesia cases, and both the mother and her infant are younger than the average age of patients in the nonobstetric files. Although the obstetric claims contained a lower proportion of deaths (either maternal or newborn), there was a greater proportion of brain injuries (either maternal or

M, million.

*Payment frequency, shown as % (n), and dollar amounts (adjusted to 2011 values). Percentages are based on the total number of claims occurring 1990 or later in each group with payment data. Statistical comparisons are made between obstetric and nonobstetric claims, between obstetric neuraxial and general anesthetics, and between vaginal and cesarean deliveries. Claims with missing payment data were excluded from the analysis.

†$P \leq .01$

‡$P \leq .001$.

Data from the American Society of Anesthesiologists Closed-Claims Project database, N = 9536, December 2010.

newborn) than in the nonobstetric claims. Such injuries typically result in higher payments for projected lifelong care requirements.

Lessons Learned

The obstetric anesthesia claims reveal a risk profile that differs from that of the nonobstetric anesthesia claims. Surprisingly, since 1990, problems involving airway management, especially difficult intubation and pulmonary aspiration, are disproportionately represented in the nonobstetric claims. The continuing decrease in the use of general anesthesia in obstetric cases, and the widespread use of difficult airway algorithms, may be factors that have contributed to improvements in obstetric patient safety. The incidence of systemic local anesthetic toxicity has diminished. However, the ASA Closed-Claims Project database continues to receive information on claims for severe adverse outcome resulting from neuraxial anesthesia–associated cardiac arrest (primarily owing to unintentional and unrecognized intrathecal injection of drug). The data suggest that we need to continue our efforts to reduce the risks of major complications of both general and neuraxial anesthesia. The large number of claims for pain during neuraxial anesthesia for cesarean delivery, however, suggests that general anesthesia should not be delayed or avoided if a patient has inadequate anesthesia from neuraxial blockade.

Unfortunately, anesthesiologists frequently are inappropriately named in lawsuits involving "bad baby" outcomes, despite increasing evidence that cerebral palsy is associated with birth asphyxia in only 6% to 8% of cases, and even in these children, prevention may not be possible.[110] In 2003, an ACOG task force published criteria to help define the causal relationship between acute intrapartum events and cerebral palsy (see Chapter 10).[111] Among cases in the ASA Closed-Claims Project database from 1990 and later, anesthesia-related events contributing to newborn death and brain damage were uncommon; a payment was made on behalf of the anesthesiologist in only 21% of claims for newborn death/brain damage.[95] Potentially preventable anesthetic causes of newborn injury included delays in anesthetic care (primarily due to the anesthesiologist being away from the hospital or poor choice of anesthesia technique), substandard anesthesia care, and poor communication between the obstetrician and the anesthesiologist (often related to the urgency of cesarean delivery).[95]

Perhaps the most surprising finding of the analysis of the obstetric cases in the ASA Closed-Claims database is the large proportion of relatively minor injuries in the obstetric claims. This proportion markedly contrasts to that in the nonobstetric claims, suggesting that efforts to reduce the incidence of major injuries will not solve the medical malpractice problem in obstetric anesthesia. Clearly, factors other than major injury must motivate patients to bring a claim. It is overly simplistic to equate lawsuits with injury. A 1991 study found that the proportion of patients harmed by negligent care who actually file a claim is only 2%.[94] However, a lawsuit does not occur unless someone perceives that he or she or a loved one has been wronged. One of the unique advantages of closed-claims studies is that they reflect the consumer perspective.

To some extent the large proportion of relatively minor injuries in the obstetric claims may reflect a higher incidence of such problems among obstetric patients. However, it is clear that many of these patients were unhappy with the care provided and believed that they had been ignored or mistreated. It has been suggested that malpractice litigation serves the purposes not only of reparation of injury and deterrence of substandard care but also of emotional vindication.[112,113] Anesthesia care providers should give attention to conducting themselves in such a manner that patients will not be motivated to bring suit for an unexpected outcome.[114] The importance of establishing good rapport with patients cannot be overemphasized. Whenever possible, anesthesiologists should involve themselves in the prenatal education process. A careful preanesthetic evaluation is very important and should occur as early in labor as possible. Special care should be taken to provide patients with realistic expectations and knowledge of potential major and minor risks associated with anesthetic procedures.

PROFESSIONAL PRACTICE STANDARDS

One beneficial effect of closed-claims analyses has been the greater attention to steps to minimize the occurrence of severe adverse outcomes. On the basis of an analysis of malpractice claims in 1985, the Harvard University–affiliated medical institutions adopted a set of minimal monitoring standards within their system. Since that time the malpractice losses (normalized for the number of anesthetics given) have declined by more than 50%.[115] In 1986, the ASA became the first professional medical society to promulgate professional standards of care. The introduction of the ASA "Standards for Basic Intra-Operative Monitoring" was accompanied by a decrease in the number of anesthesia-related liability claims. Although it is difficult to prove a cause-and-effect relationship between the introduction of these standards and fewer claims and payments, the arguments seem compelling.[115] Better monitoring, especially the greater use of pulse oximetry and capnography, has undoubtedly contributed to the decrease in severe complications and associated large awards.[116]

The ASA also has directed its efforts at improving obstetric anesthesia care in this country through a variety of position statements. In 1986, the ASA House of Delegates and the ACOG approved a joint statement entitled "Optimal Goals for Anesthesia Care in Obstetrics" (see Appendix C). This policy-oriented document recognized the need for (1) appropriately trained physicians to provide anesthesia care, (2) a qualified obstetrician to be readily available during the administration of anesthesia, and (3) equipment, facilities, and support personnel for labor and delivery units equal to that provided in the surgical suite. The document served as the basis for the ASA "Standards for Conduction Anesthesia in Obstetrics," which was approved by the ASA House of Delegates in 1988. Unfortunately, unlike the widely acclaimed "Standards for Basic Intra-Operative

Monitoring," these obstetric anesthesia practice standards generated immediate and widespread controversy. In part, this was because they had implications with regard to nursing, obstetric, and pediatric practices and were considered too restrictive and too difficult to meet, especially for smaller or rural obstetric facilities. Consequently, in 1991, the document was revised and renamed "Guidelines for Regional Anesthesia in Obstetrics." The current document was revised in 2010 and renamed "Guidelines for Neuraxial Anesthesia in Obstetrics" (see Appendix A).

In October 1998, the ASA House of Delegates approved a document developed by the ASA Task Force on Obstetrical Anesthesia. This evidence-based document, titled "Practice Guidelines for Obstetrical Anesthesia," is more clinically oriented than the aforementioned guidelines and was last amended in 2007 (see Appendix B). It synthesizes a large body of published studies "to enhance the quality of anesthesia care for obstetric patients, reduce the incidence and severity of anesthesia-related complications, and increase patient satisfaction." The document provides systematic analyses and meta-analyses of specific anesthetic techniques and practices, along with general recommendations.

It is hoped that these practice guidelines will positively affect the quality of care and the liability profiles in obstetric anesthesia practice. Practice guidelines suggest a standard of care and are based on both evidence and expert opinion. As such they often are used as evidence in cases of medical malpractice. Such documents can be used for exculpatory purposes (i.e., to exonerate a defendant physician) or as inculpatory evidence (i.e., to implicate a defendant physician). A two-part study surveyed 960 randomly selected malpractice attorneys and 259 open and closed claims from two malpractice insurance companies.[117] The claims were opened during a 2-year period (1990 to 1992) and included all claims involving obstetric and anesthetic cases. Practice guidelines played a pivotal role in 17 cases. In 12 cases they were used as inculpatory evidence and in 4 as exculpatory evidence (in 1 case the use of practice guidelines could not be classified). Similarly, the surveyed attorneys responded that guidelines were used to implicate malpractice more than twice as often as they were used to defend against a claim of malpractice (54% versus 23%). The ACOG guidelines were used most frequently in these claims, but the ASA guidelines were used rarely. The authors speculated that the simplicity and clarity of the ASA guidelines may make compliance easier. Clearly, practice guidelines may act as a double-edged sword in medical litigation. Nonetheless, guidelines may reduce litigation expenses by dissuading plaintiffs' attorneys from pursuing cases in which guidelines have been met or by encouraging early settlement by the defense in cases in which guidelines were not followed without good reason.

POTENTIAL RISK MANAGEMENT PROBLEM AREAS

Obstetric anesthesia often is an unpredictable, difficult, and high-stress environment for the anesthesia provider. Compared with the operating room environment, the typical obstetric service is less familiar and more chaotic. The role and responsibility of the anesthesia provider is less clearly defined. Anesthesia services may be urgently requested in a situation in which there is little information available about the patient and the patient is unable or unwilling to answer questions. Laboring women typically are not sedated and calm when they request neuraxial anesthesia. Rather, women in active labor may be uncooperative and even combative during the administration of neuraxial anesthesia. The anesthesia provider may need to provide care for multiple patients simultaneously and may need to entrust some monitoring responsibilities to nurses. In some situations the choice of anesthesia may be dictated by others, and anesthesia providers may feel that they are little more than technicians. Perhaps it is not surprising that many anesthesia providers are uncomfortable in this environment and prefer to minimize their liability and discomfort by limiting their time practicing obstetric anesthesia.

Support Persons during Labor

Unique to obstetric anesthesia care is the presence of the patient's partner or other support persons during anesthesia care. In the past it was considered a privilege for a husband or relative to be present during a cesarean delivery, and often there were preconditions such as documentation of attendance at prenatal classes. Today, in many obstetric centers, it is taken for granted that one or more support persons will be present for virtually any type of delivery. Undoubtedly, this trend has resulted in part from a sincere desire to facilitate a more family-centered experience. A second motivation may be to attract patients in a competitive, market-oriented environment.

We are not aware of specific case law regarding issues involving support persons. However, the topic does raise a number of risk management questions. What are the parturient's rights with regard to having support personnel present during labor and delivery? What are the rights of the institution and health care providers? The presence of a support person often helps reassure and calm the parturient, but this is not always true. In some cases the presence of a support person can adversely affect patient care. Melzack[118] found that women have higher pain scores during labor when the husband is present. Similarly, Orbach-Zinger et al.[119] found that parturient anxiety and pain during the epidural procedure were higher in parturients randomized to the partner's presence during the neuraxial procedure compared with the partner's absence from the labor room.

Many anesthesia providers are not accustomed to having lay observers present during anesthesia procedures. Their presence can distract the provider's attention and adversely affect judgment and performance. It is helpful, especially in obstetrics, for the anesthesiologist to develop a close physician-patient relationship. The presence of a support person often distracts the patient's attention away from the conversation and activities of the anesthesiologist. In some cases this is helpful, but in others that distraction interferes with the provision of anesthesia care.

The support person also may be at risk for unanticipated injury.[120] We are aware of a number of instances in which a father suffered an injury as a consequence of a vasovagal episode. In one case the father dropped the newborn on the floor as he lost consciousness. Although there was no legal action in any of these cases, the potential liability issues are self-evident.

In some cases, support persons may request that they be present during the delivery even when the patient receives general anesthesia. At the University of Washington we do not allow support persons in the operating room during administration of general anesthesia; the patient undergoing general anesthesia does not require "support" in the traditional sense, and the possibility for complications is ever present. Even under the best of circumstances, the presence of such a person makes it more difficult for the anesthesia provider to give full attention to the patient. Routine anesthesia practices and procedures during general anesthesia may be frightening and misunderstood by laypersons. No matter how well intentioned and well prepared, the sight of a loved one who is unresponsive, intubated, and mechanically ventilated can be traumatic emotionally.

Videotaping

Physicians and hospitals also should consider policies regarding the use of audio/video equipment in the delivery room. Clearly all patients have a right to refuse to be photographed, filmed, or videotaped. However, a woman often wants a photographic record or videotape of events surrounding her delivery. Such a record can provide dramatic documentation of unfortunate interactions or suboptimal medical care. Courts typically allow videotapes to be entered into evidence and permit videotapes to be edited reasonably.[121] The visual impact of delivery room events can have a profound impact on a jury, regardless of whether the videotape has been edited to the advantage of the plaintiff. After the presentation of such evidence, it may be difficult to convince a jury of the appropriateness of treatment.

A survey of 35 members of the American College of Legal Medicine identified nine cases in which an obstetric videotape was used as evidence.[121] In response to such cases, some hospitals have instituted policies to limit the use of video equipment in their labor and delivery suites. Such policies may antagonize patients and prompt them to seek care elsewhere. A balanced approach may be the best solution (i.e., it may be reasonable to allow use of video equipment but to establish clear, fair, and unambiguous policies regarding its use). The policies must be understood by all members of the staff and should be made known to patients and their families, preferably before the patient is admitted to the hospital. Prenatal classes can serve as a means to disseminate such information. One approach is to have informational material and/or specific consent forms for patients and their families. Another option is to combine such policy statements with a "hold harmless" waiver for the support person. Although none of these measures can eliminate the potential liability risks associated with these issues, they may serve to educate patients and their families about their rights and about hospital policies and procedures.

KEY POINTS

- Effective communication with the parturient and her family is an important component of obstetric anesthesia practice.
- Honest, caring, and comprehensive discussion with the patient before the administration of anesthesia meets legal and ethical standards, improves the image of the anesthesiologist, and reduces the likelihood of dissatisfaction and possible litigation after unanticipated complications.
- Informed consent may be either verbal or both verbal and written. Written consent provides documentation that the consent process has occurred. If possible, it is best to obtain consent early in labor, before the onset of severe pain.
- Refusal of care by pregnant patients may raise unique legal and ethical concerns. In such situations, the woman's competency or ability to make an informed medical decision may be an issue. When the patient is competent, the health care providers should attempt to resolve treatment conflicts through additional patient education and discussion. Rarely, it may be advisable to seek a court order to resolve competency and/or medical treatment issues.
- Maternal nerve injury was the most common damaging event in obstetric anesthesia claims in the American Society of Anesthesiologists (ASA) Closed-Claims Project database from 1990 onwards. Detailed neurologic examination, involvement of neurologic specialists, and appropriate investigations can assist in making an accurate diagnosis.
- Critical events involving the respiratory system were the most common anesthesia-related events leading to adverse outcome in both obstetric claims and nonobstetric claims involving general anesthesia in the ASA Closed-Claims Project database. Use of a difficult airway algorithm, availability of specialized equipment (e.g., a video laryngoscope), and high-quality postoperative care after general anesthesia may help reduce the incidence of these events.
- Obstetric claims include a much higher proportion of relatively minor injuries (e.g., headache, pain during anesthesia, back pain, emotional distress) than nonobstetric claims.
- Guidelines for obstetric anesthesia practice have been published by the ASA, and a joint statement has been published by the ASA and the American College of Obstetricians and Gynecologists.

PART IX

OBSTETRIC COMPLICATIONS

Donald Caton, MD

The philosophy of obstetric management changed in the early decades of the twentieth century, and this change had a profound effect on the use of obstetric anesthesia. Until 1900, obstetricians considered childbirth a physiologic process best left to proceed without interference by physician or midwife. They criticized "meddlesome practices" for normal deliveries. Then a new generation of obstetricians, concerned about the high rate of complications associated with routine deliveries, began to advocate more active management of childbirth. They envisioned the practice of obstetrics as a form of preventive medicine. Leaders of this movement, such as Joseph DeLee of Chicago, became strong advocates for the routine use of episiotomy, forceps delivery, and manual removal of the placenta. Of course, these measures also necessitated greater use of anesthesia.[1]

DeLee acknowledged that his method "interferes much with Nature's process," but he felt justified. With conservative management, he said, a dismal outcome was so common that he "often wondered whether Nature did not deliberately intend women should be used up in the process of reproduction, in a manner analogous to that of the salmon, which dies after spawning. Perhaps laceration, prolapse and all the evils are, in fact, natural to labor and therefore normal.…If you adopt this view, I have no ground to stand on, but, if you believe that a woman after delivery should be as healthy, as well as anatomically perfect as she was before, and that the child should be undamaged, then you will have to agree with me that labor is pathogenic, because experience has proved such ideal results exceedingly rare."[2] Other physicians agreed with DeLee. Austin Flint asked how a "process that kills thousands of women each year, leaves a quarter of all cases more or less invalidate, is attended by severe pain and tearing of tissues, and kills three to seven percent of all babies, can be called a normal or physiologic function?"[3]

The change in the philosophy of obstetric management was further stimulated by early feminists. In the United States, but especially in Great Britain, feminists formed a coalition with obstetricians to improve teaching, build new facilities, and fund better care for women in hospitals. They also demanded better anesthesia coverage and even funded research to develop new anesthetic techniques. In response to this movement, physicians developed many new techniques for laboring patients. Many of the anesthetic methods now favored for normal deliveries are a direct outgrowth of public support for innovation and improvement that began during this time.

CHAPTER 34

Preterm Labor and Delivery

Janelle R. Walton, MD • William A. Grobman, MD, MBA

CHAPTER OUTLINE

Preterm delivery is defined as delivery before 37 weeks' gestation. It occurs in 12% to 13% of all pregnancies in the United States and in 5% to 9% of pregnancies in other developed countries.[1] Preterm delivery is responsible for 75% to 80% of all neonatal deaths and significant neonatal morbidity.[1,2] Birth statistics in the United States reveal a 20% increase in the preterm delivery rate between 1990 and 2006 (from 10.6% to 12.8%) and a 30% increase since 1981.[3] Subsequently, the preterm delivery rate declined to 11.72% of all births in 2011 (Figures 34-1 and 34-2).[4] Preterm births not only account for a significant degree of neonatal morbidity and mortality but also are responsible for a large economic burden to society. For example, in 2005, the costs associated with preterm birth were at least $26.2 billion.[3]

In 2010, late preterm deliveries comprised 71% of all preterm births (see Figure 34-2). There is a notable racial/ethnic disparity in the frequency of preterm birth. In 2010, 10.8% of non-Hispanic whites, 17.1% of non-Hispanic blacks, and 11.8% of Hispanics delivered preterm. Women age 25 to 34 years were least likely to deliver preterm (11.4%), whereas women 40 years or older were most likely to deliver preterm (25.9%).[5]

The concern about preterm birth is not confined to the United States; the World Health Organization (WHO) and other nongovernmental organizations have identified the frequency of preterm birth as a critical health issue. The WHO uses low birth weight as an indicator of early delivery because true gestational age at delivery is often not available (see Figure 34-1). Worldwide, the incidence of low birth weight, defined as a birth weight less than 2500 g, is 15.5 per 1000 births.[6] Africa and Asia have the highest incidence of low birth weight, at 14.3 and 18.3 per 1000, respectively. In contrast, in Europe and North America the incidence of low birth weight is 6.4 and 7.7 per 1000, respectively.[6] Likewise, infant mortality rates are significantly higher in developing nations, particularly the sub-Saharan African countries. The United States has a higher infant mortality rate than Europe (6 versus 3 per 1000 births, respectively), which reflects the higher preterm birth rate in the United States.[7]

In 2006, the Institute of Medicine recommended that investigators focus on (1) better defining the problem; (2) developing treatments to prevent both preterm delivery and morbidity for children born preterm; (3) identifying the causes of preterm birth, including modifiable risk factors and the reasons for disparity among different ethnic, racial, and socioeconomic groups; and (4) developing policies and public programs that can be used to reduce the rate of preterm birth.[3]

DEFINITIONS

A preterm infant is defined as one who is born between 20 0/7 weeks and 36 6/7 weeks, inclusive, after the first day of the last menstrual period. If a good basis does not exist for establishing the gestational age from maternal history, the exact gestational age is difficult to determine. A low birth weight does not necessarily signify that a neonate has been born preterm, because some newborns have a low birth weight because they are small for gestational age (SGA) rather than preterm. A neonate who weighs less than 2500 g at birth is considered to have a low birth weight (LBW), regardless of gestational age. Likewise, an infant who weighs less than 1500 g at birth is considered to have a very low birth weight (VLBW), and an infant who weighs less than 1000 g at birth is considered to have an extremely low birth weight (ELBW).

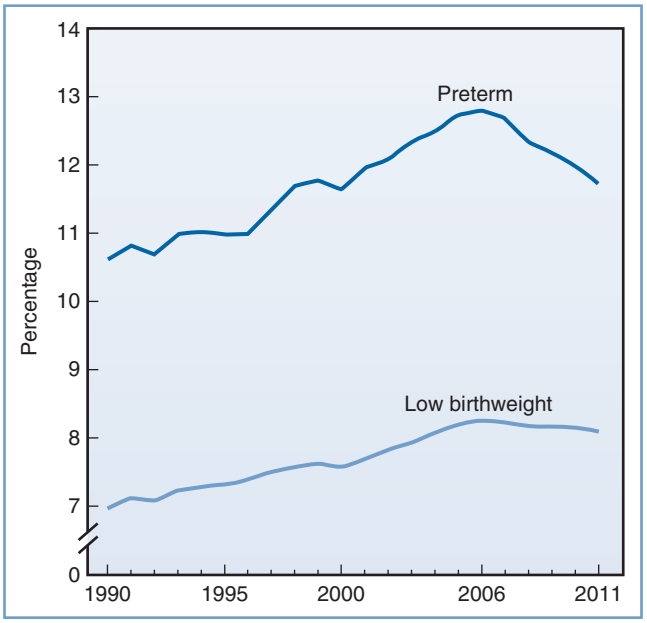

FIGURE 34-1 ■ Preterm and low birth weight rates: United States, final data from 1990 to 2010, preliminary data from 2011. (From Hamilton BE, Martin JA, Ventura SJ. Births: Preliminary data for 2011. Natl Vital Stat Rep 2012; 61[5].)

NEONATAL MORTALITY

The survival rate among neonates increases as the birth weight and/or gestational age increases (Figure 34-3; Table 34-1).[8] After data are controlled for gestational age and weight, male infants have a higher mortality than female infants.[9] During the past three decades, there has been a significant improvement in the survival rate for preterm infants, with the greatest improvement occurring in the subgroup with a birth weight between 501 and 1250 g.[10] The rate of neonatal survival now exceeds 90% for infants born after 30 weeks' gestation, and a neonatal survival rate close to that of a term infant can be expected for those born after 32 weeks' gestation.

However, despite this improvement, infants with a birth weight between 501 and 750 g continue to have high mortality rates (Table 34-2). For example, in a cohort of neonates delivered between 2000 and 2009, the mortality rate for infants weighing between 501 and 1500 g decreased from 14.3% to 12.4%.[10] When stratified by birth weight, mortality ranged from 36.6% for infants who weighed between 501 and 750 g to 3.5% for infants who weighed between 1251 and 1500 g.[10] A retrospective cohort study assessed survival rates for infants delivered between 24 and 26 weeks' gestation.[11] Neonatal survival was 43%, 74%, and 83% at 24, 25, and 26 weeks' gestation, respectively. The majority of women received antenatal corticosteroids, and the majority of neonates received exogenous surfactant. A delay in delivery of even 1 week at this time in gestation leads to significantly better outcome and reduced cost. A similar study that examined a cohort of infants born between 1998 and 2002 showed a survival rate of 0% for infants born at 21 completed weeks' gestation; the survival rate rose steadily to 75% at 25 completed weeks' gestation (see Table 34-1).[12]

Infants born at the threshold of viability (22 to 24 weeks' gestation) continue to have the greatest risk for

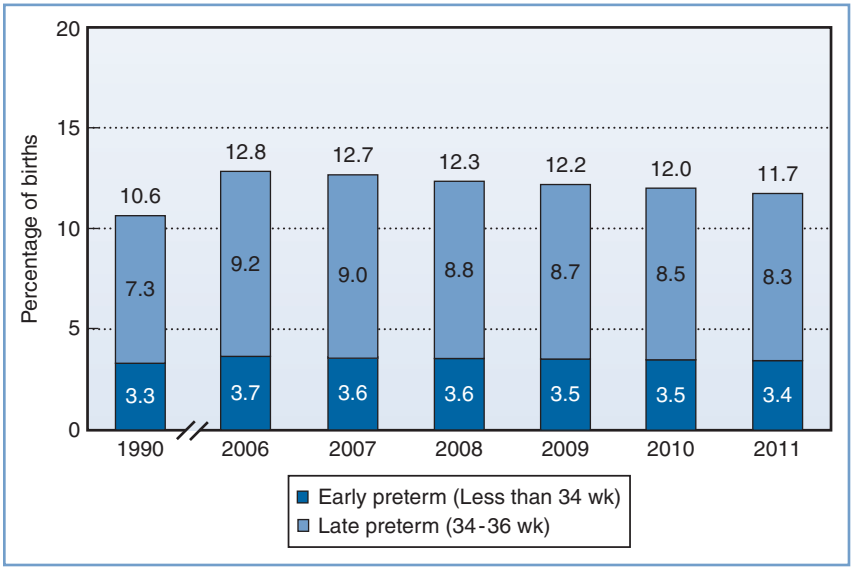

FIGURE 34-2 ■ Total, early, and late preterm birth rates: United States 1990 and 2006 to 2010 (final) and 2011 (preliminary). Preterm birth is defined as less than 37 weeks' completed gestation. Early preterm is defined as less than 34 weeks' completed gestation. Late preterm is defined as 34 to 36 completed weeks' gestation. TABLE 34-2 Selected Outcomes for Extremely Preterm Infants*

Outcome	Percent (Range†)
Use of antenatal therapy	
Maternal corticosteroid administration	80 (45-97)
Maternal antibiotic administration	67 (55-85)
ROM > 24 h before delivery	25 (18-32)
Cesarean delivery	59 (47-81)
Male gender	53 (47-58)
Multiple birth	25 (18-34)
Delivery room resuscitation	
Delivery room infant tracheal intubation	67 (41-85)
5-min Apgar score ≤ 3	16 (3-25)
Surfactant therapy	76 (58-88)
Survival	72 (55-95)
Survived without morbidity‡	37 (7-50)

ROM, rupture of membranes.

*Birth weight < 1000 g. Data are from the Eunice Kennedy Shriver National Institute of Child Health Development Neonatal Research Network for 9575 infants, gestational ages 22 to 28 weeks, birth weight 401 to 1500 g, between 2003 and 2007.

†Ranges are across 19 Neonatal Research Network centers.

‡Morbidities included severe intraventricular hemorrhage, periventricular leukomalacia, bronchopulmonary dysplasia, necrotizing enterocolitis, infections, and retinopathy of prematurity (ROP) stage ≥ 3.

Data from Stoll BJ, Nansen NI, Bell EF, et al. Neonatal outcomes of extremely preterm infants from the NICHD Neonatal Research Network. Pediatrics 2010; 126:443-56.

poor outcome. A recent study examined outcome for infants born between 22 and 27 weeks' gestation between the years 2002 and 2008. The mortality rate for those born between 22 and 24 weeks' gestation was 61% compared with 19% for those born between 25 and 27 weeks' gestation.[13] Compared with infants born at 22 to 24 weeks' gestation, infants born at 25 to 27 weeks' gestation were more likely to have been exposed to antenatal maternal corticosteroid administration (87% versus 62%), to be delivered by cesarean (70% versus 39%), and to be resuscitated at birth (99% versus 75%). It is estimated that 2% to 5% of VLBW infants who survive to hospital discharge die within 2 years because of medical complications of prematurity.[13]

NEONATAL MORBIDITY

Approximately 90% of preterm births occur between 32 and 36 6/7 weeks' gestation. Compared with earlier gestational ages, mortality is less common, but morbidity is a relatively greater concern in this gestational age range. As with mortality, most morbidity decreases in frequency as the gestational age increases. For example, the incidence of high-grade (III or IV) intraventricular hemorrhage (IVH) diminishes rapidly after 27 weeks' gestation and grade III or IV intraventricular hemorrhages are very rare after 32 weeks' gestation. Likewise, neonatal morbidity from patent ductus arteriosus and

necrotizing enterocolitis diminishes significantly after 32 weeks' gestation.[12] Data from the National Institute of Child Health and Development (NICHD) Neonatal Research Network sites from 1997 through 2002 indicate that survival without complications (e.g., bronchopulmonary dysplasia, severe intraventricular hemorrhage, necrotizing enterocolitis, or a combination of these disorders) ranged from 20% for infants with a birth weight between 501 and 750 g to 89% for those with a birth weight between 1251 and 1500 g.[2]

Piecuch et al.[14] reported data for a cohort of 138 nonanomalous infants delivered between 24 and 26 weeks' gestation between 1990 and 1994. The incidence of cerebral palsy did not differ significantly among the three groups born at 24, 25, and 26 weeks' gestation (11%, 20%, and 11%, respectively). However, the incidence of normal cognitive outcome rose with increasing gestational age at birth (28%, 47%, and 71% at 24, 25, and 26 weeks' gestation, respectively).

The EPICure study group assessed the association between extreme preterm delivery and long-term physical and mental disability in a cohort of infants delivered between 22 and 25 weeks' gestation during a 10-month period in 1995.[15] These investigators noted rates of severe disability of 54%, 52%, and 45% among infants delivered at 23, 24, and 25 weeks' gestation, respectively. In a later cohort of infants, born between 1997 and 2002, the rates of severe disability were 33%, 21%, and 12% for infants delivered at 23, 24, and 25 weeks' gestation, respectively.[16] A 6-year follow-up to the EPICure study cohort showed persistent severe disability in 25%, 29%, and 18% of infants born at 23, 24, and 25 weeks' gestation, respectively.[17]

Hack et al.[18] monitored a cohort of ELBW infants born between 1992 and 1995 until they were 8 years old. The mean birth weight was 810 g, and the mean gestational age at delivery was 26 weeks. Compared with a cohort of age-matched children of normal birth weight, the ELBW group had a higher incidence of significant neurosensory impairment (16% versus 0%, respectively) and asthma (21% versus 9%). The ELBW children differed significantly from the cohort with normal birth weight in rates of suboptimal intelligence, academic achievement, motor skills, and adaptive functioning. These data illustrate the long-term medical, educational, and social services required by these children.

Correspondingly, the economic costs for the care of surviving preterm infants (especially VLBW infants) can be enormous. The Institute of Medicine estimated that the societal economic burden associated with preterm birth in the United States was at least $26.2 billion in 2005, or $51,600 per infant born preterm.[3] These figures likely will continue to rise with the escalating cost of health care.

PRETERM LABOR

Risk Factors

Box 34-1 lists factors associated with preterm labor.[1,19,20] These associations do not necessarily indicate cause-and-effect relationships. Significant risk factors include a history of preterm delivery, non-Hispanic black race (irrespective of socioeconomic status), and multiple gestation.

BOX 34-1 Factors Associated with Preterm Labor

Demographic Characteristics

- Non-Caucasian race
- Extremes of age (<17 or >35 years)
- Low socioeconomic status
- Low prepregnancy body mass index
- History of preterm delivery
- Interpregnancy interval < 6 months
- Abnormal uterine anatomy (e.g., myomas)
- Trauma
- Abdominal surgery during pregnancy

Behavioral Factors

- Tobacco use
- Substance abuse

Obstetric Factors

- Vaginal bleeding
- Infection (systemic, genital tract, periodontal)
- Short cervical length
- Multiple gestation
- Assisted reproductive technologies
- Preterm premature rupture of membranes
- Polyhydramnios

Data from references 1, 19, and 20. Modified from Muir HA, Wong CA. Preterm labor and delivery. In Chestnut DH, Tsen LC, Polley LS, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

The process of normal parturition involves anatomic, physiologic, and biochemical changes that lead to (1) greater uterine contractility, (2) cervical ripening, and (3) membrane/decidual activation.[19,20] The fetus also appears to play a role in parturition. It is hypothesized that the mature fetal hypothalamus secretes more corticotropin-releasing hormone (CRH), which in turn stimulates fetal adrenal production of adrenocorticotropic hormone (ACTH) and cortisol.[19] Preterm labor results from the pathologic activation of one or more of these components (Figure 34-4).[21] Preterm delivery results from (1) preterm premature rupture of membranes (preterm PROM) in approximately 30% of cases, (2) spontaneous preterm labor in approximately 45% of cases, and (3) maternal or fetal indications for early delivery in approximately 25% of cases.[22] However, the "spontaneous" causes do not have a uniform underlying pathophysiology, and it appears that preterm labor is a syndrome with multiple causes influenced by a number of genetic, biologic, biophysical, psychosocial, and environmental factors.

Two emerging factors of interest are the influences of **infection** and **uterine distention** on initiation of myometrial contractility. Infection is thought to be present in up to 40% of preterm deliveries.[1] Commonly identified organisms include *Ureaplasma urealyticum*, *Bacteroides* species, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, group B streptococci, *Staphylococcus aureus*,

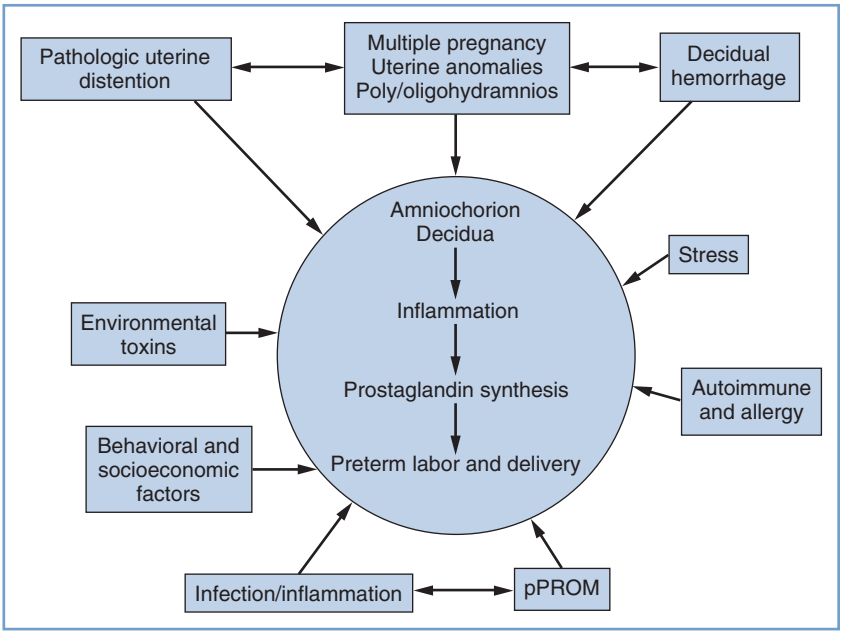

FIGURE 34-4 ■ Major etiologic factors in preterm birth, including activation of the maternal or fetal hypothalamic-pituitary axis (stress), inflammation, decidual hemorrhage, and pathologic distention of the myometrium. The pathways are not mutually exclusive and may overlap, and they share a common biochemical pathway. *pPROM,* preterm premature rupture of membranes. (From Menon R. Spontaneous preterm birth, a clinical dilemma: etiologic, pathophysiologic and genetic heterogeneities and racial disparity. Acta Obstet Gynecol Scand 2008; 87:590-600.)

Treponema pallidum, and enteropharyngeal bacteria.[23-25] Although approximately 50% of preterm deliveries occur in women with no apparent risk factors, subclinical infection may precipitate preterm labor in some of these cases.[24]

In the past three decades there has been a significant rise in the incidence of **multiple gestation** (see Chapter 35). The twin birth rate increased by 76% from 1980 to 2009.[5] The triplet and higher-order multiple birth rate rose by over 400% during the 1980s and 1990s but has declined 29% since the 1998 peak.[4] The increased incidence of multiple gestation is due, in part, to the significant increase in the use of **assisted reproductive technologies** (ARTs).[26] Over 50% of all twins and 90% of all triplets are born preterm.[5] Consequently, multiple gestations account for 17% of all preterm births.[27] ART pregnancies are also associated with an increase in risk for preterm delivery, even for singleton pregnancies.[28] A 2004 meta-analysis of 15 studies, which compared outcomes for 12,283 ART singleton pregnancies with outcomes for 1.9 million spontaneously conceived singleton pregnancies, demonstrated a higher risk for preterm and SGA deliveries in the ART group.[28] Placenta previa, gestational diabetes, preeclampsia, and neonatal intensive care unit admission were also more prevalent in the ART group.[28]

Approximately 25% of all preterm deliveries do not result from spontaneous preterm labor or preterm PROM. The obstetrician may choose to perform indicated delivery for maternal or fetal indications, such as severe preeclampsia or a nonreassuring fetal status.

Prediction of Preterm Labor

The ability to prevent spontaneous preterm birth would be facilitated if it were possible to intervene prophylactically to prevent preterm labor or to effectively treat preterm labor once it occurs. Both prophylaxis and treatment would be facilitated if it were possible to accurately predict which asymptomatic or symptomatic patients would have spontaneous preterm delivery. Several methods of predicting preterm delivery have been proposed, including home uterine activity monitoring, salivary estriol measurement, fetal fibronectin screening, and transvaginal cervical ultrasonography.[29]

The use of **home uterine activity monitoring** to identify women at risk for preterm labor has been investigated in a number of randomized controlled trials.[29] Likewise, **salivary estriol** levels have been assessed as a marker of risk for preterm delivery. Neither has been shown to be clinically useful in the prevention of preterm birth.

Fetal fibronectin (fFN) is a basement membrane glycoprotein produced by the fetal membranes. It functions as an adhesive protein of the placental membranes to the decidua.[30] fFN is normally absent from vaginal secretions from 20 weeks' gestation until near term. Detection of elevated levels of fFN is associated with an increased risk for preterm delivery. It is hypothesized that the presence of fFN is a marker of choriodecidual disruption. A study from the Maternal-Fetal Medicine Units Network documented that a positive fFN test result at 22 to 24 weeks' gestation had a sensitivity of 63% in predicting preterm labor before 28 weeks' gestation.[31] If fFN is absent (i.e., a negative result), the risk for preterm delivery within 1 or 2 weeks is less than 1%.[32] The high negative predictive value of this test may make it a useful tool to help triage symptomatic patients more efficiently, although this remains to be demonstrated in randomized trials[33]; currently, there is no role for this test in screening low-risk asymptomatic women.[29]

Short cervical length, as assessed by transvaginal ultrasonography, also is associated with a greater risk for preterm delivery.[34] In a 2006 systematic analysis, Kagan et al.[35] concluded that cervical length is associated with preterm delivery (i.e., the shorter the cervix the greater the risk for preterm delivery) in *symptomatic* women.

Further, multiple studies have shown an increased risk for preterm delivery in asymptomatic women with a shortened cervix.[29] A Maternal-Fetal Medicine Units Network study of nearly 3000 women found that the risk for spontaneous preterm delivery is increased in women with evidence of a short cervix detected by transvaginal ultrasonography between 24 and 28 weeks' gestation. A cervical length below the 10th percentile had a sensitivity of 37% and a specificity of 92% in predicting preterm birth before 35 weeks' gestation, with a corresponding positive predictive value of 18% and a negative predictive value of 97%.[34]

A history of cervical surgery, including conization and loop electrosurgical excision procedure, traditionally has been thought to be a risk factor for preterm birth because of associated cervical injury. However, this relationship may be related to environmental factors and/or behavioral factors that underlie the progression of cervical dysplasia. Uterine instrumentation, such as dilation and curettage, also has been associated with an increased risk for preterm birth in some, but not all, studies; the mechanism is unclear, but it may be a result of intrauterine microbial colonization, injury to the endometrium, or both, together with host and environmental factors.[29]

Prevention of Preterm Labor

Antenatal screening for risk factors for preterm labor and delivery is of value only if interventions are available that can decrease the frequency of preterm delivery and improve neonatal outcome.[29] Unfortunately, few if any interventions have been shown to definitively reduce these outcomes. Interventions that have been studied include detection and suppression of uterine contractions, antimicrobial therapy, prophylactic cervical cerclage, maternal nutritional supplements, and reduction of maternal stress.[20] It is not surprising that most of these simple interventions have not been shown to alter outcome, given that preterm labor is increasingly understood to be a complex syndrome with multiple, overlapping causes.[20]

Prophylactic **cervical cerclage** in the early second trimester has been performed to prevent preterm birth, typically in women with a history of mid-trimester pregnancy loss. Evidence that supports the efficacy of this practice is weak.[36] There remains controversy with regard to whether cerclage should be placed in response to transvaginal ultrasonographic evidence of a short cervix in the second half of the mid trimester. Data do not support such a practice in a general population,[37] but there is some evidence that such a practice may be beneficial among high-risk women, such as those with a prior preterm birth.[38]

Evidence does *not* support the administration of **prophylactic antibiotics** in asymptomatic women at risk for preterm labor.[39] Likewise, evidence does not support the prophylactic use of **beta-adrenergic receptor agonists** to prevent preterm labor in high-risk women.[40]

In contrast, evidence suggests that **progesterone** therapy may be effective in reducing the rate of preterm birth in some patient populations. The Maternal-Fetal Medicine Units Network performed a randomized controlled trial that compared prophylactic intramuscular 17α-hydroxyprogesterone caproate (17P) (250 mg weekly beginning at 16 to 20 weeks' gestation, and continued until delivery or 36 weeks' gestation) with placebo in women with a history of spontaneous preterm delivery.[41] The risk for delivery before 37 weeks' gestation was reduced in the 17P group (relative risk [RR], 0.66; 95% confidence interval [CI], 0.54 to 0.81). Similarly, da Fonseca et al.[42] demonstrated a decreased risk for preterm delivery (< 34 weeks' gestation) in high-risk women randomly assigned to receive either vaginal progesterone (100 mg daily) or placebo. A systematic review of 11 randomized controlled trials (n = 2425) also concluded that progesterone administration was associated with a significant reduction in recurrent preterm birth in women with a history of spontaneous preterm delivery.[43]

Progesterone therapy also has been shown to be efficacious in preventing preterm delivery among women with a short cervix identified by transvaginal ultrasonography. In two double-blind, placebo-controlled trials, women with a mid-trimester diagnosis of a short cervix (< 15 mm in one trial[44] and 10 to 20 mm in the other[45]) were randomized to receive either vaginal progesterone or placebo. Women who received vaginal progesterone experienced a significant reduction in the frequency of preterm delivery before 33 weeks' gestation.[44,45] In contrast, in a trial that enrolled nulliparous women with a cervical length less than 30 mm, women randomized to receive 17P did not experience a reduction in preterm delivery compared with women who received placebo.[46]

A number of studies have examined whether progesterone is efficacious in reducing preterm birth among women with multiple gestation. Uniformly, progesterone therapy has *not* been shown to be beneficial in this population.[47-49]

Even among women for whom progesterone is thought to be indicated, the optimal type, timing, and dosing of progesterone is unclear. Based on existing evidence, the American College of Obstetricians and Gynecologists (ACOG)[29] has concluded that vaginal progesterone should be offered to asymptomatic women with a singleton gestation without a previous preterm delivery, who have a very short cervical length (i.e., ≤ 20 mm at or before 24 weeks' gestation).

Diagnosis

Determining whether a woman is in early preterm labor or in false labor is often difficult. Criteria for the diagnosis of preterm labor include gestational age between 20 0/7 and 36 6/7 weeks' gestation and regular uterine contractions accompanied by a change in cervical dilation, effacement, or both (or initial presentation with regular contractions and cervical dilation of 2 cm or more).[19] Less than 10% of women with the clinical diagnosis of preterm labor actually give birth within 7 days of presentation.[19]

Assessment and Therapy

Initial assessment of the patient with possible preterm labor includes physical examination and external monitoring of contractions with a tocodynometer (and fetal heart

rate if indicated by the gestational age). Acute conditions associated with preterm labor should be considered, including infection and placental abruption. Maternal physical examination may include a sterile speculum examination to exclude preterm PROM if symptoms or signs indicate this possibility. In many women who have preterm uterine contractions, these contractions will cease spontaneously. In the past, clinicians assumed that intravenous hydration was a useful component of therapy. However, there is no evidence that intravenous hydration reduces the chance of preterm delivery.[50]

Once the diagnosis of preterm labor is established, the obstetric care provider must decide whether intervention is warranted. The therapeutic agents currently thought to be associated with improved neonatal outcomes include antenatal maternal corticosteroid administration to accelerate maturation of fetal lungs and other developing organ systems, and the targeted use of magnesium sulfate for fetal neuroprotection (see later discussion).[51,52] Although widely used before 34 weeks' gestation, acute tocolytic therapy remains a source of controversy. There is no consistent evidence that the use of acute tocolysis reduces the chance of preterm birth or improves neonatal outcome. However, because acute tocolysis has been associated with a short (approximately 48 hour) prolongation of pregnancy, it may be used to facilitate transfer of the patient from a community hospital to a tertiary care facility that can provide optimal care for the preterm neonate. Moreover, a short course of tocolytic therapy may delay delivery for 24 to 48 hours, allowing maternal administration of (1) a corticosteroid to accelerate fetal lung maturity and (2) antibiotic therapy to prevent neonatal group B streptococcal infection. Thus, the ACOG has supported the use of acute tocolysis to allow administration of a complete course of antenatal corticosteroids, but the ACOG discourages the continued use of tocolysis after corticosteroid administration is complete.[19]

Criteria for the use of tocolytic therapy include (1) gestational age after viability and before 34 weeks' gestation, (2) reassuring fetal status, and (3) no overt clinical signs of infection. The potential benefits of delaying delivery of the preterm infant (i.e., decreased neonatal morbidity and mortality) must be weighed against the maternal and fetal risks (e.g., maternal side effects of tocolytic drugs, deterioration of a compromised fetus). Box 34-2 lists contraindications to the inhibition of labor.

In the setting of preterm PROM, obstetricians have worried that tocolytic therapy might increase the risk for maternal and/or fetal infection. It also seems logical that tocolytic therapy is less effective in patients with preterm PROM. Prospective, randomized studies have shown that tocolytic therapy does not improve neonatal outcome compared with conservative expectant management in patients with preterm PROM.[53]

Antenatal Administration of Corticosteroids

The neonatal benefits of corticosteroid administration (Table 34-3) before preterm delivery have been clearly demonstrated in large clinical trials. The NICHD Neonatal Research Network evaluated outcomes for 11,718 preterm infants delivered after antenatal maternal corticosteroid administration between 1988 and 1992. Antenatal corticosteroid treatment significantly reduced the incidence of neonatal respiratory distress syndrome, intraventricular hemorrhage, and neonatal death in all subgroups of the population studied (including male and female infants, African and Caucasian race infants, and infants delivered before 30 weeks' gestation).[54] The reduction in neonatal morbidity and mortality from antenatal corticosteroid administration is additive to the reduction observed with the use of neonatal surfactant alone.[55]

Although there is little controversy about the efficacy of a single course of antenatal corticosteroids, there remains debate over the use of multiple courses of corticosteroids for women who remain undelivered 7 days after the initial dose of corticosteroids. A 2001 review[56] and a National Institutes of Health (NIH) consensus panel statement[57] did not recommend multiple courses of corticosteroids; however, both documents cited some evidence of their possible benefit. These documents also identified possible risks, including a higher incidence of neonatal infection and potentially deleterious effects on neuronal and organ growth.[56,57] A large study performed by the Maternal-Fetal Medicine Units Network randomly assigned women at risk for preterm delivery between 23 and 32 weeks' gestation to receive either a single course or repeated (weekly) courses of antenatal corticosteroids.[58] Weekly corticosteroid administration did not significantly reduce the composite primary morbidity outcome, but it significantly reduced the need for neonatal surfactant, mechanical ventilation, and continuous positive airway pressure (CPAP), as well as the incidence of pneumothorax. In contrast, weekly corticosteroid administration was associated with an increase in the delivery of SGA infants, and there was a significant reduction in the birth weight of the infants whose mothers received four or more courses of corticosteroids.

BOX 34-2 Contraindications to Tocolytic Therapy for Preterm Labor

- Fetal death
- Fetal anomalies incompatible with life
- Nonreassuring fetal status
- Chorioamnionitis
- Severe hemorrhage

Modified from Muir HA, Wong CA. Preterm labor and delivery. In Chestnut DH, Tsen LC, Polley LS, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

TABLE 34-3 Antenatal Corticosteroid Therapy

Drug	Dose and Route	Frequency/Duration
Betamethasone	12 mg IM	Every 24 h × 2
Dexamethasone	6 mg IM	Every 12 h × 4

IM, intramuscular.

From National Institutes of Health Consensus Development Panel. Antenatal corticosteroids revisited: Repeat courses—National Institutes of Health Consensus Development Conference Statement, August 17-18, 2000. Obstet Gynecol 2001; 98:144-50.

To balance the potential beneficial effects and risks of additional courses of corticosteroids, some have advocated for a *single* "rescue" course (i.e., a second course of corticosteroids), which is administered at the time of a second episode of preterm labor with a high probability of preterm delivery. One randomized trial demonstrated that additional neonatal benefit could be derived from a single "rescue" course of corticosteroids.[59] The investigators reserved this intervention for patients with intact membranes, whose antecedent corticosteroid treatment had been given at least 2 weeks before the "rescue" course, whose gestational age was less than 33 weeks, and who were judged by the clinician as likely to give birth within the next week. A meta-analysis[60] concluded that a single "rescue" course of antenatal corticosteroids should be considered in women whose prior course of antenatal corticosteroids was administered at least 7 days previously and who were at acute risk for preterm delivery before 34 weeks' gestation. The ACOG[51] has stated that one "rescue" course of corticosteroids may be considered in these specific populations. However, regularly scheduled repeat courses or multiple courses (more than two) of corticosteroids are not currently recommended.[51]

Antibiotic Therapy

The results of a large multicenter randomized controlled trial[61] and a meta-analysis[62] do *not* support the use of prophylactic antibiotic therapy in the management of preterm labor in patients with intact membranes as a method to reduce the likelihood of preterm birth. In fact, in one study that assessed long-term outcome for offspring born to women who participated in a randomized placebo-controlled trial of antibiotic administration in the setting of preterm labor, children born to women who received antibiotic treatment had more functional health impairment.[63] Accordingly, the ACOG[19] does not recommend empirical antibiotic therapy in this population. It should be noted, however, that prophylactic antibiotic administration remains appropriate in women who are positive for group B streptococcus (GBS) and who are thought to be in preterm labor.[64]

In contrast, in patients with preterm PROM, randomized controlled trials and a meta-analysis have concluded that antimicrobial therapy prolongs pregnancy and reduces both maternal and neonatal morbidity.[65,66] Thus, when preterm PROM is diagnosed, the ACOG[67] recommends a 7-day course of antimicrobial therapy; the best antibiotic regimen is not known with certainty, although intravenous ampicillin and erythromycin (48 hours), followed by oral amoxicillin and erythromycin (5 days), is a commonly used regimen for women with preterm PROM who are receiving expectant management.[67]

Neuroprotection

Several clinical trials have provided evidence that maternal administration of magnesium sulfate provides fetal neuroprotection when given to women at risk for preterm delivery. In 2003, Crowther et al.[68] reported the results of a multicenter randomized, placebo-controlled study of 1062 women (1255 infants) at less than 30 weeks' gestation, in whom delivery was planned or expected within 24 hours. The investigators observed no significant difference between groups in the primary outcomes, which included total pediatric mortality, cerebral palsy, or both, at a corrected age of 2 years. However, they observed a significantly reduced rate of substantial gross motor dysfunction, as well as a reduced combined rate of death or substantial gross motor dysfunction, in the children exposed to magnesium sulfate *in utero*.[68] Similarly, a randomized controlled trial of magnesium sulfate administration in 573 pregnant women at less than 33 weeks' gestation, and in whom delivery was planned or expected within 24 hours, found that infants exposed to magnesium sulfate had a reduced rate of total neonatal mortality, severe cerebral white matter injury (which is associated with cerebral palsy), and the combination of severe white matter injury and/or death, but the differences were not statistically significant.[69] In the largest randomized trial,[70] 2241 women at imminent risk for delivery before 32 weeks' gestation were randomized to receive magnesium sulfate or placebo. The offspring who had been exposed to magnesium sulfate *in utero* were significantly less likely to develop moderate/severe cerebral palsy (1.9% versus 3.5%; RR, 0.55; 95% CI, 0.32 to 0.95).[70]

A recent meta-analysis has synthesized the data from the clinical trials and suggests that prenatal administration of magnesium sulfate reduces the occurrence of cerebral palsy when given with neuroprotective intent (RR, 0.71; 95% CI, 0.55 to 0.91).[71] The ACOG[52] recently stated that, based on available evidence, magnesium sulfate—given before anticipated early preterm birth—reduces the risk for cerebral palsy in surviving infants. Because the best regimen of magnesium sulfate administration remains unclear, physicians electing to use magnesium sulfate for fetal neuroprotection should develop specific guidelines regarding inclusion criteria, treatment regimens, concurrent tocolysis, and monitoring based on the protocols of the larger published trials.[52]

Selection of Tocolytic Agents

Once the obstetrician has decided to begin tocolytic therapy, an appropriate agent must be selected (Table 34-4). (Each specific class of tocolytic agent is discussed in detail later in this chapter.) A 2003 analysis of studies that compared the four classes of tocolytic agents currently in use (i.e., beta-adrenergic receptor agonists, calcium entry–blocking agents, magnesium sulfate, and nonsteroidal anti-inflammatory drugs [NSAIDs]) concluded that all are more effective than placebo in prolonging pregnancy, but the investigators found no evidence of a beneficial effect on neonatal morbidity or mortality.[72] A more recent analysis suggested that magnesium sulfate specifically is not efficacious and should not be used for tocolysis.[73]

Physiology of Uterine Contractions

The contractile elements in myometrial smooth muscle consist of thick (myosin) and thin (actin) filaments that interact and slide past one another, generating the contractile force for uterine contractions. The myometrium

TABLE 34-4 **Tocolytic Drugs for Preterm Labor**

Drug	Contraindications	Maternal Side Effects	Fetal/Neonatal Side Effects
Calcium entry–blocking agents	Cardiac disease Renal disease (use with caution) Maternal hypotension	Transient hypotension, flushing, headache, dizziness, nausea	None identified
Cyclooxygenase inhibitors (NSAIDs)	Significant renal or hepatic impairment Active peptic ulcer disease Coagulation disorders or thrombocytopenia NSAID-sensitive asthma Other NSAID sensitivities	Nausea, heartburn	Constriction of the ductus arteriosus, pulmonary hypertension, reversible renal dysfunction (leading to oligohydramnios), IVH,* hyperbilirubinemia, necrotizing enterocolitis*
Beta-adrenergic receptor agonists	Cardiac dysrhythmias Poorly controlled thyroid disease Poorly controlled diabetes mellitus	*Cardiopulmonary:* dysrhythmias, pulmonary edema, myocardial ischemia, hypotension, tachycardia *Metabolic:* hyperglycemia, hyperinsulinemia, hypokalemia, antidiuresis, altered thyroid function *Other:* tremor, palpitations, nervousness, nausea/vomiting, fever, hallucinations	*Fetal:* tachycardia, hyperinsulinemia, hyperglycemia, myocardial and septal hypertrophy, myocardial ischemia *Neonatal:* tachycardia, hypoglycemia, hypocalcemia, hyperbilirubinemia, hypotension, IVH
Magnesium sulfate	Myasthenia gravis Myotonic dystrophy	Flushing, lethargy, headache, muscle weakness, diplopia, dry mouth, pulmonary edema, cardiac arrest	Lethargy, hypotonia, respiratory depression, demineralization (prolonged use)

IVH, intraventricular hemorrhage; *NSAIDs,* nonsteroidal anti-inflammatory drugs.
*Data are conflicting as to whether cyclooxygenase inhibitors increase risk.

Modified from Hearne AE, Nagey DA. Therapeutic agents in preterm labor: tocolytic agents. Clin Obstet Gynecol 2000; 43:787-801.

has pacemaker cells with spontaneous contractile ability, which spread activity throughout the rest of the uterus by means of gap junctions between myometrial cells. Myometrial contractions are preceded by a rise in intracellular calcium concentration through the influx of calcium across the sarcolemma and/or release from internal stores such as the sarcoplasmic reticulum. Hormones and neurotransmitters may play a role in the regulation of uterine activity by causing agonist-induced entry of calcium or other ions by means of receptor-controlled channels and the release of calcium from internal stores.[74]

The rise in intracellular calcium results in the formation of a complex between calcium and calmodulin (a regulatory enzyme), which activates myosin light-chain kinase (MLCK). Activated MLCK then phosphorylates the light-chain subunit of myosin, allowing actin to bind to myosin and activate myosin adenosine triphosphatase. Adenosine triphosphate (ATP) is then hydrolyzed, and muscle shortening or contraction results. Relaxation of smooth muscle results from a reduction in the intracellular calcium concentration and/or dephosphorylation of the myosin light chain by myosin light-chain phosphatase. Increases in intracellular cyclic adenosine monophosphate (cAMP) also can result in muscle relaxation by two mechanisms: (1) activation of a cAMP-dependent protein kinase, which decreases the activity of MLCK; and (2) a reduction of the intracellular calcium concentration.

The control of labor and the processes for signaling its onset are complex and incompletely understood. During pregnancy, the uterus remains in a state of functional quiescence as a result of the activity of various inhibitors, including progesterone, prostacyclin, relaxin, nitric oxide, parathyroid hormone–related peptide, corticotropin-releasing hormone, human placental lactogen, calcitonin gene–related peptide, adrenomedullin, and vasoactive intestinal peptide (Figure 34-5).[25] Before term the uterus goes through an activation phase in response to uterotropins, including estrogen. This activation phase is characterized by (1) greater expression of a series of contraction-associated proteins (including myometrial receptors for prostaglandins and oxytocin), (2) activation of certain ion channels, and (3) an increase in connexin-43 concentration. Once activated, the uterus can be stimulated to contract by the action of uterotonics such as oxytocin and prostaglandins E_2 and $F_{2\alpha}$. A parturition cascade likely removes the mechanisms that have maintained uterine quiescence and recruits factors that promote uterine activity.

Once the uterus has been "activated," endocrine, paracrine, and autocrine factors from the fetoplacental unit initiate a change in the pattern of uterine activity from irregular to regular contractions. Evidence from animal models suggests that the fetus may coordinate this change in activity through (1) its influence on the production of placental steroid hormones, (2) mechanical distention of the uterus, and (3) secretion of neurohypophyseal hormones and other stimulators of prostaglandin synthesis. The final common pathway for labor in all species is thought to be the activation of the fetal hypothalamic-pituitary-adrenal axis. Of interest, however, is the observation that spontaneous labor occurs in women with an

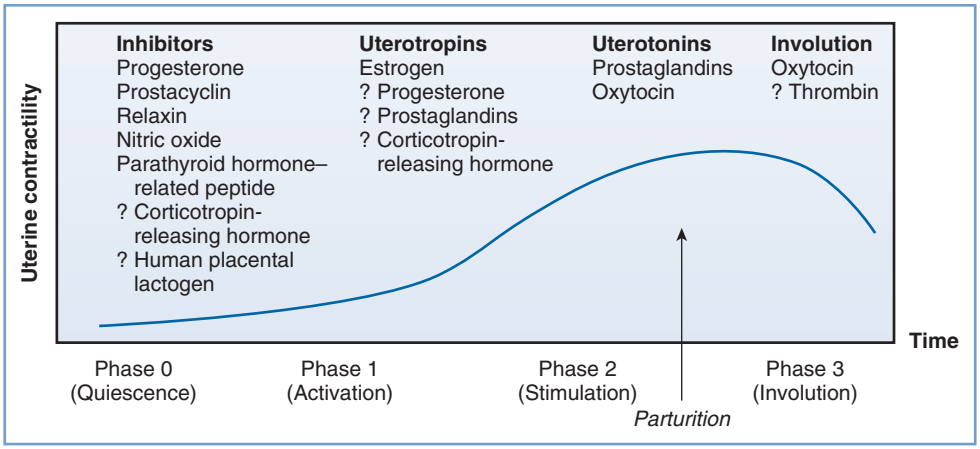

FIGURE 34-5 ■ The regulation of uterine activity during pregnancy and labor can be divided into four distinct physiologic phases—quiescence, activation, stimulation, and involution—that are, or may be, influenced by a number of stimulatory and inhibitory factors. (From Liao JB, et al. Normal labor: mechanism and duration. Obstet Gynecol Clin North AM 2005; 32:146; adapted from Challis JRG, Gibb W. Control of parturition. Prenat Neonat Med 1996; 1:283.)

anencephalic fetus (with no residual pituitary/adrenal function), suggesting that intact neurohypophyseal function is not a prerequisite for the onset of human labor.[75]

Preterm labor may result from a loss of inhibitory factors on uterine quiescence or may represent a short-circuiting of the normal parturition cascade through the overproduction of a critical factor. As the understanding of the physiology of uterine activity increases, the approach to both predicting and treating preterm labor will become more focused. Multimodal therapy may become a standard, given that evidence now suggests that labor is initiated by the interaction of multiple factors.

Significant attention has focused on the role of progesterone in parturition. In nonhuman mammals, the onset of labor is associated with progesterone withdrawal.[75] Although the understanding of its role in human labor remains incomplete, a number of isoforms of the progesterone receptor (PGR) have been identified. One isoform, PGR-B, may play a role in quiescence, whereas another, PGR-A, may act to initiate functional progesterone withdrawal. PGR-A receptors are increasingly expressed with the onset of labor. In concert with the increase in PGR-A relative to PGR-B, an increase in estrogen receptor transcripts is observed. This change may lead to an increase in estrogen responsiveness. A third isoform, PGR-C, may also contribute to antagonism of uterine quiescence. Through a complex interplay of co-regulators such as cAMP, progesterone receptors seem to be responsible for both uterine quiescence and the stimulation of the onset of labor.[75]

Gap junctions facilitate the propagation of electrical impulses and movement of small molecules between cells. Gap junction protein alpha-1 (GJA1, or connexin-43) is one of the main protein components of myometrial gap junctions. The appearance of gap junctions in myometrium is thought to herald the onset of labor.[75] GJA1 expression is stimulated by estradiol and is inhibited by progesterone. Microarray studies of human myometrium (i.e., preterm myometrium, term myometrium not in labor, term myometrium in labor) have added to the knowledge of the genetic modulation that occurs during pregnancy and labor.[76] Differential expression of 118 genes has been identified. A process of remodeling and maturation of the uterus, and the differential expression of the genes that regulate this process, are evident throughout gestation. Further work is needed to fully elucidate the signaling pathways that contribute to human labor.[76]

Efficacy of Tocolytic Therapy

There is general consensus that acute tocolytic therapy for the treatment of preterm labor offers only limited benefit and does not reduce the rate of preterm birth.[77] A meta-analysis suggested that **calcium entry–blocking agents** such as nifedipine are as efficacious as beta-adrenergic receptor agonists, with fewer maternal and fetal side effects.[78] The mechanism of action is thought to be inhibition of voltage-dependent calcium channels, which results in decreased calcium influx into smooth muscle cells, as well as decreased release of intracellular calcium stores into the myoplasm.

The **beta-adrenergic receptor agonists** (e.g., ritodrine, terbutaline) have been widely used as tocolytic agents for many years but have fallen out of favor because other tocolytic agents (e.g., nifedipine, oxytocin antagonists) are equally efficacious with fewer side effects.[78,79] Intravenous ritodrine, for example, is no longer marketed in the United States. Beta-adrenergic receptor agonists relax smooth muscle via β_2-adrenergic receptor stimulation. A 2004 meta-analysis included 17 studies, 11 of which compared beta-adrenergic agonists with placebo.[80] Use of beta-adrenergic agonists reduced the number of women who delivered within 48 hours, but there was no decrease in the number of births within 7 days or in perinatal death or neonatal morbidity. Tocolysis was significantly associated with adverse maternal side effects (see Table 34-4). In 2011, the United States Food and Drug Administration (FDA) issued a warning regarding terbutaline use. Specifically, it stated that *injectable* terbutaline should not be used in pregnant women for prolonged treatment (beyond 48 to 72 hours) of preterm labor in either the hospital or outpatient setting because

of the potential for serious maternal heart problems and death. It also warned that oral terbutaline should not be used for prevention or treatment of preterm labor because it had not been shown to be effective and was associated with similar safety concerns.[81]

Prostaglandins are mediators in the final pathways of uterine contraction. They increase intracellular calcium concentrations, increase activation of MLCK, and promote gap junction formation.[19] The nonselective **cyclooxygenase inhibitor** indomethacin is the agent in this class most often studied as a tocolytic agent. Serious maternal side effects are uncommon. Fetal concerns, in particular in the setting of prolonged use (> 48 hours), include a risk for constriction of the ductus arteriosus and oligohydramnios (due to fetal renal dysfunction).

The **oxytocin receptor antagonist** atosiban has received attention as a tocolytic agent. Although available in Europe, the drug was not approved by the FDA because of a higher rate of fetal deaths in the atosiban arm of a randomized controlled trial.[82] However, this finding may have been due to an imbalance in the number of women less than 26 weeks' gestation who were randomly assigned to receive atosiban. A 2005 meta-analysis concluded that atosiban did not achieve a lower rate of preterm birth than placebo or beta-adrenergic agonists. Several small, randomized controlled trials comparing atosiban with nifedipine have suggested that the drugs are equally efficacious for acute tocolysis.[83,84]

Magnesium sulfate also has been used as a tocolytic agent. A 2002 meta-analysis of nine high-quality randomized controlled trials that compared magnesium with placebo concluded that magnesium is ineffective in delaying or preventing preterm birth.[73]

The **nitric oxide donor** nitroglycerin has also been studied. A meta-analysis suggested that nitroglycerin does not delay delivery or improve neonatal outcome in comparison with placebo or other tocolytic agents.[85]

The ACOG[77] has stated that evidence supports the use of tocolytic treatment with beta-adrenergic agonist therapy, calcium entry–blocking agents, or NSAIDs for short-term prolongation of pregnancy (up to 48 hours) to allow for antenatal maternal corticosteroid administration. Multiple clinical trials have demonstrated that prolonged use of tocolytic agents (as prophylactic therapy or after completion of acute treatment) does not alter outcome. No matter which tocolytic agent is chosen, the risk for side effects increases when more than one tocolytic agent is administered simultaneously. Thus, combining tocolytic agents is not routinely recommended.

THE PRETERM INFANT

Physiology

Several, but not all, studies have suggested that the incidence of intrapartum acidosis is greater in the preterm fetus than in the term fetus.[86,87] The preterm fetus has lower hemoglobin concentration and oxygen-carrying capacity than a term fetus.[86] Nonetheless, these characteristics do not translate into a higher risk for intrapartum fetal neurologic injury.

Preterm infants are at risk for a number of complications, including respiratory distress syndrome, hyperbilirubinemia, necrotizing enterocolitis, intraventricular hemorrhage, perinatal infection, retinopathy of prematurity, patent ductus arteriosus, pulmonary hypertension, water and electrolyte imbalances, acid-base disturbances, anemia, and hypoglycemia.[2] In the long term, preterm infants also are more likely to experience adverse outcomes such as bronchopulmonary dysplasia, reactive airway disease, failure to thrive, cerebral palsy, neurodevelopmental delay, hearing loss, blindness, pulmonary hypertension, adult hypertension, and impaired glucose regulation.[2]

Method of Delivery

Evidence does not support a conclusion that routine cesarean delivery of preterm infants improves outcome. Malloy et al.[88] analyzed birth and death certificate information from Missouri for the years 1980 to 1984. The cesarean delivery rate for VLBW infants (500 to 1499 g) rose from 24% to 44%. During the same period, the cesarean delivery rate increased from 21% to 26% for infants weighing 1500 to 2499 g and from 14% to 18% for infants weighing 2500 g or more. The first-day death rates were significantly higher among the smallest infants (weighing 500 to 749 g) that were delivered vaginally than among those delivered by cesarean (59% and 33%, respectively), although this finding may very well be related to confounding by indication (i.e., cesarean delivery was more likely to be deferred for those judged to have the least chance of survival). In contrast, the mortality rates for the two methods of delivery for these infants did not differ after the first 6 days of life. There was no association between the method of delivery and first-day death rates for infants weighing between 750 and 1500 g. The investigators concluded that the use of cesarean delivery did *not* improve overall survival for VLBW infants.

Malloy et al.[89] later reviewed the incidence of intraventricular hemorrhage and neonatal mortality in 1765 VLBW infants admitted to seven neonatal intensive care units between 1987 and 1988. After adjusting the data for gestational age at birth and other maternal and fetal factors, these investigators concluded that cesarean delivery did not lower the risk for either mortality or intraventricular hemorrhage for infants who weighed less than 1500 g at birth.

A systematic review of six randomized controlled trials comparing elective with selective cesarean delivery for preterm infants (n = 122) found no difference in outcomes between groups, although the confidence intervals were wide because of the small number of patients included in the analysis.[90] A retrospective analysis of 2466 VLBW preterm infants in the state of Washington between 1994 and 2003 did not demonstrate any benefit of cesarean delivery for improving survival.[91] In a study published in 2012, Reddy et al.[92] examined neonatal outcomes by attempted route of delivery for singleton births that occurred between 24 0/7 and 31 6/7 weeks' gestation. Among women who delivered between 24 0/7 and 27 6/7 weeks' gestation with a vertex presentation, 77.2%

attempted vaginal delivery (85% success rate) with the remainder undergoing scheduled cesarean delivery. No difference was observed in neonatal mortality or other adverse neonatal outcomes between the two groups. Similarly, when examining outcomes in women with a vertex presentation between 28 0/7 and 31 6/7 weeks' gestation, no difference in neonatal mortality was found in women who attempted vaginal delivery compared with those who underwent planned cesarean delivery.[92]

Aside from operative risks in the index pregnancy, preterm cesarean delivery may increase maternal risk in subsequent pregnancies. In an observational study that involved 26,454 women with previous cesarean delivery, the Maternal-Fetal Medicine Units Network noted that women with a prior *preterm* cesarean delivery were at higher risk for uterine rupture than women with a prior *term* cesarean delivery (odds ratio [OR], 1.6; 95% CI, 1.01 to 2.50; $P = .043$).[93]

Most obstetricians perform cesarean delivery for the delivery of VLBW singleton fetus in a breech presentation.[88,89] Head entrapment behind an incompletely dilated cervix is more common in preterm singleton fetuses with a breech presentation because the head is larger than the wedge formed by the buttocks and thighs. Similarly, cesarean delivery has been recommended for preterm twins in whom the presenting fetus has a nonvertex presentation, although there are no prospective, controlled studies to support this practice.[94] The management of preterm twins when twin A is vertex and twin B is nonvertex is more controversial; there are no good data from clinical trials, and the results from observational studies suffer from potential selection bias.[95] Thus, a definitive recommendation regarding whether a breech second twin should be delivered by cesarean remains elusive; it seems reasonable that practitioners with experience can individualize care, taking into account the clinical circumstances, and offer certain patients the option of delivering preterm twins vaginally if the first twin has a vertex presentation.

The survival rate remains low for infants with a birth weight between 500 and 750 g. In these cases, obstetricians must decide whether to recommend cesarean delivery for fetal indications, such as in cases of nonreassuring fetal status or breech presentation. The neonatologist is frequently asked to speak with the patient about the risk for neonatal morbidity and mortality so that the patient can make an informed decision about the method of delivery. Regardless of the mode of delivery, if resuscitation is planned, additional support personnel (ideally a neonatologist and a neonatal resuscitation team) should be prepared and present for the delivery.

Ethical Issues

The antenatal maternal administration of corticosteroids, the application of advanced neonatal ventilation techniques, the use of neonatal surfactant therapy, and the use of extracorporeal membrane oxygenation (ECMO) have reduced mortality and morbidity for preterm neonates. However, below a certain gestational age (i.e., < 23 0/7 weeks), survival is not typically possible and the relationship between new treatments and reduced mortality is not relevant. Around the time when survival becomes at least possible, the chance of survival, and particularly survival without long-term major adverse outcomes, remains low and difficult to predict for any individual neonate. These uncertainties often lead to controversy about the decision to resuscitate (or not resuscitate) a preterm infant. Parents, obstetricians, and neonatologists should all be involved in the decision-making process.

Anesthesia providers may find themselves in the middle of these ethical dilemmas if they are practicing in a location at which the anesthesia provider is responsible for neonatal resuscitation. Although no firm rules exist, some basic principles can be applied. First, the parents should have a critical role in the decision-making process. Second, as much data as possible should be obtained to provide a prognostic assessment. Third, discussion of these issues ideally should be held before delivery, not in the moment of crisis. The ACOG[95] has published general recommendations about the care of infants on the threshold of viability but has not made specific recommendations for neonatal resuscitation on the basis of gestational age. In contrast, the Canadian Paediatric Society and the Society of Obstetricians and Gynaecologists of Canada have issued relatively specific recommendations.[96] For an infant born at 22 to 23 weeks' gestation, they suggest that resuscitation efforts be initiated only if uncertainty about gestational age exists or fully informed parents request that resuscitation be performed. For an infant born at 23 to 24 weeks' gestation, resuscitation can be offered as long as parents are informed of the need to reassess this decision at critical intervals and possibly withdraw therapy. For an infant born at 25 weeks' gestation, full resuscitation in the absence of lethal anomalies is recommended.[96] The American Heart Association and the American Academy of Pediatrics have stated that, with few exceptions, resuscitation is not indicated if the infant is delivered at less than 23 completed weeks' gestation or with a birth weight less than 400 g.[97] Revised neonatal resuscitation guidelines have addressed the ethical issues of non-initiation or discontinuation of resuscitation in the delivery room.[16,97] In some cases, a trial of therapy may be appropriate, but such a trial does not always mandate continued support.

Fetal Heart Rate Monitoring

Most obstetricians use continuous electronic fetal heart rate (FHR) monitoring once preterm labor becomes established and the gestational age and circumstances are consistent with the possibility of neonatal survival. Preterm gestation may complicate the interpretation of FHR patterns, given that the FHR pattern of preterm fetuses may have relatively decreased variability and magnitude of accelerations compared with the FHR pattern of term fetuses.[98]

The value of continuous electronic FHR monitoring over intermittent auscultation of the FHR remains controversial. Luthy et al.[99] performed a randomized trial comparing continuous electronic FHR monitoring (with selective fetal blood gas assessment) with periodic auscultation of the FHR during preterm labor in women with fetuses weighing between 700 and 1750 g. There was no

significant difference between groups in the incidence of cesarean delivery, low 5-minute Apgar scores, intrapartum acidosis, intracranial hemorrhage, or perinatal death. At 18 months of age, the incidence of cerebral palsy was significantly higher in the electronic FHR group than in the intermittent auscultation group (20% versus 8%, respectively).[100]

ANESTHETIC MANAGEMENT

Anesthesia providers often participate in the care of preterm parturients. Many women who deliver preterm request neuraxial analgesia for labor and vaginal delivery. These patients may also require cesarean delivery, for example, in situations of nonreassuring fetal status, and may require urgent administration of anesthesia.

Conventional wisdom holds that the preterm fetus is more vulnerable than the term fetus to the depressant effects of analgesic and anesthetic drugs, for the following reasons: (1) less protein available for drug binding, leading to a reduction in protein-drug affinity; (2) higher levels of bilirubin, which may compete with the drug for protein binding; (3) greater drug access to the central nervous system (CNS) because of the presence of an incomplete blood-brain barrier; (4) decreased ability to metabolize and excrete drugs; and (5) a higher incidence of acidosis during labor and delivery.[87,101] However, few controlled studies have documented the maternal and fetal pharmacokinetics and pharmacodynamics of anesthetic agents throughout gestation. The preterm fetus may be less vulnerable to the depressant effects of local anesthetics than originally thought. The human fetal liver cytochrome P450 system is present as early as 14 weeks' gestation and has the capability to oxidize several drugs.[102,103]

Teramo et al.[104] noted that the amount of lidocaine necessary to produce seizure activity in preterm fetal lambs was greater than that required in older fetal lambs. These investigators also observed that the cardiovascular response to lidocaine (i.e., increases in blood pressure and heart rate) was less severe in fetuses with a younger gestational age. Pedersen et al.[105] evaluated the effects of gestational age on the pharmacokinetics and pharmacodynamics of lidocaine in gravid ewes and fetal lambs. They studied two groups of animals, preterm (119 ± 1 days' gestation or 0.8 of term pregnancy) and near-term (138 ± 1 days' gestation or 0.95 of term pregnancy). They administered an intravenous infusion of lidocaine to obtain a maternal steady-state plasma concentration of 2 μg/mL. Transplacental transfer of lidocaine did not adversely affect fetal cardiac output, organ blood flow, or blood gas and acid-base measurements in either group. Tissue uptake of lidocaine was similar in the two groups of fetal lambs, except that it was greater in the lungs and liver of the term fetuses. The investigators concluded that there was no significant difference in the pharmacokinetics and pharmacodynamics of lidocaine between the two gestational ages studied.[105]

Smedstad et al.[106] also concluded that there was no difference in fetal blood pressure, heart rate, or blood gas measurements in response to maternal intravenous infusion of lidocaine or bupivacaine between early preterm (119 days' gestation) and late preterm (132 days' gestation) fetal lambs. In addition, the plasma concentrations of bupivacaine and lidocaine and the fetal-to-maternal ratios of both drugs were similar in the two groups of fetuses.

None of these studies evaluated the effects of anesthetic agents on the acidotic preterm fetus. Asphyxia may increase the risk for adverse effects by causing the following changes in the fetal environment: (1) reduced plasma protein-binding capacity (which increases the proportion of free drug available)[107]; (2) greater maternal-fetal hydrogen ion difference, which causes "ion trapping" of weak bases (e.g., amide local anesthetics, opioids) on the fetal side of the circulation[108]; (3) greater blood-brain barrier permeability[109]; and (4) enhanced susceptibility to the myocardial depressant effects of local anesthetics.[110,111]

Morishima et al.[110] subjected a group of preterm fetal lambs (0.8 of term gestation) to asphyxia by causing partial occlusion of the umbilical cord. They subsequently administered either lidocaine or saline-control intravenously to the gravid ewes for 180 minutes. The mean (± SD) maternal and fetal steady-state plasma lidocaine concentrations were 2.32 ± 0.12 and 1.23 ± 0.17 μg/mL, respectively. (These concentrations are similar to those that occur during administration of epidural anesthesia in humans.) Umbilical cord occlusion resulted in the typical fetal compensatory response to hypoxia (i.e., decreased FHR and increased blood flow to the fetal brain, heart, and adrenal glands). Maternal administration of saline-control did not result in additional deterioration of the fetus. However, maternal administration of lidocaine resulted in a significant increase in $Paco_2$, and decreases in pH, mean arterial pressure (MAP), and blood flow to the brain, myocardium, and adrenal glands. Thus, lidocaine attenuated the normal fetal compensatory response to asphyxia.

In an earlier study, the same investigators observed that lidocaine did not affect the fetal compensatory response to asphyxia in term fetuses.[111] They concluded that "the immature fetus loses its cardiovascular adaptation to asphyxia when exposed to clinically acceptable plasma concentrations of lidocaine obtained transplacentally from the mother."[110] Limitations of this study include (1) a failure to compare the fetal response to lidocaine with the response to other anesthetic, analgesic, or sedative drugs and (2) consideration of only the effects of a steady-state concentration of lidocaine in the presence of asphyxia. That is, the investigators did not evaluate the potential benefits derived from epidural anesthesia, such as reduced maternal concentrations of catecholamines and the ability of epidural anesthesia to facilitate a controlled, atraumatic delivery of the preterm infant.

Bupivacaine has a low fetal-to-maternal plasma concentration ratio because of its relatively high (96%) maternal protein binding; therefore, the potential for fetal toxicity seems minimal.[101] Studies of the effects of bupivacaine on the compensatory response to asphyxia in preterm fetal lambs have demonstrated results similar to those seen with lidocaine. Santos et al.[112] observed that bupivacaine abolished the compensatory increase in blood flow to vital organs in asphyxiated preterm fetal lambs. However, bupivacaine did not affect fetal heart rate, blood pressure, or acid-base measurements. The investigators

suggested that these changes were less severe than those seen with lidocaine in their earlier study.[110,112]

Ropivacaine and bupivacaine have almost identical dissociation constants (pK_B of 8.0 and 8.2, respectively), but ropivacaine's protein binding is slightly less than that for bupivacaine (92% versus 96%, respectively), and it is substantially less lipid soluble than bupivacaine.[113] These differences may affect maternal and fetal free plasma concentrations of drug. Investigators have documented higher maternal and fetal plasma concentrations with ropivacaine than with bupivacaine.[114,115] Studies suggest that ropivacaine is less cardiotoxic than bupivacaine. However, no study has evaluated the effect of ropivacaine on the fetal compensatory response to hypoxia.

2-Chloroprocaine also is a good choice of local anesthetic in preterm patients because it is rapidly metabolized in both the maternal plasma and fetal plasma.[116] Further, placental transfer of 2-chloroprocaine is not increased by fetal acidosis.[117]

Vaginal Delivery

Neither pudendal nerve block nor local infiltration of the perineum provides profound relaxation of the levator ani and bulbocavernosus muscles. Thus, for women in whom more profound analgesia is desired, either for elective or medical indications, neuraxial analgesia is the technique of choice during labor and vaginal delivery.

Neuraxial analgesia decreases maternal concentrations of catecholamines, and in some patients, it may improve uteroplacental perfusion as long as hypotension is avoided.[118] No prospective, controlled studies have evaluated the effect of neuraxial analgesia on preterm infant outcome. The timing of the intrapartum administration of neuraxial analgesia in preterm parturients may be problematic for several reasons. First, there may be uncertainty as to whether women who have contractions are in labor. Second, even women with a clear diagnosis of preterm labor often have a prolonged latent phase of labor, with or without the use of tocolytic agents. Third, once active labor begins, patients often progress though labor very quickly. Thus, in some cases, it may be appropriate to establish neuraxial analgesia even before it is clear that a preterm delivery will soon occur. An advantage of early initiation of neuraxial analgesia is the ability to rapidly convert labor analgesia to surgical anesthesia if emergency cesarean delivery should be necessary.

Cesarean Delivery

Administration of general anesthesia for preterm cesarean delivery is similar to that for parturients at term (see Chapter 26). Most anesthetic agents that are used for induction and maintenance of general anesthesia cross the placenta. If cesarean delivery is necessary, conventional wisdom holds that it is preferable to give either epidural or spinal anesthesia to avoid the depressant effects of agents given for general anesthesia. Rolbin et al.[119] observed that preterm infants exposed to epidural anesthesia for cesarean delivery had higher 1- and 5-minute Apgar scores than similar infants exposed to general anesthesia. Laudenbach et al.[120] performed a secondary analysis of prospectively gathered data from a population-based cohort study of all deliveries before 33 weeks' gestation in nine regions in France in 1997 (n = 1338). Of concern, after controlling for known confounders, infants born by cesarean delivery to mothers who received spinal anesthesia had a higher mortality rate than those born to mothers who received general or epidural anesthesia (adjusted OR, 1.7; 95% CI, 1.1 to 2.6).[120] However, the authors noted that the secondary analysis of a preexisting database did not allow them to adjust for confounders known to affect anesthetic outcome (e.g., intraoperative hypotension, choice of vasopressor, fluid management). Nonetheless, for these high-risk births, it seems reasonable that anesthesia providers should pay meticulous attention to maternal hemodynamic variables regardless of the type of anesthesia that is administered.

Many anesthesiologists have considered the maternal administration of supplemental oxygen during cesarean delivery essential, regardless of the choice of anesthetic technique. Recent studies, however, have questioned this practice. Fetal or neonatal hyperoxia may lead to production of oxygen free radicals that ultimately may result in neuronal damage.[121] Investigators have not demonstrated any clear improvement in neonatal outcome with maternal supplemental oxygen administration, even after a prolonged uterine incision-to-delivery interval.[122,123] Currently, it is not clear whether the maternal administration of supplemental oxygen affects neonatal outcome.

Some data from animal studies have suggested that exposure of the immature brain to anesthetic agents such as propofol, thiopental, ketamine, and inhalation agents can trigger significant brain cell apoptosis in the developing fetal/neonatal brain and cause functional learning deficits later in life.[124,125] However, in these animal studies, the duration of exposure to anesthetic agents was much longer than is typical for cesarean delivery in humans. Whether clinical exposure to anesthetic agents during general anesthesia for cesarean delivery results in clinically significant brain cell apoptosis in humans remains to be determined (see Chapters 10 and 17).

In summary, at the current time there is no evidence to support altering the anesthetic technique for cesarean delivery merely because the infant is preterm. Further study is necessary to determine whether one technique (e.g., spinal or epidural) or specific drug(s) (e.g., ephedrine or phenylephrine) have specific risks or benefits relative to the preterm infant.

INTERACTIONS BETWEEN TOCOLYTIC THERAPY AND ANESTHESIA

Indications for Anesthesia during and after Tocolytic Therapy

There are several situations in which obstetric patients require analgesia or anesthesia during or after tocolytic therapy. First, preterm labor may progress and delivery may occur despite tocolysis. In this case, the patient may desire pain relief during labor and vaginal delivery or may require anesthesia for cesarean delivery. Second, some

obstetricians give a tocolytic agent before and during the performance of cervical cerclage. Third, some obstetricians advocate the bolus injection of a tocolytic agent when there is a tetanic uterine contraction or tachysystole in the setting of an FHR abnormality. Fourth, many obstetricians administer tocolysis when attempting external cephalic version, a procedure that may also involve the request for neuraxial analgesia.

Calcium Entry–Blocking Agents

Among this class of drugs, **nifedipine** has undergone the most extensive evaluation as a tocolytic agent. Many obstetricians have suggested that calcium entry–blocking drugs should become first-line therapy in the treatment of preterm labor because of their low incidence of significant maternal and fetal side effects. Typical nifedipine dose regimens for preterm labor are listed in Table 34-5.

Mechanism of Action

Calcium entry–blocking drugs act by blocking the aqueous voltage-dependent cell membrane channels that are selective for calcium. They also act by preventing calcium release from the sarcoplasmic reticulum. The net result is a decrease in available intracellular calcium, which inhibits MLCK activity. This inhibition leads to decreased actin-myosin interaction, which results in relaxation of smooth muscle (including myometrial smooth muscle).[126,127]

Side Effects

Nifedipine has fewer side effects than beta-adrenergic receptor agonists. Hypotension is the most common side effect. Other side effects include headache, flushing, dizziness, and nausea.[128] Most effects are mild, but pulmonary edema[129] and myocardial infarction[130] have been reported after calcium entry–blocking agent therapy for preterm labor.

Although early animal studies noted that nifedipine and nicardipine decreased uterine blood flow and resulted in fetal hypoxemia and acidosis,[131,132] clinical studies have suggested that short-term administration of nifedipine does not adversely affect the uteroplacental or fetal circulation.[133,134]

Anesthetic Management

Although nifedipine has fewer effects on cardiac conduction than some of the other calcium entry–blocking agents, it has the potential to cause vasodilation, hypotension, myocardial depression, and conduction defects when used in combination with one of the volatile halogenated anesthetic agents.[135] One report noted that administration of both nifedipine and magnesium sulfate was associated with neuromuscular blockade in a preeclamptic patient at 28 weeks' gestation.[136]

Cyclooxygenase Inhibitors

Indomethacin is the prototype cyclooxygenase inhibitor used for tocolysis. Both **sulindac** and **ketorolac** also have been evaluated and found to be effective. Typical doses of this class of medication used for tocolysis are listed in Table 34-5.

Mechanism of Action

Cyclooxygenase inhibitors inhibit cyclooxygenase and thus prevent the synthesis of prostaglandins from the precursor, arachidonic acid. Prostaglandins E_2 and $F_{2\alpha}$ play an important role in the stimulation of uterine contractions by increasing intracellular calcium and activation of MLCK and promoting gap junction formation.[19]

Side Effects

Maternal side effects from indomethacin are minimal when it is used for tocolytic therapy. Indomethacin does not alter maternal heart rate or blood pressure. The most common complaints are nausea and heartburn.[137] Inhibition of cyclooxygenase results in decreased production of thromboxane A_2 and abnormal platelet aggregation. In contrast to aspirin, which permanently inhibits cyclooxygenase and therefore inhibits platelet aggregation for the lifetime of the platelet (7 to 10 days), indomethacin and other cyclooxygenase inhibitors reversibly inhibit cyclooxygenase; thus, their effect on platelet function is only transient.[138]

Maternal administration of a cyclooxygenase inhibitor may cause premature closure of the ductus arteriosus *in utero*. Indomethacin is often used to promote closure of the ductus arteriosus in the preterm neonate.[137] Moise et al.[139] used fetal echocardiography to evaluate the fetal response to short-term (< 72 hours) indomethacin therapy. They observed evidence of transient ductal

TABLE 34-5 Tocolytic Dose Regimens for Preterm Labor

Drug	Initiation Dose	Maintenance Dose
Nifedipine	20-30 mg PO	10-20 mg every 4-6 h
Cyclooxygenase inhibitors (NSAIDs)*:		
Indomethacin	50-100 mg PO or per rectum	25-50 mg every 4 h
Ketorolac	60 mg IM	30 mg every 6 h
Sulindac	200 mg PO	200 mg every 12 h
Terbutaline†	0.25 mg SQ	0.25 mg every 20 min to 3 h
Magnesium sulfate	4-6 g IV bolus over 20 min	2-4 g/h continuous IV infusion

IM, intramuscularly; *IV,* intravenously; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PO,* per os (orally); *SQ,* subcutaneously.
*NSAID administration should be limited to 48 to 72 hours and restricted to gestations < 32 weeks.
†Terbutaline is given until uterine quiescence occurs or maternal heart rate reaches 120 bpm.
Data from references 19 and 143. Modified from Muir HA, Wong CA. Preterm labor and delivery. In Chestnut DH, Tsen LC, Polley LS, Wong CA, editors. Chestnut's Obstetric Anesthesia. 4th edition. Philadelphia, Mosby, 2009.

constriction in 7 of 14 fetuses between 26 and 31 weeks' gestation. Tricuspid regurgitation was also noted in three fetuses. These changes were reversed within 24 hours of discontinuation of indomethacin. Clinical studies suggest that indomethacin is less likely to cause intrauterine closure of the ductus arteriosus at earlier gestational ages.[137,140-142] Also, studies suggest that adverse neonatal effects (including closure of the ductus arteriosus) are unlikely if indomethacin is used in short courses (e.g., 24 to 48 hours).[137,141,142] For example, investigators[142] retrospectively analyzed fetal echocardiograms performed in 44 patients with preterm labor or polyhydramnios who were treated with indomethacin. The frequency of ductal constriction was relatively low (5% to 10%) until 32 weeks' gestation, when it rose to approximately 50%. Vermillion et al.[142] concluded that ductal constriction can occur at any gestational age but that it is reversible with early identification followed by timely discontinuation of indomethacin therapy.

Indomethacin administration may result in fetal oligohydramnios secondary to decreased fetal urine output.[143] Kirshon et al.[144] noted reduced fetal urine output after short-term[145] and long-term (15 to 28 days) maternal administration of indomethacin for tocolytic therapy. Amniotic fluid volume reaccumulated within 1 week after the discontinuation of indomethacin. Indomethacin may be used to treat polyhydramnios in selected cases. One proposed mechanism for the decrease in fetal urine output is an enhanced antidiuretic hormone effect after inhibition of cyclooxygenase.[146] Wurtzel[147] evaluated renal function during the first 10 postnatal days in 14 preterm infants exposed to indomethacin *in utero* and in 10 control infants. This investigator found that maternal administration of indomethacin did not significantly alter neonatal renal function.

Data are conflicting as to whether maternal cyclooxygenase inhibitor administration increases the risk for adverse neonatal outcomes, including intraventricular hemorrhage and necrotizing enterocolitis. A 2005 meta-analysis concluded that maternal administration of indomethacin at less than 34 weeks' gestation did not lead to an increased risk for adverse events.[148] However, the investigators cautioned that the significant heterogeneity in study design makes it difficult to draw definitive conclusions.

The current recommendation for use of cyclooxygenase inhibitors is to limit the course of therapy to less than 72 hours. This approach may delay delivery and allow maternal administration of corticosteroids to accelerate fetal lung maturity.

Anesthetic Management

The effects of indomethacin on platelet function are transient. Several large studies have demonstrated the safety of epidural and spinal anesthesia in patients receiving low-dose aspirin or one of a variety of cyclooxygenase inhibitors.[149-151] The Consensus Conference on Neuraxial Anesthesia and Anticoagulation (sponsored by the American Society of Regional Anesthesia and Pain Medicine) concluded that such therapy is not a contraindication to administration of neuraxial anesthesia.[152]

Beta-Adrenergic Receptors Agonists

In the past, **ritodrine** and **terbutaline,** among other agents, were commonly used beta-adrenergic tocolytic agents; however, their use has declined substantially. Maternal side effects continue to be a limiting factor in their use.[80]

Mechanism of Action

All beta-adrenergic tocolytic drugs have both β_1-receptor and β_2-receptor effects, but in different proportions. β_2-Receptors are found in smooth muscle (uterus, blood vessels, bronchi, intestine, detrusor, and spleen capsule), adipose tissue, liver, skeletal muscle, pancreas, and salivary glands. Ritodrine and terbutaline are relatively selective for β_2-receptors; stimulation of these receptors in the myometrium results in relaxation of uterine smooth muscle. Unfortunately, other undesired β_2-adrenergic agonist effects (e.g., vasodilation) and β_1-effects still occur. β_1-Receptors are located predominantly in the heart and adipose tissue. β_1-Receptor stimulation has clinically significant cardiovascular side effects, such as increased maternal heart rate and cardiac output.[153]

Beta-adrenergic agonists interact with β_2-receptor sites on the outer membrane of uterine myometrial cells, activating the enzyme adenyl cyclase. This enzyme catalyzes the conversion of ATP to cAMP, causing a rise in the intracellular concentration of cAMP. The higher cAMP concentration decreases the available intracellular concentration of calcium and inhibits MLCK activity. This inhibition, in turn, decreases the interaction between actin and myosin, resulting in myometrial relaxation.[143]

Treatment Regimen

Before beginning tocolytic therapy with a beta-adrenergic agonist, the obstetrician should determine baseline maternal vital signs and weight and exclude significant cardiovascular or pulmonary disease. Prolonged administration results in down-regulation (or desensitization) of the myometrial β_2-receptors.[154] There is no evidence that a continuous long-term infusion of terbutaline alters outcome.[155]

Side Effects

The administration of beta-adrenergic tocolytic therapy may result in the following maternal side effects: (1) hypotension; (2) tachycardia, with or without cardiac arrhythmias and myocardial ischemia; (3) pulmonary edema; (4) hyperglycemia; and (5) hypokalemia.[143] The reported frequency of these side effects has varied. Earlier studies reported an incidence of 2% to 9%.[156,157] However, Perry et al.[158] performed a retrospective review of outcomes for 8709 patients who had received a low-dose, continuous infusion of terbutaline. These investigators noted adverse cardiopulmonary effects in only 47 of 8709 patients, an incidence of 0.54%.

Other uncommon maternal side effects reported with the use of beta-adrenergic agents are elevations in serum transaminase levels,[159] paralytic ileus,[160] cerebral

vasospasm in patients with a previous history of migraine,[161] and respiratory arrest due to increased muscle weakness in a patient with myasthenia gravis.[162]

Anesthetic Management

It would seem ideal to delay administration of anesthesia until maternal tachycardia subsides. A delay of 15 minutes often results in slowing of the maternal heart rate. However, advanced labor, an abnormal presentation, and/or nonreassuring fetal status often require emergency administration of anesthesia. Published reports of anesthetic management after administration of a beta-adrenergic agent are scarce.[163-167] Ravindran et al.[165] reported one case each of intraoperative pulmonary edema, sinus tachycardia, and ventricular arrhythmia during general anesthesia in patients who had received terbutaline therapy immediately before or 15 minutes after the induction of anesthesia. These investigators recommended that induction of general anesthesia be delayed at least 10 minutes after discontinuation of the beta-adrenergic agent.

Chestnut et al.[168] performed a controlled study to determine whether administration of ritodrine worsens maternal hypotension during epidural anesthesia in gravid ewes. Prior administration of ritodrine did not worsen maternal hypotension during epidural lidocaine anesthesia in gravid ewes.

Theoretically, induction of epidural analgesia or anesthesia after beta-adrenergic agonist therapy may cause less hemodynamic compromise than spinal anesthesia because of the slower onset of sympathetic blockade. However, this theory remains unproven. Patients receiving beta-adrenergic agonist therapy are at risk for development of pulmonary edema (as discussed earlier). Therefore, aggressive hydration should be avoided before and during the induction of anesthesia in these patients.

If general anesthesia is required in a patient who has recently received beta-adrenergic tocolysis, agents that might exacerbate maternal tachycardia (e.g., atropine, glycopyrrolate, pancuronium) should be avoided. Residual maternal tachycardia may make it more difficult to assess volume status and depth of anesthesia. Halothane, which sensitizes the myocardium to catecholamine-induced arrhythmias, should not be used. Hyperventilation should be avoided, because it may exacerbate hypokalemia and potentiate the hyperpolarization of the cell membrane. In nonpregnant patients, Slater et al.[169] found that terbutaline pretreatment shortened the onset time and recovery of succinylcholine-induced neuromuscular blockade. It seems prudent to monitor neuromuscular function with a peripheral nerve stimulator during general anesthesia.

Oxytocin Antagonists

Atosiban (1-deamino-2-D-Tyr-[OEt]-4-Thr-8-Orn-vasotocin/oxytocin) is an oxytocin antagonist. It is a competitive inhibitor of oxytocin that binds to both myometrial and decidual receptors. It does not alter the subsequent sensitivity of the myometrium to oxytocin.[170] Clinically, this feature represents a major advantage; it should reduce the risk for postpartum uterine atony and hemorrhage.

Phase II and III studies have shown that atosiban is an effective tocolytic agent.[82,171-175] It has few maternal side effects, undergoes minimal placental transfer, and does not increase maternal blood loss at delivery.[82,171] Studies have suggested that atosiban has efficacy similar to that of beta-adrenergic agonists[174,175] and nifedipine[176] in obtaining and maintaining uterine quiescence. However, a meta-analysis of studies comparing atosiban with either placebo or beta-adrenergic agonists did not demonstrate that atosiban resulted in a reduction in preterm birth or improved neonatal outcome,[177] although side effects were fewer with atosiban. The FDA has not approved atosiban for use in the United States because of a higher rate of perinatal deaths in the atosiban arm of the study that it reviewed.[82]

There are no data on the interaction between atosiban and anesthetic agents. However, given the hemodynamic profile of this agent, one would not expect significant interactions. Atosiban is widely used in Europe.

Magnesium Sulfate

Mechanism of Action

Extracellular magnesium functions as a competitive antagonist of calcium either at the motor end plate or cell membrane, thus reducing calcium influx into the myocyte.[19,143] It also competes with calcium for low-affinity calcium-binding sites on the outside of the sarcoplasmic reticulum membrane and prevents the rise in free intracellular calcium concentration. Hypermagnesemia results in abnormal neuromuscular function. Magnesium also decreases the release of acetylcholine at the neuromuscular junction and the sensitivity of the end plate to acetylcholine.

Side Effects

Most studies have reported that magnesium sulfate results in less frequent and less severe cardiovascular side effects than the beta-adrenergic tocolytic agents.[178-180] Nonetheless, magnesium sulfate may have side effects similar to those that occur during beta-adrenergic tocolytic therapy. Chest pain and tightness, palpitations, nausea, transient hypotension, blurred vision, sedation, and pulmonary edema have been reported.[179,180] Hypermagnesemia may attenuate the normal compensatory responses to hemorrhage in the mother and fetus.[181,182]

Magnesium is eliminated almost entirely by renal excretion. Therefore, patients with abnormal renal function should be monitored carefully if they receive magnesium sulfate.

Anesthetic Management

It has been suggested that magnesium sulfate should be discontinued before the administration of epidural anesthesia because magnesium may increase the likelihood of hypotension through its generalized vasodilating properties. Vincent et al.[183] observed that magnesium sulfate

reduced maternal mean arterial pressure but not uterine blood flow or fetal oxygenation during epidural lidocaine anesthesia in gravid ewes. This study suggests that hypermagnesemia may increase the likelihood of modest hypotension during neuraxial anesthesia in normotensive parturients.

Magnesium attenuates the release of acetylcholine at the neuromuscular junction, reduces the sensitivity of the end plate to acetylcholine, and decreases the excitability of the muscle membrane. The drug potentiates the action of both depolarizing and nondepolarizing muscle relaxants.[184] A defasciculating dose of a nondepolarizing muscle relaxant should not be given before administration of succinylcholine in hypermagnesemic women. A standard intubating dose of muscle relaxant (e.g., succinylcholine 1 mg/kg) should be used because the extent of potentiation by magnesium sulfate is variable.[185] However, a lower dose of a nondepolarizing muscle relaxant should be administered during the maintenance of anesthesia.

Parturients receiving magnesium sulfate often appear sedated. Thompson et al.[186] evaluated the anesthetic effects of magnesium sulfate and ritodrine on the minimum alveolar concentration of halothane in pregnant and nonpregnant rats and reported a 20% decrease with serum magnesium levels of 7 to 11 mg/dL. A more detailed discussion of magnesium sulfate and its interactions with anesthetic agents is found in Chapter 36.

KEY POINTS

- Despite improved antenatal care, the incidence of preterm delivery in the United States remains approximately 12%.
- Preterm birth is a leading cause of neonatal mortality. Survivors have an increased chance of disability.
- Spontaneous preterm labor or preterm premature rupture of membrane (preterm PROM) account for the majority of preterm births.
- Treatment with tocolytic therapy may prolong labor by up to 48 hours, facilitate transfer of the patient from a small community hospital to a tertiary care facility, and delay delivery to allow maternal administration of a corticosteroid to accelerate fetal lung maturity. Long-term tocolytic therapy does not improve neonatal outcome.
- Nifedipine and indomethacin are still used commonly to treat preterm labor in the United States. The oxytocin antagonist atosiban is widely used in Europe. Magnesium sulfate has been widely used as a tocolytic agent in the United States, but it may be falling out of favor because of failure to demonstrate efficacy. Magnesium sulfate is now considered beneficial when it is used specifically for neuroprotection in reducing rates of cerebral palsy in preterm infants. Terbutaline is associated with a relatively high incidence of maternal and fetal side effects.
- Side effects of beta-adrenergic tocolytic therapy include (1) hypotension; (2) tachycardia, with or without cardiac arrhythmias and myocardial ischemia; (3) pulmonary edema; (4) hyperglycemia; and (5) hypokalemia. Pulmonary edema is the most serious complication, and it may be life threatening.
- Prior administration of a beta-adrenergic tocolytic agent does not contraindicate the administration of neuraxial anesthesia.
- Cyclooxygenase inhibitors reversibly inhibit cyclooxygenase, resulting in a transient effect on platelet function. However, their use does not necessitate the assessment of platelet or coagulation function before administration of neuraxial analgesia/anesthesia in a patient whose only risk factor for bleeding is recent ingestion of a cyclooxygenase inhibitor.

CHAPTER 35

Abnormal Presentation and Multiple Gestation

Joy L. Hawkins, MD • BettyLou Koffel, MD

CHAPTER OUTLINE

The labor and delivery of a parturient with a multiple gestation and/or fetal breech presentation represents a major challenge for the obstetrician and the anesthesia provider. Anesthetic requirements may change from moment to moment, and an obstetric emergency may necessitate immediate intervention. All members of the perinatal care team must communicate directly and clearly with each other as well as with the parturient and her family to ensure the best possible outcome for both the mother and the neonate(s).

The **presentation** denotes that portion of the fetus that overlies the pelvic inlet. In most cases, the fetal presenting part can be palpated through the cervix during a vaginal examination. The presentation may be **cephalic**, **breech**, or **shoulder**. Breech and shoulder presentations occur with increased frequency in patients with multiple gestation. Cephalic presentations are further subdivided into **vertex**, **brow**, and **face** presentations according to the degree of flexion of the neck. With an **asynclitic** presentation, the fetal head is tilted toward one shoulder and the opposite parietal eminence enters the pelvic inlet first.

The **lie** refers to the alignment of the fetal spine with the maternal spine. The fetal lie can be either longitudinal or transverse. A fetus with a vertex or breech presentation has a longitudinal lie. A persistent oblique or transverse lie typically requires cesarean delivery.

The **position** of the fetus denotes the relationship of a specific fetal bony point to the maternal pelvis. The position of the **occiput** defines the position for vertex presentations. Other markers for position are the **sacrum** for breech presentations, the **mentum** for face presentations, and the **acromion** for shoulder presentations. The **attitude** of the fetus describes the relationship of the fetal parts with one another; the term is typically used to refer to the position of the head with regard to the trunk, as in flexed, military, or hyperextended.

ABNORMAL POSITION

During normal labor, the fetal occiput rotates from a transverse or oblique position to a direct **occiput anterior** position. In a minority of patients with an oblique posterior position, the occiput rotates directly posteriorly and results in a **persistent occiput posterior** position. The occiput posterior position may lead to a prolonged labor that is associated with increased maternal discomfort. Less often, the vertex remains in the **occiput transverse** position; this condition is known as **deep transverse arrest**.

In the past, obstetricians performed manual or forceps rotation to hasten delivery and lessen perineal trauma in women with an abnormal position of the vertex. Today, many obstetricians are reluctant to perform rotational forceps delivery for fear of causing excessive maternal and/or fetal trauma. In cases of persistent occiput posterior position, the contemporary obstetrician is more likely to allow the head to remain in the occiput posterior position at vaginal delivery. Only 29% of nulliparous women and 55% of parous women with a persistent occiput posterior position will achieve spontaneous vaginal delivery.[1] Some cases of persistent occiput

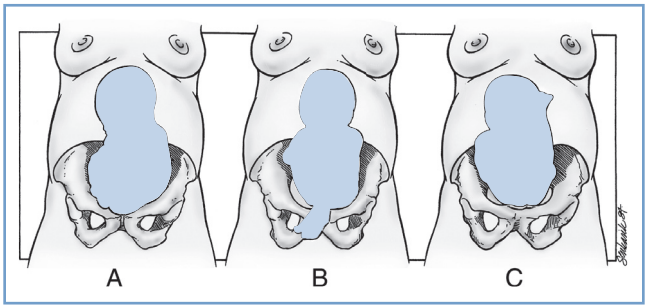

FIGURE 35-1 ■ Three possible breech presentations. **A,** The *complete breech* demonstrates flexion of the hips and flexion of the knees. **B,** The *incomplete breech* demonstrates intermediate deflexion of one or both hips and knees. **C,** The *frank breech* shows flexion of the hips and extension of both knees. (From Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:396.)

posterior position, and many cases of deep transverse arrest, require cesarean delivery because of dystocia.

During administration of epidural analgesia to a patient with an abnormal position, the addition of a lipid-soluble opioid to a dilute solution of local anesthetic is particularly useful. This combination provides analgesia while preserving pelvic muscle tone. Relaxation of the pelvic floor and perineum may prevent the spontaneous rotation of the vertex during labor.[2] In contrast, profound pelvic floor relaxation is needed to facilitate instrumental vaginal delivery with forceps.

BREECH PRESENTATION

Breech presentation describes a longitudinal lie in which the fetal buttocks and/or lower extremities overlie the pelvic inlet. Figure 35-1 shows the three varieties of breech presentation:

- **Frank breech**—lower extremities flexed at the hips and extended at the knees
- **Complete breech**—lower extremities flexed at both the hips and the knees
- **Incomplete breech**—one or both of the lower extremities extended at the hips

Ultrasonographic or radiographic examination typically allows the obstetrician to confirm the type of breech presentation and to exclude the presence of associated severe congenital anomalies (e.g., anencephaly). The type of breech presentation may influence the obstetrician's decision regarding the mode of delivery. The fetus with a frank breech presentation tends to remain in that presentation throughout labor. In contrast, a complete breech presentation may change to an incomplete breech presentation at any time before or during labor.

Epidemiology

The breech presentation is the most common of the abnormal presentations. Both the incidence and the type of breech presentation vary with gestational age (Table 35-1). Before 28 weeks' gestation, approximately 25% of fetuses are in a breech presentation.[3] Most change to a vertex presentation by 34 weeks' gestation, but 3% to 4% of fetuses remain in a breech presentation at term.[3]

Many factors predispose to breech presentation (Box 35-1).[4] Abnormalities of the fetus or the maternal pelvis or uterus may play a role. Among patients with pelvic or uterine abnormalities, a breech presentation may allow more room for fetal growth and movement. Likewise, hydrocephalic fetuses are more likely to assume a breech presentation. Multiparity, multiple gestation, polyhydramnios, and anencephaly also predispose to breech presentation. These conditions may interfere with the normal process of accommodation between the fetal head and the uterine cavity and maternal pelvis. Other factors may also play a role. In a prospective cohort study, low

TABLE 35-1 Types of Breech Presentation

Type of Breech	Percentage of All Breech Presentations	Percentage of Preterm Gestation Breech Presentations
Frank	48-73	38
Complete	5-12	12
Incomplete	12-38	50

Modified from Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012: 396.

BOX 35-1 Factors Associated with Breech Presentation

Uterine Distention or Relaxation
- Multiparity
- Multiple gestation
- Hydramnios
- Macrosomia

Abnormalities of the Uterus or Pelvis
- Pelvic tumors
- Uterine anomalies
- Pelvic contracture

Abnormalities of the Fetus
- Hydrocephalus
- Anencephaly

Obstetric Conditions
- Previous breech delivery
- Preterm gestation
- Oligohydramnios
- Cornual-fundal placenta
- Placenta previa

Modified from Cunningham FG, Leveno KJ, Bloom SL, et al. In Williams Obstetrics. 22nd edition. New York, McGraw-Hill, 2005:565-86; and Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:396-407.

TABLE 35-2 Incidence of Complications Associated with Breech Presentation

Complication	Incidence
Intrapartum fetal death	Increased 16-fold*
Intrapartum asphyxia	Increased 3.8-fold*
Umbilical cord prolapse	Increased 5- to 20-fold*
Birth trauma	Increased 13-fold*
Arrest of aftercoming head	4.6%-8.8%
Spinal cord injuries with deflexion	21%
Major congenital anomalies	6%-18%
Preterm delivery	16%-33%
Hyperextension of head	5%

*Compared with cephalic presentation.
Modified from Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:401.

TABLE 35-3 Risk for Umbilical Cord Prolapse

Type of Breech	Risk for Cord Prolapse (%)
Frank	0.5
Complete	4-6
Incomplete	15-18

Modified from Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:396.

free thyroid hormone (T_4) levels at 12 weeks' gestation were associated with breech presentation at term.[5]

Obstetric Complications

Obstetric complications are more likely with a breech presentation (Table 35-2). Cesarean delivery decreases the risk for some of these complications. Vaginal breech delivery entails a higher risk for neonatal trauma than delivery of an infant with a vertex presentation, but cesarean delivery does not eliminate the risk for trauma to the infant.[6] Rather, cesarean delivery of a breech presentation can be difficult and traumatic, especially if the skin and uterine incisions are insufficient or maternal muscle relaxation is inadequate.

The risk for umbilical cord prolapse varies with the type of breech presentation (Table 35-3). In the parturient with an incomplete breech presentation, the presenting part does not fill the cervix as well as the vertex or buttocks, allowing the umbilical cord to prolapse into the vagina before delivery. Umbilical cord prolapse typically necessitates emergency cesarean delivery.

Morbidity and Mortality

There is a higher risk for **perinatal morbidity and mortality** with a breech presentation, even when the risk is adjusted for preterm gestation. The factors that cause breech presentation are often more important than the presentation itself. For example, the severe congenital anomalies that predispose to breech presentation (e.g., hydrocephalus, anencephaly) significantly contribute to neonatal morbidity and mortality. Relative perinatal mortality rates (calculated from data for linked siblings from the Medical Birth Registry of Norway) confirm that breech presentation is a marker of perinatal risk, regardless of the mode of delivery.[7] Both nonreassuring fetal heart rate (FHR) tracings and dystocia occur more commonly in patients with a term breech presentation, even those who have undergone successful external cephalic version.[8]

Vaginal breech delivery entails a higher risk for **maternal morbidity** (e.g., infection, perineal trauma, hemorrhage) than vertex delivery.[4] However, among women with a fetal breech presentation, maternal outcomes are similar between women who had a planned cesarean delivery and those who had a trial of labor. At 2 years postpartum, maternal morbidity assessed by questionnaire (917 responses for a 79% return) was not different for urinary incontinence, breast-feeding, pain, depression, menstrual problems, fatigue, and distressing memories of the birth experience.[9] In a single-center study of 846 singleton breech deliveries, Schiff et al.[10] also did not find a higher risk for maternal morbidity in women who underwent cesarean delivery during labor than in women who underwent planned cesarean delivery.

Obstetric Management

External Cephalic Version

The process of external cephalic version converts a breech or shoulder presentation to a vertex presentation. The average success rate for this procedure is 58%, with a wide range reported in published studies.[11,12] External cephalic version is most likely to be successful if (1) the presenting part has not entered the pelvis, (2) amniotic fluid volume is normal, (3) the fetal back is not positioned posteriorly, (4) the patient is not obese, (5) the patient is parous, and (6) the presentation is either frank breech or transverse.[13] Early labor does not preclude successful external cephalic version, but external cephalic version is rarely successful when the cervix is fully dilated or when the membranes have ruptured. No scoring system has been developed that reliably predicts which candidates will have a successful version attempt, although the variables just listed can be used when obtaining informed consent.

The optimal timing of external cephalic version is after 36 or 37 weeks' gestation, for the following reasons.[11,14] First, if spontaneous version to a vertex presentation is going to occur, it will likely happen by 36 or 37 weeks' gestation, and successful performance of external cephalic version after 37 weeks' gestation decreases the likelihood of reversion from a vertex to a breech presentation. Second, if complications occur during external cephalic version performed after 37 weeks'

gestation, emergency delivery will not result in delivery of a preterm infant.

Successful external cephalic version helps reduce the risk for perinatal morbidity and mortality associated with breech delivery. The American College of Obstetricians and Gynecologists (ACOG)[11] has suggested that "because the risk of an adverse event occurring as a result of external cephalic version is small and the cesarean delivery rate is significantly lower among women who have undergone successful version, all women near term with breech presentations should be offered a version attempt." Labor and vaginal delivery occur in the majority of patients who have undergone successful external cephalic version, albeit with an increased risk for intrapartum cesarean delivery because of dystocia or a nonreassuring FHR tracing.[15] A meta-analysis found that the intrapartum cesarean delivery rate was 27.6% after successful external cephalic version versus 12.5% in women with a spontaneous cephalic presentation.[15]

External cephalic version is associated with a low rate of morbidity in contemporary obstetric practice, although placental abruption and preterm labor have been reported.[11] Safe external cephalic version requires FHR monitoring and access to cesarean delivery services. In a systematic review of 84 studies that involved 12,955 women, complications included transient (6.1%) and persistent (0.22%) FHR abnormalities, vaginal bleeding (0.30%), placental abruption (0.08%), emergency cesarean delivery (0.35%), and stillbirth (0.19%).[12] Fetal-maternal hemorrhage is another potential complication of external cephalic version.[12] In one study, 16 of 89 (18%) patients undergoing external cephalic version had Kleihauer-Betke stains that signaled the occurrence of fetal-maternal hemorrhage.[16]

Obstetricians usually administer a tocolytic agent (e.g., terbutaline) before performing external cephalic version. A randomized placebo-controlled trial found that the success rate of version was doubled when terbutaline was given rather than placebo.[16] Several studies have shown a benefit to tocolysis only in nulliparous women.[11] A randomized controlled trial of intravenous nitroglycerin for tocolysis (100- to 300-μg bolus doses, up to a maximum total dose of 1000 μg) found that the success rate was 24% in nulliparous women who received nitroglycerin versus 8% in the placebo group.[17] The success rate was higher in parous women (43%), but it did not differ between the nitroglycerin and placebo groups.[17] Interestingly, the rates of hypotension were similar between groups. A Cochrane Review[18] found that tocolytic therapy for external cephalic version increases the number of women with a cephalic presentation at the onset of labor (relative risk [RR], 1.38; 95% confidence interval [CI], 1.03 to 1.85) and reduces the number of cesarean deliveries (RR, 0.82; 95% CI, 0.71 to 0.94).

Several studies have described the use of epidural or spinal analgesia or anesthesia for external cephalic version.[19] Maternal discomfort may be significant during external cephalic version; greater pain during the procedure is associated with a lower chance of success.[20] Some obstetricians argue that the absence of anesthesia limits the force that the obstetrician can apply during the procedure. They contend that administration of anesthesia may encourage the obstetrician to use excessive force, possibly increasing the risk for perinatal morbidity and mortality, but that concern is not supported by published evidence. In fact, spinal anesthesia reduces the force required for successful version.[21]

Weiniger et al.[22] randomly assigned 70 nulliparous women to receive either spinal anesthesia with bupivacaine 7.5 mg or no anesthesia for external cephalic version. The success rate was 67% in those receiving spinal anesthesia, 32% in those without analgesia, and 42% in those who did not consent to enroll in the study. A randomized controlled trial in parous women using similar methodology also found an increased success rate with spinal anesthesia (87% versus 58%).[23] In contrast, Sullivan et al.[24] randomized 96 parturients to receive either intrathecal bupivacaine 2.5 mg with fentanyl 15 μg as part of a combined spinal-epidural (CSE) technique or intravenous fentanyl 50 μg before attempted external cephalic version. There was no difference between groups in the rate of successful external cephalic version (47% with CSE analgesia and 31% with intravenous fentanyl) or vaginal delivery (36% versus 25%), although pain scores were lower and satisfaction scores were higher with CSE analgesia.

A meta-analysis of seven studies using neuraxial blockade to facilitate external cephalic version concluded that administration of an *anesthetic* dose of local anesthetic doubles the success rate of external cephalic version (RR, 1.95; 95% CI, 1.46 to 2.60), whereas an *analgesic* dose does not have any effect (RR, 1.18; 95% CI, 0.94 to 1.49).[25] A subsequent meta-analysis confirmed that neuraxial blockade increases the rate of successful version (60%) compared with no neuraxial block (38%); when the authors calculated the number needed to treat, they determined that five women must receive a neuraxial block to achieve one additional successful version.[19] There was no difference between groups in the rate of cesarean delivery; however, this second meta-analysis failed to distinguish between neuraxial anesthesia and analgesia, and it included at least one trial that allowed both vaginal breech delivery and spinal anesthesia for a subsequent version attempt among control patients who had a failed version.[19] Several investigators have reported successful outcomes with neuraxial analgesia or anesthesia in women in whom the first attempt at external cephalic version without neuraxial analgesia had been unsuccessful.[22,26] These patients elected to undergo another version attempt with neuraxial analgesia. Weiniger et al.[22] found that failure of external cephalic version was attributed to pain in 15 women in their control group. Eleven of those 15 (73%) women subsequently had successful external cephalic version with spinal analgesia. Cherayil et al.[26] reported successful version in 13 of 15 (87%) repeat procedures performed with neuraxial blockade.

In our practices, we do not routinely provide spinal or epidural analgesia during external cephalic version. However, emerging evidence suggests that it may help facilitate successful version and vaginal delivery. If a neuraxial technique is used, administration of an *anesthetic* dose of local anesthetic appears to result in higher success rates than use of an *analgesic* dose.

Mode of Delivery

A substantial number of obstetricians recommend the routine performance of cesarean delivery in patients with a breech presentation. The publication of the Term Breech Trial in 2000 changed clinical practice around the world.[6] In contemporary obstetric practice in the United States, most parturients with a breech presentation are delivered abdominally.

The Term Breech Trial Collaborative Group[6] enrolled 2088 women from 26 countries with a singleton fetus in a frank or complete breech presentation. These women were randomly assigned to undergo planned cesarean delivery or planned vaginal delivery. Using an intent-to-treat analysis, the investigators noted that perinatal and neonatal mortality rates, and serious neonatal morbidity, were significantly lower in the planned cesarean delivery group (1.6% versus 5%). This difference was greatest in those countries with a low perinatal mortality rate (e.g., Canada, United Kingdom, United States).[6] Secondary analysis of perinatal outcomes demonstrated that the lowest risk for adverse outcome occurred when a prelabor cesarean delivery was performed at term gestation. The risk for adverse outcome progressively increased with cesarean delivery performed during early labor and active labor and was highest with a vaginal birth. Labor augmentation and a longer time between the start of pushing and delivery were associated with an increased risk for adverse perinatal outcome, whereas the presence of an experienced clinician at delivery was associated with a reduced risk for adverse perinatal outcome.[27] Interestingly, in a 2-year follow-up study in some centers that participated in the Term Breech Trial there was no difference in the risk for death or neurodevelopmental delay between children delivered by planned cesarean and those delivered by planned vaginal delivery.[28] The following two factors may have contributed to the lack of significant differences in outcome at 2 years of age: (1) the sample size may have been inadequate, and (2) measures of early neonatal morbidity have a low predictive value for long-term outcomes (i.e., most children with early neonatal morbidity survive and develop normally).[28]

In the Term Breech Trial,[6] maternal morbidity and mortality did not differ between the two groups for the first 6 postpartum weeks. Women who underwent planned cesarean delivery were less likely to report urinary incontinence at 3 months[29]; however, there was no difference at 2 years.[9] As assessed by questionnaire, maternal outcomes at 2 years after delivery were similar after planned abdominal delivery and after planned vaginal delivery for singleton breech infants born at term.[9]

As a result of the Term Breech Trial, the number of planned vaginal breech deliveries has decreased in many regions of the world. For example, in Denmark, the proportion of singleton term breech infants delivered vaginally decreased abruptly from 20% before 1999 to 6% after 2001.[30] At the same time, intrapartum or early neonatal mortality among all term breech infants decreased from 0.13% to 0.05% (RR, 0.38; 95% CI, 0.15 to 0.98).[30] These kinds of trends are self-reinforcing. As the number of practitioners with experience in performing vaginal breech delivery has decreased, the number of vaginal breech deliveries available to teach obstetric residents may no longer be adequate.[31] Results from an Australian survey suggest that "few of the next generation of … obstetricians plan to offer vaginal breech delivery to their patients."[32]

Nevertheless, obstetricians in selected regions of the world retain a strong tradition of offering vaginal breech delivery for selected patients. Published in 2006, the PREsentation et MODe d 'Accouchement (PREMODA; presentation and mode of delivery) study[33] described birth outcomes for all term breech deliveries in 2001 through 2002 in 174 centers in France and Belgium. The study included 5579 women who planned cesarean breech delivery and 2526 women who planned vaginal breech delivery, of whom 1796 actually delivered vaginally.[33] The primary outcome captured a composite of fetal and neonatal mortality and serious morbidity and was not different between women who planned to undergo vaginal delivery (1.60%; 95% CI, 1.14 to 2.17) and women who planned to undergo cesarean delivery (1.45%; 95% CI, 1.16 to 1.81), with an overall odds ratio of 1.10 (95% CI, 0.75 to 1.61).[33] The authors suggested that rigorous adherence to protocols for patient selection, intrapartum fetal surveillance, and second-stage management contributed to improved outcomes for women attempting vaginal breech delivery.

In 2006, in recognition of results from the PREMODA study and other single-center descriptions of excellent outcomes for vaginal breech delivery, the American College of Obstetricians and Gynecologists (ACOG) made the following recommendations about mode of singleton breech delivery at term[31]:

- "The decision regarding the mode of delivery should depend on the experience of the health care provider. Cesarean delivery will be the preferred mode of delivery for most physicians because of the diminishing expertise in vaginal breech delivery."
- "Obstetricians should offer and perform external cephalic version whenever possible."
- "Planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines for both eligibility and labor management."
- "In those instances in which breech vaginal deliveries are pursued, great caution should be exercised, and detailed patient informed consent should be documented."
- "Before embarking on a plan for a vaginal breech delivery, women should be informed that the risk of perinatal or neonatal mortality or short-term serious neonatal morbidity may be higher than if a cesarean delivery is planned."

Although a planned trial of labor and vaginal breech delivery occurs uncommonly in most hospitals in North America and the United Kingdom, vaginal breech delivery still occurs because some patients present in advanced labor. Selection criteria such as those listed in Box 35-2 are used by advocates of a trial of labor and vaginal delivery.[4] The availability of personnel experienced in obstetric anesthesia and neonatal resuscitation are prerequisites for a trial of labor. Hyperextension of the fetal head

BOX 35-2 Criteria for a Trial of Labor and Vaginal Delivery for Patients with Fetal Breech Presentation

- Frank breech presentation
- Adequate pelvis by imaging pelvimetry
- Estimated fetal weight between 2000 and 3500 g by ultrasonography or by two experienced examiners
- Flexion of the fetal head (the neutral position—the so-called military position—is also acceptable)
- Continuous electronic fetal heart rate monitoring
- Spontaneous progression of labor, with timely effacement and dilation of the cervix and timely descent of the breech
- Availability of an individual skilled in vaginal breech delivery and an assistant
- Availability of an individual skilled in the administration of obstetric anesthesia
- Spontaneous delivery to the level of the umbilicus
- Ability to perform an abdominal delivery promptly
- Availability of an individual with skills in neonatal resuscitation

remains an absolute contraindication to a trial of labor in the patient with a breech presentation.[4]

Vaginal Breech Delivery

Several aspects of the conduct of breech labor differ from those for a vertex presentation. The cervix must be fully dilated before the patient begins to push. Indeed, some obstetricians delay maternal expulsive efforts until 30 minutes after the diagnosis of full cervical dilation. Others delay expulsive efforts until the breech is at the perineum.

There are three varieties of vaginal breech delivery. **Spontaneous breech delivery** is delivery without any traction or manipulation other than support of the infant's body. With **assisted breech delivery** (also known as partial breech extraction), the infant is delivered spontaneously as far as the umbilicus; at that time, the obstetrician assists delivery of the chest and the aftercoming head. With **total breech extraction,** the obstetrician applies traction on the feet and ankles to deliver the entire body of the infant. Except for vaginal delivery of a second twin, obstetricians almost never perform total breech extraction. Total breech extraction increases the likelihood of difficult, traumatic delivery, including entrapment of the fetal head.

During assisted breech delivery or total breech extraction, the obstetrician attempts to maintain flexion of the cervical spine during delivery of the aftercoming head. This may be accomplished manually or by the application of Piper forceps (Figures 35-2 through 35-4). In most cases the obstetrician performs a generous episiotomy to prevent perineal obstruction of the aftercoming head.

Cesarean Delivery

Cesarean delivery does not guarantee an atraumatic delivery, especially if the skin and uterine incisions are inadequate. Before 32 weeks' gestation, the lower uterine

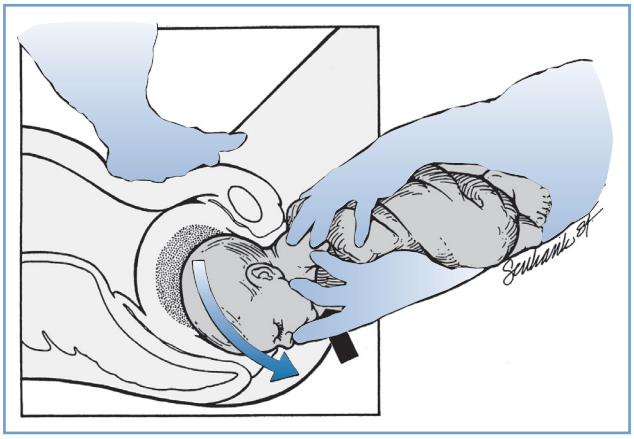

FIGURE 35-2 ■ Vaginal breech delivery. The *black arrow* indicates the direction of pressure from two fingers of the operator's right hand on the fetal maxilla (not the mandible). This maneuver assists in maintaining appropriate flexion of the fetal vertex (*direction of blue arrow*), as does moderate suprapubic pressure from an assistant. Delivery of the head may be accomplished with continued maternal expulsive forces and gentle downward traction. (From Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:400.)

FIGURE 35-3 ■ Vaginal breech delivery. Demonstration of ***incorrect assistance*** during the application of Piper forceps; the assistant hyperextends the fetal neck. Such positioning increases the risk for neurologic injury. (From Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:400.)

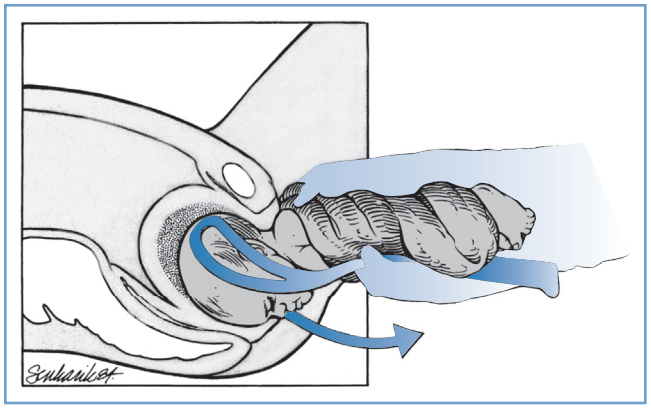

FIGURE 35-4 ■ Vaginal breech delivery. Once the Piper forceps are applied, the fetal trunk is supported by one hand, and gentle traction on the forceps (*arrow*) in the direction of the pelvic axis results in a controlled delivery. (From Lanni SM, Seeds JW. Malpresentations and shoulder dystocia. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:401.)

segment may be inadequate to allow an atraumatic delivery through a low transverse uterine incision. In such cases, the obstetrician should perform a low vertical uterine incision, which can be extended to facilitate an atraumatic delivery. Unfortunately, such incisions often extend to the body of the uterus, which does not heal as well as the lower uterine segment. It is unclear whether this situation increases the risk for uterine rupture during a trial of labor in a subsequent pregnancy (see Chapter 19).

Anesthetic Management

Benefits of neuraxial analgesia during labor include (1) pain relief, (2) inhibition of early pushing by blocking the perineal reflex, (3) ability of the parturient to push during the second stage and spontaneously deliver the infant to the level of the umbilicus, (4) a relaxed pelvic floor and perineum at delivery, and (5) the option to extend analgesia to surgical anesthesia for emergency cesarean delivery if needed.

Analgesia for Labor

Emergency cesarean delivery may be required at any time during a trial of labor. Epidural analgesia and CSE analgesia are excellent choices during a trial of labor in patients with a breech presentation. The anesthesia provider should tailor the analgesic technique to the needs of the individual patient. Patients with a breech presentation often have earlier complaints of rectal pressure than patients with a vertex presentation. It is important to provide sufficient sacral analgesia to inhibit pushing during the first stage of labor. The patient must not push before the cervix is fully dilated; otherwise, the patient might push a fetal lower extremity through her partially dilated cervix, which may result in fetal head entrapment. Early pushing may also increase the risk for a prolapsed umbilical cord. A bolus dose of local anesthetic solution that includes a lipid-soluble opioid (e.g., fentanyl, sufentanil) may be required to block the sacral segments and the reflex urge to push during the late first stage of labor. Use of a local anesthetic alone to eliminate low back and perineal discomfort results in extensive motor blockade, which may decrease the effectiveness of maternal expulsive efforts during the second stage. The advantages of the epidural administration of both a local anesthetic and a lipid-soluble opioid were confirmed by Benhamou et al.,[34] who observed that a continuous epidural infusion of bupivacaine 0.0625% with sufentanil 0.25 μg/mL produced better maternal analgesia and less motor block than administration of bupivacaine 0.125% in parturients with a breech presentation.

Anesthesia for Vaginal Breech Delivery

The patient with a breech presentation should deliver in an operating room where an emergency abdominal delivery can be performed immediately. The anesthesia provider should consider administration of a nonparticulate antacid at the time of transfer to the delivery/operating room. The anesthesia provider should be prepared for emergency administration of general anesthesia at any time. Umbilical cord compression is common during the second stage of labor in a patient with a breech presentation. For these reasons, the mother may receive supplemental oxygen during vaginal breech delivery.

Provision of effective analgesia/anesthesia for vaginal breech delivery represents a true challenge for the anesthesia provider. During the second stage of labor, the anesthesia provider is asked to provide adequate analgesia (which should include neuroblockade of the sacral segments) while maintaining adequate maternal expulsive efforts. If a patient is unable to achieve spontaneous delivery of a *vertex* presentation, the obstetrician may perform instrumental vaginal delivery. In contrast, total breech extraction of a singleton fetus is unacceptable in modern obstetric practice. Most obstetricians insist on spontaneous delivery of the infant to the level of the umbilicus.

At any time, the anesthesia provider may be asked to quickly provide dense anesthesia for vaginal or cesarean delivery. Many obstetricians routinely apply Piper forceps to the aftercoming head. This maneuver requires adequate anesthesia and perineal muscle relaxation. Because a dilute solution of local anesthetic has been administered during the first stage of labor, it is often necessary to administer a more concentrated solution of local anesthetic at the time of delivery. Either 3% 2-chloroprocaine or 2% lidocaine with epinephrine and bicarbonate may be used to rapidly extend the epidural analgesia to anesthesia for operative delivery. To ensure adequate anesthesia for operative delivery, we begin to inject a more concentrated solution of local anesthetic at the first evidence of difficulty.

Perhaps the obstetrician's greatest fear is the risk for **fetal head entrapment**. Most cases of this complication involve entrapment of the fetal head behind a partially dilated cervix. The head may also be entrapped by the perineum. Fetal head entrapment is more likely to occur in patients at less than 32 weeks' gestation. Before 32

weeks' gestation, the fetal head is larger than the wedge formed by the fetal buttocks and thighs. The lower extremities, buttocks, and abdomen may deliver before the cervix is fully dilated, and the cervix may then entrap the head. If this complication occurs, the obstetrician may choose one of the following three options: (1) performance of Dührssen incisions in the cervix, (2) relaxation of skeletal and cervical smooth muscle, or (3) cesarean delivery.

The performance of **Dührssen incisions** may be technically difficult. The obstetrician makes two or three radial incisions in the cervix at the 2-, 6-, and 10-o'clock positions.[4] This procedure is associated with a high risk for maternal morbidity (e.g., genitourinary trauma, hemorrhage). The blood loss may be substantial and concealed. Bleeding within the peritoneal cavity may not be visible externally.

More often, the obstetrician requests that the anesthesia provider establish **relaxation of skeletal and cervical smooth muscle**. Smooth muscle represents less than 15% of total cervical tissue,[35] and some physicians argue that it is not possible to provide profound relaxation of the cervix through smooth muscle relaxation. Nonetheless, the provision of both skeletal and smooth muscle relaxation often facilitates vaginal delivery of the aftercoming head. In the past, the technique of choice was rapid-sequence induction of general anesthesia, followed by administration of a high concentration (2 to 3 minimum alveolar concentration [MAC]) of a volatile halogenated agent. This technique results in uterine and cervical relaxation in 2 to 3 minutes. If fetal head entrapment results from perineal obstruction, delivery may soon follow the administration of succinylcholine.

Immediately after delivery, the anesthesia provider should discontinue administration of the volatile halogenated agent and substitute nitrous oxide, with or without an opioid. Administration of a high concentration of a volatile halogenated agent increases the risk for uterine atony and hemorrhage after delivery. Prompt discontinuation of the volatile halogenated agent, along with intravenous administration of oxytocin, should facilitate adequate uterine tone in most patients. Anesthesia should be maintained until the placenta is delivered, the episiotomy and lacerations are repaired, and hemostasis is secured.

In modern practice, intravenous or sublingual administration of nitroglycerin has nearly replaced the use of volatile halogenated agents as agents for uterine relaxation. Administration of nitroglycerin results in the release of nitric oxide, which helps mediate the relaxation of smooth muscle. Transient hypotension is common. Use of nitroglycerin for this purpose is based on case reports and small series of cases. Well-designed clinical trials of the use of nitroglycerin to provide uterine relaxation in obstetric emergencies are lacking, although the administration of nitroglycerin for this purpose appears safe for both the mother and the infant.[36]

Buhimschi et al.[37] attempted to provide an objective assessment of the effect of nitroglycerin on uterine tone and contractility in laboring women. In a double-blind fashion, 12 parturients were randomly assigned to receive either placebo or sublingual nitroglycerin (three doses, 800 μg each) 10 minutes apart. Intrauterine pressure was measured with a sensor-tip catheter. Sublingual nitroglycerin did not reduce either uterine activity or tone, despite a significant (20%) reduction in maternal mean arterial pressure. The authors suggested that higher doses may be required but may increase the risk for maternal hypotension.

Published case reports have described clinically apparent uterine relaxation achieved with intravenous nitroglycerin doses ranging from 50 to 1500 μg. Sublingual sprays of metered-dose nitroglycerin (400 to 800 μg) may provide a more convenient means of administration, whereas intravenous administration may allow for more rigorous titration. Either sublingual or intravenous routes of administration appear to provide a rapid onset of uterine relaxation, and the effect typically is very brief. The patient should be warned about the acute onset of headache, and she should be treated with a vasopressor such as phenylephrine if hypotension occurs. The anesthesia provider should simultaneously prepare for the induction of general anesthesia should nitroglycerin not provide enough relaxation.

The use of epidural analgesia has likely lowered the incidence of fetal head entrapment during vaginal breech delivery for at least two reasons. First, epidural analgesia inhibits early pushing during the first stage of labor. Second, although epidural analgesia does not relax the cervix at delivery, it provides effective pain relief and skeletal muscle relaxation. A relaxed pelvic floor and perineum facilitates placement of Piper forceps and delivery of the aftercoming head. Moreover, effective analgesia and skeletal muscle relaxation allow an assistant to provide maternal suprapubic pressure, which helps maintain flexion of the fetal cervical spine during delivery.

Anesthesia for Cesarean Delivery

Spinal, epidural, or general anesthesia can be administered for cesarean delivery. At cesarean delivery, the obstetrician should perform a uterine incision that allows an atraumatic delivery of the infant. Rarely, the obstetrician may request provision of uterine relaxation even when a vertical uterine incision has been performed. Uterine relaxation may be necessary in cases of fetal malformations (e.g., sacral teratoma, hydrocephalus). When general anesthesia is used, the anesthesia provider may increase the concentration of the volatile halogenated agent. When neuraxial anesthesia is used, intravenous or sublingual administration of nitroglycerin, or intravenous administration of a beta-adrenergic tocolytic agent such as terbutaline, typically provides adequate relaxation. Rarely, it is necessary to perform intraoperative induction of general anesthesia followed by administration of a high concentration of a volatile halogenated agent.

Regardless of the route of delivery, all members of the obstetric care team should remember that newborn infants with a breech presentation tend to be more depressed than infants with a vertex presentation. An individual skilled in neonatal resuscitation should be immediately available.

OTHER ABNORMAL PRESENTATIONS

Face Presentation

Face presentation occurs in 1 in 500 live births. Vaginal delivery can be achieved in 70% to 80% of infants with a face presentation if the mentum rotates to an anterior position.[4] Manual efforts to flex the fetal cervical spine or convert an unfavorable mentum posterior position to a more favorable mentum anterior position are rarely successful.[4]

Brow Presentation

In patients with a brow presentation, the cervical spine position is intermediate between the full flexion of a normal vertex presentation and the full extension of a face presentation. Brow presentation occurs in approximately 1 in 1500 deliveries. Persistent brow presentation typically requires cesarean delivery due to dystocia. Spontaneous flexion or extension of the neck may occur during labor, which may allow vaginal delivery.[4]

Compound Presentation

Compound presentation (an extremity is prolapsed alongside the main presenting fetal part) occurs in 1 in 400 to 1 in 1200 deliveries. Most often, an upper extremity presents with the vertex. Umbilical cord prolapse is more common (10% to 20%), as is neurologic or musculoskeletal damage to the involved extremity.[4] Labor and delivery may occur safely, but abdominal delivery is needed in patients with cord prolapse or arrest of labor. Manipulation of the prolapsed extremity should be avoided.[4]

Shoulder Presentation

A shoulder presentation (also known as a transverse lie) mandates performance of cesarean delivery except in two circumstances. First, successful external cephalic version may allow vaginal delivery. Second, the obstetrician may perform internal podalic version and total breech extraction of a second twin with a shoulder presentation.

Cesarean delivery of a fetus with a back-down transverse lie can be especially difficult with no presenting part to grasp. This presentation represents one of the few indications in contemporary obstetric practice for a classical uterine incision.

MULTIPLE GESTATION

Epidemiology

Monozygotic twins (which occur when a single fertilized ovum divides into two distinct individuals after a variable number of divisions) exhibit a constant incidence of approximately 4 per 1000 births. The incidence of **dizygotic twins** (which occur when two separate ova are fertilized) varies among races and by maternal age. In the United States, dizygotic twins occur most frequently among non-Hispanic black and white Americans, with an intermediate frequency among Asian Americans and Puerto Ricans, and least frequently among Native Americans and other Hispanic groups.[38] The incidence increases from 15 per 1000 among women younger than 20 years of age to 53 per 1000 among women 35 to 39 years of age, 63 per 1000 among women 40 to 44 years of age, and 227 per 1000 among those 45 years of age and older.[38] The incidence also increases with parity, independent of maternal age.[39] In the United States the rate of multiple gestation increased by 75% between 1980 and 2010.[38] Twin births represented 3.3% of all births in 2010.[38] Higher-order multiples (e.g., triplets) have declined in frequency from 0.2% of all live births in 1998 to 0.14% in 2010. Delayed childbearing and spontaneous twinning among women older than age 30 appears to explain one third of the increase in the rate of multiple gestation between 1980 and 2010, with the remainder attributed to greater use of assisted reproductive technologies.[40]

Placentation

Placentas in multiple gestation may be (1) **dichorionic diamniotic,** (2) **monochorionic diamniotic,** or (3) **monochorionic monoamniotic** (Figure 35-5). In all occurrences of dizygotic twins, the placenta is dichorionic diamniotic. A dichorionic diamniotic placenta is also present if monozygotic twinning occurs during the first 2 to 3 days after fertilization. Twinning between 3 and 8 days commonly results in a monochorionic diamniotic

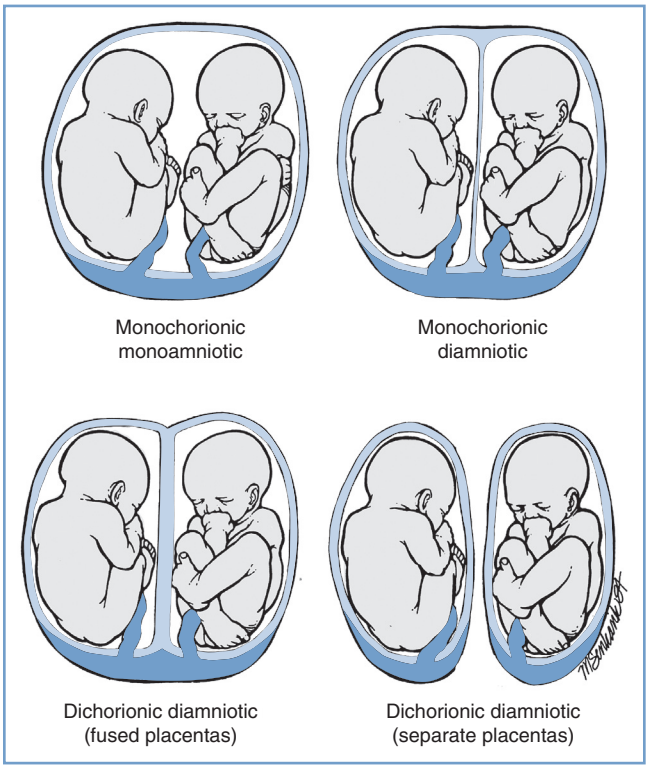

FIGURE 35-5 ■ **Placentation in twin pregnancies.** (Newman R, Unal ER. Multiple gestations. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:674.)

placenta. Monochorionic monoamniotic placentas are found when twinning occurs at 8 to 13 days. Embryonic cleavage between 13 and 15 days results in conjoined twins with a monochorionic monoamniotic placenta. Chorionicity is best determined by ultrasonography in the first or early second trimester.[41]

The type of placentation determines the likelihood of vascular communications. Vascular communications occur in nearly all monochorionic placentas and are rare in dichorionic placentas.[42] Vascular communications may result in twin-to-twin transfusion syndrome and intrauterine fetal death. Monochorionic placentation also increases the risk for intrauterine fetal death from other causes (e.g., cord accident).[42]

Physiologic Changes

Multiple gestation accelerates and may exaggerate the physiologic and anatomic changes of pregnancy. Of interest to the anesthesia provider, multiple gestation intensifies the cardiovascular and pulmonary changes of pregnancy. In contrast, the renal, hepatic, and central nervous system changes resemble those that occur in women with a singleton fetus.

Increased uterine size, especially near term, results in a reduction in both total lung capacity and functional residual capacity. During periods of hypoventilation or apnea, hypoxemia develops more rapidly because of the decreased functional residual capacity and an increased maternal metabolic rate. However, a cross-sectional study demonstrated no significant difference in respiratory function between 68 women with a twin pregnancy and 140 women with a singleton pregnancy.[43] Maternal weight increases at a greater rate after 30 weeks' gestation in women with multiple gestation,[44] a process that may increase the risk for difficult tracheal intubation and ventilation. Greater uterine size displaces the stomach cephalad, decreasing the competence of the lower esophageal sphincter and increasing the risk for pulmonary aspiration of gastric contents.

Maternal plasma volume increases by an additional 750 mL with twin gestation.[45] Relative or actual anemia often occurs. Likewise, multiple gestation results in a 20% greater increase in cardiac output than occurs in women with a singleton fetus, owing to a greater stroke volume (15%) and a higher heart rate (3.5%).[46] The greater fetal weight and larger volume of amniotic fluid predispose the mother with multiple gestation to aortocaval compression and the supine hypotension syndrome.

Obstetric Complications

Fetal Complications

Fetal complications include those related solely to multiple gestation (e.g., twin-to-twin transfusion syndrome) and those related to abnormal presentation (e.g., prolapsed cord) (Box 35-3).

BOX 35-3 Fetal Complications Associated with Multiple Gestation

- Preterm delivery
- Congenital anomalies
- Polyhydramnios
- Cord entanglement
- Umbilical cord prolapse
- Fetal growth restriction
- Twin-to-twin transfusion
- Malpresentation

Twin-to-Twin Transfusion. Nearly all monochorionic twin placentas have vascular anastomoses. Deep arteriovenous anastomoses create a common villous compartment in about half of monochorionic twin placentas. Most of these anastomoses have little fetal consequence. Those with deep arteriovenous vascular communications may result in twin-to-twin transfusion,[47] in which one twin becomes the donor and the other twin becomes the recipient. The donor twin is smaller and is at risk for fetal growth restriction (also known as intrauterine growth restriction) and anemia. The recipient twin is plethoric and is at risk for volume overload and cardiac failure. Alternative explanations for the syndrome include unequal blood volumes secondary to compression of a velamentous umbilical cord insertion and higher arterial blood pressure in the donor than in the recipient. Twin-to-twin transfusion increases both the perinatal mortality rate and the risk for adverse neurodevelopmental outcome in survivors.[48]

The therapeutic options most often considered are decompression amniocentesis, interruption of the placental vessel communications, amniotic septostomy, and selective feticide.[49] Selective fetoscopic laser photocoagulation may be sufficient to address the vascular anastomoses. Decompression amniocentesis or serial amnioreduction may improve circulation to a "stuck" donor twin, allowing restoration of normal amniotic fluid volume and "catch-up" fetal growth. Compared with serial amnioreduction, septostomy has the advantage of requiring only a single procedure.[50] Increasing evidence supports the use of endoscopic laser coagulation to improve perinatal outcome.[51-53]

Fetal Growth Restriction. Twin-to-twin transfusion represents only one of the potential causes of fetal growth restriction in multiple gestation. The polyhydramnios within one fetal sac may limit the growth of the other fetus. In patients with three or more fetuses, limited intrauterine size may restrict fetal growth. Of course, factors that cause fetal growth restriction in singleton pregnancies also may cause fetal growth restriction in multiple gestation (e.g., uteroplacental insufficiency, chromosomal abnormalities).

Preterm Labor. Patients with multiple gestation are at high risk for preterm labor and delivery. Preterm labor occurs in 52% of women with twins resulting from *in vitro* fertilization compared with 22% of women with spontaneous twins.[54] Sixty percent of women with twins deliver before 37 weeks' gestation, and only 6.4% of

triplet pregnancies reach term.[55] Routine use of bed rest, prophylactic cerclage, vaginal progesterone, and/or tocolytic therapy has not been shown to improve perinatal outcome in multiple gestation pregnancies.[56] When preterm labor occurs, the patient may receive parenteral tocolytic therapy to facilitate administration of betamethasone to accelerate fetal lung maturation, or magnesium sulfate for fetal neuroprotection, or both. The side effects of magnesium and other tocolytic agents may affect the response to anesthesia (see Chapter 34) and may increase the risk for postpartum hemorrhage. Multiple gestation most likely increases the risk for pulmonary edema associated with tocolytic therapy.[57]

Abnormal Presentation. Multiple gestation is associated with a higher incidence of abnormal presentation, which results in part from the need to accommodate two or more fetuses within the uterine cavity. Malpresentation increases the risk for umbilical cord prolapse, which may occur either before or after delivery of the first infant.

Morbidity and Mortality. Approximately 9% of all cases of perinatal mortality result from multiple gestation.[58] The perinatal mortality rate in twin pregnancies is almost three times greater than that associated with singleton pregnancies (16 deaths per 1000 births versus 6 per 1000 births, respectively).[58] Preterm delivery accounts for most of this increase, although twins and triplets also have a higher weight-specific mortality, which may be related to twin-to-twin transfusion, congenital malformations, preeclampsia, malpresentation, and/or prolapsed umbilical cord. Some maternal-fetal medicine specialists advocate selective multifetal reduction to reduce the risk for maternal morbidity and the perinatal morbidity and mortality associated with three or more fetuses; this issue is a matter of great controversy. The ACOG[59] has stated:

> *High-order multiple gestation creates a medical and ethical dilemma. If a pregnancy with 4 or more fetuses is continued, the probability is high that not all fetuses will survive intact and that the woman will experience serious morbidity. However, fetal reduction to triplet or twin gestations is associated with a significant risk of losing either another fetus or the whole pregnancy.*

Intensive inpatient monitoring may improve perinatal survival of *monoamniotic* twins. In a retrospective analysis of 87 women who had living twins at 24 weeks' gestation, there were no intrauterine fetal deaths among 43 women who were admitted electively for inpatient surveillance (at a median gestational age of 26.5 weeks).[60] In comparison, among women who were monitored as outpatients and admitted only for routine obstetric indications (at a median gestational age of 30.1 weeks), the rate of intrauterine fetal death was 14.8%.[60] Intensive surveillance may also benefit *monochorionic diamniotic* pregnancies.[61] The long-term outcome of the complications of monochorionicity remains an area of limited knowledge.[62]

Johnson and Zhang[63] evaluated outcome for 150,386 sets of twins and 5240 sets of triplets born between 1995 and 1997; fetal death at 20 weeks' gestation or later occurred in 2.6% of twin gestations and 4.3% of triplet gestations. The investigators noted that "survival of the remaining fetuses was inversely related to the time of the first fetal demise."[63] Opposite-gender twins were more likely to survive, possibly reflecting the absence of monochorionic placentation. In monochorionic twin gestations complicated by twin-to-twin transfusion and fetal death, approximately 40% of the surviving twins experience mortality or serious neurodevelopmental morbidity.[64] Death of one fetus may occur well before term. Obstetric management decisions are based on the cause of death and the status of both the surviving fetus and the mother. If the cause of death was an abnormality of the fetus rather than maternal or uteroplacental pathology, expectant management of the pregnancy may be warranted.[42,59] Development of maternal disseminated intravascular coagulation from dead fetal tissue is a theoretical complication that appears to occur rarely.[59]

Multiple gestation is also associated with an increased risk for neonatal morbidity and mortality. Despite a 95% neonatal survival rate, triplets may have a significantly greater risk for intraventricular hemorrhage and retinopathy of prematurity.[65]

Order of Delivery. Birth order does not seem to influence perinatal outcome in contemporary obstetric practice.[59,66] Administration of neuraxial anesthesia may improve the outcome for the second twin. In 1987, Crawford[67] observed that among women who received epidural analgesia, the two twins had similar umbilical cord blood pH measurements. In contrast, among women who received general anesthesia, the second twin tended to be more acidotic than the first. Likewise, Jarvis and Whitfield[68] reported no difference in outcome for first and second twins when the mother received epidural analgesia. Administration of general anesthesia is increasingly rare for cesarean delivery in women with multiple gestation.[69]

Maternal Complications

Multiple gestation increases the incidence of maternal morbidity and mortality (Box 35-4), even with adjustment of data for confounding factors.[70] The ACOG[59] has

BOX 35-4 Maternal Complications Associated with Multiple Gestation

- Preterm premature rupture of membranes
- Preterm labor
- Prolonged labor
- Preeclampsia/eclampsia
- Placental abruption
- Disseminated intravascular coagulation
- Operative delivery (forceps and cesarean)
- Uterine atony
- Obstetric trauma
- Antepartum and/or postpartum hemorrhage

stated: "Women with multiple gestations are nearly 6 times more likely to be hospitalized with complications, including preeclampsia, preterm labor, preterm premature rupture of membranes, placental abruption, pyelonephritis, and postpartum hemorrhage."[59] The incidence of maternal complications increases in proportion to the number of fetuses. Nearly all triplet gestations are associated with antenatal and/or postnatal maternal complications.[71] Abdominal distention and diaphragmatic elevation can cause respiratory distress and may necessitate early delivery in some patients with three or more fetuses. The increased incidence of cesarean delivery contributes to the higher risk for maternal morbidity and mortality associated with multiple gestation.

Multiple gestation (and the use of assisted reproductive technologies[72]) increases both the incidence and severity of preeclampsia.[42] Preeclampsia prompts delivery by 34 weeks' gestation in as many as 70% of patients with quadruplet pregnancies.[73]

Blood loss with delivery is approximately 500 mL greater in multiple gestation pregnancies than in singleton pregnancies.[42] Uterine distention increases the risk for uterine atony and postpartum hemorrhage. Most cases of atony respond to standard pharmacologic therapy (e.g., oxytocin, methylergonovine, 15-methyl prostaglandin $F_{2\alpha}$ [carboprost]). Persistent uterine atony may require the performance of a uterine brace suture or emergency hysterectomy.

Obstetric Management

Delivery at 38 weeks' gestation for twins and 35 weeks' gestation for triplets may be associated with the lowest risk for perinatal mortality.[59] Twin gestation itself does not contraindicate labor and vaginal delivery. However, multiple gestation is associated with a higher incidence of cesarean delivery. Most obstetricians favor cesarean delivery for all patients with three or more fetuses.[42]

A meta-analysis of four studies involving 1932 infants found no difference in perinatal or neonatal mortality, neonatal morbidity, or maternal morbidity between twins born through planned cesarean delivery and those born through vaginal delivery unless the first twin (twin A) was in a breech presentation.[74] Other studies have shown no maternal benefit to a prophylactic cesarean delivery, whereas maternal febrile morbidity is higher and the mother's risks for future pregnancies are increased.[75,76] Recent studies have found that neonatal morbidity is lower after vaginal delivery compared with scheduled cesarean delivery, even if only the second twin is considered.[77,78] A cohort study of 2597 twin deliveries at or after 34 weeks' gestation, with the first twin in a cephalic presentation, found that intrapartum and postpartum neonatal complications occurred in 26.5% of vaginal deliveries and 31.7% of scheduled cesarean deliveries ($P = 0.005$).[77] The authors concluded that their findings do not support a policy of planned cesarean delivery for twin pregnancies at or after 34 weeks' gestation.[77] A meta-analysis of 39,571 twin pregnancies found that neonatal morbidity was lower after vaginal delivery than after cesarean delivery for twin A, but there was no significant difference in neonatal morbidity between the two modes of delivery for twin B.[78] When outcomes were stratified for both presentation and mode of delivery, the mortality rate was lower after vaginal delivery than after cesarean delivery for both vertex and non-vertex twin B.[78]

Both fetuses have a vertex presentation in 30% to 50% of cases of twin gestation, and in 25% to 40% of cases the presentation is a vertex/breech combination. The remaining patients have various combinations of vertex, breech, and transverse lie. Most obstetricians allow a trial of labor if both twins have vertex presentation. Similarly, a majority of obstetricians opt for cesarean delivery if the first twin has a breech or shoulder presentation. Notwithstanding the results of recent studies,[74,77,78] controversy remains regarding the ideal management in cases in which twin A has a vertex presentation and twin B has a nonvertex presentation.[59,75]

Twin A

Decisions regarding the method of delivery typically revolve around the gestational age and presentation of twin A. An obstetrician who is unwilling to allow a trial of labor in a patient with a singleton breech presentation is unlikely to allow a trial of labor in a patient with a breech presentation for twin A. Moreover, if twin A has a breech presentation and twin B has a vertex presentation, the chins may become interlocked during labor and delivery. This complication occurs infrequently, but the consequences can be devastating.[42] Other indications for cesarean delivery of twin A include (1) evidence of discordant growth (especially if twin B is larger than twin A), (2) twin-to-twin transfusion syndrome, (3) selected congenital anomalies, and (4) evidence of uteroplacental insufficiency.[42] A trial of labor mandates continuous FHR monitoring of both fetuses. After amniotomy, an electrocardiography lead may be placed on the scalp of twin A and Doppler ultrasonography may be used to monitor twin B.

The unanticipated case of head entrapment, deflexed head, or locked twins may necessitate emergency abdominal delivery of both twins. The obstetrician proceeds with cesarean delivery while an assistant supports the exteriorized body of twin A. The obstetrician applies gentle traction on the head while the infant's body is guided back into the vagina. This can be accomplished without major injury to the infant or the mother.[79]

Twin B

If twin A is delivered vaginally, the obstetrician must make a decision about the method of delivery of twin B. If twin B has a vertex presentation and the head is well applied to the cervix, the obstetrician may allow the patient to resume labor and await spontaneous vaginal delivery. Rarely, if twin B has a vertex presentation but the head is not well applied to the cervix, the obstetrician may perform internal podalic version and total breech extraction.

For the twin B with nonvertex presentation, options include (1) external cephalic version followed by a resumption of labor, (2) internal podalic version and total breech extraction, and (3) performance of cesarean

delivery. Real-time ultrasonography facilitates the performance of external cephalic version. This procedure is successful in approximately 70% of cases. The likelihood of success is not associated with parity, gestational age, or birth weight.[80] One study noted that mothers who received epidural anesthesia were more relaxed and tolerated the procedure better than those who did not receive epidural anesthesia.[80]

Delivery of twin B is the one situation in contemporary obstetric practice in which internal podalic version and total breech extraction are considered appropriate. Indeed, breech extraction may be preferable to external cephalic version at the time of delivery. After vaginal delivery of twin A, the second twin requires cesarean delivery in approximately 10% of cases.[81] Predictors of emergency cesarean delivery of twin B include malpresentation, nonreassuring FHR tracing, cephalopelvic disproportion, and cord prolapse.[81] In a cohort study of twin pregnancies that used active management of the second stage of labor, which included breech extraction of the second twin and internal version of a nonengaged second twin, no patients required a cesarean delivery for the second twin after vaginal delivery of the first twin.[82] The investigators stated that an epidural catheter was placed and tested before delivery in all patients that had a trial of labor, and all twin deliveries occurred in the operating room with an anesthesiologist present.[82] The obstetrician will opt for total breech extraction of twin B only if there is evidence that twin B is not larger than twin A. Antepartum ultrasonographic examination allows the obstetrician to assess the head size and weight of both fetuses. If twin B is not larger than twin A, the pelvis and cervical dilation are probably adequate for vaginal delivery of twin B, provided that the cervix has not begun to contract.

In the past, obstetricians favored the delivery of twin B within 15 to 30 minutes of delivery of twin A. However, most data supporting this practice were obtained before the use of intrapartum FHR monitoring. In a review of 118 twin deliveries, Leung et al.[83] demonstrated an association between the twin-twin delivery interval and the umbilical cord blood gas and pH measurements for twin B. The investigators noted that continuous FHR monitoring is essential; 73% of the second twins not delivered by 30 minutes required operative delivery because of a nonreassuring FHR tracing. A German retrospective analysis of 4110 twin pregnancies suggested that the interval between delivery of twins is an independent risk factor for adverse short-term outcomes for twin B.[84] Continuous FHR monitoring of twin B is essential.

Anesthetic Management

Labor and Vaginal Delivery

Epidural analgesia provides optimal analgesia and flexibility for subsequent anesthetic needs. The anesthesia provider must be vigilant, because obstetric conditions and anesthetic requirements may change rapidly. Given the greater risk for cesarean delivery in patients with multiple gestation, the anesthesia provider should aim for optimal epidural anesthesia. If there is any question regarding the location of the catheter or the efficacy of the block, the catheter should be removed and replaced.

Patients with multiple gestation may be at increased risk for aortocaval compression and hypotension during the administration of neuraxial anesthesia. Use of the full lateral position, both during and after induction of epidural anesthesia, reduces the risk for aortocaval compression. Because these patients are at increased risk for uterine atony and postpartum hemorrhage, establishment of large-bore intravenous access is recommended before delivery.

Patients with multiple gestation should deliver in a room where an emergency abdominal delivery can be performed immediately. As the time for delivery of twin A nears, we augment the intensity of epidural blockade to optimize analgesia. We typically extend the sensory level to approximately T8 to T6 using a solution of local anesthetic that is more concentrated than that used earlier during labor. Effective anesthesia facilitates the performance of internal podalic version and total breech extraction of twin B, and it also enables the extension of anesthesia for cesarean delivery if necessary. We prepare a syringe of 3% 2-chloroprocaine to be used if emergency extension of epidural anesthesia is required.

We prefer to administer CSE anesthesia for vaginal delivery in patients with multiple gestation who do not have preexisting epidural analgesia. We prefer *not* to administer single-shot spinal anesthesia for vaginal delivery in those patients because of its lack of flexibility in cases of rapidly changing conditions. However, spinal anesthesia may be appropriate when delivery appears imminent in a patient without preexisting epidural labor analgesia.

Vaginal Delivery of Twin A/Operative Delivery of Twin B

The flexibility associated with epidural analgesia is especially advantageous if the obstetrician delivers twin A vaginally and twin B abdominally. We administer a nonparticulate antacid at the first sign of obstetrician concern, or even before proceeding to the operating room. We inject additional local anesthetic to extend the surgical sensory level to approximately T4. In cases of prolonged fetal bradycardia, it may be necessary to administer general anesthesia if adequate neuraxial anesthesia cannot be achieved rapidly. Typically this problem can be avoided if (1) both the level and intensity of anesthesia are optimized at the time of delivery of twin A and (2) the anesthesia provider is present in the room and gives attention to both the FHR tracing and the obstetrician.

If the obstetrician opts for internal podalic version and total breech extraction of twin B, it is better to perform the procedure shortly after the delivery of twin A, before the uterus and the cervix begin to contract. Pain relief and skeletal muscle relaxation (both provided by epidural anesthesia) facilitate internal version and total breech extraction of twin B. In some cases, pharmacologic uterine relaxation may be required to facilitate internal version and breech extraction of twin B. Sublingual (400 to 800 μg) or intravenous (100 to 250 μg) administration of nitroglycerin should provide adequate relaxation for

internal podalic version.[85,86] Intravenous or subcutaneous terbutaline 250 µg may also be used for uterine relaxation. If this maneuver is unsuccessful, rapid-sequence induction of general anesthesia, followed by administration of a high concentration of a volatile halogenated agent (as discussed earlier) may be needed.

Cesarean Delivery

Epidural, spinal, or general anesthesia can be safely administered for elective abdominal delivery. Spinal anesthesia is increasingly preferred by many anesthesia providers. A historical preference for epidural anesthesia was based on the gradual onset of sympathetic blockade, which was thought to reduce the incidence of severe hypotension. It has been long believed that women with multiple gestation are at higher risk for hemodynamic instability during administration of neuraxial anesthesia than women with a singleton gestation. Ngan Kee et al.[87] compared the incidence of hypotension and vasopressor requirements in women with multiple and singleton gestations undergoing cesarean delivery with spinal anesthesia. There were no differences between groups in maternal and neonatal outcomes.

Comparison of brachial artery and popliteal artery blood pressures allows the detection of occult supine hypotension, which results in reduced uteroplacental perfusion in the presence of a normal brachial artery pressure. If either hypotension or occult supine hypotension is detected, additional left uterine displacement or displacement to the other side may resolve the problem. A nonreassuring FHR tracing for either infant should also prompt the administration of additional efforts to optimize uteroplacental perfusion.

Jawan et al.[88] found that women with multiple gestation had a greater cephalad spread of neuroblockade with spinal anesthesia than women with a singleton gestation, whereas Ngan Kee et al.[87] did not. Similarly, Behforouz et al.[89] found no difference in the extent of sensory blockade after administration of epidural anesthesia between women with higher-order multiple gestation pregnancies and women with a singleton gestation. In any case, any difference that may exist is likely to be of little clinical significance.

Vallejo and Ramanathan[90] demonstrated that mean umbilical venous and umbilical arterial lidocaine concentrations were 35% to 53% higher in twin newborns than in singleton newborns exposed to epidural anesthesia for cesarean delivery. Mean fetal-to-maternal lidocaine ratios were at least 18% higher in the twin newborns than in the singleton newborns. The investigators speculated that this difference may be a result of the greater maternal cardiac output and plasma volume associated with twin gestation as well as the decreased total plasma protein concentration, which leads to an increase in the free lidocaine concentration.[90] The clinical relevance of these findings is unclear.

When general anesthesia is used, the greater oxygen consumption and decreased functional residual capacity associated with multiple gestation increase the risk for maternal hypoxemia during periods of apnea. Adequate denitrogenation (preoxygenation) is essential.

The presence of two or more fetuses results in a prolonged uterine incision-to-delivery interval because of the longer time required to deliver multiple infants. A prolonged interval increases the risk for umbilical cord blood acidemia and neonatal depression. Neonatal depression is less likely with neuraxial anesthesia than with general anesthesia.[68] In any case, an individual skilled in neonatal resuscitation should be immediately available.

KEY POINTS

- A higher incidence of breech presentation occurs among patients with preterm labor.
- External cephalic version is associated with a low rate of morbidity in contemporary obstetric practice and is recommended by the ACOG for all women with a breech presentation near term. Successful external cephalic version helps reduce the risk for perinatal morbidity and mortality associated with breech delivery and lowers the cesarean delivery rate. Neuraxial anesthesia may improve the success rate of external cephalic version, especially after an initial failed attempt.
- Both breech presentation and multiple gestation are associated with an increased incidence of perinatal morbidity and mortality, regardless of the method of delivery.
- Epidural analgesia offers several advantages during a trial of labor in the patient with a breech presentation. Specifically, it (1) provides effective pain relief; (2) inhibits early pushing; (3) relaxes the pelvic floor and perineum, facilitating atraumatic delivery of the aftercoming head; and (4) enables provision of anesthesia for emergency cesarean delivery.
- Multiple gestation exaggerates the physiologic and anatomic changes of pregnancy.
- Epidural analgesia is the analgesic technique of choice during labor in the patient with multiple gestation. Provision of pain relief and skeletal muscle relaxation facilitates the vaginal delivery of twin B. Provision of epidural analgesia also facilitates the administration of anesthesia for emergency cesarean delivery if it is needed.
- The obstetrician may request pharmacologic provision of uterine and/or cervical relaxation to facilitate vaginal delivery of twin B or, in cases of breech presentation, to facilitate the delivery of the aftercoming fetal head. Intravenous or sublingual nitroglycerin may provide rapid-onset uterine relaxation of short duration. Rapid-sequence induction of general anesthesia followed by administration of a high concentration of a volatile halogenated agent is another reliable method of providing uterine and cervical relaxation.

CHAPTER 36

Hypertensive Disorders

Brian T. Bateman, MD, MSc • Linda S. Polley, MD

CHAPTER OUTLINE

Hypertension is the most common medical disorder of pregnancy, affecting 6% to 10% of pregnancies.[1-4] It is a leading cause of maternal mortality, accounting for approximately 26% of maternal deaths in Latin America and the Caribbean, 9% of deaths in Africa and Asia, and 16% of deaths in the developed world.[5] Hypertensive disorders are an important risk factor for fetal complications, including preterm birth, fetal growth restriction (also known as intrauterine growth restriction), and fetal/neonatal death.[4,6-7]

CLASSIFICATION OF HYPERTENSIVE DISORDERS

Hypertensive disorders of pregnancy encompass a range of conditions—chronic hypertension, gestational hypertension, preeclampsia, preeclampsia superimposed on chronic hypertension, and eclampsia—that can be difficult to diagnose because the clinical presentation is often similar despite complex differences in their underlying pathophysiologies and prognoses. Adding to the challenges for clinicians and researchers alike was a long-standing absence of consensus guidelines for categorizing hypertensive disorders. This lack resulted in the use of conflicting definitions that confounded attempts to compare and interpret data from many older clinical studies. This problem was resolved in 2000, when the National High Blood Pressure Education Program (NHBPEP) Working Group on High Blood Pressure in Pregnancy[3] published a classification scheme establishing definitions that subsequently gained wide international acceptance (Box 36-1). This classification was updated in 2013 when the American College of Obstetricians and Gynecologists (ACOG) Taskforce on Hypertension in Pregnancy reviewed available literature and published a summary of current knowledge and recommendations.[4]

Gestational hypertension is the most frequent cause of hypertension during pregnancy, affecting approximately 5% of parturients.[2,8,9] When mild, it results in outcomes that are generally similar to those of normotensive pregnancies,[10,11] but when severe, it can result in rates of adverse pregnancy outcome that approximate those observed in preeclamptic women.[12] Gestational hypertension presents as elevated blood pressure after 20 weeks' gestation without proteinuria (in the absence of chronic hypertension) that resolves by 12 weeks postpartum.[13,14] Most cases of gestational hypertension develop after 37 weeks' gestation. Approximately one fourth of patients diagnosed with gestational hypertension will develop preeclampsia. A definitive diagnosis of gestational hypertension can be made only in retrospect after delivery when the diagnosis of chronic hypertension can be excluded based on a return to a normotensive state.

Preeclampsia is defined as the new onset of hypertension and proteinuria after 20 weeks' gestation (Box 36-2). The NHBPEP recommends that clinicians also consider the diagnosis of preeclampsia in the absence of proteinuria when any of the following signs or symptoms of end-organ involvement are present: (1) persistent epigastric or right upper quadrant pain, (2) persistent cerebral symptoms, (3) fetal growth restriction, (4) thrombocytopenia, or (5) elevated serum liver enzymes.[3] The term **eclampsia** is used when central nervous system (CNS) involvement results in the new onset of seizures in a

BOX 36-1 Classification of Hypertensive Disorders in Pregnancy

- Gestational hypertension
- Preeclampsia
  - Preeclampsia without severe features*
  - Severe
- Chronic hypertension
- Chronic hypertension with superimposed preeclampsia

*Previously referred to as *mild* preeclampsia.

From the Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy. Am J Obstet Gynecol 2000; 183:S1-S22; and American College of Obstetricians and Gynecologists Taskforce on Hypertension in Pregnancy. Hypertension in pregnancy. ACOG. Washington, DC, 2013.

BOX 36-2 Diagnostic Criteria for Preeclampsia

Preeclampsia without Severe Features

- BP ≥ 140/90 mm Hg after 20 weeks' gestation
- Proteinuria (≥ 300 mg/24 h, protein-creatinine ratio ≥ 0.3, or 1+ on urine dipstick specimen)

Severe Preeclampsia*

- BP ≥ 160/110 mm Hg†
- Thrombocytopenia (platelet count < 100,000/mm^3)
- Serum creatinine concentration > 1.1 mg/dL or > 2 times the baseline serum creatinine concentration
- Pulmonary edema
- New-onset cerebral or visual disturbances
- Impaired liver function‡

*Fetal growth restriction and severe proteinuria (> 5 g in 24 hours) are no longer considered features of severe preeclampsia.

†Blood pressures should be measured on two occasions at least 4 hours apart while the patient is on bed rest.

‡Indicated by elevated blood concentrations of liver enzymes (more than twice normal) and severe persistent right upper quadrant, or epigastric pain.

BP, blood pressure; *HELLP*, hemolysis, elevated liver enzymes, and low platelets.

Modified from American College of Obstetricians and Gynecologists Task Force on Hypertension in Pregnancy. Hypertension in pregnancy. ACOG. Washington, DC, 2013.

woman with preeclampsia. **HELLP syndrome** refers to the development of hemolysis, elevated liver enzymes, and a low platelet count in a woman with preeclampsia. This condition may be a variant of severe preeclampsia, but this classification is controversial because the disease may represent a pathophysiologically distinct entity.

Chronic hypertension involves either (1) prepregnancy systolic blood pressure of 140 mm Hg or higher and/or diastolic blood pressure of 90 mm Hg or higher or (2) elevated blood pressure that fails to resolve after delivery. Chronic hypertension develops into preeclampsia in approximately one fifth to one fourth of affected patients. However, even in the absence of preeclampsia, chronic hypertension is an important risk factor for adverse maternal and fetal pregnancy outcomes.[6,15]

Chronic hypertension with superimposed preeclampsia occurs when preeclampsia develops in a woman with chronic hypertension before pregnancy. The diagnosis is made in the presence of a new onset of proteinuria or a sudden increase in proteinuria or hypertension or both, or when other manifestations of severe preeclampsia appear. Morbidity is increased for both mother and fetus compared with preeclampsia alone.[16]

The clinical findings in chronic hypertension, gestational hypertension, and preeclampsia are compared in Table 36-1.

PREECLAMPSIA

Preeclampsia is a multisystem disease unique to human pregnancy. It is characterized by diffuse endothelial dysfunction with maternal complications including placental abruption, pulmonary edema, acute renal failure, liver failure, stroke, and neonatal complications, including indicated preterm delivery, fetal growth restriction, hypoxic-neurologic injury, and perinatal death.[17] Although significant advances have been made in the understanding of the pathophysiology of the disease, the specific proximal cause remains unknown. Management is supportive; delivery of the infant and placenta remains the only definitive cure.

The clinical syndrome of preeclampsia is defined as the new onset of hypertension and proteinuria after 20 weeks' gestation. Previous definitions included edema,

TABLE 36-1 **Hypertensive Disorders of Pregnancy**

Clinical Feature	Chronic Hypertension	Gestational Hypertension	Preeclampsia
Time of onset of hypertension	< 20 weeks' gestation	Typically in third trimester	≥ 20 weeks' gestation
Severity of hypertension	Mild or severe	Mild	Mild or severe
Proteinuria*	Absent	Absent	Typically present
Serum uric acid > 5.5 mg/dL (0.33 mmol/L)	Rare	Absent	Present in almost all cases
Hemoconcentration	Absent	Absent	Present in severe disease
Thrombocytopenia	Absent	Absent	Present in severe disease
Hepatic dysfunction	Absent	Absent	Present in severe disease

*Defined as ≥ 300 mg in a 24-h urine collection, urine protein-creatinine ratio ≥ 0.3, or ≥ 1+ result on urine dipstick testing.

but edema is no longer part of the diagnostic criteria because it lacks specificity and occurs in many healthy pregnant women. Preeclampsia is classified as **preeclampsia without severe features** or **severe** (see Box 36-2). The ACOG now discourages use of the term "mild" for preeclampsia without severe features because preeclampsia is progressive, and appropriate management involves frequent reevaluation for severe features.[4]

Some authors suggest classifying preeclampsia into the **early form (type I)**, with symptom onset before 34 weeks' gestation, or the **late form (type II)**, with symptom onset after 34 weeks' gestation (Table 36-2).[18] Early-onset preeclampsia begins with abnormal placentation, has a high rate of recurrence, and has a strong genetic component.[19-21] In contrast, late-onset preeclampsia generally occurs in women metabolically predisposed to the disease, and abnormal placentation may feature less prominently in the pathogenesis. These women, who often have long-standing hypertension, obesity, diabetes, or other forms of microvascular disease, are challenged to meet the demands of the growing fetoplacental unit and decompensate near term. Decompensation manifests as late-onset or, less frequently, postpartum preeclampsia.[18]

Epidemiology

Preeclampsia occurs in 3% to 4% of pregnancies in the United States.[2,9] Delivery of the infant and placenta is the only definitive treatment; thus, preeclampsia is a leading cause of indicated preterm delivery in developed countries.[22] Low-birth-weight and preterm infants born to preeclamptic mothers present major medical, social, and economic burdens to families and societies.[23] Preterm delivery is the most common indication for admission to the neonatal intensive care unit.[24] Preeclampsia is also a leading indication for maternal peripartum admission to an intensive care unit.[25,26]

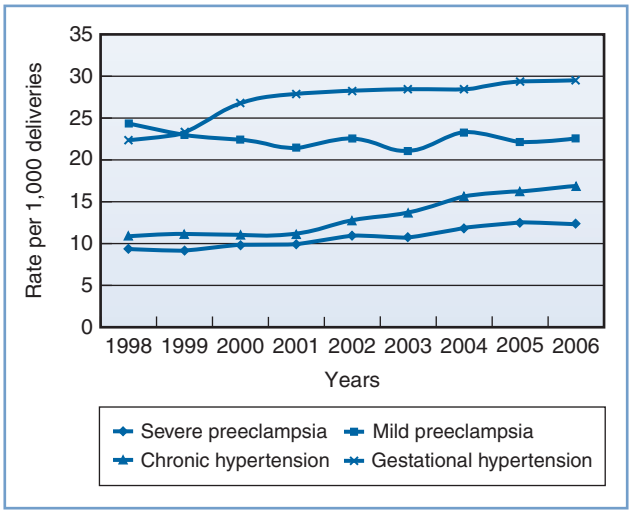

FIGURE 36-1 ■ Age-adjusted prevalence of hypertensive disorders during delivery hospitalization in the United States. (From Kuklina EV, Ayala C, Callaghan WM. Hypertensive disorders and severe obstetric morbidity in the United States. Obstet Gynecol 2009; 113:1299-306.)

The clinical findings of preeclampsia can manifest as a **maternal syndrome** (e.g., hypertension and proteinuria with or without other systemic abnormalities) with or without an accompanying **fetal syndrome** (e.g., fetal growth restriction, oligohydramnios, abnormal oxygen exchange).[3,17] In approximately 75% of cases, preeclampsia occurs without severe features near term or during the intrapartum period.[17] In contrast, disease onset prior to 34 weeks' gestation correlates with increased disease severity and worse outcomes for both mother and fetus.

A significant increase in the incidence of hypertensive disorders of pregnancy has occurred over the past decade (Figure 36-1), including an alarming 30% increase in

BOX 36-3 Risk Factors for Preeclampsia

Demographic Factors
- Advanced maternal age > 35 years
- Black race
- Hispanic ethnicity

Genetic Factors
- History of preeclampsia in previous pregnancy
- Family history of preeclampsia
- History of placental abruption, fetal growth restriction, or fetal death
- Partner who fathered a preeclamptic pregnancy in another woman (through fetal genes)

Medical Conditions
- Obesity
- Chronic hypertension
- Diabetes mellitus
- Chronic renal disease
- Antiphospholipid antibody syndrome
- Systemic lupus erythematosus

Obstetric Conditions
- Multiple gestation
- Hydatidiform mole

Behavioral Factor
- Cigarette smoking (risk reduction)

Partner-Related Factors
- Nulliparity
- Limited preconceptional exposure to paternal sperm*

*Teenage mother, primipaternity, assisted reproductive technique.

severe preeclampsia/eclampsia.[2] These increases are at least partially explained by major shifts in the demographics and clinical conditions of pregnant women in the United States and other developed countries. Average maternal age is increasing; advanced maternal age is a recognized risk factor for preeclampsia. Both the growing epidemic of obesity and the increased prevalence of diabetes and chronic hypertension in the developed world may also contribute to this trend. An increase in the use of assisted reproductive techniques and the use of donated gametes is contributory; these techniques increase risk for the disease by altering the maternal-fetal immune reaction[27] and by increasing the incidence of multiple gestation. Last, improvements in record-keeping and the use of consistent disease definitions since 2000 may have contributed to the increased number of reported cases.[3]

Numerous preconception and pregnancy-related risk factors associated with the development of preeclampsia have been identified (Box 36-3). Risk factors for preeclampsia can be divided into maternal demographic factors, genetic factors, medical conditions, obstetric conditions, behavioral factors, and partner-related factors.

Risk Factors

Demographic Factors. Advanced maternal age has consistently been shown to be a risk factor for preeclampsia, with women who are 40 years or older having an approximately twofold increase in risk compared with women between 20 and 29 years of age.[28,29] This risk may be independent of the increased prevalence of medical conditions and obesity that accompany advancing age.[28] Teenage pregnancy may also be a risk factor for preeclampsia,[30-32] but data are mixed.[33]

Black women constitute a high-risk group, with increased rates of chronic hypertension,[34,35] obesity,[35,36] and preeclampsia.[37-40] Black women with severe preeclampsia demonstrate more extreme hypertension, require more antihypertensive therapy,[41] and are more likely to die of the condition, compared with women of other racial backgrounds.[42] Hispanic ethnicity may also confer increased risk for developing preeclampsia.[43,44]

Genetic Factors. Maternal genetic factors are known to be important risk factors for the development of preeclampsia. Pregnant women with a family history of preeclampsia are approximately twice as likely to develop the disorder.[45,46] It is estimated that about one third of the variance in liability to preeclampsia is caused by maternal genetic factors.[47]

In a study of 1.7 million births in the Medical Birth Registry of Norway, men who fathered one preeclamptic pregnancy were found to be nearly twice as likely to father a preeclamptic pregnancy in a different woman, irrespective of her previous obstetric history.[48] Therefore, **paternal genes** (in the fetus) contribute significantly to a pregnant woman's risk for preeclampsia. It is estimated that approximately one fifth of the variance in liability for preeclampsia is conferred through the fetal genes.[47]

Women with a history of preeclampsia in a previous pregnancy are at increased risk for preeclampsia in a subsequent pregnancy,[29,49] particularly if the preeclampsia was of early-onset in the previous pregnancy.[50] Risk for recurrence increases with multiple affected pregnancies.[50] In addition, women with a history of previous placental abruption and fetal growth restriction are at increased risk for preeclampsia in a subsequent pregnancy,[51] and women with a history of preeclampsia are at risk for these outcomes even in the absence of recurrent preeclampsia.[52] These associations suggest that some women harbor a susceptibility (potentially genetically mediated) to obstetric conditions caused by placental dysfunction, which manifests differently in different pregnancies.

Medical and Obstetric Conditions. Obesity is an important risk factor for preeclampsia, and risk escalates with increasing body mass index (BMI).[53,54] A systematic review found that an increase in BMI of 5 to 7 kg/m^2 was associated with a twofold increased risk for preeclampsia.[53] Obesity is strongly associated with insulin resistance, another risk factor for preeclampsia. As the prevalence of obesity continues to increase worldwide, it is likely that the incidence of preeclamptic pregnancies will increase as well.

Women with **chronic hypertension** are also at increased risk for preeclampsia. A 2012 population-based study found that primary hypertension increased the odds of developing preeclampsia 10-fold and that secondary hypertension increased the odds nearly 12-fold.[6] Chronic hypertension in association with other risk

factors, including diabetes, renal disease, and collagen vascular disease, confers particularly elevated risk.[6] As women in developed countries delay childbirth, the impact of chronic hypertension will increase because of the increased prevalence of hypertension with advancing age.[55] Indeed, recent data from the United States show a substantial increase in the prevalence of chronic hypertension during pregnancy.[2,6]

Diabetes mellitus is associated with the development of preeclampsia.[6,29] In a study of 334 diabetic pregnancies, the incidence of preeclampsia was 9.9%, compared with 4.3% in nondiabetic control pregnancies. The incidence of preeclampsia also increased with the severity of diabetes as determined by the White classification.[56]

The **metabolic syndrome**, which occurs in 7% of women of childbearing age in the United States, is characterized by the presence of obesity, hyperglycemia, insulin resistance, and hypertension.[57] The metabolic syndrome increases risk for preeclampsia.[58] The insulin resistance and microvascular dysfunction observed in this condition have been implicated as a common factor in both preeclampsia and cardiovascular disease; these conditions may partially mediate the association of preeclampsia and increased risk for cardiovascular disease later in life.[59-61]

Additional maternal medical conditions that are well recognized risk factors for preeclampsia include **chronic renal disease**,[62,63] **antiphospholipid antibody syndrome**,[29] and **systemic lupus erythematosus**.[6,64] Pregnancy-related conditions that increase placental mass, including **multifetal gestation**[29,65] and **hydatidiform mole**,[66] are associated with higher rates of preeclampsia as well.

Behavioral Factors. Paradoxically, **cigarette smoking** during pregnancy has been associated with a decreased risk for preeclampsia,[67,68] an effect consistently observed across studies in various countries. Women who smoke during pregnancy have a 30% to 40% lower risk for developing preeclampsia compared with women who do not smoke. The protective effect is dose related[67]; heavier smokers have a lower incidence of preeclampsia than those who smoke fewer cigarettes.

The duration of this protective effect after smoking cessation has been studied with conflicting results. Its biologic mechanism remains unknown, but it is believed that the mechanism may include nicotine inhibition of thromboxane A_2 synthesis,[69] simulation of nitric oxide release,[70] or a combination of these factors. Further research of this protective mechanism may help elucidate the pathogenesis of preeclampsia.

Recreational Physical Activity. Recreational physical activity during pregnancy has been associated with a decrease in the risk for preeclampsia,[71,72] particularly in nonobese women.[73] Mechanistically, this may occur through exercise promoting placenta growth, decreasing oxidative stress, enhancing endothelial function, and modulating the immune and inflammatory response.[72]

Partner-Related Risk Factors. The unifying theme among partner-related risk factors is limited maternal exposure to paternal sperm antigens before conception, which suggests an immunologic role in the pathophysiology of preeclampsia. A leading risk factor for preeclampsia is nulliparity; the incidence is approximately threefold higher compared with parous women.[29] Long considered a disease of primigravid women, preeclampsia is also more common in (1) parous women who have conceived with a new partner, (2) women who have used barrier methods of contraception prior to conception, and (3) women who have conceived with donated sperm.[74,75] Long-term sperm exposure with the same partner appears to be protective; this protective effect is lost in a pregnancy conceived with a new partner.

Pathogenesis

The exact pathogenic mechanisms responsible for the initiation and progression of preeclampsia are not known. The placenta is the focus of hypotheses regarding disease pathogenesis; delivery of the placenta results in the resolution of disease, and the disease can occur in the absence of a fetus (e.g., a molar pregnancy).[76]

Preeclampsia as a Two-Stage Disorder

Contemporary hypotheses generally conceptualize preeclampsia as a two-stage disorder.[77] The **asymptomatic first stage** occurs early in pregnancy with impaired remodeling of the spiral arteries (the end branches of the uterine artery that supply the placenta).[76] In normal pregnancy, embryo-derived cytotrophoblasts invade the decidual and myometrial segments of the spiral arteries, replacing endothelium and causing remodeling of vascular smooth muscle and the inner elastic lamina (Figure 36-2).[78,79] The luminal diameter of the spiral arteries increases fourfold, resulting in the creation of flaccid tubes that provide a low-resistance vascular pathway to the intervillous space. Furthermore, the remodeled arteries are unresponsive to vasoactive stimuli. These alterations in maternal vasculature ensure adequate blood flow to nourish the growing fetus and placenta.

In contrast, in preeclamptic pregnancies, cytotrophoblast invasion is incomplete and only the decidual segments undergo change; the myometrial spiral arteries are not invaded and remodeled and thus remain small, constricted, and hyperresponsive to vasomotor stimuli.[76] This failure of normal angiogenesis results in superficial placentation. Abnormal placentation results in decreased placental perfusion and placental infarcts, predisposing the fetus to growth restriction (Figure 36-3). Placental ischemia worsens throughout pregnancy as narrowed vessels are increasingly unable to meet the needs of the growing fetoplacental unit.

In some women, the reduced perfusion of the intervillous space in the first stage leads to the **symptomatic second stage**, which is characterized by the release of antiangiogenic factors from the intervillous space into the maternal circulation; these factors cause widespread maternal endothelial dysfunction and an accentuated systemic inflammatory response. In the absence of preeclampsia, healthy endothelium prevents platelet activation, activates circulating anticoagulants, buffers the

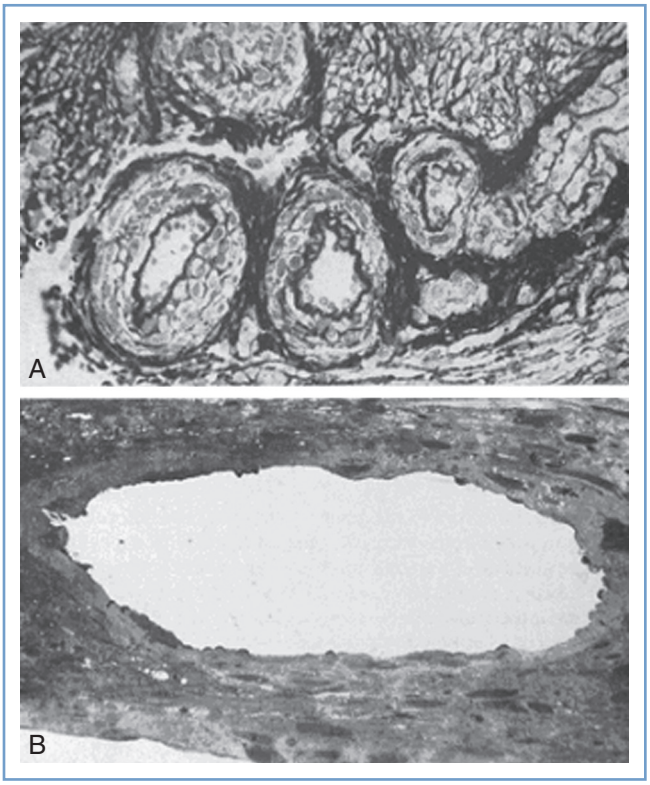

FIGURE 36-2 ■ Sections through spiral arteries (**A**) at the myometrial-endometrial junction of the nonpregnant uterus and (**B**) at the myometrial-decidual junction in late normal pregnancy (×150). (From Sheppard BL, Bonnar J. Uteroplacental arteries and hypertensive pregnancy. In Bonnar J, MacGillivray I, Symonds G, eds. Pregnancy Hypertension. Baltimore, University Park Press, 1980:205.)

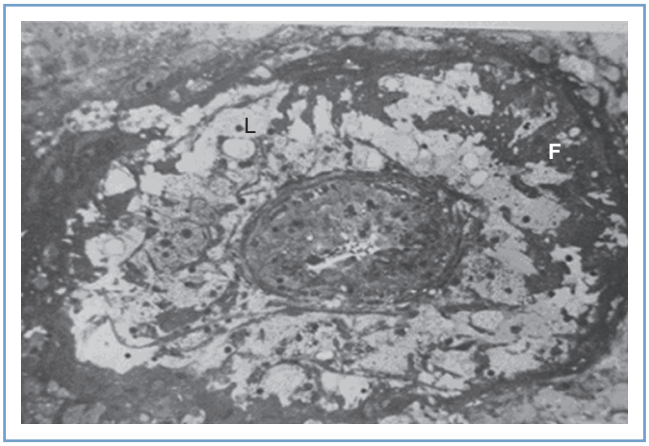

FIGURE 36-3 ■ This figure shows lipid-laden cells (L) and fibrin deposition (F) in this occluded decidual vessel characteristic of both severe preeclampsia and severe fetal growth restriction (×150). (From Sheppard BL, Bonnar J. Uteroplacental arteries and hypertensive pregnancy. In Bonnar J, MacGillivray I, Symonds G, eds. Pregnancy Hypertension. Baltimore, University Park Press, 1980:205.)

response to pressors, and maintains fluid in the intravascular compartment. These normal functions are disrupted in preeclampsia. As a result, the pregnant woman develops hypertension and proteinuria, and is at risk for other manifestations of severe systemic disease (e.g., HELLP syndrome, eclampsia, end-organ damage). These clinical manifestations usually occur after 20 weeks' gestation.

Not all women with impaired placental perfusion develop preeclampsia. The same failure of uterine vascular remodeling occurs in women with isolated fetal growth restriction[80] and in approximately one third of cases of spontaneous preterm birth without maternal clinical manifestations of preeclampsia.[81]

Abnormal Placentation

The basis for abnormal uteroplacental development has not been fully elucidated and is likely due to a complex interaction of immunologic, vascular, environmental, and genetic factors. The hypothesis that immune maladaptation may play a central role in predisposing to abnormal placentation and subsequent preeclampsia is supported by evidence showing that long-term exposure to paternal antigens in sperm is protective. Furthermore, the importance of an intact immune system in the development of preeclampsia is demonstrated by the lower incidence of preeclampsia in women with untreated human immunodeficiency virus; the incidence returns to baseline after treatment with antiretroviral therapy.[82,83]

The immune cells present in the decidua—the endometrium in the nonpregnant state becomes the decidua in pregnancy—include macrophages, dendritic cells, and natural killer (NK) cells. Macrophages and dendritic cells are found in greater density in preeclamptic placentas than in control placentas.[82,84] Similarly, levels of chemokines that attract these immune cells are also elevated.[82,84] Excess macrophages in the decidua are associated with impaired trophoblast invasion, suggesting that excess inflammation may be one of the causal components of impaired placentation.[84] NK cells may also be important in regulating vascular development during placentation. NK cells interact with fetal trophoblast cell markers via killer immunoglobulin receptors (KIR) to influence trophoblastic invasion. Specific genotypic combinations of maternal KIR and trophoblastic human leukocyte antigen C (HLA-C) may increase the risk for preeclampsia.[85] A systematic review of 22 studies examining the association between HLA type and the risk for preeclampsia suggested that HLA-DR correlates with preeclampsia, but it is unclear if this, or any other HLA genotype, is causally related to preeclampsia risk; the authors called for additional studies with larger sample sizes to examine maternal-fetal HLA combinations and the risk for preeclampsia.[86]

Agonistic autoantibodies to the angiotensin receptor-1 (AT_1) are present in many preeclamptic women in association with defective remodeling of the uteroplacental vasculature.[87,88] These autoantibodies activate AT_1 receptors on trophoblast cells, endothelial cells, and vascular smooth muscle cells.[89-91] They appear to block trophoblastic invasion[90] and may induce the production of reactive oxygen species[91] and thus play a significant role in the pathophysiology of preeclampsia (Figure 36-4). Furthermore, introduction of these autoantibodies into pregnant mice increases production of **soluble fms-like tyrosine kinase-1 (sFlt-1)** and results in hypertension

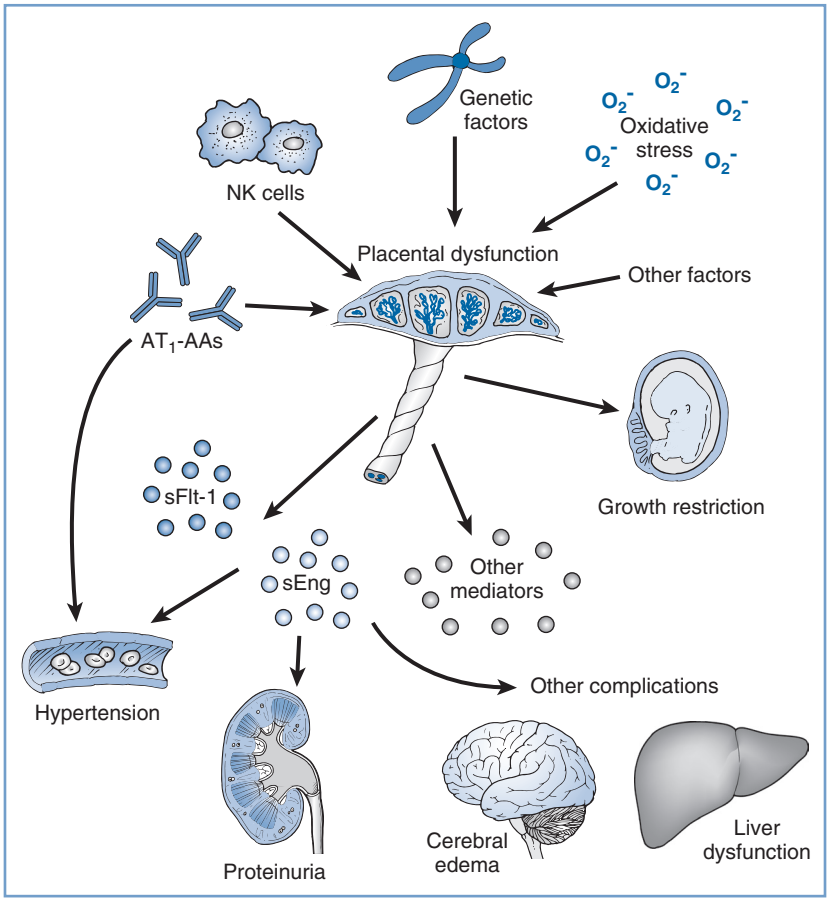

FIGURE 36-4 ■ Angiotensin receptor autoantibodies (AT_1-AAs) in preeclampsia. AT_1-AAs and other factors (e.g., oxidative stress and genetic factors) may cause placental dysfunction, which, in turn, leads to the release of antiangiogenic factors (e.g., sFlt-1 and sEng) and other inflammatory mediators to induce preeclampsia. AT_1-AAs may also act directly on the maternal vasculature to enhance angiotensin II sensitivity and hypertension. (From Parikh SM, Karumanchi SA. Putting pressure on preeclampsia. Nat Med 2008; 14:810-2.)

and proteinuria.[92] Thus, these autoantibodies may play an important role in the pathogenesis of preeclampsia at several different stages.

Oxidative stress is another mechanism that has been postulated as an important component of impaired placentation.[82] Oxidative stress and the resultant free radicals are known to contribute to atherosclerosis and thus may contribute to placental atherosis.[82] Volatile organic compounds measured in a breath test, a marker for oxidative stress, are found in greater quantity in preeclamptic women compared with healthy pregnant controls.[93] Enthusiasm for this theory is tempered by the failure of antioxidant supplementation to decrease the risk for preeclampsia in clinical trials.[82]

Maternal Systemic Disease

The symptomatic second stage of preeclampsia is marked by widespread endothelial activation/dysfunction, and the signs and symptoms of preeclampsia are attributable to the manifestations of endothelial dysfunction specific to each organ system.[76] This notion is supported by studies showing increased levels of biomarkers indicating endothelial activation or injury, or both, in preeclamptic women, including endothelin-1, fibronectin, von Willebrand factor, and thrombomodulin.[76] The central role of endothelial dysfunction is further evidenced by the fact that chronic conditions that cause prepregnancy endothelial injury, including chronic hypertension, preexisting diabetes, and renal disease, are risk factors for preeclampsia. A predilection for endothelial dysfunction may similarly explain the association of preeclampsia and future cardiovascular disease.[76,94]

The mechanistic link between abnormal placentation and subsequent widespread endothelial dysfunction is an area of great interest and ongoing investigation. The prevailing hypothesis is that as the pregnancy progresses, the placenta becomes relatively hypoxic and this change results in an overexpression and release into the maternal circulation of placentally derived antiangiogenic factors, including sFlt-1 and **soluble endoglin (sEng)**.[76,77]

The vascular endothelium requires proangiogenic factors for normal function. sFlt-1 antagonizes the angiogenic growth factors vascular endothelial growth factor (VEGF) and placental growth factor (PlGF).[95,96] Evidence for a central role for sFlt-1 in the pathogenesis of preeclampsia comes from both animal and human studies. Maynard et al.[95] demonstrated that sFlt-1 levels increase during gestation and fall after delivery and that increased circulating sFlt-1 levels reduce circulating levels of free

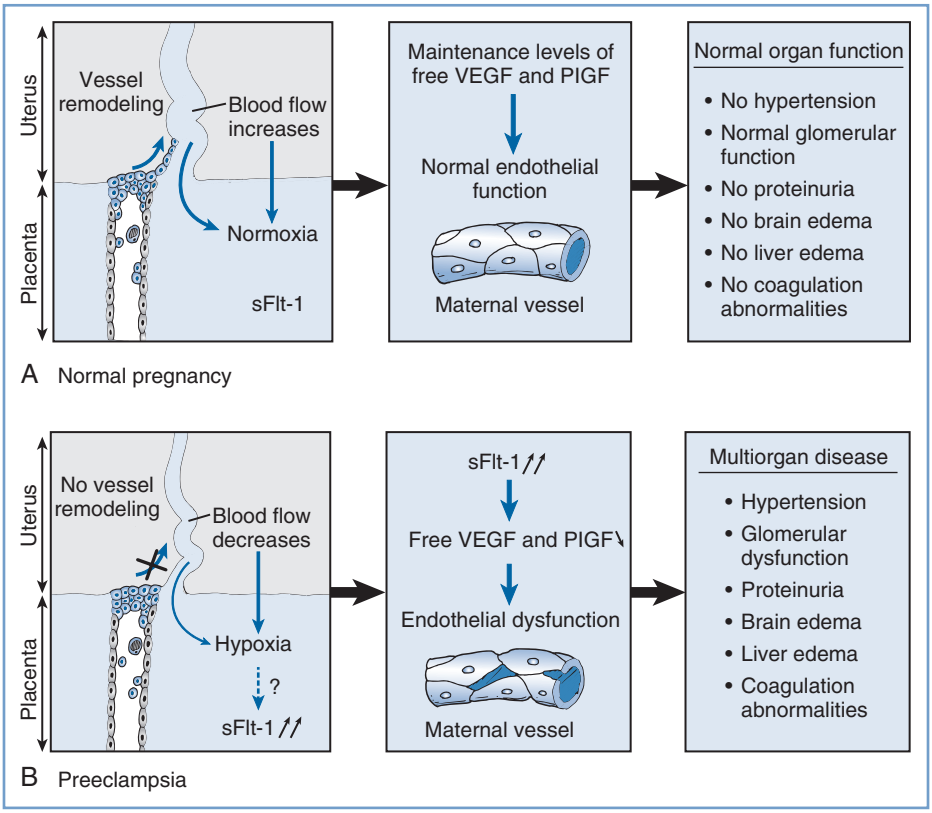

FIGURE 36-5 ■ Hypothesis on the role of soluble fms-like tyrosine kinase (sFlt-1) in preeclampsia. **A,** During normal pregnancy, the uterine spiral arteries are infiltrated and remodeled by endovascular invasive trophoblasts, thereby increasing blood flow significantly to meet the oxygen and nutrient demands of the fetus. **B,** In the placenta of preeclamptic women, trophoblast invasion does not occur and blood flow is reduced, resulting in placental hypoxia. In addition, increased amounts of soluble sFlt-1 are produced by the placenta and scavenge vascular endothelial growth factor (VEGF) and placental growth factor (PlGF), thereby lowering circulating levels of unbound VEGF and PlGF. This altered balance causes generalized endothelial dysfunction, resulting in multiorgan disease. (From Luttun A, Carmeliet P. Soluble VEGF receptor Flt1: the elusive preeclampsia factor discovered? J Clin Invest 2003; 111:600-2.)

VEGF and PlGF, causing endothelial dysfunction that can be rescued by exogenous VEGF and PlGF. Furthermore, these investigators found that the administration of sFlt-1 to pregnant rats induced hypertension, proteinuria, and glomerular endotheliosis, which is the classic renal lesion of preeclampsia. When administered *in vitro*, VEGF and PlGF cause rat renal arteriolar relaxation, which is blocked by sFlt-1. In response to increased circulating levels of sFlt-1, VEGF and PlGF levels are reduced, resulting in endothelial dysfunction in maternal vessels (Figure 36-5). In a study in humans, elevated sFlt-1 levels and reduced levels of PlGF predicted the subsequent development of preeclampsia before the development of any maternal symptoms.[97] Subsequent studies have confirmed the importance of the sFlt-1-to-PlGF ratio as a marker of preeclampsia.[98] Of interest, cigarette smoking, which is known to be protective against preeclampsia, is associated with lower maternal sFlt-1 concentrations during pregnancy compared with nonsmokers.[99]

sEng is another placentally derived antiangiogenic protein that appears to be important in the pathogenesis of preeclampsia.[96] Circulating levels of sEng are markedly increased in women who subsequently develop preeclampsia. Furthermore, if women have both elevated sEng and increased sFlt-1/PlGF ratios, their risk for preeclampsia is elevated approximately 30-fold compared with women with normal levels of both factors/ratios.[100]

The study of antiangiogenic proteins is an active area of current research, and rapid progress is being made in understanding the role of these proteins in the pathogenesis of preeclampsia. However, the importance of recent findings is tempered by the knowledge that preeclampsia does not develop in all women with high sFlt-1 and low PlGF levels, and the syndrome occurs in some women with low sFlt-1 and high PlGF levels.[97,101] These observations are consistent with those from a large, longitudinal study involving 2246 singleton pregnancies that found that PlGF and sFlt-1 levels had limited sensitivity, specificity, and positive predictive value for predicting the development of preeclampsia.[102]

Kanasaki et al.[103] hypothesized that a molecular defect upstream from the soluble factors contributes to preeclampsia. The investigators demonstrated that pregnant mice deficient in **catechol-*O*-methyltransferase (COMT)** demonstrate a preeclampsia-like phenotype in response to the absence of **2-methoxyestradiol (2-ME)**, a natural metabolite of estradiol that is elevated during the third trimester of normal pregnancy. Administration of 2-ME to COMT-deficient mice suppresses placental hypoxia and sFlt-1 elevation. In addition, women with severe preeclampsia have significantly lower

levels of COMT and 2-ME than women with healthy pregnancies. However, a subsequent study in humans failed to find a significant difference in placental COMT expression in women with early-onset, severe preeclampsia compared with normotensive women[104]; therefore, further research is needed to determine what, if any, role COMT plays in the pathogenesis of preeclampsia.

Genetic Factors

There is a strong genetic basis underlying the risk for preeclampsia that is attributable to both maternal and fetal genetic factors. It is estimated that approximately one fifth of the variance in disease risk is attributable to fetal genetic effects, and one third is attributable to maternal genetic factors.[47] Despite this, with the possible exception of thrombophilia genes, no genetic variants have been robustly associated with preeclampsia. Because preeclampsia is extremely likely to be polygenic, genome-wide association studies may provide a useful approach to identify preeclampsia genes. A large, international collaborative is currently undertaking a genome-wide association study of this disease and results are expected soon. In addition to increasing the understanding of the genetic architecture of preeclampsia, the identification of genetic variants associated with the disease may provide new avenues to understanding the basic pathophysiology of this disorder.

Prophylaxis

Administration of **low-dose aspirin** has been proposed for the prevention of preeclampsia based on the observation that thromboxane is increased relative to prostacyclin in preeclamptic pregnancies. Aspirin inhibits the synthesis of prostaglandins by the irreversible acetylation and inactivation of cyclooxygenase. Thromboxane and prostacyclin are arachidonic acid metabolites and physiologic antagonists important in vasoregulation. Thromboxane is a potent vasoconstrictor, and prostacyclin is a strong vasodilator. Aspirin inhibits the biosynthesis of platelet thromboxane A_2, and it has been hypothesized that preeclampsia could be prevented by preventing the imbalance in the thromboxane-to-prostacyclin ratio. Meta-analysis of available data points to a 10% to 20% reduction in the risk for developing preeclampsia in women treated with aspirin or other antiplatelet agents.[105,106] The reduction in risk is most evident in women at moderate or high risk for preeclampsia who initiate aspirin prophylaxis at 16 weeks' gestation or earlier.[107,108] The ACOG suggests daily low-dose aspirin, beginning in the late first trimester, specifically for women with a history of preeclampsia leading to prior preterm delivery before 34 weeks' gestation, or preeclampsia in more than one prior pregnancy.[4]

Calcium supplementation has been studied for preeclampsia prophylaxis based on observations that dietary calcium intake is inversely related to the incidence of preeclampsia.[109] A 2010 meta-analysis of available randomized controlled clinical trial data showed that calcium supplementation decreased the risk for preeclampsia by approximately 50%.[110] The reduction in risk was most pronounced in high-risk women and those with low baseline calcium intake.[110] However, in a large multicenter, randomized, placebo-controlled trial involving 2589 healthy, nulliparous women conducted in the United States, ingestion of 2 g of elemental calcium daily did not reduce the occurrence of preeclampsia or gestational hypertension overall or in a subset of women with low baseline calcium intake.[111] The ACOG does not recommend calcium supplementation to prevent preeclampsia for women with normal dietary calcium intake.[4]

Antioxidant supplementation has also been investigated as prophylaxis because of the important role oxidative stress is thought to play in the pathogenesis of preeclampsia. Numerous studies have been conducted to investigate a possible prophylactic or therapeutic role for antioxidant supplementation in the hypertensive disorders of pregnancy. Although some early, small studies suggested that this may be a promising approach, subsequent larger, high-quality studies have not shown a benefit.[112] In randomized, controlled clinical trials, supplementation with 1000 mg of vitamin C and 400 IU of vitamin E did not reduce the incidence of preeclampsia in healthy nulliparous women[113] or in women at increased risk for preeclampsia.[114,115] One of these trials even showed evidence of harm, with a greater incidence of (1) low birth weight, (2) unexplained fetal death after 24 weeks' gestation, and (3) umbilical cord blood acidemia in patients randomized to the antioxidant group.[115] The ACOG does not recommend the administration of vitamin C or vitamin E to prevent preeclampsia.[4]

Clinical Presentation

Preeclampsia occurs more frequently in nulliparous women and most commonly presents during the third trimester, often near term. Women with early-onset disease (before 34 weeks' gestation) have worse outcomes than women with late-onset disease. The disease typically regresses rapidly after delivery, with resolution of symptoms within 48 hours. However, preeclampsia can also manifest postpartum with hypertension, proteinuria, or the occurrence of seizures (eclampsia). Postpartum preeclampsia usually presents within 7 days of delivery.[116]

Disease manifestations of severe preeclampsia occur in all body systems as the result of widespread endothelial dysfunction.

Central Nervous System

Although the term *preeclampsia* suggests that eclampsia is the end stage of preeclampsia, it is more accurate to consider eclampsia as the outward manifestation of disease progression in the brain, similar to other organ involvement. Central nervous system manifestations include severe headache, hyperexcitability, hyperreflexia, and coma.[3,117] Visual disturbances can include scotoma, amaurosis, and blurred vision.[118]

Noninvasive measurements of cerebral blood flow and resistance, along with other neuroimaging approaches, suggest that the loss of cerebral vascular autoregulation and vascular barotrauma occur with preeclampsia and eclampsia.[118,119] Hyperperfusion of the

brain, particularly in the setting of the endothelial dysfunction present in preeclampsia, causes vasogenic edema. Failure of autoregulation occurs most commonly in the posterior circulation, such that the changes in the brain with severe preeclampsia/eclampsia result in the posterior reversible leukoencephalopathy syndrome (PRES).[118,120-122]

Airway

In pregnant women, the internal diameter of the trachea is reduced because of mucosal capillary engorgement. In women with preeclampsia, these changes can be exaggerated with upper airway narrowing as a result of **pharyngolaryngeal edema**; these changes may compromise visualization of airway landmarks during direct laryngoscopy.[123] **Subglottic edema** can cause airway obstruction. Signs of airway obstruction include dysphonia, hoarseness, snoring, stridor, and hypoxemia.[124,125]

Pulmonary

Pulmonary edema is a severe complication that occurs in approximately 3% of women with preeclampsia.[126] It is relatively infrequent in healthy, younger women; the risk increases in older multigravid women, in women with preeclampsia superimposed on chronic hypertension or renal disease, and among those whose preeclampsia leads to oliguria.

Plasma colloid osmotic pressure is reduced in normal pregnancy because of decreased plasma albumin concentration, and it is decreased even further in preeclamptic women.[127] Women with normal pregnancies have a mean osmotic pressure of approximately 22 mm Hg in the third trimester and approximately 17 mm Hg during the early postpartum period. In contrast, a study of women with preeclampsia demonstrated a mean colloid osmotic pressure of approximately 18 mm Hg before delivery and 14 mm Hg after delivery.[128] Decreased colloid osmotic pressure, in combination with increased vascular permeability and the loss of intravascular fluid and protein into the interstitium, increases the risk for pulmonary edema.[129] Excess intravenous fluid is an important risk factor for pulmonary edema in preeclamptic patients.[130]

Cardiovascular

Women with preeclampsia have increased vascular tone and increased sensitivity to vasoconstrictor influences, which result in the clinical manifestations of hypertension, vasospasm, and end-organ ischemia.[131] Preeclampsia is characterized by severe vasospasm as well as exaggerated hemodynamic responses to circulating catecholamines.[132,133] Characteristically, blood pressure and systemic vascular resistance are elevated. In preeclampsia without severe features, plasma volume may be normal; however, it may be reduced as much as 40% in women with severe disease.[134]

Severe preeclampsia is usually a **hyperdynamic state**. Many studies have attempted to characterize the hemodynamic characteristics of preeclampsia using invasive monitoring techniques or echocardiography.[135-138] Interpretation and comparison of the results of these studies have been difficult because of variation in patient populations, definitions of preeclampsia, disease severity, prior treatment, and the presence or absence of concomitant comorbid disease. Hemodynamic characteristics in preeclamptic women are more complex than originally thought, in part, because hemodynamic measurements change with treatment and disease progression. Overall, studies have found that the majority of affected women exhibit increased cardiac output,[138] hyperdynamic left ventricular function,[135] and mild to moderately increased systemic vascular resistance.[135,138] A smaller group of women comprise a high-risk group who present with decreased left ventricular function, markedly decreased systemic vascular resistance, and severely decreased intravascular volume.[135,139]

Hematologic

Thrombocytopenia is the most common hematologic abnormality in women with preeclampsia. Platelet counts less than 100,000/mm^3 occur most commonly in women with severe disease or HELLP syndrome[17] and correlate with the severity of the disease process.

Studies using thromboelastography have found that women with preeclampsia without severe features are *hyper*coagulable relative to women without preeclampsia and that those with severe disease are relatively *hypo*coagulable.[140] In contrast to normal pregnancies and other hypertensive disorders, platelets are activated in preeclampsia[141]; subsequent platelet degranulation is believed to account for the decreases in platelet function, and aggregation appears to account for the decrease in platelet count.[142]

The syndrome of **disseminated intravascular coagulation** (DIC) occurs in some women with preeclampsia, generally in the setting of severe liver involvement, intrauterine fetal demise, placental abruption, or postpartum hemorrhage.[143] Activation of the coagulation system is marked by consumption of procoagulants, increased levels of fibrin degradation products, and end-organ damage secondary to microthrombi formation. In advanced DIC, procoagulants (e.g., fibrinogen, platelets) decrease to a level that may lead to spontaneous hemorrhage.

Hepatic

Hepatic manifestations include periportal hemorrhage and fibrin deposition in hepatic sinusoids. Hepatic involvement frequently presents as right upper quadrant or epigastric pain. Damage ranges from mild hepatocellular necrosis to the more ominous HELLP syndrome and can be associated with subcapsular bleeding and risk for hepatic rupture. Spontaneous hepatic rupture is rare but is associated with a 32% maternal mortality rate.[144]

Renal

Renal manifestations of preeclampsia include persistent proteinuria, changes in the glomerular filtration rate, and hyperuricemia. The presence of **proteinuria** is a defining

element of preeclampsia. The characteristic renal histologic lesion of preeclampsia is glomerular capillary endotheliosis and manifests as glomerular enlargement and endothelial and mesangial cell swelling. Increasing urinary excretion of protein likely results from changes in the pore size or charge selectivity of the glomerular filter and impaired proximal tubular reabsorption.[145]

During normal pregnancy, the **glomerular filtration rate** (GFR) *increases* by 40% to 60% during the first trimester,[146,147] with a resulting decrease in the serum markers of renal clearance, including blood urea nitrogen (BUN), creatinine, and uric acid. In preeclampsia, this increase in GFR is blunted compared with normal pregnancy.[145] Notably, women with preeclampsia may have BUN and creatinine measurements in the normal range for nonpregnant women despite significantly decreased GFR relative to healthy pregnant women.

The association between preeclampsia and **hyperuricemia** was recognized as early as 1917.[148] Most evidence suggests that decreased renal clearance is the primary mechanism for elevated uric acid levels.[149] Because levels of serum uric acid begin to increase as early as 25 weeks' gestation,[150] it has been investigated as a possible early predictor of preeclampsia.

Oliguria is a possible late manifestation of severe preeclampsia and parallels the severity of disease. Persistent oliguria (< 500 mL urine output in 24 hours) requires immediate assessment of intravascular volume status. Progression to renal failure is rare and is typically preceded by hypovolemia, placental abruption, or DIC.

Uteroplacental Perfusion

Uteroplacental perfusion can be impaired in pregnancies complicated by preeclampsia. In contrast to normal pregnancy, downstream resistance in the uteroplacental bed increases, diastolic flow velocity decreases, and the systolic-to-diastolic flow velocity ratio increases.[151] The systolic-to-diastolic ratio, calculated from Doppler ultrasonographic determination of blood flow velocities, reflects intrinsic arterial resistance. Pathophysiologic changes can result in fetal growth restriction (the fetal syndrome) in some pregnancies complicated by severe preeclampsia.

Obstetric Management

Optimal management of the woman with preeclampsia requires a team approach. There is considerable overlap in areas of concern to the obstetrician and the anesthesia provider.

Obstetric management of preeclampsia centers on the following: (1) fetal and maternal surveillance, (2) treatment of hypertension, (3) seizure prophylaxis, and (4) decisions regarding the timing and route of delivery. Delivery remains the only cure for preeclampsia. Obstetric care of women with preeclampsia without severe features differs little from routine management of healthy pregnant women, with the exception of careful monitoring to detect the progression of disease to severe preeclampsia. Data suggest induction of labor for pregnancies beyond 37 weeks' gestation in women with gestational hypertension or preeclampsia without severe features is associated with improved maternal outcomes compared with expectant management.[4,152] Outcomes in these pregnancies are similar to those in uncomplicated pregnancies.[4,13,77]

In general, induction of labor is recommended for women presenting with severe preeclampsia at 34 weeks' gestation or later.[4,17] For women at less than 34 weeks' gestation, expectant management may improve fetal outcomes without substantially endangering the mother,[77,153] but data are few.[154] Delay of delivery for 24 to 48 hours allows for the administration of corticosteroids to facilitate fetal lung maturity and transfer to a facility with maternal and neonatal intensive care resources. Expedited delivery, regardless of corticosteroid administration, is indicated for patients with eclampsia, pulmonary edema, DIC, placental abruption, abnormal fetal surveillance, a previable or nonviable fetus, or intrauterine fetal demise (Figure 36-6).[4,155] If a woman develops refractory severe hypertension despite maximum doses of antihypertensive agents *or* persistent cerebral symptoms while receiving magnesium sulfate, delivery should occur within 24 to 48 hours, regardless of gestational age or corticosteroid administration.[4,155] Expectant management before 34 weeks' gestation should be undertaken at facilities with neonatal and maternal intensive care resources.[4]

Maternal and Fetal Surveillance

Maternal surveillance is indicated for all preeclamptic women. In women with preeclampsia without severe features, the goal is early detection of severe disease. In women with severe disease, the goal is detection of worsening organ dysfunction. All women should be evaluated for signs or symptoms indicating end-organ involvement, including (1) severe headache, (2) visual disturbances, (3) altered mentation, (4) dyspnea, (5) right upper quadrant or epigastric pain, (6) nausea and vomiting, (7) decreased urine output, and (8) CNS hyperexcitability.[3]

Initial laboratory investigations for the pregnant woman who develops hypertension after 20 weeks' gestation are listed in Table 36-3. The admission platelet count is an excellent predictor of subsequent thrombocytopenia.[156] For preeclamptic women with a platelet count exceeding 100,000/mm^3, further coagulation testing is not required because coagulopathy is rarely present in severely preeclamptic women who have a normal platelet count.[156] If the platelet count is less than 100,000/mm^3, other hemostatic abnormalities (e.g., prolonged prothrombin time [PT] and activated partial thromboplastin time [aPTT], reduced fibrinogen concentration) may be present.[156] Further coagulation studies may be useful, particularly if risk factors for DIC are present (e.g., placental abruption, liver dysfunction, HELLP syndrome). Liver function tests are obtained in all women with preeclampsia because abnormal levels indicate more severe disease and may prompt delivery. Approximately 20% of preeclamptic women have elevated serum aminotransferase levels.[157] The value of uric acid testing is controversial, with conflicting evidence regarding its association with increased fetal or maternal risk for complications.[158-160]

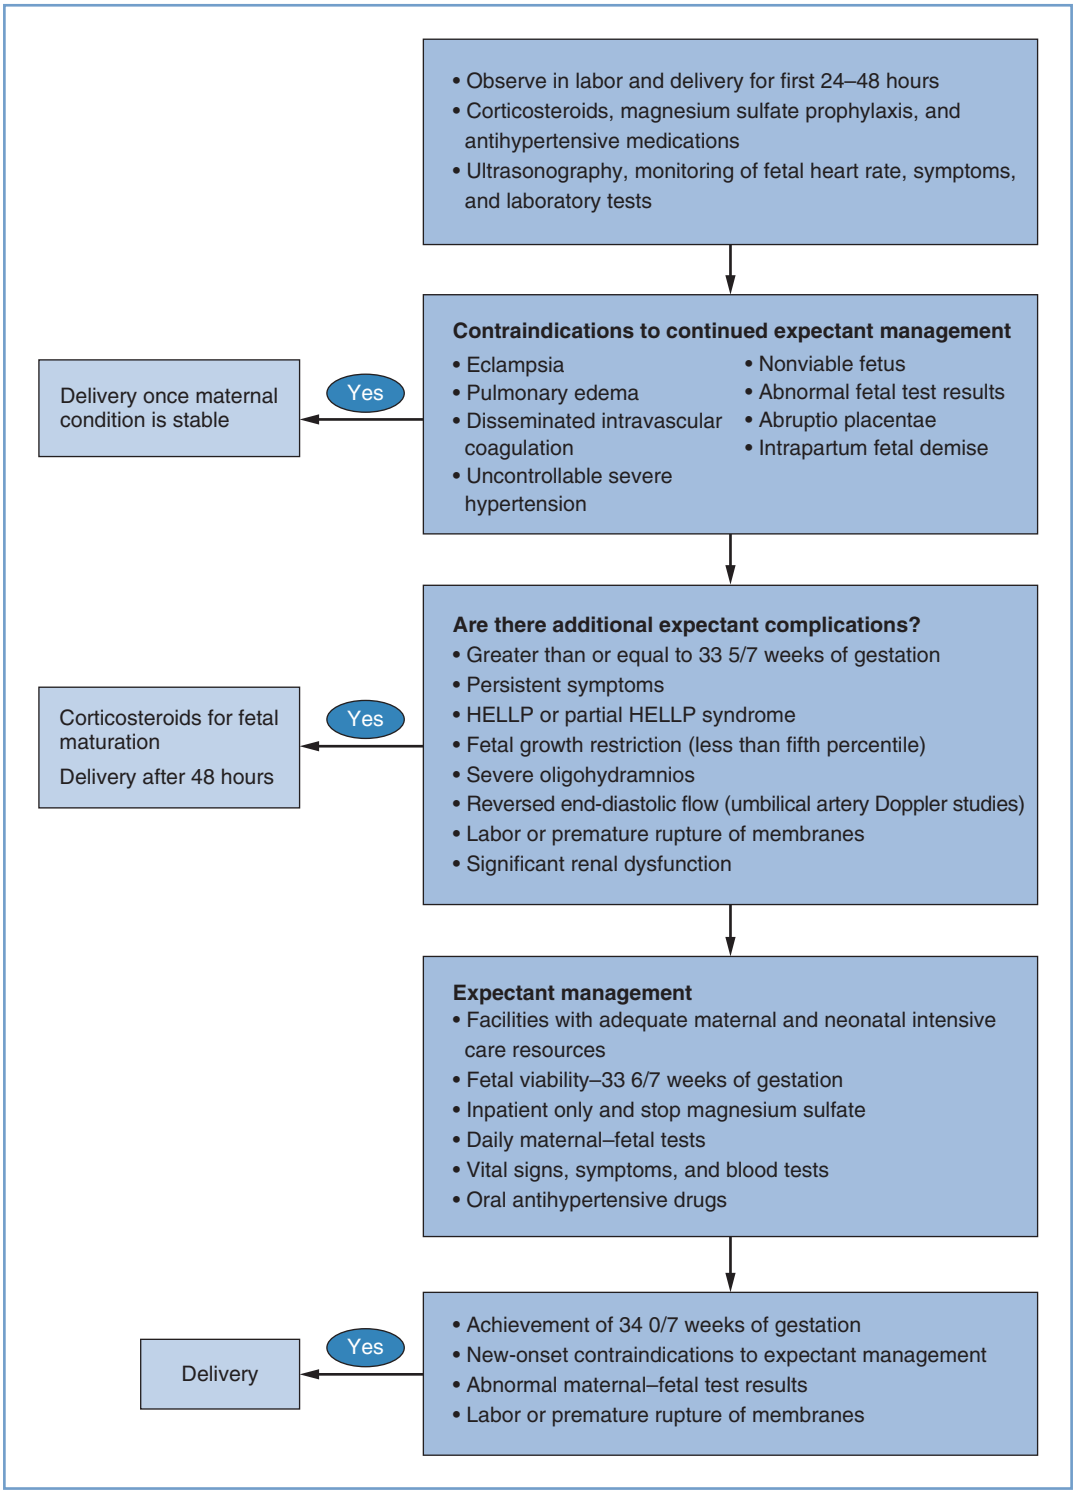

FIGURE 36-6 ■ Suggested algorithm for the management of severe preeclampsia at less than 34 weeks' gestation. *HELLP,* hemolysis, elevated liver enzymes, and low platelet count. (From American College of Obstetricians and Gynecologists Taskforce on Hypertension in Pregnancy. Hypertension in pregnancy. ACOG. Washington, DC, 2013.)

TABLE 36-3 Initial Laboratory Investigations for Women in Whom Hypertension Develops after 20 Weeks' Gestation

Test	Rationale
Hemoglobin and hematocrit	Hemoconcentration supports diagnosis of preeclampsia and is an indicator of severity. Values are decreased if hemolysis is present.
Platelet count	Thrombocytopenia suggests severe preeclampsia.
Urine protein-creatinine ratio or 24-h urine protein excretion	Presence of proteinuria distinguishes preeclampsia from gestational hypertension.
Serum creatinine level	Abnormal or rising creatinine level suggests severe preeclampsia, especially in presence of oliguria.
Serum aminotransferase levels	Elevated serum aminotransferase levels suggest severe preeclampsia with hepatic involvement.

Modified from Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy. Am J Obstet Gynecol 2000; 183:S1-S22; and American College of Obstetricians and Gynecologists Taskforce on Hypertension in Pregnancy. Hypertension in pregnancy. ACOG. Washington, DC, 2013.

In general, the frequency of subsequent laboratory evaluation will be guided by the initial findings and the severity of illness and disease progression.[155] A diagnosis of preeclampsia without severe features should prompt at least weekly laboratory investigations, with the frequency modified based on subsequent clinical findings.[4] In the expectant management of severe preeclampsia, hemoglobin, platelet count, liver function tests, creatinine, and coagulation parameters should be assessed daily or every other day.[4,161] For women undergoing induction of labor for whom initial laboratory measurement or daily platelet counts demonstrate thrombocytopenia, serial platelet counts at least every 6 hours may be useful to detect declining platelet counts and to guide decision-making about the timing of delivery and analgesic or anesthetic technique. Finally, for women with indicated delivery, an active type and screen is indicated, with consideration of type and crossmatch of 2 units of packed red blood cells or more, because these women are at increased risk for postpartum hemorrhage.[162]

Preeclampsia is a known risk factor for perinatal death. The ACOG Taskforce on Hypertension in Pregnancy recommends daily fetal movement counts with either nonstress testing or biophysical profile testing at the time of diagnosis and at regular intervals thereafter.[4,163] Ultrasonography is used to estimate fetal weight and amniotic fluid volume. Doppler ultrasonography is used to measure fetal blood flow velocimetry when fetal growth restriction is suspected.[4,164,165]

Treatment of Acute Hypertension

Antihypertensive medications are used to treat severe hypertension (systolic blood pressure ≥ 160 mm Hg or diastolic blood pressure ≥ 110 mm Hg) with the goal of preventing adverse maternal sequelae such as hypertensive encephalopathy, cerebrovascular hemorrhage, myocardial ischemia, and congestive heart failure.[163,166]

Although acute control of maternal blood pressure is critical, rapid changes in maternal perfusion pressure may adversely affect uteroplacental perfusion and oxygen delivery to the fetus. Antihypertensive medications should be carefully titrated to avoid abrupt changes in maternal blood pressure. The aim of therapy is to lower the mean arterial blood pressure by no more than 15% to 25%, with a target systolic blood pressure between 120 and 160 mm Hg and a diastolic blood pressure between 80 and 105 mm Hg.[4,167,168] Commonly used drugs include labetalol, hydralazine, and nifedipine. Nicardipine, sodium nitroprusside, and esmolol may be considered second-line agents (Table 36-4). In usual clinical doses, all are considered safe for the fetus.

Systematic review and meta-analysis of available studies show insufficient data regarding the relative efficacy of these commonly used agents and recommend selection based on clinician familiarity and what is known about adverse effects.[169] The systematic review does, however, suggest that some agents are inferior and recommends avoiding diazoxide, katanserin, nimodipine, and magnesium sulfate for the treatment of severe hypertension in pregnancy (although magnesium is recommended for seizure prophylaxis).[169] A 2011 ACOG Committee Opinion recommends labetalol or hydralazine as first-line treatment for acute-onset, severe hypertension in pregnant or postpartum patients.[166]

Labetalol. Labetalol is a combined alpha- and beta-adrenergic receptor antagonist with a 1-to-7 ratio of alpha- to beta-adrenergic receptor antagonism when administered intravenously. Labetalol should be avoided in women with severe asthma or congestive heart failure.[170]

A systematic review[169] and a meta-analysis[171] of small, randomized controlled trials concluded that intravenous labetalol has efficacy similar to intravenous hydralazine but with fewer maternal side effects.

Hydralazine. Hydralazine has been used safely in pregnant women for decades and is also considered a first-line drug for treating severe hypertension in pregnancy.[166] Hydralazine exerts a potent direct vasodilating effect. Plasma volume expansion before administration decreases the risk for maternal hypotension. Other side effects include tachycardia, palpitations, headache, and neonatal thrombocytopenia.[172,173] In a randomized clinical trial, hydralazine was associated with more maternal tachycardia and palpitations and less neonatal bradycardia and hypotension than labetalol,[174] but both antihypertensive drugs are considered safe and effective for the treatment of severe hypertension in pregnant women.

TABLE 36-4 Treatment of Acute Severe Hypertension* In Preeclampsia/Eclampsia

Medication	Onset of Action†	Dose
Labetalol	5-10 min	20 mg IV, then 40-80 mg every 10 min up to maximum dose of 220 mg IV
Hydralazine	10-20 min	5 mg IV every 20 min up to maximum dose of 20 mg IV
Nifedipine	10-20 min	10 mg PO every 20 min up to a maximum dose of 50 mg
Nicardipine	10-15 min	Initial infusion 5 mg/h, increase by 2.5 mg/h every 5 min to a maximum of 15 mg/h
Sodium nitroprusside‡	0.5-1 min	0.25-5.0 μg/kg/min IV infusion

IV, intravenously; *PO,* per os.
*Systolic blood pressure ≥ 160 mm Hg, diastolic blood pressure ≥ 110 mm Hg, or both, if sustained.

‡Risk for fetal cyanide poisoning with treatment > 4 hours.
Modified from Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy. Am J Obstet Gynecol 2000; 183:S1-S22; Marik PE, Rivera R. Hypertensive emergencies: an update. Curr Opin Crit Care 2011; 17:569-80; and Shekhar S, Sharma C, Thakur S, Verma S. Oral nifedipine or intravenous labetalol for hypertensive emergency in pregnancy: a randomized controlled trial. Obstet Gynecol 2013; 122:1057-63.

Nifedipine. Nifedipine is a calcium entry–blocking agent that lowers blood pressure by relaxing arterial and arteriolar smooth muscle. It can be administered as a long-acting oral medication once the severe hypertension has stabilized. Nifedipine immediate-release capsules should never be administered to women with known coronary artery disease, long-standing diabetes mellitus or aortic stenosis, or to women older than 45 years of age because of an increased risk for sudden cardiac death.[77] Although earlier reports suggested that the coadministration of nifedipine with magnesium sulfate causes adverse effects in both mother and fetus, including severe maternal hypotension,[175,176] neuromuscular blockade,[177,178] and nonreassuring FHR patterns,[175,176] subsequent data suggest that these drugs can be used together safely.[179,180]

Other Agents. If labetalol, hydralazine, or nifedipine are not effective in controlling blood pressure, consideration may be given to using a nicardipine or labetalol infusion or other antihypertensive agents.[166]

Nicardipine is a calcium entry–blocking agent that can be administered by intravenous infusion and has been shown to achieve rapid decreases in systolic and diastolic blood pressures in pregnant women.[181] It is an excellent option for treating severe hypertension that is not responsive to labetalol or hydralazine.[166]

Sodium nitroprusside is a potent smooth muscle vasodilator that interacts with sulfhydryl groups on endothelial cells and results in the release of nitric oxide.[182,183] It relaxes arterial vessels and reduces both afterload and venous return, with an almost instantaneous onset. The drug is used in pregnant women with severe hypertension who do not respond to hydralazine or labetalol therapy. It should be used only in emergency situations and then for the shortest time period possible because sodium nitroprusside metabolism produces cyanide, which undergoes placental transfer, thus exposing the fetus to potential cyanide toxicity. However, fetal harm is unlikely to result from short-term use of sodium nitroprusside in doses of 2 μg/kg/min or less. Use of the drug requires careful titration; continuous intra-arterial blood pressure monitoring is mandatory.

Esmolol is a short-acting beta-adrenergic receptor antagonist that can be used to treat acute hypertension. Concerns regarding the use of esmolol during pregnancy arose in 1989 after a report of dose-dependent prolonged fetal bradycardia in a study of gravid ewes receiving esmolol by stepped infusion.[184] Subsequent human case reports have reported variable responses,[185-187] but in most cases fetal bradycardia was transient and FHR returned to baseline after discontinuation of the drug. Placental transfer is rapid and the anesthesia provider should expect to observe the clinical effects of beta-adrenergic receptor blockade in the fetus. Maternal administration of esmolol produces a greater degree of beta-adrenergic receptor blockade in the fetal lamb than that observed after maternal administration of an equipotent dose of labetalol.[184,188]

Seizure Prophylaxis

The routine use of magnesium sulfate for seizure prophylaxis in women with *severe* preeclampsia is an established obstetric practice in the United States and has gained popularity throughout the world. There is clear evidence that magnesium sulfate is the best available agent for prevention of recurrent seizures in women with eclampsia[189,190]; thus, its use has been extended to seizure prophylaxis in women with severe preeclampsia.[4]

A 2010 meta-analysis of the available data identified six trials involving 11,444 women that compared magnesium sulfate for the treatment of preeclampsia with either placebo or no anticonvulsant.[191] Magnesium decreased the risk for developing eclampsia (relative risk [RR], 0.41; 95% confidence interval [CI], 0.29 to 0.58); there was also a trend toward lower risk for maternal death (RR, 0.54; 95% CI, 0.26 to 1.10) but no effect on serious maternal morbidity.[191] Additionally, magnesium therapy reduced the risk for placental abruption but did not adversely affect fetal and/or neonatal outcomes, including stillbirth, perinatal death, or neurosensory disability.[191] Treatment with magnesium increased the risk for maternal respiratory depression (RR, 1.98; 95% CI, 1.24 to 3.15) and cesarean delivery (RR, 1.05; 95% CI, 1.01 to 1.10).[191] Other side effects that were significantly more common in those treated with magnesium included feeling warm or flushed, nausea/vomiting, muscle weakness, hypotension, dizziness, drowsiness/confusion, and headache.[191]

There are insufficient data to justify the use of magnesium sulfate for seizure prevention in preeclampsia without severe features.[4] Studies have failed to show a difference in the number of women who progressed to severe preeclampsia.[192-195]

The mechanism of the anticonvulsant effect of magnesium is not well understood. It was previously believed that eclamptic seizures were the result of cerebral vasospasm, and it was also believed that the cerebral vasodilating properties of magnesium reduced the rate of eclamptic seizures by relieving vasospasm.[196] However, more recent evidence suggests that abrupt, sustained blood pressure elevation overwhelms myogenic vasoconstriction and causes forced dilation of the cerebral vessels, hyperperfusion, and cerebral edema.[119,196-198] This evidence raises the question of how magnesium sulfate—a vasodilator—could be effective in seizure prophylaxis; magnesium would be expected to worsen cerebral hyperperfusion and edema. Using a rat model, Euser and Cipolla[196] demonstrated that the mesenteric vessels are more sensitive to magnesium-induced vasodilation than are cerebral vessels, suggesting that part of the effect may be mediated through decreasing peripheral vascular resistance.[199] Magnesium may also protect the blood-brain barrier,[199] decrease cerebral edema,[199] or act centrally at *N*-methyl-D-aspartate (NMDA) receptors to raise the seizure threshold.[200]

No consensus exists regarding the following: (1) the ideal time to initiate treatment with magnesium sulfate, (2) the best loading and maintenance doses, and (3) the optimal duration of therapy. Many obstetricians administer a loading dose of 4 to 6 g over 20 to 30 minutes, followed by a maintenance infusion of 1 to 2 g/h. The infusion is commonly initiated once the decision is made to deliver and is continued for 24 hours postpartum. Expert opinion recommends that severely preeclamptic women undergoing cesarean delivery should receive magnesium sulfate at least 2 hours before the procedure, during surgery, and for 12 hours postpartum.[4,194]

Magnesium sulfate is eliminated almost entirely by renal excretion,[201] and serum levels may become dangerously high in the presence of renal insufficiency. Side effects include chest pain and tightness, palpitations, nausea, blurred vision, sedation, transient hypotension, and, rarely, pulmonary edema.[202,203] In untreated patients, the normal range for serum magnesium concentrations is 1.7 to 2.4 mg/dL. The therapeutic range lies between 5 and 9 mg/dL.[193] Reflex testing is used as a clinical screen for hypermagnesemia; when deep tendon reflexes are preserved, the more serious side effects are usually avoided. Patellar reflexes are lost at serum magnesium levels of approximately 12 mg/dL. Respiratory arrest occurs at levels of 15 to 20 mg/dL, and asystole occurs when the level exceeds 25 mg/dL.[204] Preeclamptic women with renal impairment should be monitored closely because magnesium toxicity can occur with usual dosing regimens. Serial measurement of serum magnesium levels may be helpful in the management of women with renal dysfunction.

Treatment of suspected magnesium toxicity includes immediate discontinuation of the infusion and the intravenous administration of **calcium gluconate** (1 g) over 10 minutes.[205] In the rare event of respiratory compromise, the patient may require tracheal intubation and mechanical ventilation until spontaneous ventilation returns.

Route of Delivery

Vaginal delivery should be attempted in all women with preeclampsia without severe features, assuming no other indications for cesarean delivery exist. Vaginal delivery should also be attempted in most women with severe disease, especially those beyond 34 weeks' gestation. The report of the NHBPEP Working Group on High Blood Pressure in Pregnancy states[3]:

> *Vaginal delivery is preferable to cesarean delivery for women with preeclampsia, because it avoids addition of the stress of surgery to the multiple physiologic aberrations [of the disease]. Acute palliation for several hours does not increase maternal risk if performed appropriately. Labor induction should be carried out aggressively once the decision for delivery has been made. In gestation remote from term in which delivery is indicated, and with fetal and maternal conditions stable enough to permit pregnancy to be prolonged 48 hours, glucocorticoids can be safely administered to accelerate fetal pulmonary maturity.*

Cesarean delivery is appropriate when the maternal or fetal condition mandates immediate delivery or when other indications for cesarean delivery exist.

Corticosteroid Administration for Severe Preeclampsia or HELLP Syndrome

To accelerate fetal lung maturity, all women who develop severe preeclampsia or HELLP syndrome between 24 and 34 weeks' gestation should receive a course of corticosteroid therapy. A randomized double-blind trial of 218 women with severe preeclampsia at 26 to 34 weeks' gestation found that the infants of those receiving betamethasone, compared with the infants of those receiving placebo, exhibited a significant reduction in the rate of the neonatal respiratory distress syndrome and reduced rates of neonatal intraventricular hemorrhage, infection, and death.[206] The available data also suggest that treatment with corticosteroids results in improvement in the maternal platelet count in women with HELLP, with dexamethasone being more efficacious than betamethasone.[207] However, these studies do not show clear benefit of corticosteroid treatment on the endpoints of severe maternal morbidity or mortality.[207]

Complications

Severe preeclampsia is associated with an increased risk for maternal morbidity and mortality, including HELLP syndrome, cerebrovascular accident, pulmonary edema, renal failure, placental abruption, and eclampsia. In general, these complications are more common in women with early-onset preeclampsia and in women with prepregnancy medical conditions, including diabetes mellitus, chronic renal disease, and thrombophilia.[38]

Cerebrovascular Accident

Although the absolute risk for cerebrovascular accident is low, preeclampsia confers markedly increased risk for intracerebral and subarachnoid hemorrhage[208,209] and ischemic stroke.[210,211] Stroke remains the leading cause of death in women with preeclampsia.[212] In the 2006-2008 Confidential Enquiry into Maternal and Child Health (CEMACH) report, 19 deaths were attributed to eclampsia and preeclampsia; 9 resulted from intracranial hemorrhage. Failure to adequately control hypertension was noted in most of these cases. The CEMACH report emphasized the importance of urgent treatment of preeclamptic women with a systolic blood pressure in excess of 150 to 160 mm Hg or at lower pressures if the clinical condition suggests rapid deterioration.[212]

The endothelial dysfunction of preeclampsia can promote edema, vascular tone instability, platelet activation, and local thrombosis. Reversible cerebral edema is the most common CNS feature of preeclampsia or eclampsia. The loss of cerebral autoregulation causes hyperperfusion that, compounded by endothelial disruption, leads to interstitial or vasogenic edema.[76,213,214] The presence of HELLP syndrome or DIC increases the risk for a hemorrhagic event.

As noted in the CEMACH recommendations,[212] there is growing recognition that mean arterial blood pressure and diastolic blood pressure may not reflect the true risk for stroke. A review of 28 case histories of severely preeclamptic women who suffered a stroke revealed that (1) systolic blood pressure in excess of 160 mm Hg was a far superior predictor of stroke than diastolic hypertension or mean arterial pressure, (2) the majority of strokes were hemorrhagic (93%) as opposed to thrombotic (7%), and (3) the majority of strokes (57%) occurred in the postpartum period.[168] Close attention to blood pressure control throughout the peripartum period is the mainstay of stroke prevention.[166] In keeping with this goal, ergot alkaloids should be avoided in hypertensive patients because their administration can result in severe hypertension.[212]

Pulmonary Edema

Pulmonary edema is a severe complication of preeclampsia that occurs in approximately 3% of affected women.[126] It is relatively infrequent in younger (previously healthy) women; risk increases in older, multigravid women and in women with preeclampsia superimposed on chronic hypertension or renal disease. The clinical presentation is characterized by worsening dyspnea and orthopnea with concomitant signs of respiratory compromise, including tachypnea, rales, and hypoxemia. Causes of pulmonary edema include low colloid osmotic pressure, increased intravascular hydrostatic pressure, and increased pulmonary capillary permeability.[215] All of these factors may coexist in a single patient.

A large proportion of cases of pulmonary edema occur postpartum, usually within 2 to 3 days after delivery, and management is directed toward the underlying cause (e.g., fluid overload, sepsis, cardiac failure).[216] Echocardiography can be helpful in the diagnosis of cardiogenic causes of pulmonary edema.[217,218] Initial treatment includes administration of supplemental oxygen, fluid restriction, and diuretic therapy (e.g., furosemide). A retrospective study of 86 women with peripartum pulmonary edema found that even in the presence of extensive radiographic infiltrates and severe hypoxemia, resolution was typically rapid, with a limited need for intensive care unit admission.[219] Placement of a pulmonary artery catheter can facilitate management of patients with severe refractory pulmonary edema, but a high rate of complications of these catheters in hypertensive patients is reported, and their use should only follow careful assessment of the risks and benefits.[220] Notably, in the last two CEMACH reports,[212,221] there were no deaths attributed solely to pulmonary causes. Presumably, this trend reflects improvements in the fluid management of women with severe preeclampsia.

Renal Failure

Acute renal failure is a rare but serious complication of severe preeclampsia and HELLP syndrome.[222] The true incidence remains unknown. Acute renal failure is divided into three categories: (1) **prerenal**, which refers to renal hypoperfusion; (2) **intrarenal**, which suggests intrinsic renal parenchymal damage; and (3) **postrenal**, which implies obstructive uropathy.[223] The majority of cases (83% to 90%) of acute renal failure in preeclampsia result from prerenal and intrarenal pathologic processes (most commonly acute tubular necrosis) and resolve completely after delivery.[224,225] In contrast, bilateral renal cortical necrosis is a rare and serious condition associated with considerable maternal and perinatal morbidity and mortality. It occurs most commonly in association with known renal parenchymal disease, chronic hypertension with superimposed preeclampsia, placental abruption, DIC, HELLP syndrome, sepsis, or fetal death.[226,227]

Placental Abruption

Placental abruption occurs in approximately 2% of women with preeclampsia and results in increased perinatal morbidity and mortality. A 2006 retrospective case-control study of 161 women with placental abruption and 2000 women without abruption found a threefold increased risk for placental abruption in women with preeclampsia.[228] The incidence is also increased in women with underlying chronic hypertension.[216] Management depends on the extent of abruption and associated hypotension, coagulopathy, or fetal compromise (see Chapter 38). Placental abruption is also associated with the development of DIC.

Prediction of Adverse Maternal Outcome

Identification of women at greatest risk for adverse maternal outcomes is potentially useful in guiding triage to high-risk centers and weighing the risks and benefits of expectant management. A 2011 multicenter, prospective study involving 2023 women with preeclampsia admitted to tertiary care centers described a model for predicting which women would develop fatal or life-threatening complications.[229] Adverse outcomes occurred

in 261 patients. Predictors of adverse maternal outcome included early gestational age, chest pain or dyspnea, oxygen saturation, platelet count, and creatinine and aspartate aminotransferase concentrations. The model showed excellent discrimination with an area under the receiver operating characteristics (ROC) curve of 0.88 for adverse events within 48 hours of admission. It continued to perform well in predicting adverse events up to 7 days after admission.[229]

HELLP Syndrome

The HELLP syndrome is characterized by hemolysis, elevated levels of liver enzymes, and a low platelet count. It may be a variant of severe preeclampsia, but this is controversial because a substantial fraction of HELLP syndrome patients do not have hypertension or proteinuria. It is associated with increased rates of maternal morbidities, including DIC, placental abruption, pulmonary edema, acute renal failure, liver hemorrhage or failure, acute respiratory distress syndrome, sepsis, stroke, and death (Table 36-5).[230] Additionally, 70% of HELLP syndrome patients deliver preterm[230]; prematurity-related neonatal complications increase the risk for perinatal morbidity and mortality. The onset of HELLP syndrome occurs antepartum in 70% of cases and postpartum in 30%.

Because of a lack of universally accepted diagnostic criteria for HELLP syndrome, its incidence cannot be determined accurately. The existence of a subset of preeclampsia complicated by abnormal peripheral blood smear, abnormal liver function tests, and thrombocytopenia has been recognized for decades; in 1982, Weinstein[231] described a series of 29 cases and coined the acronym HELLP. Women who do not demonstrate one or more of these clinical features are said to have "partial" HELLP syndrome.

Hemolysis, defined as the presence of microangiopathic hemolytic anemia, is the classic hallmark of HELLP syndrome; peripheral blood smear demonstrates schistocytes, burr cells, and echinocytes.[232] Common histopathologic findings are periportal hepatic necrosis and hemorrhage.[233] Sibai[232] has proposed standardized laboratory diagnostic criteria, as outlined in Table 36-6. Maternal signs and symptoms include right upper quadrant or epigastric pain, nausea and vomiting, headache, hypertension, and proteinuria. Notably, clinical presentation varies; 12% to 18% of women may be normotensive, and proteinuria is absent in approximately 13% of affected women. Diagnosis can be especially challenging because numerous medical and surgical disorders, including acute fatty liver of pregnancy, hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, idiopathic thrombocytopenic purpura, and lupus, can mimic HELLP syndrome (Box 36-4). Pregnant women likely to have preeclampsia, but who demonstrate atypical symptoms, should be screened with a complete blood cell count, platelet count, and liver enzyme assessment.

In general, patients with HELLP syndrome are not considered candidates for expectant management[155]; however, deferred delivery for 24 to 48 hours to allow for corticosteroid administration to accelerate fetal lung maturity may be appropriate for women less than 34 weeks' gestation if the maternal and fetal condition remain stable.[4] Women with HELLP syndrome who have not yet reached 34 weeks' gestation should be managed in a tertiary care facility with a neonatal intensive care unit capable of caring for a compromised preterm neonate.[4] Clinical management is similar to that for severe preeclampsia and includes intravenous magnesium sulfate for seizure prophylaxis and antihypertensive medications to maintain a systolic blood pressure below 160 mm Hg and a diastolic blood pressure below 110 mm Hg.[232] The first priority is to assess and stabilize the maternal condition, with particular attention given to hypertension and coagulation abnormalities. Next, the fetal condition should be assessed with FHR monitoring, Doppler ultrasonography of fetal vessels, a biophysical profile, or several of these options.

TABLE 36-5 Serious Maternal Complications in a Series of 442 Patients with Hemolysis, Elevated Liver Enzymes, and Low Platelets (HELLP) Syndrome

Complication*	No. Patients	Percent
Disseminated intravascular coagulopathy	92	21
Placental abruption	69	16
Acute renal failure	33	8
Severe ascites	32	8
Pulmonary edema	26	6
Pleural effusions	26	6
Cerebral edema	4	1
Retinal detachment	4	1
Laryngeal edema	4	1
Subcapsular liver hematoma	4	1
Acute respiratory distress syndrome	3	1
Maternal death	4	1

*Some women had multiple complications.

Modified from Sibai BM, Ramadan MK, Usta I, et al. Maternal morbidity and mortality in 442 pregnancies with hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome). Am J Obstet Gynecol 1993; 169:1000-6.

TABLE 36-6 Diagnostic Criteria for Hemolysis, Elevated Liver Enzymes, and Low Platelets (HELLP) Syndrome

Criteria	Laboratory Tests
Hemolysis	Abnormal peripheral blood smear Increased bilirubin > 1.2 mg/dL Increased LDH > 600 IU/L
Elevated liver enzyme levels	Increased AST ≥ 70 IU/L Increased LDH > 600 IU/L
Thrombocytopenia	Platelet count < 100,000/mm^3

LDH, lactic dehydrogenase; *AST*, aspartate aminotransferase.

Modified from Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? Am J Obstet Gynecol 1990; 162:311-6.

BOX 36-4 Differential Diagnosis of Hemolysis, Elevated Liver Enzymes, and Low Platelets (HELLP) Syndrome

- Acute fatty liver of pregnancy
- Appendicitis
- Cholestasis of pregnancy
- Diabetes insipidus
- Gallbladder disease
- Gastroenteritis
- Glomerulonephritis
- Hemolytic-uremic syndrome
- Hepatic encephalopathy
- Hyperemesis gravidarum
- Idiopathic thrombocytopenia
- Nephrolithiasis
- Peptic ulcer
- Systemic lupus erythematosus
- Thrombotic thrombocytopenic purpura
- Viral hepatitis

From O'Brien JM, Barton JR. Controversies with the diagnosis and management of HELLP syndrome. Clin Obstet Gynecol 2005; 48:460-77

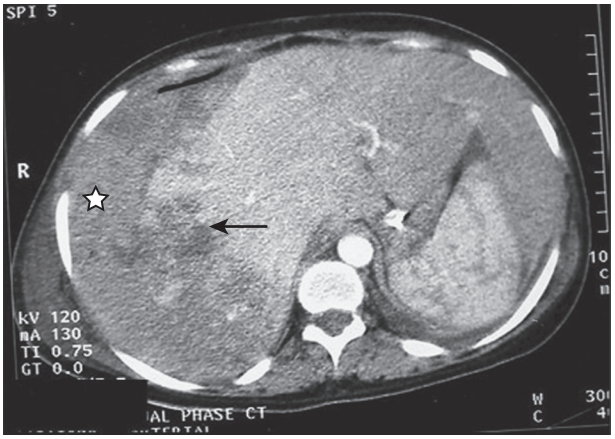

FIGURE 36-7 ■ Contrast-enhanced computed tomography scan showing a large area of parenchymal hemorrhage with hepatic rupture (*arrow*) and subcapsular hematoma (*star*) in the right lobe of the liver. (From Das CJ, Srivastava DN, Debnath J, et al. Endovascular management of hepatic hemorrhage and subcapsular hematoma in HELLP syndrome. Indian J Gastroenterol 2007; 26:244-5.)

The platelet count can fall precipitously in the presence of HELLP syndrome, and it should be evaluated before the administration of neuraxial anesthesia. Women with a platelet count less than 50,000/mm^3 are at significantly increased risk for bleeding,[234] and general anesthesia is the method of choice for cesarean delivery. Data suggest treatment with dexamethasone may improve the platelet count in women with HELLP.[207] If treatment with dexamethasone improves the patient's platelet count, the decision as to whether to use neuraxial anesthesia must weigh the risk of recurrent thrombocytopenia against the risk for a difficult airway and hypertension during induction of general anesthesia.

Platelet transfusions are indicated in the presence of significant bleeding and in all parturients with a platelet count less than 20,000/mm^3. For women with a platelet count less than 40,000/mm^3 who are scheduled for cesarean delivery, the preincision administration of 6 to 10 units of pooled random-donor platelets (or 1 to 2 units of apheresis platelets) has been recommended.[235] The risk for postpartum hemorrhage is significantly increased in patients with HELLP syndrome; at least 2 red blood cell units should be type and crossmatched and large-bore intravenous access obtained.

Rupture of a subcapsular hematoma of the liver is a life-threatening complication of HELLP syndrome and severe preeclampsia[236] that can manifest as abdominal pain, nausea and vomiting, and headaches; the pain worsens over time and becomes localized to the epigastric area or right upper quadrant. Hypotension and shock typically develop, and the liver is enlarged and tender.[237] Diagnosis is confirmed with ultrasonography, computed tomography (CT), or magnetic resonance imaging of the liver (Figure 36-7). Subcapsular hematoma rupture *with shock* is a surgical emergency that requires immediate multidisciplinary treatment that includes intravascular volume resuscitation and blood and plasma transfusions.[237] In some circumstances, selective arterial embolization by an interventional radiologist might be useful.[236,238,239] Patients with fulminant hepatic failure may require liver transplantation.[236] Prompt surgical intervention and refinements in surgical technique have substantially reduced the maternal mortality rate associated with spontaneous hepatic rupture to less than 20% in the past decade.[236] The most common causes of death are coagulopathy and exsanguination.[230,240]

Conservative management is recommended for subcapsular hematoma or intraparenchymal hemorrhage without capsular rupture in *stable* women.[235] Careful monitoring with ultrasonography or CT scan or both is required. An important component of conservative management is to avoid all potential trauma to the liver, including seizures, vomiting, and manual palpation of the abdomen. Patient transport and transfers should be conducted with care to avoid maneuvers that might result in rupture of a hematoma.

Anesthetic Management

The anesthetic management of the woman with preeclampsia without severe features differs little from the management of a healthy pregnant woman. However, the potential for rapid progression to the severe form of the disease mandates careful observation of the patient. The anesthesia provider must recognize the unpredictability of the development and progression of severe preeclampsia and should be prepared at all times for immediate cesarean delivery.

Preanesthetic Evaluation

The preanesthetic assessment of women with confirmed or suspected preeclampsia should focus on the airway examination, maternal hemodynamic and coagulation status, and fluid balance.

Airway. Generalized edema can involve the airway and obscure visualization of anatomic landmarks at laryngoscopy.[123] The anesthesia provider should anticipate the possibility of difficult airway management (see Chapter 30).

Hemodynamic Monitoring. Systemic arterial blood pressure can change rapidly in women with severe preeclampsia, both as a result of disease progression and in response to the administration of intravenous fluids and antihypertensive drugs. In addition, preeclampsia is associated with variable degrees of intravascular volume depletion and the clinical assessment of intravascular volume status can be difficult. Therefore, the use of invasive vascular monitoring may be useful in the management of some women with severe preeclampsia.

The most frequent indications for radial artery catheter insertion are (1) poorly controlled maternal blood pressure; (2) need for frequent arterial blood gas measurements, especially in the context of pulmonary edema; (3) planned use of a rapid-acting vasodilator (e.g., sodium nitroprusside, nitroglycerin, nicardipine infusion); (4) use of calculated systolic pressure variation (SPV)[241] to estimate intravascular volume status; and (5) need for continuous blood pressure monitoring during the induction of and emergence from general anesthesia in hypertensive women with severe preeclampsia.

Invasive central monitoring has been advocated in the assessment of oliguria and to monitor patient responses to fluid administration, but in practice it is rarely used. When invasive central monitoring is desired, a central venous pressure (CVP) catheter is adequate in the majority of cases; a pulmonary artery catheter is generally only used in patients with severe cardiac disease. The placement of an invasive CVP or pulmonary artery catheter is not a benign procedure. Well-recognized risks include arterial trauma, pneumothorax, venous air embolism, neuropathy, and cardiac arrhythmias. Additional risks for an indwelling pulmonary artery catheter include potentially fatal pulmonary artery hemorrhage, thromboembolism, sepsis, and endocardial damage.[242]

The 1991 to 1993 Report on Confidential Enquiries into Maternal Deaths in the United Kingdom described the postpartum death of a woman after several unsuccessful attempts at internal jugular line placement and a likely carotid artery puncture.[243] Despite digital pressure and application of a pressure dressing after vessel puncture, she developed neck tightness and dyspnea 4 hours later. Attempts at reintubation and resuscitation were unsuccessful, and she died. In the 2003 to 2005 CEMACH report, an anesthesia-related maternal death occurred in a woman with fulminant preeclampsia and HELLP syndrome who developed a large right hemothorax after a subclavian line insertion.[221] Because both immediate and delayed[244] maternal deaths have been attributed to the use of invasive central catheters, insertion of these catheters should be done only after careful consideration of risks and benefits.

Further, the timing of the use of invasive central monitoring is important and requires clinical judgment. Many patients are better served by immediate transfer to the operating room for delivery rather than delaying delivery for central line placement. In one study of a critical care unit in an academic hospital, the time from the decision to proceed with placement of a pulmonary artery catheter until the first pressure measurement was obtained was always more than 45 minutes.[245] Insertion time would likely exceed 45 minutes in most labor and delivery settings where the procedure is rarely performed and qualified assistance may not be available. In the majority of cases, the preoperative placement of an invasive central line will not change the intraoperative anesthetic management. Many obstetric care providers prefer to proceed immediately to delivery in women with persistent oliguria and to optimize fluid status after delivery.

Transthoracic echocardiography (TTE) can be used in place of invasive monitoring to quantify cardiac function and volume status.[138] In the hands of experienced practitioners, TTE may be useful in guiding fluid management for women with severe preeclampsia at risk for pulmonary edema and with oliguria.[246] Lung ultrasonography may also be useful in severe preeclampsia to diagnosis the presence of pulmonary edema.[247] Pulse waveform analysis has been suggested as a minimally invasive method to measure cardiac output in patients with severe preeclampsia; cardiac output measurements using this approach closely match those obtained from thermodilution in preeclamptic patients.[248]

In summary, the presence of severe preeclampsia *per se* is not an indication for CVP or pulmonary artery pressure monitoring. There is no indication for central hemodynamic monitoring that is unique to preeclampsia. Preeclampsia is a disorder of the peripheral circulation, not the central circulation. Indications for invasive central monitoring are similar to those in other multisystem disorders such as severe sepsis, multisystem organ dysfunction, pulmonary edema, congenital heart disease, and cardiomyopathy. TTE and arterial waveform monitoring may provide less invasive means of assessing hemodynamic parameters in these patients. Some women will require transfer to an intensive care unit for specialized nursing care and management directed by a critical care medicine specialist.

Neuraxial Analgesia for Labor and Delivery

During labor, early administration of neuraxial analgesia is recommended for several reasons: (1) to avoid general anesthesia and the possibility of airway catastrophe and marked hypertension with laryngoscopy in the event of emergency cesarean delivery, (2) to optimize the timing of epidural catheter placement in the setting of a declining platelet count, and (3) to obtain the beneficial effects of neuraxial analgesia on uteroplacental perfusion.

Continuous lumbar epidural analgesia or combined-spinal epidural (CSE) analgesia are the preferred methods of pain management during labor in women with preeclampsia. Advantages include (1) provision of high quality analgesia, which attenuates the hypertensive response to pain[249]; (2) a reduction in levels of circulating catecholamines and stress-related hormones[250]; (3) possible improvement in intervillous blood flow[251]; and (4) provision of a means for administration of local anesthetic for emergency cesarean delivery, thus

obviating the need for general anesthesia with its attendant risks.

One disadvantage of the CSE technique is that epidural catheter function cannot be fully evaluated until after resolution of the intrathecal analgesia. For this reason, some anesthesia providers avoid the CSE technique in favor of a standard epidural technique in women with severe preeclampsia who have an increased risk for emergency cesarean delivery. Use of a standard epidural technique allows for verification of catheter function within 15 to 20 minutes.

Continuous epidural infusion of local anesthetic has been used in the antepartum period to optimize uteroplacental blood flow in the hope of prolonging pregnancy and avoiding preterm delivery in preeclamptic women remote from term. Kanayama et al.[252] studied 20 severely preeclamptic women at 28 to 32 weeks' gestation who were assigned by physician choice to receive either long-term epidural bupivacaine combined with routine supportive management or routine supportive management alone. Gestational age at delivery and birth weight were greater in the treatment group, and maternal blood pressure and platelet count were also improved, compared with the routine management group. Although promising, this technique remains unproven, and randomized controlled trials are needed to verify that antepartum epidural local anesthetic infusion may facilitate expectant management of women with preeclampsia remote from term.

For the most part, the clinical administration of epidural analgesia to women with preeclampsia does not differ from that in healthy pregnant women without preeclampsia (see Chapter 23). The choice of local anesthetic, method of epidural space identification, and maintenance of analgesia are not affected by the presence of preeclampsia. However, four special considerations exist in preeclamptic women: (1) assessment of coagulation status, (2) intravenous hydration before the epidural administration of a local anesthetic, (3) treatment of hypotension, and (4) use of epinephrine-containing local anesthetic solutions.

Coagulation Status. Platelets contribute to coagulation and hemostasis in two important ways. First, their adhesive and cohesive functions lead to the formation of the hemostatic plug. Second, they activate the coagulation process by exposing a phospholipid surface and acting as a catalytic site for subsequent coagulation and consolidation of the initial platelet plug. Activated platelets release adenosine diphosphate, serotonin, thromboxane A_2, and other adhesive proteins, coagulation factors, and growth factors.[253]

Women with preeclampsia without severe features are usually hypercoagulable relative to women with an uncomplicated pregnancy and should not be denied neuraxial labor analgesia.[140] Women with *severe* preeclampsia (particularly those with HELLP syndrome) may develop thrombocytopenia, which increases the risk for bleeding into the epidural or spinal space with a neuraxial procedure (see Chapter 32). Neuraxial hematoma formation can result in permanent neurologic sequelae. Therefore, documentation of the platelet count is necessary before provision of epidural analgesia in women with severe preeclampsia. The incidence of neuraxial hematoma cannot be precisely determined because not all cases are reported and because there is no accurate method to determine the denominator of all preeclamptic women who have received neuraxial anesthesia. That said, the incidence of epidural hematoma in contemporary obstetric anesthesia practice is exceptionally low.[254]

In the past, a platelet count greater than or equal to 100,000/mm^3 was considered necessary for the safe administration of neuraxial anesthesia. This threshold probably originated from the results of a 1972 study that correlated platelet counts with bleeding times.[255] Critical appraisal of 1,083 human studies concluded that the bleeding time is not a reliable method of assessing the risk for bleeding for a single individual.[256] Coagulopathy is rare in preeclamptic women with a platelet count exceeding 100,000/mm^3, and in the absence of other risk factors for coagulopathy, neuraxial block placement is considered safe without further coagulation testing.[156]

Currently, many anesthesiologists agree that neuraxial procedures may be initiated in pregnant women without other risk factors if the platelet count is higher than 80,000/mm^3.[234] There is general consensus among anesthesia providers that a platelet count less than 50,000/mm^3 precludes the administration of neuraxial anesthesia. For women with a platelet count between 50,000 and 80,000/mm^3, the risks and benefits of neuraxial anesthesia must be weighed against the risks of general anesthesia for the individual patient if emergency cesarean delivery is required, including whether anatomic features of the patient's airway are favorable. Two additional considerations include the trend in the platelet count and any coexisting coagulopathy.

In certain cases, the platelet count decreases rapidly and the nadir in the platelet count cannot be identified prospectively. If serial platelet counts are stable and remain in the normal range, platelet count measurement every 24 to 48 hours is adequate to monitor women undergoing expectant management of severe preeclampsia remote from term.[4,161] Once a decision is made to induce labor, platelet count determination at least every 6 hours will ensure a timely measurement has been obtained at the time of request for neuraxial analgesia. If the platelet count is low (80,000 to 100,000/mm^3), early epidural catheter insertion is recommended in anticipation of worsening thrombocytopenia. If an epidural catheter is inserted before labor pain becomes significant, dilute solutions of local anesthetic may be infused at a low rate.

If the platelet count is less than 100,000/mm^3, other hemostatic abnormalities, including prolonged PT and aPTT and hypofibrinogenemia, may be present.[156] Further coagulation studies may be useful, particularly if risk factors for DIC are present (e.g., placental abruption, HELLP syndrome).[156] Thus, in the presence of thrombocytopenia or abnormal results of liver function tests, the PT and aPTT should be assessed before the initiation of neuraxial anesthesia.[257]

Viscoelastic monitors of coagulation may expedite decision-making about neuraxial block administration for women with preeclampsia-related hemostatic dysfunction. Although thromboelastography (TEG) has shown

some promise in the assessment of coagulation status in pregnant patients with thrombocytopenia,[140] it has been criticized for its inability to diagnose specific coagulation defects, particularly for impairments in primary hemostasis.[258] Platelet function analysis (PFA-100) appears to be more sensitive to coagulation dysfunction in severe preeclampsia.[142] However, with both TEG and PFA, the ability to predict the risk for epidural hematoma after the administration of neuraxial anesthesia is unproven and requires further study.[259]

The risk for **epidural hematoma** formation exists not only at the time of epidural catheter placement but also at the time of its removal. In patients with thrombocytopenia, the catheter should not be withdrawn from the epidural space until there is evidence of an acceptable (and increasing) platelet count. A platelet count of 75,000 to 80,000/mm^3 seems reasonable for epidural catheter removal. The platelet count in women with HELLP syndrome usually reaches a nadir on the second or third postpartum day and then gradually returns to the patient's normal baseline.

If the decision is made to proceed with a neuraxial technique when the platelet count is less than 100,000/mm^3, the following suggestions may help reduce the risk for epidural hematoma and its sequelae:

1. The **most skilled anesthesia provider** available should perform the neuraxial procedure to minimize the number of needle passes and subsequent bleeding.
2. **A spinal technique may be preferable to an epidural technique** (when appropriate) because of the smaller needle size, although supporting data are lacking.
3. **Use of a flexible wire-embedded epidural catheter** may reduce epidural vein trauma.
4. The patient should be carefully monitored after delivery for **neurologic signs that may signal bleeding into the epidural space**.
5. **The platelet count should be checked for evidence of a return toward normal measurements (at least 75,000 to 80,000/mm^3) before removal of the epidural catheter.** Epidural vein trauma at the time of catheter discontinuation can result in epidural bleeding and perhaps epidural hematoma.
6. **Imaging studies and neurologic or neurosurgical consultation should be obtained immediately if there is any question of an epidural hematoma.** Prompt surgical intervention may be required to avoid permanent neurologic injury.

Intravenous Hydration. In the past, when high concentrations of local anesthetic solution (e.g., 0.25% to 0.5% bupivacaine) were administered during labor, intravenous crystalloid hydration preceded epidural local anesthetic administration to prevent or ameliorate hypotension. In contemporary practice, lower concentrations of local anesthetic are used (e.g., 0.0625% to 0.125% bupivacaine in combination with an opioid), hypotension is less common, and fluid administration at the time of analgesia initiation is of less clinical importance. Furthermore, the rapid administration of a large bolus of intravenous fluid (preload) results in only a transient increase in CVP and has little impact on the risk for hypotension.[260] Although the use of a fluid bolus has decreased with current techniques for labor analgesia, careful attention to intravenous fluid infusion rates is necessary in women with severe preeclampsia because of the increased risk for pulmonary edema in these patients.

Treatment of Hypotension. A retrospective study found that parturients with severe preeclampsia were more susceptible to hypotension after initiation of epidural labor analgesia than healthy parturients.[261] The hypotension was associated with an increase in FHR abnormalities,[261] suggesting the need for close attention to maternal blood pressure at the time of initiation of analgesia. Women with preeclampsia may be treated with phenylephrine or ephedrine (although the latter is no longer the agent of choice in healthy women—see Chapter 26). There is an often-expressed concern that severely preeclamptic women may have an exaggerated response to vasopressors that might result in a sharp increase in blood pressure.[262,263] However, supportive data are lacking. The anesthesia provider should initiate treatment with low doses of phenylephrine (25 to 50 μg) or ephedrine (5 to 10 mg) to assess maternal blood pressure response before administration of a larger dose. With careful dosing, increased sensitivity to vasopressors is rarely a clinical problem.

Epinephrine. It has been suggested that local anesthetic solutions containing epinephrine (including the standard epinephrine-containing test dose) should be avoided during the administration of epidural analgesia in preeclamptic women. This concern arises from observations that preeclamptic women exhibit an increased sensitivity to vasopressors, including angiotensin II,[264,265] norepinephrine and epinephrine,[133,266] and a thromboxane A_2-mimetic agent.[267] In addition, clinical studies have demonstrated that smaller doses of ephedrine and phenylephrine are required to restore maternal blood pressure during spinal anesthesia in preeclamptic women compared with healthy women.[262,263,268,269] One case report described a hypertensive crisis in a preeclamptic woman after the incremental administration of 30 mL of freshly mixed 2% lidocaine with epinephrine 5 μg/mL for planned cesarean delivery.[270] However, the onset and duration of hypertension were atypical and a drug error could not be excluded.[270] In contrast, several other case series have used the same solution without adverse effects in women with preeclampsia.[271,272]

No randomized controlled trials have assessed the effects of epidural epinephrine in women with severe preeclampsia. In the absence of malignant hypertension, epinephrine is unlikely to pose a significant risk for hypertensive crisis, given the absence of confirmed reports after decades of its use in obstetric anesthesia practice. Although not necessarily harmful for women with preeclampsia, the use of epinephrine in epidural test doses or analgesic solutions may not be particularly helpful. Patients who have received beta-adrenergic receptor antagonists (e.g., labetalol) do not demonstrate the typical tachycardic response to intravascular

administration of epinephrine.[273] This lack of response will decrease the sensitivity of the epinephrine test dose to detect intravascular administration of local anesthetic solution, and alternative testing strategies to detect intravascular catheter location may be preferred.[274] The addition of epinephrine to local anesthetic solutions results in a modest local anesthetic-sparing effect, at best,[275] and increases the density of motor blockade.[276] Finally, consideration should be given to the consequences of an unintentional intravascular injection of an epinephrine-containing test dose in a patient with baseline hypertension.

Anesthesia for Cesarean Delivery

The administration of neuraxial anesthesia for cesarean delivery in women with preeclampsia does not differ greatly from administration in healthy pregnant women (see Chapter 26). Hepatic dysfunction can result in reduced drug clearance but has little clinical impact on choice of anesthetic or analgesic agents.

The choice of local anesthetic, method of epidural space identification, and maintenance of anesthesia are not affected by the presence of preeclampsia. However, there are three special considerations in preeclamptic women undergoing cesarean delivery: (1) choice of anesthetic technique, (2) technique for induction of general anesthesia, and (3) the interaction between magnesium sulfate and nondepolarizing muscle relaxants.

Neuraxial Anesthesia. In the Seventh and Eighth Reports of the Confidential Enquiries into Maternal Deaths from the United Kingdom,[212,221] the leading cause of death in women with preeclampsia was **intracranial hemorrhage**. Disadvantages of general anesthesia in the presence of preeclampsia include the risk for intracranial hemorrhage from the hypertensive response to both tracheal intubation and extubation. In a study involving more than 300,000 women in Taiwan, general anesthesia for cesarean delivery was associated with a greater than twofold increase in the risk for stroke after adjusting for confounders compared with neuraxial anesthesia.[277] Neuraxial anesthesia also avoids the possibility of difficult tracheal intubation secondary to airway edema. Therefore, neuraxial anesthesia is preferred whenever clinical circumstances permit its use.

The traditional view was that spinal anesthesia is relatively contraindicated in severe preeclampsia because of the possibility of marked hypotension as a result of the rapid onset of spinal anesthesia–induced sympathetic blockade. However, data that have emerged over the past decade suggest that this concern is not supported by evidence, and that both spinal and epidural anesthesia are reasonable anesthetic modalities for women with severe preeclampsia. Wallace et al.[278] randomized 80 women with severe preeclampsia who required cesarean delivery to receive general, epidural, or CSE anesthesia. Notably, the initial spinal dose in the CSE group (hyperbaric bupivacaine 11.25 mg) is a dose comparable to that often used for a single-shot spinal technique. There was no significant difference between the CSE and epidural anesthesia groups in maternal mean arterial pressure over time. Another small prospective study randomized women with severe preeclampsia to receive either spinal or epidural anesthesia, with similar results.[279] Hood and Curry[280] retrospectively reviewed cesarean delivery records for 138 women with severe preeclampsia who received either spinal or epidural anesthesia and found that the lowest mean blood pressure measurements did not differ between groups. Because of the retrospective study design, the possibility that the groups were dissimilar cannot be excluded (i.e., the anesthesia providers may have chosen to administer epidural anesthesia to the more severely ill women). Nonetheless, the expected marked hypotension after spinal anesthesia did not occur. These studies lend support to the safety of spinal anesthesia in women with severe preeclampsia.

In two prospective cohort studies of women undergoing cesarean delivery, Aya et al.[262,268] compared women with severe preeclampsia to healthy pregnant women (both preterm and at term) and found that the risk for significant spinal anesthesia–induced hypotension (defined as requiring the administration of ephedrine) was significantly lower in the preeclampsia group than in the control groups. The authors speculated that the known increased vascular sensitivity to vasoconstrictors may explain the infrequent incidence of hypotension after spinal anesthesia and the ease with which mean arterial blood pressure can be restored to baseline with small doses of vasopressor.

A randomized multicenter study[281] comparing the hemodynamic effects of spinal anesthesia with epidural anesthesia for cesarean delivery in women with severe preeclampsia found that significantly *more* women in the spinal anesthesia group experienced hypotension. However, the duration of hypotension was less than 1 minute in both groups and, although there was more ephedrine use in the spinal group than the epidural group, hypotension was easily treated in both groups. In addition, there was no significant difference in neonatal outcome between infants whose mothers received spinal anesthesia compared with those whose mothers received epidural anesthesia.[282] Another study suggested that spinal anesthesia has little effect on cardiac output in severely preeclamptic women.[263] These data, taken together, suggest that the use of spinal anesthesia for cesarean delivery in women with severe preeclampsia is appropriate.

General Anesthesia. General anesthesia is less desirable than neuraxial anesthesia because of (1) the possibility of difficult tracheal intubation secondary to airway edema and (2) the transient but severe hypertension that accompanies tracheal intubation and extubation. Nonetheless, there are situations in which general anesthesia is the best anesthetic option. Clinical indications include severe ongoing maternal hemorrhage, sustained fetal bradycardia with a reassuring maternal airway examination, and severe thrombocytopenia or other coagulopathy, or a combination of these indications. The platelet count can fall dramatically with rapidly progressing severe preeclampsia or HELLP syndrome and may mandate administration of general anesthesia. Major placental abruption, intrauterine fetal demise, and preeclampsia all increase the risk for DIC. The safe

administration of general anesthesia in women with preeclampsia requires an advanced state of readiness and careful preparation.

Once the decision has been made to proceed with general anesthesia, the anesthesia provider faces three specific challenges: (1) the potential difficulty of securing the airway, (2) the hypertensive response to direct laryngoscopy and tracheal intubation, and (3) the effects of magnesium sulfate on neuromuscular transmission and uterine tone. A suggested technique for the administration of general anesthesia is outlined in Box 36-5.

Airway Considerations. Before proceeding with general anesthesia, careful airway examination is mandatory. Airway edema may be present even with a relatively reassuring airway examination; thus, many anesthesia providers try to avoid emergency administration of general anesthesia if there is any suspicion of a difficult airway. Endotracheal tubes in various sizes and difficult airway equipment should be immediately available (see Chapter 30). In unusually difficult situations, it may be prudent to have a surgeon immediately available to establish a surgical airway, if needed. One of the dangers of repeated tracheal intubation attempts is the risk for traumatic bleeding in the airway, which may make ventilation difficult or even impossible. It is wise to avoid repeated attempts and proceed with insertion of a supraglottic airway device (e.g., laryngeal mask airway) before the airway is irretrievably lost. Because the supraglottic airway devices do not protect the patient from pulmonary aspiration of gastric contents, the obstetrician should be encouraged to complete the procedure as quickly as possible.

If indicated, an awake fiberoptic tracheal intubation should be used to secure the airway. Ideally, invasive blood pressure monitoring should be initiated before tracheal intubation and the induction of general anesthesia in patients with severe preeclampsia so that hypertension can be promptly recognized and treated. Effective topical anesthesia of the airway with nebulized or atomized lidocaine can enhance patients' comfort and decrease the hypertensive response to airway manipulation. Airway injections (including glossopharyngeal nerve blocks and transtracheal injections) are usually best avoided because of coagulopathy in this population.

Hypertensive Response to Laryngoscopy. The hemodynamic instability associated with rapid-sequence induction and tracheal intubation presents a serious problem. The transient but severe hypertension that may accompany tracheal intubation can result in cerebral hemorrhage or pulmonary edema, both potentially fatal complications. Continuous arterial blood pressure monitoring is required for severely hypertensive women to monitor the effects of antihypertensive drugs administered before and after tracheal intubation and to allow rapid detection of adverse hemodynamic responses to laryngoscopy.

Medications that have been used to blunt the hemodynamic response to laryngoscopy include labetalol, esmolol, nitroglycerin, sodium nitroprusside, and remifentanil.[283-287] The goal of treatment is to reduce the arterial blood pressure to approximately 140/90 mm Hg before the induction of general anesthesia and to maintain the systolic blood pressure between 140 to 160 mm Hg and the diastolic blood pressure between 90 to 100 mm Hg throughout laryngoscopy and tracheal intubation.[166] If possible, the FHR should be monitored during intravenous antihypertensive therapy.

BOX 36-5 A Suggested Technique for Administration of General Anesthesia in Women with Severe Preeclampsia

1. Place a radial arterial cannula for continuous blood pressure monitoring in women with severe hypertension.
2. Place an additional large-bore intravenous catheter given the increased risk for postpartum hemorrhage.
3. Verify that smaller-sized endotracheal tubes and supraglottic airway devices are immediately available. Equipment needed for difficult airway management should also be immediately available.
4. Consider the administration of an H_2-receptor antagonist and metoclopramide IV between 30 and 60 minutes before induction of anesthesia.
5. Administer 0.3 M sodium citrate 30 mL by mouth less than 30 minutes before induction of anesthesia.
6. Denitrogenate (3 minutes of tidal-volume breathing or 8 vital capacity breaths with an F_{IO_2} of 1.0 and a tight-fitting facemask).
7. Give labetalol (10-mg bolus doses) IV to titrate systolic blood pressure to 140/90 mm Hg before the induction of anesthesia.
8. Continue to monitor the FHR during labetalol administration.
9. Consider alternative antihypertensive agents for patients who do not respond to labetalol (or those with a contraindication to labetalol). Alternatives include hydralazine or nicardipine, sodium nitroprusside, or nitroglycerin infusion. Consider remifentanil infusion at 0.05 μg/kg/min. (See Table 36-4.)
10. Perform rapid-sequence induction with propofol 2.0 to 2.8 mg/kg and succinylcholine 1.0 to 1.5 mg/kg (avoid ketamine as an induction agent given its sympathomimetic properties). Consider the administration of a bolus dose of labetalol, esmolol, nitroglycerin, sodium nitroprusside, or remifentanil to blunt the hemodynamic response to laryngoscopy.
11. Maintain anesthesia with a volatile halogenated agent and 100% oxygen before delivery. After delivery, decrease the concentration of the volatile halogenated agent to prevent uterine atony and consider using nitrous oxide or a propofol infusion and administering an opioid with or without a benzodiazepine. Avoid giving additional muscle relaxants; if absolutely required, administer a *low dose* of a short-acting nondepolarizing muscle relaxant because of the exaggerated effect of these medications when coadministered with magnesium.
12. At the end of surgery, reverse neuromuscular blockade and give labetalol 5 to 10 mg IV bolus, titrated to effect, to prevent hypertension during emergence and tracheal extubation.

FHR, fetal heart rate; *IV*, intravenously.
Modified from Ramanathan J, Bennett K. Pre-eclampsia: fluids, drugs, and anesthetic management. Anesthesiol Clin North Am 2003; 21:145-63.

Most anesthesia providers consider **labetalol** to be the drug of choice for attenuating the hypertensive response to laryngoscopy in women with severe preeclampsia. Ramanathan et al.[285] compared intravenously administered labetalol with no treatment in a randomized study of preeclamptic women who received general anesthesia for cesarean delivery. Mean arterial blood pressure increased after tracheal intubation in both study groups, but the hypertensive response was significantly less pronounced in the labetalol group. Women in the control group also developed tachycardia (in response to laryngoscopy and tracheal intubation), which did not occur in the labetalol group. Labetalol can be administered using either a bolus technique or a continuous intravenous infusion, or both.

There is also evidence of safe short-term administration of **esmolol** in this setting. A randomized double-blind study of 80 hypertensive women presenting for cesarean delivery demonstrated that intravenous esmolol—in doses as high as 2 mg/kg—can be safely used to dampen the hemodynamic response to laryngoscopy and tracheal intubation.[288]

Nitroglycerin has many desirable properties for blunting the hypertensive response to tracheal intubation. It is a direct vasodilator with a rapid onset, is rapidly metabolized, and has no apparent maternal or fetal toxicity. In a randomized controlled trial, Hood et al.[284] administered intravenous nitroglycerin (200 μg/mL), which decreased mean arterial blood pressure by approximately 20%, before the induction of general anesthesia. Compared with women who did not receive nitroglycerin, the maximal blood pressure with tracheal intubation was significantly lower in the nitroglycerin group. Both Apgar scores and umbilical cord blood gas and acid-base measurements were similar in the two groups.

Sodium nitroprusside infusions have also been used to attenuate hemodynamic responses to tracheal intubation in women with severe preeclampsia. An intravenous infusion can be initiated at 0.5 μg/kg/min and titrated to blood pressure response. Short-term infusions are considered safe for the fetus.

The short-acting opioid **remifentanil** is rapidly metabolized by both mother and neonate by nonspecific blood and tissue esterases and has been administered to preeclamptic women. A clear advantage of remifentanil compared with other opioids is the rapid onset and short duration of the drug; the limited duration of action should not interfere with the resumption of spontaneous ventilation if tracheal intubation is unsuccessful. Ngan Kee et al.[287] randomly allocated 40 pregnant women without preeclampsia who required general anesthesia for cesarean delivery to receive either a one-time intravenous dose of remifentanil 1 μg/kg or saline immediately before induction of anesthesia. The primary outcome was the maximum increase in systolic blood pressure (compared with a baseline measurement). Administration of remifentanil significantly decreased the maximum increase in systolic blood pressure. However, remifentanil crosses the placenta, and two neonates in the remifentanil group required naloxone administration for poor respiratory effort. Park et al.[289] randomized 48 patients with severe preeclampsia to receive remifentanil 0.5 μg/kg or 1 μg/kg before tracheal intubation. Both doses prevented a hypertensive response, but three patients treated with the higher dose required ephedrine to treat hypotension. Apgar scores and umbilical cord blood gas measurements were comparable in both groups. The lower remifentanil dose, 0.5 μg/kg, is therefore likely preferable.

Effects of Magnesium Sulfate. Most severely preeclamptic women will present to the operating room after receiving magnesium sulfate for seizure prophylaxis. The magnesium infusion should continue throughout surgery to minimize the risk of eclampsia.[4] The primary anesthetic considerations for women receiving magnesium sulfate are (1) interaction with nondepolarizing muscle relaxants, (2) effects on uterine tone, and (3) interaction with calcium entry–blocking agents.

Magnesium inhibits the release of acetylcholine at the neuromuscular junction, decreases the sensitivity of the neuromuscular junction to acetylcholine, and depresses the excitability of the muscle fiber membrane. Magnesium sulfate increases the potency and duration of vecuronium, rocuronium, and mivacurium.[290-292] Several case reports have described a requirement for overnight mechanical ventilation after administration of routine doses of vecuronium in women receiving magnesium sulfate.[290,293] Thus, if nondepolarizing muscle relaxants are used, they should be administered in very small doses and the response should be monitored carefully with a peripheral nerve stimulator. Many practitioners avoid the use of depolarizing neuromuscular blocking agents in this setting because of the concern for residual postoperative neuromuscular blockade, which can lead to respiratory complications. Because of abdominal wall distention in the term parturient, neuromuscular blockade is rarely required to facilitate surgical closure after cesarean delivery.

Even though succinylcholine mimics acetylcholine at the nerve terminal, the onset and duration of a single intubating dose is not prolonged when administered concurrently with a magnesium sulfate infusion[294]; a routine intubating dose of 1 to 1.5 mg/kg should be used during rapid-sequence induction of anesthesia.

Used for many years as a tocolytic agent, magnesium depresses smooth muscle contractions and inhibits CNS catecholamine release.[295-297] Therefore, it seems intuitive that the risk for uterine atony and excessive blood loss might be increased in women receiving magnesium sulfate.[193] However, studies[193,203] have not found an increased risk for blood loss in women receiving magnesium sulfate. A blood sample for a type and screen should be sent to the blood bank before cesarean delivery, and uterotonic agents should be immediately available. Although some reports have suggested that coadministration of a calcium entry–blocking agent and magnesium may cause hypotension and/or neuromuscular blockade,[176-179] more recent information suggests that these medications can be used safely together.[180]

Postoperative Analgesia. Options for postoperative analgesia are the same as for healthy pregnancies and include patient-controlled intravenous opioids, neuraxial opioids (single injection), and continuous epidural

infusion of analgesic agents. Many anesthesia providers prefer neuraxial opioid administration for postcesarean analgesia (see Chapter 28). For women whose postpartum hypertension persists longer than one day, the ACOG has suggested that nonsteroidal anti-inflammatory medications be replaced by alternative analgesics, as nonsteroidal anti-inflammatory drugs may contribute to hypertension.[4] In the rare case of a woman with continuing severe refractory hypertension, continuous epidural analgesia is attractive for its blood pressure–modulating properties.

Regardless of the postoperative analgesic technique, all women should be carefully monitored with pulse oximetry for signs of respiratory depression or airway obstruction.

Postpartum Management

The risks of severe preeclampsia do not end with delivery. Postpartum women are at significant risk for pulmonary edema, sustained hypertension, stroke, venous thromboembolism, airway obstruction, and seizures and should receive close monitoring of blood pressure, fluid intake, and urinary output. In addition, severe preeclampsia, the HELLP syndrome, and eclampsia can present for the first time in the postpartum period, with delayed presentation as late as 4 weeks after delivery.[4] A study of almost 4000 women diagnosed with preeclampsia found that the incidence of postpartum onset of disease was 5.7%,[116] and hypertension is the leading indication for postpartum hospital readmission.[298]

The risk for **pulmonary edema** is also highest in the postpartum period. The resolution of preeclampsia usually occurs within 5 days of delivery and is heralded by a marked diuresis that follows mobilization of extracellular fluid and an increase in the intravascular volume. As a consequence, women with severe preeclampsia, particularly those with early-onset disease, renal insufficiency, or pulmonary capillary leak, are at increased risk for the development of postpartum pulmonary edema.[163]

In contrast to women with gestational hypertension, who typically become normotensive within a week of delivery, women with severe preeclampsia may have a longer duration of hypertension; the risk for **cerebrovascular accident** is highest during this time.[168,208,209,299,300] Given the increased risk of postpartum cerebrovascular accident, the ACOG recommends antihypertensive therapy in the postpartum period when systolic blood pressure persistently exceeds 150 mm Hg or diastolic blood pressure exceeds 100 mm Hg.[4] Antihypertensive therapy should be continued, started, or resumed for these women, and blood pressure should be closely monitored. For women in the postpartum period who develop new-onset hypertension associated with headaches or other neurologic symptoms, or new-onset severe hypertension, a 24-hour course of magnesium sulfate administration may help prevent eclampsia or a cerebrovascular accident.[4]

Postpartum venous thromboembolism (VTE) has an estimated incidence of 1 to 18 per 1000 cesarean deliveries[301,302] and is a leading cause of maternal mortality in pregnancy.[303] The risk factors for antepartum and postpartum events differ, suggesting a different pathophysiology for each.[304] Both cesarean delivery[304-307] and preeclampsia[304,305] are independent risk factors for postpartum VTE. An emergency cesarean delivery doubles the risk for VTE compared with a nonemergent cesarean delivery.[308]

The 2012 American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend that women with a risk for postcesarean VTE greater than 3% receive either pharmacologic thromboprophylaxis or mechanical prophylaxis (elastic stockings or intermittent pneumatic compression) during hospitalization after cesarean delivery.[301] Preeclampsia in the absence of fetal growth restriction is considered a minor risk factor for VTE. VTE prophylaxis is indicated in patients with two or more minor risk factors (e.g., BMI > 30 kg/m^2, use of > 10 cigarettes per day, multiple pregnancy, emergency cesarean delivery, postpartum hemorrhage > 1 L) (see Box 39-4).[301] Preeclampsia with fetal growth restriction is considered a major risk factor (with risk for VTE > 3%), such that all patients with this condition merit VTE prophylaxis after cesarean delivery.[301] The ACOG recommends pneumatic compression devices for all patients undergoing cesarean delivery.[309]

Preeclampsia has been associated with increased upper airway resistance and an increased risk of obstructive sleep apnea.[310,311] A review of anesthesia-related maternal deaths in Michigan[312] described a series of postoperative and postpartum deaths attributed to **airway obstruction** or **hypoventilation**, including the death of one women with severe preeclampsia and sleep-disordered breathing who likely experienced opioid-related respiratory depression while receiving patient-controlled intravenous analgesia after cesarean delivery. Such findings highlight the need for close monitoring and consistent vigilance in the postoperative care of women with severe preeclampsia—particularly those with generalized edema, known airway swelling, snoring, and obesity.

Long-Term Outcomes

Women with a history of preeclampsia are at increased risk for chronic hypertension and cardiovascular disease, including ischemic heart disease and stroke, later in life,[59,61,313-316] and an earlier onset of cardiovascular disease than women with healthy pregnancies.[60,317,318] Risks for ischemic heart disease and stroke are elevated approximately twofold.[61]

In addition, there is evidence of a dose-response relationship between preeclampsia and cardiovascular disease. Women with severe and/or early-onset preeclampsia, and whose pregnancies are complicated by both preeclampsia (the maternal syndrome) and fetal growth restriction (the fetal syndrome) are at higher risk than women with preeclampsia without severe features or gestational hypertension.[59] Women with preeclampsia in both their first and second pregnancies are at even greater risk for future ischemic heart disease.[318]

The mechanism of increased risk for cardiovascular disease in preeclampsia is unclear. It is possible that

preeclampsia causes permanent damage to the endothelium and hastens the onset of cardiovascular disease. Women with a history of preeclampsia have persistent impairment of brachial artery endothelium-dependent vascular relaxation at 1 to 3 years after delivery compared with healthy control women.[319,320] A more likely explanation is that preeclampsia and cardiovascular disease have a common pathogenesis because of shared risk factors. Common risk factors for preeclampsia and atherosclerosis include hypertension, obesity, insulin resistance, advanced age, hypercholesterolemia, and dyslipidemia.[317,321,322] Cigarette smoking is the notable exception in that it is an established risk factor for cardiovascular disease but is protective against preeclampsia.[67,68] Preeclampsia may be a cardiovascular risk marker in women with an underlying predisposition to vascular disease; the hemodynamic and metabolic stress of pregnancy causes the predisposition to manifest as preeclampsia. After pregnancy, women return to a normal state until the threshold for disease development is exceeded in later life.

Regardless of the mechanism of increased risk, these observations represent a potential opportunity for primary disease prevention and risk factor modification. In a 2004 multinational study, 90% of the risk for a first myocardial infarction was attributed to potentially modifiable risk factors.[323] Possible interventions include earlier cardiovascular disease screening and individual counseling regarding the importance of smoking cessation, regular exercise, and a diet low in saturated fat and high in antioxidants.

In contrast to the increased risk for cardiovascular disease, a history of preeclampsia has been associated with a *decreased* risk for cancer. Several earlier studies have suggested that women who have been diagnosed with preeclampsia have a slightly lower risk for breast cancer in later life compared with other parous women.[324,325] However, a 2007 systematic review and meta-analysis of almost 200,000 women with a history of preeclampsia found no association between preeclampsia and future cancer risk.[61]

Evidence indicates that preeclampsia may also result in psychological sequelae. A woman with a history of severe preeclampsia (particularly with early-onset disease and preterm delivery) has experienced a serious complication that threatened her life and the life of her child. In one study, approximately one fourth of women developed post-traumatic stress disorder (PTSD) after early-onset preeclampsia.[326] This association may be mediated by the condition of the offspring after preterm delivery.[327-329] Further research is required to characterize women at risk for PTSD and to investigate strategies for PTSD prevention and intervention.

ECLAMPSIA

Eclampsia is defined as the new onset of seizures or unexplained coma during pregnancy or the postpartum period in a woman with signs and symptoms of preeclampsia and without a preexisting neurologic disorder.[330-333]

Epidemiology

Findings from population-based studies in the past 10 years suggest that the incidence of eclampsia varies from 0.1 to 5.9 per 10,000 pregnancies in developed countries.[9,38,334-338] The variation in rates of eclampsia among studies likely reflects reporting differences among countries or differences in treatment for severe preeclampsia.[335,339] On average, studies have shown a decrease in the incidence of eclampsia in developed countries over time; this decrease is likely attributable to an increase in the use of magnesium for seizure prophylaxis.[335,337,338]

Eclampsia can occur suddenly at any point in the puerperium; however, most seizures occur intrapartum or within the first 48 hours after delivery. Late eclampsia is defined as seizure onset from 48 hours after delivery to 4 weeks postpartum.[331,340] The majority of eclamptic women have evidence of severe preeclampsia, but in 10% to 15% of cases, hypertension is absent or modest and/or proteinuria is not detected.[340] Reported risks include young maternal age, nulliparity, multiple gestation, molar pregnancy, triploidy, preexisting hypertension, renal or cardiac disease, previous severe preeclampsia or eclampsia, nonimmune hydrops fetalis, and systemic lupus erythematosus.[338,341] Major maternal complications of eclampsia include pulmonary aspiration, pulmonary edema, cerebrovascular accident, cardiopulmonary arrest, venous thromboembolism, acute renal failure, and death.[333-335,338] Eclampsia is associated with a high perinatal death rate and has also been associated with placental abruption, severe fetal growth restriction, and extreme prematurity.[330,334,335,338]

Clinical Presentation and Diagnosis

Any of the pathophysiologic changes of preeclampsia can be present in eclampsia. About 80% of patients will have premonitory neurologic symptoms, the most common of which are headache and visual disturbances.[342] Other premonitory signs and symptoms can include photophobia, epigastric or right upper quadrant pain, hyperreflexia, and altered mental status[330,340]; these symptoms can occur before or after the onset of seizures.[330]

Seizures have an abrupt onset, typically beginning as facial twitching that is followed by a tonic phase that persists for 15 to 20 seconds. This phase progresses to a generalized clonic phase characterized by apnea, which lasts approximately 1 minute. Breathing generally resumes with a long stertorous inspiration, and the patient enters a postictal state with a variable period of coma. Cardiorespiratory arrest and pulmonary aspiration of gastric contents can complicate a seizure. Although the definitive diagnosis for eclampsia is a sudden seizure in a pregnant woman who has signs and symptoms of preeclampsia, a woman who lapses into coma without witnessed convulsions can also be classified as eclamptic.[330]

The mechanism of eclamptic seizures remains poorly understood.[332] It may involve a loss of the normal cerebral autoregulatory mechanism, resulting in hyperperfusion and leading to interstitial or vasogenic cerebral

edema and decreased cerebral blood flow.[213,214,332] Neuroradiologic studies suggest that eclampsia might be a form of PRES.[121,122]

Until proven otherwise, the occurrence of seizures during pregnancy should be considered eclampsia. Conditions simulating eclampsia include seizure disorder, stroke, hypertensive encephalopathy, ischemia or hypoxia, cerebral space-occupying lesion, systemic disease (e.g., systemic lupus erythematosus, sickle cell anemia), infection (e.g., meningitis, encephalitis), electrolyte and endocrine disturbances, PRES, vasculitis or angiopathy, amniotic fluid embolism, medications (withdrawal, illicit drug use), and organ failure.[330,331]

Obstetric Management

Immediate goals are to stop convulsions, establish a patent airway, and prevent major complications (e.g., hypoxemia, aspiration). Further obstetric management includes antihypertensive therapy, induction or augmentation of labor, and expeditious (preferably vaginal) delivery. Fetal bradycardia typically begins during or immediately after a seizure but does not mandate immediate delivery unless it is persistent.

Resuscitation and Seizure Control

During the seizure, oxygenation may prove impossible but supplemental oxygen should be delivered by means of a facemask (Box 36-6). Attempts to insert an oral airway should be withheld until the seizure abates. As soon as breathing resumes, ventilation may be gently augmented with a bag-mask device. Pulse oximetry should be used to assess maternal oxygenation. Blood pressure and the electrocardiogram should be monitored to identify hypertension, arrhythmia, or cardiac arrest. While initial resuscitation is underway, an assistant should establish intravenous access, which may be difficult in a combative postictal woman. Judicious sedation might be required to allow further treatment in some patients.

Magnesium sulfate is the preferred drug for the prevention of further seizures in eclampsia.[189,190] The administration of magnesium sulfate in eclamptic women is associated with significantly lower maternal death rates. An initial intravenous bolus of 4 to 6 g is administered, followed by an infusion at 1 to 2 g/h, assuming the patient has adequate renal function.[343] Recurrent convulsions should prompt administration of an additional bolus of 2 to 4 g, infused over 5 to 10 minutes.[343] The patient should be carefully monitored for signs of magnesium toxicity.

BOX 36-6 Eclampsia: The ABCs of Eclamptic Seizure Control

Airway

- Turn patient to left side; apply jaw thrust.
- Attempt bag and mask ventilation (F_{IO_2} = 1.0).
- Insert soft nasopharyngeal airway if necessary.

Breathing

- Continue bag and mask ventilation (F_{IO_2} = 1.0).
- Apply pulse oximeter and monitor S_{PO_2}.

Circulation

- Secure intravenous access.
- Check blood pressure at frequent intervals.
- Monitor electrocardiogram.

Drugs

- Magnesium sulfate
  - 4 to 6 g IV over 20 min
  - 1 to 2 g/h IV for maintenance therapy
  - 2 g IV over 10 min for recurrent seizures
- Antihypertensive agents
  - Labetalol or hydralazine as needed to treat hypertension (see Table 36-4)

IV, intravenously.

Anesthetic Management

The preanesthetic management of an eclamptic woman parallels that of a patient with severe preeclampsia. Considerations[330,344] specific to the woman with eclampsia are as follows:

1. **Assessment of seizure control and neurologic function.** The possibility of increased intracranial pressure is not a cause for concern if the patient remains conscious, alert, and free of seizures. Persistent coma and localizing signs may indicate a major intracranial pathologic process that could affect anesthetic management.
2. **Maintenance of fluid balance.** Intake should be restricted to 75 to 100 mL/h to minimize the risk for exacerbating cerebral edema.
3. **Blood pressure control.** Antihypertensive therapy should be instituted if the systolic pressure is 160 mm Hg or higher, or if the diastolic pressure is 110 mm Hg or higher.
4. **Continuous pulse oximetry monitoring of maternal oxygenation.**
5. **Continuous FHR monitoring.**
6. **Laboratory investigations mimic those for preeclampsia.** Additionally, coagulation studies should be obtained regardless of the platelet count.

The anesthetic plan is tailored to each individual case. In conscious, eclamptic women with no evidence of increased intracranial pressure and whose seizures are well controlled, neuraxial analgesia/anesthesia can be considered. In a retrospective review of 66 stable eclamptic South African women, Moodley et al.[345] found no difference in maternal and neonatal outcomes in women who received epidural anesthesia compared with general anesthesia for cesarean delivery.

Eclamptic seizures are likely associated with an increase in intracranial pressure. In the rare instance of requirement for immediate delivery in a woman with ongoing seizures, a technique similar to that used for neuroanesthesia in patients with increased intracranial pressure should be considered. Intravenous induction agents such as propofol[346] or thiopental[347] will reduce the cerebral metabolic rate and cerebral blood flow, with a consequent decrease in cerebral blood volume and

intracranial pressure. These agents are also effective in terminating seizures.[348,349] Because hyperventilation reduces cerebral blood flow without a reduction in cerebral metabolic rate, it should be employed with caution. On the other hand, hypoventilation is associated with hypercarbia, which can lower the seizure threshold. To prevent further neurologic injury, it is important not to be overly aggressive in the reduction of systemic pressure because cerebral perfusion pressure is the difference between mean arterial pressure and intracranial pressure.[350] Avoidance of hypoxia, hyperthermia, and hyperglycemia is also important in avoiding an exacerbation of neurologic injury.[351] The tracheas of patients who have not recovered neurologically should remain intubated, and these patients should be monitored in an intensive care unit. If unconsciousness persists, further neurologic evaluation with electroencephalography and brain imaging to rule out persistent seizures and/or other underlying neurologic problems should be performed.

Long-Term Outcomes

Neurologic abnormalities occurring in patients with eclampsia (e.g., cortical blindness, focal motor deficits, coma) do not usually result in permanent neurologic deficits.[330] However, recent studies suggest that formerly eclamptic women had significantly poorer neurocognitive function as well as an increase in visual impairment years after the index pregnancy, both of which may be attributable to permanent white matter changes caused by eclampsia.[352-354]

KEY POINTS

- Preeclampsia is a multisystem disorder of pregnancy characterized by a maternal syndrome with or without a fetal syndrome.
- Preeclampsia is a leading cause of maternal and perinatal morbidity and mortality worldwide, particularly in developing countries.
- Disease pathophysiology involves superficial placentation related to abnormal angiogenesis leading to placental hypoxia and the release of soluble substances toxic to vascular endothelium.
- Management of preeclampsia is supportive, and delivery of the fetus and placenta is the only definitive cure.
- Antihypertensive drugs should be used when systolic blood pressure is 160 mm Hg or higher, or the diastolic blood pressure is 110 mm Hg or higher.
- Preeclampsia likely consists of more than one disease; early-onset disease (earlier than 34 weeks' gestation) carries a worse prognosis than late-onset disease.
- Systemic disease manifestations result from widespread maternal vascular endothelial dysfunction.
- Complications of severe preeclampsia include severe refractory hypertension, cerebrovascular accident, pulmonary edema, placental abruption, renal failure, and the HELLP syndrome.
- Important hematologic changes in severe preeclampsia include the potential for thrombocytopenia and disseminated intravascular coagulation.
- There are no indications for invasive central monitoring unique to preeclampsia; indications are similar to those in other multisystem disorders such as severe sepsis or multisystem organ dysfunction.
- Preeclamptic women are at risk for airway edema. The anesthesia provider should anticipate the possibility of difficult airway management.
- The hypertensive response to direct laryngoscopy and tracheal intubation can cause intracranial hemorrhage in women with severe preeclampsia.
- Spinal anesthesia is acceptable for women with severe preeclampsia, especially as an alternative to general anesthesia for emergency cesarean delivery.
- The risks for pulmonary edema, cerebrovascular accident, and venous thromboembolism are increased in the postpartum period.

CHAPTER 37

Fever and Infection

Scott Segal, MD, MHCM

CHAPTER OUTLINE

FEVER

Definition and Pathophysiology

In 1868, Carl Wunderlich analyzed more than 1 million axillary temperature measurements from 25,000 patients.[1] He concluded that the average normal temperature of healthy adults was 37°C (98.6°F). However, he found a range of temperatures, with a nadir of 36.2°C between 2:00 and 8:00 AM and a zenith of 37.5°C between 4:00 and 9:00 PM. He also observed that women had slightly higher mean temperatures than men. A 1992 study using modern oral thermometers largely confirmed Wunderlich's original data.[2]

Well-regulated temperature results from hypothalamic integration of afferent thermal information from the skin, spinal cord, and other sites within the central nervous system (CNS). When this integrated temperature deviates from normal, thermoregulatory responses are triggered.[3] In humans, the first (and least metabolically "expensive") response to temperature perturbations is behavioral (e.g., moving to a different environment, putting on appropriate clothing, adjusting room temperature). Such responses obviously are unavailable to an anesthetized patient, although some may be implemented by those caring for the patient. Further responses to temperature perturbations are mediated by the autonomic nervous system. Hypothermia prompts vasoconstriction in peripheral tissues to decrease skin blood flow, decrease heat loss, and retain heat in the core compartment. If vasoconstriction is not adequate to prevent hypothermia, thermoregulatory shivering is triggered to increase heat production. The CNS controls the metabolic activity of skeletal muscle, which converts chemical energy into heat by shivering.

Increased body temperature initially prompts vasodilation. This vasodilation is passive. It results from the release of sympathetic tone, and it is observed in unanesthetized adults exposed to a hot environment before any significant change in central temperature occurs. If vasodilation is not adequate to prevent hyperthermia, thermoregulatory sweating occurs, which increases evaporative heat loss.

An abnormal body temperature can result from drugs or diseases that either change thermoregulatory thresholds or impair thermoregulatory responses. Hypothalamic activity and fever may be triggered by endogenous pyrogens released from immune effector cells in response to invasion by microorganisms (Figure 37-1). Although no single endogenous pyrogen has been conclusively identified as the mediator of the febrile response, tumor necrosis factor seems capable of reproducing many components of the febrile response.[4] Endogenous pyrogen activity appears to depend largely on increased endothelial cell production of prostaglandins. Of interest, many of these substances help mediate uterine activity and parturition.[5] The central neural pathways leading to changes in thermoregulatory physiology are increasingly well understood and involve pathways coordinated in the preoptic area and projecting to the dorsomedial hypothalamus or to the rostral medullary raphe region.[3]

Clinically, temperature measurements greater than 38°C represent fever. During episodes of fever, the thermoregulatory set point is elevated and the normal thermoregulatory mechanisms are used to maintain the elevated temperature. However, there are circumstances in which an abnormally high temperature is measured in the absence of a change in thermoregulatory set point, such as when thermoregulatory responses to

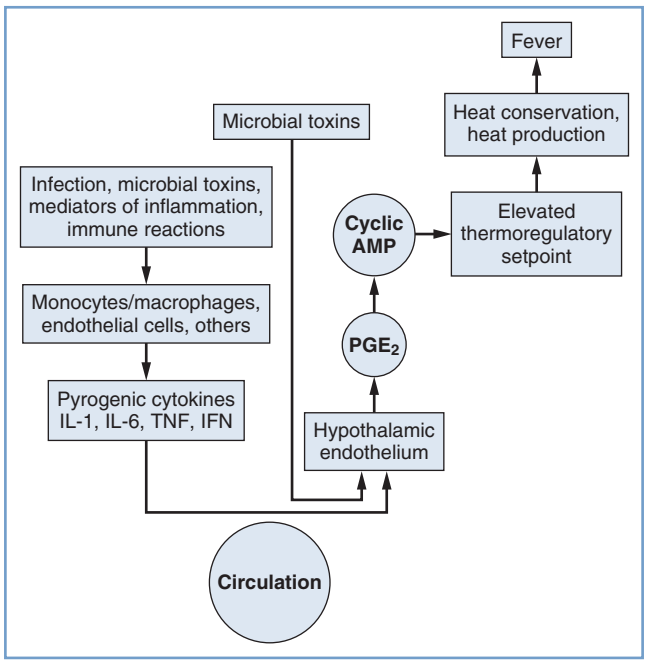

FIGURE 37-1 ■ Chronology of events in the pathophysiology of fever. *AMP,* adenosine-5′-monophosphate; *IFN,* interferon; *IL,* interleukin; *TNF,* tumor necrosis factor; *PGE_2,* prostaglandin E_2. hyperthermia are prevented (e.g., block of sympathetically mediated sweating) or overwhelmed (e.g., immersion in hot water, malignant hyperthermia).

The fetus, by virtue of its intra-abdominal location, has a unique problem with heat elimination. The only anatomic routes for egress of heat are the fetal skin surface (through the amniotic fluid) or the uteroplacental circulation. Evidence suggests that the fetus relies on heat exchange across the uteroplacental circulation to dissipate most of its metabolic heat. The normal fetus maintains a temperature that is approximately 0.5° C to 0.75° C higher than maternal temperature.[6-8]

Consequences of Maternal Fever and Infection

Maternal-fetal infection is associated with increased perinatal morbidity.[9,10] The increased morbidity is the result of many factors, including preterm delivery (perhaps related to an increased release of prostaglandins) and direct effects of the infection. Fever, irrespective of its etiology, may be harmful to the fetus, although the mechanisms of injury may differ with various causes. Conversely, some infections may be harmful without producing fever. Infection is the most common cause of fever and involves liberation of inflammatory cytokines, which are implicated in the pathogenesis of many fetal and neonatal injuries (see Chapter 10).[11,12] Noninfectious inflammatory fever, also leading to elevated cytokines, may complicate neuraxial analgesia in the absence of clinical infection (see later discussion).

Experimental evidence suggests that extreme levels of hyperthermia, independent of infection or inflammation, may have a deleterious effect on the fetus. Morishima et al.[13] reported increased uterine activity and fetal deterioration during maternal hyperthermia produced by radiant heat in anesthetized baboons. However, the extreme degree of hyperthermia (approximately 41.7° C) employed in this study produced maternal as well as fetal deaths. Such extreme hyperthermia exceeds the modest fever that often occurs clinically; thus the clinical relevance of this study is unclear. Similarly, Cefalo and Hellegers[14] demonstrated fetal deterioration at levels of hyperthermia that produced maternal cardiovascular collapse in anesthetized gravid ewes. However, the investigators also observed increased umbilical blood flow with clinically relevant, mild to moderate hyperthermia (0.5° C to 1.5° C above baseline). They suggested that increased umbilical blood flow in response to moderate degrees of hyperthermia might be beneficial to the fetus by increasing oxygen delivery and heat removal. Harris et al.[15] demonstrated the preservation of fetal oxygenation and acid-base status during moderate degrees of fever (approximately 1° C above baseline) produced by the injection of bacterial pyrogen in awake pregnant ewes. However, they also observed an increase in fetal heart rate (FHR) and a greater incidence of fetal arrhythmias during fever.

Nonetheless, in humans, hot tub and sauna use in pregnancy has been linked epidemiologically to neural tube defects in the fetus with attributable risk comparable to that observed with febrile illness.[16] Spontaneous abortion[17] and major structural birth defects[18] have similarly been associated with the frequency of use of hot tubs and saunas. Neonatal hypoxic encephalopathy has been observed after prolonged immersion in 39.7° C water during otherwise uncomplicated labor.[19]

Epidemiologic evidence suggests that mild maternal intrapartum fever may not be as benign as has been assumed on the basis of animal studies. Macauley et al.[8] measured fetal scalp temperature *in utero* using a modified intrauterine pressure catheter. They concluded that fetal core temperature may exceed 40° C in some febrile women (Figure 37-2). Lieberman et al.[20] retrospectively reviewed the records of 1218 nulliparous women with singleton, term pregnancies in spontaneous labor who were afebrile on admission. They found fever (> 38° C) in 10% of the patients, nearly all of whom had received epidural analgesia. One-minute Apgar scores less than 7 and hypotonia were more common in the newborns of febrile mothers. Fever higher than 38.3° C was associated with more frequent requirement for bag-and-mask ventilation in the delivery room and need for supplemental oxygen in the nursery. There was also a nonsignificant increase in the incidence of neonatal seizures.[20] The same group performed a case-control study of unexplained neonatal seizures in term infants and found a strong association with intrapartum fever and seizures (odds ratio [OR], 3.4).[21] A similar finding was reported by Perlman,[22] who found a high incidence of maternal fever among a cohort of infants with a 5-minute Apgar score of 5 or less and those requiring resuscitation with chest compressions in the delivery room. The same group found a

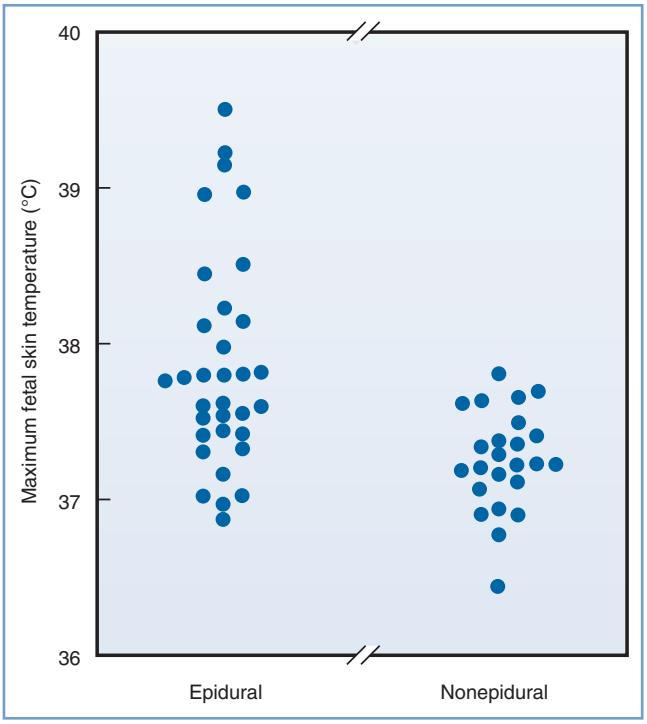

FIGURE 37-2 ■ Maximum fetal scalp temperatures measured *in utero* in women who selected epidural analgesia and those in women selecting other forms of analgesia. $P = .004$ epidural compared with nonepidural group. (From Macaulay JH, Bond K, Steer PJ. Epidural analgesia in labor and fetal hyperthermia. Obstet Gynecol 1992; 80:665-9.)

higher incidence of prolonged positive-pressure ventilation in the delivery room, tracheal intubation, admission to a neonatal intensive care unit, and 5-minute Apgar score less than 6 in febrile newborns born to women with chorioamnionitis compared with afebrile newborns born to women with chorioamnionitis.[23] Similarly, Greenwell et al.[24] found an association between low-grade fever (37.5°C) and adverse neonatal outcomes, including hypotonia and low 1-minute Apgar scores. More extreme fever (> 38.3°C) was also associated with low 5-minutes Apgar scores, assisted ventilation, and seizures.[24]

Even more ominous is the suggestion that maternal fever may correlate with neonatal brain injury, particularly when the fever is associated with clinical or pathologically diagnosed chorioamnionitis (see Chapter 10). In several large epidemiologic studies, otherwise unexplained cerebral palsy was two to nine times more common in infants born to mothers with intrapartum fever (> 38°C) than in those born to afebrile mothers.[25-29] An equally strong association has been observed between maternal fever and neonatal encephalopathy.[30] Even if not apparent at birth or in early infancy, neurologic injury related to maternal fever may appear later in childhood. Dammann et al.[31] reported an increased risk for cognitive deficits (> 2 standard deviations below the mean on a nonverbal intelligence scale) at age 9 among children whose mothers were febrile in labor. Fever during pregnancy, not specifically in the intrapartum period, has also been linked to subsequent development of autism[32,33] and schizophrenia.[34]

The mechanism linking neurologic injuries to maternal fever likely involves the liberation of inflammatory cytokines.[11,12,29,34] Animal models of chorioamnionitis suggest that fetal brain lesions can be induced by infection and blocked by anti-inflammatory cytokines.[35] Infants developing neonatal encephalopathy in the setting of maternal fever do not generally exhibit positive blood cultures, implying that it is neuroinflammation, rather than infection, that causes damage.[30,36] It remains unclear whether intrapartum temperature elevation itself can cause neurologic injury, as distinct from underlying infection or other inflammatory processes that cause both elevated inflammatory cytokines and fever.

Fever also produces significant maternal effects. Elevated temperature is associated with increased maternal heart rate, cardiac output, oxygen consumption, and catecholamine production. Evidence has linked fever after cesarean delivery to risk for uterine rupture during subsequent trial of labor after cesarean delivery.[37] Women who develop fever are more likely to shiver and experience uncomfortable rigors.[38-40] Not surprisingly, obstetricians fearing infection are more likely to treat febrile women with antibiotics.[41,42] Even low-grade fever may prompt obstetricians to choose instrumental vaginal or cesarean delivery over expectant labor management. Lieberman et al.[43] found a twofold higher incidence of operative vaginal as well as cesarean delivery in a retrospective analysis of nulliparous women who were afebrile at admission but developed fever greater than 37.5°C during labor compared with those who remained afebrile, even after controlling for birth weight, duration of labor, and analgesic choice.

Together, these studies suggest that the fetus acutely tolerates modest degrees of maternal fever. Transient neonatal depression, neonatal seizures, and other neurologic disorders may be associated with inflammatory processes that produce maternal fever, although not clearly with fever *per se*. Inflammatory processes resulting in fever, and perhaps severe hyperthermia itself, may be risk factors for neonatal brain injury and other abnormalities.

Infections in Pregnant Women

Fever is most often the result of an infectious process. The most common sites for infection in pregnant women are the fetal membranes, urinary tract, respiratory tract, and postpartum uterine cavity.

Chorioamnionitis

Chorioamnionitis is one of the most common infections in pregnant women. It occurs with variable frequency; reported event rates range from 0.5% to 10%, depending on the means of ascertainment and the demographic and obstetric characteristics of the population. In one review, the incidence was 41% for deliveries occurring at less than 27 weeks' gestation, 15% from 28 to 36 weeks' gestation, and 2% at term.[44] Independent risk factors include low parity, a history of chorioamnionitis in a prior delivery,[45] the number of vaginal examinations, duration of total labor, duration of ruptured membranes, and use

of internal monitors.[45,46] The diagnosis of chorioamnionitis is based on clinical signs, which include temperature greater than 38°C, maternal and/or fetal tachycardia, uterine tenderness, and/or foul-smelling amniotic fluid.[9] Unfortunately, the laboratory diagnosis of chorioamnionitis is neither sensitive nor specific and may not correlate with the clinical presentation.[9,47-51] Moreover, the classic clinical signs of chorioamnionitis often are absent. Goodman et al.[51] reviewed the records of 531 women with pathologically proven chorioamnionitis. They found that only 10% of the patients had abdominal tenderness and only 1% had foul-smelling amniotic fluid. Moreover, histologic evidence of chorioamnionitis can develop without producing clinical signs or symptoms.[52,53]

In most cases, bacteria gain access to the amniotic cavity and the fetus by ascending through the cervix after rupture of the membranes. Chorioamnionitis develops in a significant number of parturients with premature rupture of the membranes. Alternatively, infectious agents present in the maternal circulation may undergo transplacental transport and gain access to the amniotic cavity.[9] Similar to other pelvic infections, chorioamnionitis often is polymicrobial in origin and bacteria normally present in the genital tract most likely are responsible for infections. *Bacteroides* species, group B streptococci, *Mycoplasma* and *Ureaplasma* species, and *Escherichia coli* are organisms commonly isolated from the amniotic fluid of parturients with chorioamnionitis.[9,54] Maternal bacteremia occurs in 7.5% to 12% of women with the clinical diagnosis of chorioamnionitis.[9,47-51,55] *Candida* species occasionally cause chorioamnionitis, especially in preterm labors, and have been associated with severe sequelae, including maternal sepsis and fetal demise.[56] *Ureaplasma urealyticum* has been implicated in intra-amniotic infections even with intact membranes, and infection with this organism is associated with preterm labor.[57]

Maternal complications of chorioamnionitis include preterm labor,[58] placental abruption,[59] postpartum infection,[60] uterine atony,[61] postpartum hemorrhage,[62] peripartum hysterectomy,[63] sepsis, and death. A large prospective observational study found uterine atony, maternal blood transfusion, septic pelvic thrombophlebitis, pelvic abscess, and maternal admission to the intensive care unit to be independently associated with chorioamnionitis.[64] In addition, several studies have noted an increased incidence of cesarean delivery for dystocia in women with chorioamnionitis.* Some investigators have suggested that infection adversely affects uterine contractility and contributes to an increased risk for cesarean delivery.[48] However, in some cases, chorioamnionitis may represent an ascending infection developing late in a labor that is already prolonged and dysfunctional.[55] Satin et al.[55] observed no increase in the incidence of cesarean delivery when chorioamnionitis was diagnosed before the administration of oxytocin. However, they observed a 44% incidence of cesarean delivery when the diagnosis was made after the administration of oxytocin. Thus, the presence of chorioamnionitis may be seen as influencing the clinical decision making of the obstetrician, rather than a direct physiologic cause of dystocia.

Neonatal complications of chorioamnionitis include pneumonia, meningitis, sepsis, and death.[9,47] A strong association between chorioamnionitis and cerebral palsy has been identified.[25,29,65,66] Meta-analyses of more than 20 studies have demonstrated relative risks of cerebral palsy ranging from 1.9 to 4.7 in preterm and term infants born to mothers with clinical chorioamnionitis.[26,66,67] Neonatal stroke has also been linked to chorioamnionitis.[68] Chorioamnionitis has been linked epidemiologically to cystic periventricular leukomalacia, which often produces devastating neurologic impairment in the child.[66,69] The link between maternal infection and neurologic injury in the neonate appears related to intra-amniotic infection or inflammation, particularly when there is evidence of fetal systemic inflammation (funisitis).[29,65]

The effect of intra-amniotic inflammation on the fetal lung is complex. Elevated amniotic cytokines may reduce the incidence of acute respiratory distress syndrome in preterm neonates by stimulating surfactant production.[70] However, chronic lung disease is increased in infants exposed to chorioamnionitis,[71] apparently also related to inflammatory mediators.[9,72] Studies in African women suggest chorioamnionitis is associated with an increased risk for peripartum vertical human immunodeficiency virus (HIV) transmission from infected mothers.[73]

Historically, prompt delivery has been the cornerstone of obstetric management of patients with chorioamnionitis. However, Gibbs et al.[47] did not identify a correlation between poor maternal or neonatal outcome and the time interval from diagnosis of chorioamnionitis to delivery. They performed cesarean delivery only for standard obstetric indications and not for the diagnosis of chorioamnionitis alone.[47] Similarly, a large prospective observational study found no relationship between the duration of infection and most measures of adverse neonatal outcome among 1965 gestations complicated by chorioamnionitis, although low 5-minute Apgar scores and neonatal mechanical ventilation were correlated with duration of chorioamnionitis.[64] No recent studies have reinvestigated this practice as it relates to neonatal neurologic injuries. Monitoring of the FHR pattern is indicated in women with the diagnosis of chorioamnionitis. Many fetuses will exhibit mild tachycardia during maternal fever and infection, but this pattern is not highly predictive of neonatal acidemia and, therefore, by itself, is not an indication for immediate delivery.[74]

For many years, pediatricians requested that obstetricians delay antibiotic therapy until after delivery. They cited the theoretical concern that intrapartum therapy might "obscure the results of neonatal blood cultures."[75] However, studies suggest that early, antepartum treatment results in decreased maternal and neonatal morbidity compared with delayed, postpartum treatment.[76,77] Gibbs et al.[76] randomized 45 women with intra-amniotic infection to receive intrapartum or postpartum antibiotic therapy with ampicillin and gentamicin. Intrapartum antibiotic therapy resulted in a decreased incidence of

*References 9, 47-49, 55, 62, 64.

neonatal sepsis and a shorter neonatal hospital stay. Mothers who received intrapartum antibiotics also had a shorter hospitalization, fewer days with fever, and a lower peak postpartum temperature than mothers whose antibiotic therapy was delayed until after delivery. Currently, most obstetricians give antibiotics before delivery in women with chorioamnionitis. The early use of antibiotics also may affect the anesthesiologist's decision regarding the administration of neuraxial labor analgesia or anesthesia (see later discussion).

Urologic Infections

Urinary tract infections are common during pregnancy, although the incidence of asymptomatic bacteriuria may not be higher than in nonpregnant women. Increased concentrations of progesterone cause the relaxation of ureteral smooth muscle. In addition, the gravid uterus causes partial ureteral obstruction. Both factors cause urinary stasis, which increases the risk for urinary tract infection.[9,78,79] Furthermore, these physiologic changes increase the likelihood that asymptomatic bladder infection will ascend into the kidneys and produce pyelonephritis. Approximately 1.3% of pregnant women will develop symptomatic cystitis,[80] and up to 25% of women with untreated bacteriuria in pregnancy may develop pyelonephritis.[81]

Acute pyelonephritis is a serious threat to maternal and fetal well-being and complicates approximately 1.4% of pregnancies. Symptoms of acute pyelonephritis include fever, chills, flank pain, and other symptoms of lower urinary tract infection. Laboratory tests reveal pyuria and leukocytosis with a left shift. Pregnant women with pyelonephritis may appear severely ill. Approximately 14% to 17% of pregnant women with pyelonephritis will develop bacteremia during the course of this infection.[82,83] Complications may also include anemia, renal insufficiency, and respiratory insufficiency.[83] The most common causative organisms are *E. coli*, gram-positive organisms, *Klebsiella*, *Enterobacter*, and *Proteus* species.[83]

Hospitalization is generally required to initiate aggressive parenteral antibiotic treatment of this serious maternal infection, although limited data support outpatient treatment for carefully selected patients in the first and second trimester.[84] Nevertheless, treatment failures and septic complications have been reported in patients randomized to outpatient therapy in clinical trials.[85]

Pyelonephritis is associated with an increased risk for preterm labor and delivery in animal models.[86] Thus, obstetricians should observe for evidence of preterm labor, although epidemiologic studies have found the incidence to be less than 5%, approximately the same as in the general pregnant population.[83,87]

Pyelonephritis may be associated with organ dysfunction. Nearly 20% of affected women have transient renal dysfunction[88] and the disease may also be complicated by pulmonary injury. Cunningham et al.[89] suggested that "this syndrome was probably caused by permeability pulmonary edema, likely mediated by endotoxin-induced alveolar-capillary membrane injury."[89] Towers et al.[90] compared 11 pregnant women who had pyelonephritis and pulmonary injury with 119 women who had pyelonephritis only. They observed that fluid overload and the use of tocolytic therapy were the most significant predictive factors associated with pulmonary injury. The authors suggested that "strict management of fluids should occur so that patients do not have fluid overload."[90] Contemporary authors, however, have questioned fluid restriction in pyelonephritis and instead suggest fluid administration sufficient to generate urine output of 30 to 50 mL/h, while observing respiratory rate, oxygen saturation, and symptoms of dyspnea to identify impending respiratory compromise. Respiratory failure should be investigated with chest radiography and arterial blood gas analysis and managed with appropriate respiratory support.[9]

Hemodynamic alterations may be present even in infected women who do not demonstrate overt signs of sepsis. Twickler et al.[91] used ultrasonographic techniques to evaluate the central hemodynamic measurements in 27 pregnant women with uncomplicated pyelonephritis. They found decreased mean arterial pressure (MAP) and systemic vascular resistance (SVR) and increased heart rate and cardiac output compared with measurements obtained from the same patients after they had recovered from their infection.[91]

Recent reviews from the Cochrane Database and the United States Preventative Services Task Force strongly support the practice of screening and treating pregnant women for asymptomatic bacteriuria, up to 30% of whom will eventually develop pyelonephritis if left untreated.[92,93] Treatment is associated with a reduced incidence of pyelonephritis (OR, 0.23) and low-birthweight infants (OR, 0.66), although not, as had been previously suggested, in the incidence of preterm delivery.[93] Definitive choice of antibiotics could not be determined in a recent systematic review,[94] but traditional 7-day regimens are likely more effective than single-dose or other abbreviated antibiotic courses.[95] Because pyelonephritis in pregnancy is thought to be preventable, its occurrence may be a marker for poor prenatal care; thus it should alert physicians to other potential pregnancy problems.[96]

Respiratory Tract Infection

Most respiratory tract infections during pregnancy are upper respiratory tract viral infections that do not pose a serious threat to the mother or fetus. Most lower respiratory tract infections are also viral and self-limiting; pneumonia occurs during pregnancy with an incidence approximating that of the nonpregnant population.[97] Pregnancy results in a number of changes that may predispose the pregnant woman to the development of serious respiratory tract infection. Hyperemia and hypersecretion are characteristic of the respiratory tract mucosa during pregnancy, and these changes may intensify the effect of the initial infection.[98] In the case of a viral infection, the excess secretions may predispose the patient to bacterial superinfection. Immunologic modulation during pregnancy may also predispose to pulmonary infection.[99] Furthermore, the increased oxygen consumption, elevation of the diaphragm, and decreased

functional residual capacity characteristic of pregnancy may increase the likelihood that infection will result in maternal hypoxemia.

Benedetti et al.[100] emphasized the importance of early diagnosis and treatment as well as the direct measurement of maternal oxygenation in cases of pneumonia during pregnancy. Most community-acquired pneumonias in healthy young women are bacterial in origin. *Streptococcus pneumoniae* is the most common pathogen.[100,101] *Mycoplasma pneumoniae* and influenza are other common pathogens. *Legionella pneumophila*, *Chlamydia*, and varicella are less common pathogens in this population. Varicella pneumonia has been associated with maternal and fetal morbidity and up to 40% maternal mortality. **Acyclovir** has been used successfully to treat varicella pneumonia during pregnancy.[102] *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia represents the most common cause of death related to acquired immunodeficiency syndrome (AIDS) in pregnancy; mortality is as high as 50%.[103]

Because morbidity and mortality from influenza are increased in pregnancy, influenza vaccination is strongly recommended for all pregnant patients, irrespective of gestational age.[104] The risk for fetal death is increased by maternal influenza infection and is reduced by vaccination.[105] The infant is also passively protected for up to 20 weeks after birth.[106] Aggressive treatment with antiviral drugs (oseltamivir, zanamivir) reduces the severity of the ensuing illness; in the 2009-2010 H1N1 influenza pandemic, initiation of therapy in the first 2 days of the infection reduced hospitalization and intensive care unit admission.[107,108]

Postpartum Infection

The most common source of postpartum infection is the **genital tract**. The urinary tract and less often the breasts or the lungs may also be infected.[9] Postpartum uterine infection typically results in fever, malaise, abdominal pain, and purulent lochia. Bacteremia may occur in as many as 5% to 10% of patients with uterine infection after delivery.[49,50,109,110] Although obstetricians typically refer to postpartum uterine infection as *endometritis*, this infection involves the decidua, myometrium, and parametrial tissues. Bacteria that colonize the cervix and vagina gain access to the amniotic fluid during labor, and they may invade devitalized uterine tissue postpartum.

Patients who undergo cesarean delivery are at increased risk for postpartum endometritis compared with similar patients who deliver vaginally.[9] Prolonged rupture of membranes and/or prolonged duration of labor increase the incidence of postpartum uterine infection. Prophylactic administration of antibiotics decreases the incidence of postpartum uterine infection and wound infection after cesarean delivery in all women, whether performed electively or emergently.[111] No important differences have been identified among various skin preparation solutions used before cesarean delivery.[112] Vaginal preparation before cesarean delivery, however, may reduce endometritis.[113] Systematic reviews have found insufficient evidence to recommend prophylactic antibiotics for operative vaginal delivery or for manual removal of the placenta after vaginal delivery; however, consideration may be given to prophylactic antibiotics in the setting of complex perineal repairs.[114-116] Endometritis typically responds to appropriate antibiotic therapy, and outcomes are generally excellent. However, serious complications (e.g., peritonitis, abscess, septic thrombophlebitis) may rarely occur.[9,49] In future pregnancies, women who have experienced endometritis are at increased risk for uterine rupture, and anesthesiologists and obstetricians should demonstrate extra vigilance for this serious complication.[37]

Sepsis and Septic Shock

Sepsis is a rare, life-threatening complication of maternal infection that complicates approximately 1 in 8000 deliveries.[117] Sepsis is defined by the American College of Chest Physicians and Society of Critical Care Medicine as infection that precipitates the **systemic inflammatory response syndrome** (SIRS), characterized by two or more of the following criteria: hyperthermia, hypothermia, tachycardia, tachypnea, or leukocytosis (see Chapter 55).[118] Pregnancy may complicate the diagnosis, because many healthy pregnant women exhibit some of these signs.[119] Noninfectious inflammation may also lead to SIRS; in all cases the syndrome appears to be triggered by mediators released from immune effector cells, including tumor necrosis factor, interleukins, and cyclooxygenase metabolites of arachidonic acid.[120]

Severe sepsis is defined as sepsis with acute organ dysfunction, hypotension, or sepsis-induced hypoperfusion,[118] and **septic shock** is defined as sepsis-induced hypotension that persists despite adequate fluid resuscitation, along with the presence of hypoperfusion abnormalities or organ dysfunction.[118] The incidence of sepsis and sepsis-related maternal mortality appears to be rising; it was the most common cause of death (1.13 per 100,000 maternities) in the most recent (2006-2008) Confidential Enquiries into Maternal Death in the United Kingdom report.[121]

In pregnant women, sepsis typically is associated with gram-negative bacteremia, although it can occur in association with gram-positive aerobic and anaerobic infections.[122] Polymicrobial etiology is common,[117,123] particularly when the source of sepsis is a pelvic infection.[122] Group A β-hemolytic streptococcal infection appears to predominate in fatal cases or those associated with major morbidity, although *Clostridium* species have been implicated in deaths of several otherwise healthy women undergoing gynecologic or obstetric procedures.[124,125] Untreated pneumonia, chorioamnionitis, pyelonephritis, endometritis, wound infection, incomplete abortion, and self-induced abortion may result in maternal sepsis, severe sepsis, and septic shock; case reports have attributed iatrogenic maternal sepsis to amniocentesis,[126-129] medical abortion,[125] dental procedures, and assisted reproductive procedures.[130] Approximately 45% of cases occur postpartum.[131] The clinical course is often fulminant. In a series of nearly 100 cases from The Netherlands, more than half of the patients demonstrated signs of severe sepsis within 48

hours of the first sign of infection and 39% did so within 24 hours.[131]

Studies have suggested that pregnancy makes laboratory animals more susceptible to infection by a number of mechanisms.[132] For example, Beller et al.[133] infused *E. coli* B6 lipopolysaccharide (endotoxin) into both nonpregnant and pregnant minipigs. The average duration of survival for the nonpregnant animals was 16 hours, whereas the average duration of survival for the pregnant animals was only 3.5 hours. The pregnant animals suffered more pronounced cardiovascular abnormalities and metabolic acidosis than the nonpregnant animals.

It is unclear whether pregnant women are more susceptible to sepsis than age-matched nonpregnant women. Case series of maternal sepsis have reported overall case-fatality rates of 6% and 7.7%.[122,131] This survival rate may reflect the relative youth of pregnant women and the effectiveness of surgical source control for most pelvic infections. Nonetheless, clinical studies have noted that once septic shock develops in pregnant patients, maternal mortality is as high as 30%.[134-136]

The mainstay of therapy is elimination and/or aggressive treatment of the source of infection with antibiotics and, if indicated, surgical extirpation. Initial antibiotic therapy should include broad-spectrum coverage for bacteria such as *E. coli*, enterococcus, and anaerobic organisms. A combination of ampicillin, gentamicin, and clindamycin represents an effective regimen, as does a combination of imipenem, cilastatin, and vancomycin.[137] A 2012 review of cases from the United Kingdom Center for Maternal and Child Enquiries (CMACE) project suggested initial broad-spectrum antibiotic coverage (e.g., gentamicin with either piperacillin-tazobactam or ciprofloxacin), consultation with an infectious disease specialist as soon as possible, and appropriate adjustment of antibiotic therapy once the causative organism and antibiotic susceptibilities have been identified.[138] Local patterns of microbial resistance should be considered when selecting broad-spectrum empirical therapy. In all cases, aggressive antibiotic initiation without delay (within 1 hour of diagnosis) appears important for a favorable outcome.[121,139]

Only a few reports have described the management of these seriously ill patients. Timezguid et al.[122] summarized 66 intensive care unit admissions for sepsis between 1977 and 2008. Seventeen of 22 women with a pelvic source of infection required surgical source control, including termination of pregnancy (n = 5), uterine exploration for removal of placental fragments (n = 6), drainage of a pelvic abscess (n = 5), or hysterectomy (n = 3). Premature termination of pregnancy was more frequent in 12 cases of chorioamnionitis (83%) than in the 32 cases of extrapelvic infections (31%). Vasopressors, mechanical ventilation, and renal replacement therapy were used in 16 (25%), 19 (28%), and 4 (6%) cases, respectively.

Lee et al.[135] reviewed 10 cases of septic shock in obstetric patients between 1984 and 1986, which were caused by pelvic infections in 9 cases and mastitis in 1. Eight of the 10 women required inotropic or vasopressor infusions, or both, guided by pulmonary arterial catheterization. Two women died. The primary hemodynamic abnormalities were decreased systemic vascular resistance and depressed myocardial function.

Mabie et al.[136] reported 18 cases of pregnancy-associated septic shock that occurred during 11 years in a single institution, an incidence of 1 per 8338 deliveries. The most common causes were pyelonephritis (n = 6), chorioamnionitis (n = 3), endometritis (n = 2), and toxic shock syndrome (n = 2). Five patients (28%) died. The hemodynamic profiles of the patients in this series were similar to those described by Lee et al.[135]: four of the five patients who died had mildly or severely depressed myocardial function.[136] Eight patients underwent at least one surgical procedure to control the source of infection.

In most cases, concomitant supportive therapy is required to decrease maternal and fetal morbidity. Physicians must give attention to the maintenance of maternal oxygenation, circulation, and coagulation. Most authorities suggest following the Surviving Sepsis guidelines for treatment of sepsis.[121,138,139] The guidelines recommend goal-directed therapy aiming to achieve a central venous pressure (CVP) between 8 and 12 mm Hg and a MAP of 65 mm Hg, urine output of 0.5 mL/kg/h, and mixed venous oxygen saturation 65% or higher (see Chapter 55).[139] Pregnant women were excluded from trials that evaluated this goal-directed therapy,[140,141] and unfortunately no evidence is available to confirm that this approach offers survival benefit for pregnant or recently delivered women. In nonpregnant patients with septic shock, norepinephrine is considered the first choice vasopressor and may be supplemented with epinephrine or vasopressin to maintain adequate blood pressure.[139]

Evidence from nonobstetric patients receiving intensive care indicates that aggressive glycemic control may not confer a survival advantage in all critically ill patients, although some evidence suggests that avoiding hyperglycemia improves outcomes in surgical patients.[142] Overly tight glycemic targets increase the risk for hypoglycemia; current guidelines recommend treatment to avoid hyperglycemia (> 180 mg/dL), hypoglycemia, and wide swings in glucose levels.[139] More intensive glucose control may be indicated in the intrapartum period to achieve optimal neonatal outcomes. Corticosteroid supplementation is indicated only when fluid resuscitation and vasopressor therapy fail to restore hemodynamic stability.[139,143]

Although the effects of maternal therapy on the fetus should be considered, treatment of the mother has first priority. Often what is best for the mother will be best for the fetus. However, in some cases, maternal sepsis may require preterm delivery, or even delivery before the age of viability, particularly if chorioamnionitis is present. Although the American College of Obstetricians and Gynecologists (ACOG) has stated that "delivery usually is not indicated in the septic pregnant patient in whom the pregnancy is not the source of infection,"[137] a multidisciplinary team should consider the mother's response to initial therapeutic interventions, her vasopressor, oxygen and ventilatory requirements, and the gestational age and fetal well-being when considering the optimal timing and route of delivery.

EPIDURAL ANALGESIA AND MATERNAL FEVER

Incidence

Epidural anesthesia administered for surgery—including cesarean delivery—typically results in hypothermia. This effect occurs because vasodilation produced by the sympathetic neuroblockade causes a redistribution of body heat from the core to the periphery, where it is lost to the environment.[144]

In 1989, Fusi et al.[145] first observed that epidural labor analgesia was associated with progressive intrapartum maternal pyrexia. They reported that the vaginal temperatures of 18 parturients who received epidural analgesia increased approximately 1° C over 7 hours, whereas the temperatures of 15 women who received intramuscular meperidine and metoclopramide remained constant. There was no evidence of infection in any of the women. The authors suggested that epidural analgesia may cause an "imbalance between the heat-producing and heat-dissipating mechanisms."

Fusi et al.[145] measured *vaginal* temperature; this measurement may be affected by the sympathectomy and vaginal mucosal vasodilation associated with epidural analgesia. Tympanic membrane temperature should not be affected by the local vasodilation associated with epidural analgesia, and it may provide a more accurate assessment of core temperature. Camann et al.[146] studied the effect of epidural analgesia on maternal oral and tympanic membrane temperature measurements in 53 laboring women. They studied three groups of patients; one group received intravenous nalbuphine, one group received epidural bupivacaine only, and one group received epidural bupivacaine with fentanyl. The patients were not randomized to receive either nalbuphine or epidural analgesia; however, the women who requested epidural analgesia were randomized to receive epidural bupivacaine only or epidural bupivacaine with fentanyl. The authors maintained ambient room temperature between 20° C to 22° C. Epidural analgesia did not affect maternal temperature during the first 4 hours of the study. At 5 hours and thereafter, the mean tympanic membrane temperatures were significantly higher in both of the epidural groups than the intravenous nalbuphine group (Figure 37-3). Among women in the bupivacaine-only group, mean tympanic temperature increased from approximately 36.6° C at 1 hour to 37.1° C at 9 hours, a rate of rise of less than 0.07° C per hour. There was no difference between the epidural bupivacaine-only and the epidural bupivacaine-fentanyl groups in maternal tympanic membrane temperature measurements.

Several other investigators have documented similar patterns of temperature elevation in laboring women receiving epidural analgesia.[41,147-152] These studies typically have found the average rate of temperature increase to be approximately 0.1° C per hour of epidural analgesia, usually after a lag time of 4 to 5 hours. Other investigations have documented an increase in clinical fever in women with epidural analgesia, usually defined as temperature greater than 37.5° C or greater than 38° C (Table 37-1).* These studies have employed various study designs, most commonly observational investigations of women self-selecting the mode of analgesia. Selection bias, reflecting greater prevalence of risk factors for fever among women choosing epidural analgesia, undoubtedly has affected the results of these reports.[163] However, other study designs have confirmed the finding of greater risk for fever in women who receive epidural analgesia. In a natural experiment, in which epidural analgesia was rapidly introduced in a facility in which it was previously unavailable, clinical fever markedly increased after epidural analgesia was widely available.[147] In addition, eight randomized controlled trials, in which women were randomly assigned to receive epidural analgesia or parenteral opioids (or nonpharmacologic analgesia in one study[155]), also confirmed an increase in clinical fever in women who were randomized to receive epidural analgesia.[152,155,156,158-162] Only one study examined fever as a primary outcome.[155] Meta-analysis of six trials found a relative risk (RR) for fever of 3.34 (95% confidence interval, 2.63 to 4.23) for epidural compared with nonepidural or no labor analgesia.[164] Most trials have investigated epidural labor analgesia, but at least one trial specifically investigated combined spinal-epidural (CSE) analgesia.[155]

Originally viewed as two separate phenomena, the slow progressive temperature rise observed by Fusi[145] and Camann[146] and the clinical fever observed in other studies may be manifestations of the same process. Two investigations have concluded that the slow rise may actually be an artifact caused by averaging the temperature curves of women who develop clinical fever with those who remain afebrile (see Figure 23-7).[165,166] Frölich et al.[167] compared

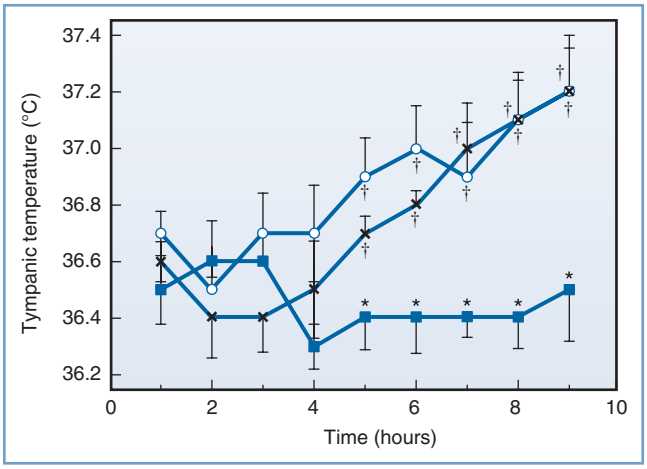

FIGURE 37-3 ■ Mean (SE) tympanic temperatures during labor in three groups of patients: Epidural bupivacaine-fentanyl (*open circles*), epidural bupivacaine-only (x), and parenteral opioid (*blue squares*) groups. **P* < .01 compared with the epidural group; †*P* < .01 compared with the pre–epidural analgesia temperature. (From Camann WR, Hortvet LA, Hughes N, et al. Maternal temperature regulation during extradural analgesia for labour. Br J Anaesth 1991; 657:565-8.)

RCT, randomized controlled trial.
[a]All patients had ruptured membranes > 6 h; outcome included fever up to 6 h postpartum.
[b]Natural experiment (impact study) compared two time periods, before and after the introduction of on-demand labor epidural analgesia to a single institution. The "after" period is reported as the epidural group (83% of nulliparous women received epidural analgesia); the "before" period is reported as the nonepidural group (1% received epidural analgesia).
[c]Fever was reported for protocol-compliant women only.
[d]Data from this investigation were reanalyzed by Philip et al.[152]
[e]Only nulliparous women participated in the study.
[f]The study included parturients with gestational hypertension or preeclampsia; the percentages were recalculated from n/N reported in the publication.
[g]The epidural group comprised three groups: (1) epidural analgesia only, (2) epidural analgesia with intravenous remifentanil, and (3) epidural analgesia with intravenous acetaminophen.
[h]Patients were randomized to receive combined-spinal epidural (CSE) analgesia or nonpharmacologic analgesia.

the slope of the temperature-time curves in women before and after receiving epidural analgesia and found no difference. They examined only women who did not develop a temperature greater than 38° C, and thus their finding supports the observation that epidural analgesia affects temperature in only a subset of women who develop clinical fever. These findings imply that an understanding of the nature of the relationship between epidural analgesia and overt fever is the key to understanding hyperthermia during labor in these patients.

Etiology

The mechanisms by which epidural analgesia produces maternal hyperthermia during labor remain unclear, and at least three types of explanation are plausible: thermoregulatory factors, effects of systemic opioids in patients not receiving epidural analgesia, and inflammation.[163]

Thermoregulatory factors that may play a role include ambient temperature, impaired heat dissipation, and increased heat production. Fusi et al.[145] attributed the maternal pyrexia to the high ambient temperature (24° C to 26° C) found in most British delivery rooms. However, other investigators have failed to find an association between ambient temperature and maternal[148] or fetal[8] temperature. Alternatively, epidural analgesia may impair heat-dissipating mechanisms. Decreased sweating and the lack of hyperventilation that follow the provision of effective epidural pain relief may predispose laboring women to pyrexia.[145,146,168] In volunteers, epidural anesthesia raised the sweating threshold by 0.55° C.[169] Moreover, epidural analgesia attenuates the significant increase in oxygen consumption observed during uterine contractions and the even greater increase observed during expulsive efforts.[170] This lack of increase in ventilation in the setting of increased energy expenditure may manifest as increased temperature in the laboring patient. Finally, the high incidence of shivering among laboring women who receive epidural analgesia may predispose them to the development of fever. Gleeson et al.[39] found that laboring patients who shivered after the administration of epidural analgesia developed pyrexia as early as 1 hour

after initiation of neuroblockade, compared with more than 4 hours after initiation neuroblockade in patients who did not shiver. Moreover, the maximum temperature was higher and the incidence of clinical fever was three times more common in the women who shivered.[39] Some shivering and sweating in labor has been demonstrated to be nonthermoregulatory (i.e., not accompanied by changes in core temperature or vasomotor tone).[40] However, it is not clear whether shivering is a cause or an effect of factors increasing body temperature.

Parenteral **opioids** administered to women for labor analgesia might suppress fever that would otherwise have been apparent. In a nonpregnant volunteer study, fever was induced by the injection of interleukin-2.[171] Epidural analgesia with ropivacaine with or without epidural fentanyl did not affect the magnitude of the fever, but intravenous fentanyl markedly attenuated the rise in temperature.[171] However, in one large retrospective study,[172] differences in intravenous nalbuphine use did not explain the increased occurrence of fever among those receiving epidural analgesia. Evron et al.[173] randomized laboring women to receive epidural ropivacaine, intravenous remifentanil, both drugs, or epidural ropivacaine and intravenous acetaminophen. They identified fever (temperature ≥ 38° C) in 14% of the ropivacaine group, 8% in the ropivacaine and remifentanil group, 8% in the ropivacaine and acetaminophen group, and 1% in the remifentanil group. Taken together, these investigations suggest that any fever-suppressing effect of parenteral opioids is relatively weak and is seen only with μ-opioid receptor agonists.

The predominant theory to date holds that **inflammation**, perhaps of a noninfectious etiology, is responsible for epidural analgesia–associated fever. Several lines of evidence support this mechanism. First, women who are more likely to request epidural analgesia during labor also are more likely to have other risk factors for fever during labor. These may include nulliparity,[151,174] premature rupture of membranes,[175] prolonged rupture of membranes,[148,151,174] induction of labor,[175] unfavorable cervical examination at admission,[175] prostaglandin exposure,[175] prolonged labor,[8,146,148,151] obesity, higher temperature on admission,[151] early chorioamnionitis,[151] and possibly more cervical examinations.[46,175,176]

Second, women with epidural analgesia and fever more frequently demonstrate placental inflammation. In a case-control study, Vallejo et al.[177] compared women without epidural analgesia and with clinical chorioamnionitis (temperature ≥ 38° C and clinical manifestations) to two groups of women who received epidural analgesia, one with and the other without clinical chorioamnionitis. The diagnosis of chorioamnionitis was confirmed histologically. Not surprisingly, fever was far more common in the women with chorioamnionitis. In fact, the incidence of fever in women with epidural analgesia but without chorioamnionitis was only 1%.[177] Similarly, Dashe et al.[154] analyzed the records and placental pathology of 149 women who delivered more than 6 hours after membrane rupture. They found an increased incidence of fever (temperature ≥ 38° C) in the 54% of their subjects who received epidural analgesia. However, histologic evidence of placental inflammation was also more common among epidural analgesia–exposed women. In the absence of placental inflammation, the incidence of maternal fever was equivalent in the epidural analgesia–exposed and unexposed patients (11% and 9%, respectively).[154]

Importantly, the placental inflammation associated with epidural analgesia–associated fever may not indicate bacterial infection. Riley et al.[52] examined the placentas of 200 women, 150 of whom received epidural analgesia, who had participated in two previous randomized trials of the presence of birthing assistants. The authors attempted to culture bacteria from the placentas, as well as to detect bacterial DNA by the polymerase chain reaction; they also measured serum interleukin concentrations. Fever was more common in women who received epidural analgesia than in those who did not (23% versus 6%, respectively; $P = .009$), but the incidence of infection was low in both groups (4.7% versus 4.0%, respectively; $P > .99$). An admission interleukin-6 (IL-6) level greater than 11 pg/mL predicted development of fever, irrespective of analgesic choice, and IL-6 levels increased more over the course of labor in women choosing epidural analgesia, irrespective of development of fever.

A third line of evidence supporting an inflammatory mechanism of epidural analgesia–associated fever is that biomarkers of inflammation are more common in women with epidural analgesia who develop fever. Goetzl et al.[178] randomized women with epidural analgesia to receive acetaminophen or placebo in labor. The incidence of fever (temperature > 38° C) was identical in the two groups. They demonstrated elevated maternal serum and umbilical cord blood markers of inflammation (IL-6) in febrile women. Pathologic examination of the placenta was not reported.[178] As discussed earlier, Riley et al.[52] also found higher IL-6 levels in women receiving epidural analgesia and in women developing fever regardless of whether they received epidural analgesia. In a second trial, Goetzl et al.[179] were able to demonstrate suppression of epidural analgesia–associated fever with high-dose maternal corticosteroid therapy (methylprednisolone 100 mg every 4 hours). Umbilical cord blood IL-6 levels were lower in corticosteroid-treated patients, indicating suppression of inflammation. However, neonatal bacteremia was significantly increased by corticosteroid exposure.[179] In a small and likely underpowered trial, Wang et al.[180] randomized low-risk parturients with epidural analgesia to receive bupivacaine and fentanyl alone or combined with epidural dexamethasone 0.2 mg/mL. They observed no difference in the incidence of overt fever or placental inflammation but a reduction in mean temperature in the dexamethasone group. Maternal and umbilical cord blood IL-6 levels were reduced in the corticosteroid group, although the differences were not significant. Fetal condition was excellent in both groups.

The mechanism by which epidural analgesia might induce inflammation in a subgroup of women remains unclear. In nonrandomized investigations, differences in patient factors among women selecting epidural analgesia may indicate confounding risk factors for inflammation. Even in randomized trials, differences in obstetric management could also confound the association, because it

is not possible to blind the treatment group in trials of epidural analgesia.[163] For example, epidural analgesia is associated with greater use of oxytocin in randomized trials, and it is conceivable that women randomly assigned to receive epidural analgesia may also receive earlier artificial rupture of membranes, more frequent cervical examinations, and greater use of internal monitoring in order to titrate oxytocin administration.[52,152] Conversely, a direct action of epidural local anesthetic in stimulating inflammation has been proposed, with the effect mediated through activation of the vanilloid receptor TRPV1.[181]

Clinical Impact

Epidural analgesia–associated maternal hyperthermia has become a subject of significant controversy. As discussed earlier, maternal fever attributed to clinical chorioamnionitis and other infection is associated with adverse neonatal condition as well as more severe neurologic injuries, including seizures, encephalopathy, and cerebral palsy. However, the effect of epidural analgesia–associated fever has not been specifically elucidated. In randomized trials comparing epidural and nonepidural analgesia, neonatal condition as measured by umbilical arterial acidosis or 5-minute Apgar score is consistently better in the epidural analgesia groups and neonatal intensive care unit admission does not differ between groups.[164] In a large retrospective analysis, epidural analgesia with fever was associated with adverse neonatal outcomes, but in the absence of fever epidural analgesia was not.[24] To date, no evidence has linked noninfectious epidural analgesia–associated fever to severe neonatal adverse outcomes.

It is possible that the mother and neonate may be placed at risk *indirectly* as a result of the interventions triggered by the occurrence of maternal fever.[41,150] For example, antibiotic administration is more likely in the setting of maternal fever. Mayer et al.[41] retrospectively analyzed the records of 300 low-risk nulliparous women who received systemic opioids, epidural analgesia, or both and identified an increased incidence of both fever (≥ 37.8°C) and antibiotic administration among the two groups who received epidural analgesia. Nonetheless, only 5 of 10 patients with culture- or pathology-proven chorioamnionitis developed fever and none had fever as the *only* presenting sign or symptom. The authors suggested that obstetricians seek additional evidence of infection before treating all maternal fever with antibiotics.

In another retrospective study, Lieberman et al.[150] reanalyzed the records of 1657 low-risk nulliparous women originally enrolled in a trial of active management of labor.[182] They, too, found a higher incidence of maternal temperature (> 38°C) in parturients who received epidural analgesia compared with those who did not (15% versus 1%, respectively). Neonates in the epidural group had a higher incidence of sepsis evaluation (34% versus 10%, respectively) and antibiotic treatment (15% versus 4%, respectively) compared with neonates in the nonepidural group. The incidence of actual neonatal sepsis was very low in both groups (0.3% and 0.2%, respectively). As in all studies in which women self-select their analgesia, the women receiving epidural analgesia were already at risk for intrapartum fever. For example, they had larger infants, longer labors, and a twofold increase in the rate of induction of labor.[150] Moreover, the active labor management protocol mandated frequent cervical examinations and early amniotomy, which may have increased the risk for fever.[183] Of interest, two thirds of the sepsis evaluations occurred in infants of mothers who did *not* have intrapartum fever.[150,183]

To further elucidate the relationship between epidural analgesia and neonatal sepsis evaluation, the same group reanalyzed the subcohort of women[182] admitted in spontaneous labor, in whom intrapartum temperature remained below 38°C throughout labor.[184] Epidural analgesia was associated with both major (rupture of membranes > 24 hours, FHR > 160 beats/min) and minor criteria (maternal temperature > 37.5°C, rupture of membranes 12 to 24 hours) for sepsis evaluation. It is likely that many of the features of labor that led to sepsis evaluations also predisposed women to choose epidural analgesia.

Subsequent work by other investigators has suggested the role of maternal temperature elevation as the key feature related to neonatal sepsis evaluations. Philip et al.[152] demonstrated that women randomized to receive epidural analgesia had a higher incidence of fever (≥ 38°C) than those randomized to receive intravenous analgesia (15% versus 4%, respectively). Neonatal sepsis evaluations were also much more common in women with fever than in those without (96% versus 13%, respectively). However, within both the febrile and the afebrile cohorts, the incidence of neonatal sepsis evaluation was independent of analgesic type. The authors concluded[152]:

> *… our results indicate that in the absence of maternal fever, epidural analgesia during labor has no bearing on the need for such neonatal management and therefore should not be considered a predictor per se for neonatal sepsis evaluations. We attribute this finding to the minimization of ascertainment bias as a result of randomization of analgesia.*

Other investigators have highlighted the importance of neonatal practice style in determining the rate of sepsis evaluations. Yancey et al.[147] studied the rates of maternal fever and neonatal sepsis evaluation during a period in which epidural analgesia use rapidly increased from 1% to 83% after the introduction of a round-the-clock, on-demand epidural analgesia service. The incidence of fever greater than 37.5°C increased threefold, and fever greater than 38°C increased 18-fold after the introduction of epidural analgesia, although numerous indices of the patients' admission status and intrapartum obstetric management did not change. The incidence of screening neonatal blood counts and blood cultures increased modestly (RR, 1.5 and 1.7, respectively), but there was no change in antibiotic treatment. The authors contrasted their results to those of Lieberman[150] and attributed the difference to neonatal practice patterns that did not require antibiotic therapy solely on the basis of maternal fever or antibiotic exposure.[147]

Kaul et al.[157] also emphasized neonatologists' practice style. They analyzed the records of 1177 nulliparous women and their neonates. Women with epidural analgesia had an increased risk for fever compared with women who received parenteral opioid analgesia (7% versus 0%, respectively), but multivariate logistic regression failed to demonstrate a significant association between epidural analgesia or maternal fever and neonatal sepsis evaluation. In contrast to Lieberman et al.,[150] the authors attributed the lack of effect of epidural analgesia to more stringent guidelines for neonatal sepsis evaluation that required at least one neonatal sign or symptom of infection regardless of the maternal condition.[157]

The ability of epidural analgesia to stimulate maternal fever is likely a real phenomenon and not purely an artifact of higher-risk patients selecting epidural analgesia more frequently. Because of the growing evidence that maternal inflammation and infection, manifesting as fever, can be detrimental to the fetal brain, anesthesiologists cannot dismiss this unique physiologic effect as a mere curiosity. Further study to elucidate the link between epidural analgesia, pregnancy and labor, and fever is crucial to developing effective and safe strategies to minimize this link. In addition, attention must be paid to the indirect effects of maternal fever on the clinical decision-making of obstetricians and neonatologists to minimize unnecessary maternal and fetal interventions. In the meantime, if maternal pyrexia occurs, good clinical practice dictates that efforts be made to lower maternal temperature and identify and treat a presumed maternal infection.

NEURAXIAL ANESTHESIA IN THE FEBRILE OR INFECTED PATIENT

Clinicians have long suspected an association between the performance of dural puncture during a period of bacteremia and the subsequent development of meningitis. Some clinicians have feared that diagnostic lumbar puncture may cause meningitis rather than aid in its diagnosis. They reasoned that lumbar puncture may disrupt the rich venous plexus surrounding the spinal cord and allow the direct introduction of infected blood into the CNS by the spinal needle. Alternatively, others have speculated that disruption of the dural barrier may permit hematogenous spread of infection into the CNS without direct vessel trauma. Similar concerns apply to the performance of neuraxial anesthesia and the development of spinal-epidural abscess (see Chapter 32). Administration of continuous epidural analgesia often results in blood vessel trauma, and it includes the introduction of a foreign body. Theoretically, this technique could produce a nidus for subsequent infection.

Laboratory Studies

Carp and Bailey[185] performed a study to assess the risk for meningitis after the performance of dural puncture in bacteremic rodents. In this study, rats were made bacteremic by producing a flank abscess using *E. coli* bacteria. The bacteremia was similar in magnitude to that which occurs during the early phase of sepsis in humans. Cisternal dural puncture was performed after the onset of bacteremia. After 24 hours, the cisterna magna was drained surgically, and the cerebrospinal fluid (CSF) was cultured for evidence of meningitis. Of the 40 animals that underwent dural puncture during *E. coli* bacteremia, 12 developed meningitis (Table 37-2). None of the 40 bacteremic animals *not* subjected to dural puncture developed meningitis. Furthermore, dural puncture did not result in infection in the 30 animals without bacteremia. Importantly, *none* of the 30 bacteremic animals given a dose of gentamicin 15 minutes before dural puncture developed meningitis.

TABLE 37-2 The Association between Bacteremia and the Recovery of *Escherichia coli* from Cerebrospinal Fluid after Dural Puncture in Rats

n	Bacteremia (CFU/mL)*	Gentamicin†	Dural Puncture	CSF *E. coli*‡
40	40 ± 22 (5-100)	No	Yes	12/40§
40	48 ± 25‖ (2-100)	No	No	0/40
30	0 (0)	No	Yes	0/30
30	49 ± 35 (5-110)	Yes	Yes	0/30

*Data expressed as mean ± SD (range in parentheses).
†Gentamicin administered before dural puncture.
‡Data expressed as the number of animals in which *E. coli* cultured from spinal fluid per total number of animals in that group.
§$P < .05$ compared with other groups.
‖Not significantly different from that in the bacteremic groups undergoing cisternal puncture.
CFU, colony-forming unit(s); *CSF,* cerebrospinal fluid; *n,* number of rats in each group.
Modified from Carp H, Bailey S. The association between meningitis and dural puncture in bacteremic rats. Anesthesiology 1992; 76:739-42.

This study is consistent with earlier laboratory studies that observed the development of meningitis after the performance of dural puncture in bacteremic laboratory animals.[186,187] Although animal models of disease permit careful control of experimental conditions, these studies do not duplicate clinical conditions. Thus, there are limitations in the application of the rat study[185] to clinical practice. First, the level of bacteremia produced in the rats exceeded the transient, low-grade bacteremia that often occurs clinically. Also, these animals most likely had hemodynamic and metabolic changes characteristic of early sepsis. Second, although *E. coli* is a common cause of bacteremia in surgical and obstetric patients, it is an uncommon cause of meningitis. Third, the relative size of the dural tear produced by the 26-gauge needle used in this study is greater in rats than humans. Fourth, the cisternal site of dural puncture is not used clinically. Fifth, spinal and epidural anesthesia involves the injection of local anesthetics, and these drugs appear to be bacteriostatic.[188] Finally, the investigators knew the identity of the

organism (*E. coli*) and also knew that it was susceptible to gentamicin.

In summary, this study suggests that high-grade bacteremia may increase the risk for meningitis after dural puncture. However, antibiotic therapy before dural puncture appears to reduce if not eliminate this risk.

Clinical Studies

At least six retrospective clinical studies have evaluated *diagnostic lumbar puncture* and the risk for meningitis.[189-194] (These studies did not evaluate the risk of neuraxial anesthesia or analgesia.) These reports provided conflicting conclusions regarding the risk for meningitis after the performance of dural puncture in bacteremic patients. Two studies suggested an association between dural puncture and meningitis.[189,192] However, both studies had serious methodologic flaws. One study was performed during an epidemic of meningitis.[189] Although the authors observed a high rate of meningitis after lumbar puncture, they did not evaluate a comparable control group who did not undergo lumbar puncture. Teele et al.[192] reported an association between lumbar puncture and meningitis only in bacteremic children younger than 1 year of age. However, they acknowledged the possibility that clinical judgment might have prompted their pediatricians to perform diagnostic lumbar puncture in children with incipient meningitis before the CSF provided diagnostic evidence of infection.

The remaining four studies clearly did not support an association between dural puncture and meningitis.[190,191,193,194] Shapiro et al.[194] concluded:

> *The development of bacterial meningitis in children with occult bacteremia is strongly associated with the species of bacteria that causes the infection, but not with a lumbar puncture.…Children with high-density bacteremia may appear to be more severely ill than children who have bacteremia with lower concentrations of bacteria, and therefore may be more likely to undergo a lumbar puncture.*

In an editorial, Chestnut[195] stated, "Physicians often perform diagnostic lumbar puncture in patients with fever and/or bacteremia of unknown origin. If dural puncture during bacteremia results in meningitis, one would expect that unequivocal clinical data should exist." However, no epidemiologic study has clearly established a causal relationship between the performance of dural puncture during bacteremia and the subsequent development of meningitis or epidural abscess. Part of the uncertainty regarding the risk of dural puncture results from awareness that processes other than meningeal integrity may help protect against the occurrence of CNS infection. For example, as many as 35% of epidural catheters used postoperatively are colonized by bacteria,[196] but epidural abscess is a *very rare* complication. Some anesthesiologists have cited anecdotal reports of meningitis after spinal anesthesia during presumed, but not documented, bacteremia as evidence that dural puncture may cause meningitis.[197-200] In one of these reports, the physicians used reusable equipment and the source of infection was traced to inadequately sterilized supplies.[197] The use of sterile, disposable equipment and strict attention to aseptic technique have largely eliminated these factors as a source of infection.

Some evidence points to external contamination as the source of meningitis after spinal anesthesia (see Chapter 32).[201-204] Rubin[203] reported six cases of meningitis after spinal anesthesia over a 5-year period; all procedures were performed by the same anesthesiologist and the infections were all caused by the same organism. Videira et al.[205] reported three cases of meningitis after 38,128 spinal anesthetics (1 : 12,709). In two cases, streptococci presumed to be skin or nasopharyngeal flora were cultured. The authors concluded that lapses in sterile technique may have been responsible for the meningitis. Poor attention to asepsis was also apparently responsible for three cases of meningitis reported in a 3-year period in a single hospital.[206] In one case, the offending organism was cultured from the nose of the anesthesiologist performing the procedure. A 2012 outbreak of fungal meningitis in patients receiving otherwise uncomplicated epidural steroid injections was traced to contaminated methylprednisolone.[207]

Several reports have described the occurrence of meningitis after CSE analgesia in obstetric patients.[208-210] None of these patients was febrile during the CSE procedure. Furthermore, in the cases with positive CSF cultures, the authors concluded that contamination by skin flora was the most likely mechanism of infection. In general, evidence does not support a greater risk for meningitis with the CSE technique than with other neuraxial procedures, but rather a reporting bias involving complications of a relatively new technique.[211]

Large epidemiologic studies have found a very low incidence of CNS infection after the administration of neuraxial anesthesia. Dripps and Vandam[212] prospectively studied 8460 patients who received 10,098 spinal anesthetics between 1948 and 1951. Similarly, Phillips et al.[213] reported the administration of spinal anesthesia to 10,440 patients between 1964 and 1966. A large number of the patients in both studies underwent obstetric or urologic procedures. Undoubtedly some patients had bacteremia during or after the performance of spinal anesthesia. However, neither study reported a single case of CNS infection.[212,213]

Some evidence supports a lower frequency of infectious complications in obstetric patients than in general surgical patients. A 10-year review in Sweden of 1,260,000 spinal anesthetics and 450,000 epidural procedures (including 200,000 labor analgesia procedures) found 29 cases of meningitis and 13 epidural abscesses. Among the obstetric patients, there were no episodes of meningitis and one abscess.[214] Similarly, four reviews that included a total of more than 500,000 obstetric patients who received epidural anesthesia reported no cases of meningitis and two cases of epidural infection.[215-218] A 2009 national audit conducted in the United Kingdom gathered data on all central neuraxial procedures over a 1-year period (707,425 total cases and 320,425 obstetric cases).[219] Three cases of meningitis and 15 epidural abscesses were reported, but no meningitis and only one abscess was observed in the obstetric population.

Undoubtedly some parturients are bacteremic during the administration of epidural or spinal anesthesia, given the frequency with which parturients develop fever and infection during labor. For example, Blanco et al.[50] found a 1% incidence of bacteremia in a random sample of patients on the labor ward. Other studies have noted an incidence of bacteremia ranging from 2.3% to 12% in parturients with chorioamnionitis.[47,49,51] Unfortunately, there are no good predictive factors for identifying the subgroup of febrile patients with chorioamnionitis who are bacteremic at the time of anesthesia. The severity of fever does not reliably predict the likelihood of bacteremia in these patients.[220] For example, Blanco et al.[50] reported that 86 (49%) of 176 patients with documented bacteremia had a temperature below 38.8° C. Furthermore, Bader et al.[220] reported no significant difference in the mean temperatures of bacteremic and nonbacteremic patients with chorioamnionitis. Similarly, in a study of 146 women with chorioamnionitis, Goodman et al.[51] found no differences in temperature, leukocytosis, or maternal symptoms between patients with positive and negative blood cultures.

Bader et al.[220] retrospectively observed no cases of CNS infection after the administration of epidural or spinal anesthesia for labor and/or cesarean delivery in 279 patients with chorioamnionitis. Only 43 of these 279 women received antibiotic therapy before the administration of neuraxial anesthesia. At least three women had positive blood cultures consistent with bacteremia, and none of these three women received antibiotics before the administration of anesthesia. Similarly, Goodman et al.[51] found no cases of meningitis or epidural abscess among 531 patients with chorioamnionitis (proven by culture or pathologic examination) who received epidural (n = 517) or spinal (n = 14) anesthesia. Eleven of 45 patients with fever before initiation of the neuraxial procedure, and 174 of 229 patients with preexisting leukocytosis, received no antibiotics before instrumentation of the epidural or subarachnoid space.

Together, these clinical studies suggest that meningitis and epidural abscess are rare complications of epidural or spinal anesthesia. Furthermore, bacteremia itself does not appear to increase the risk for CNS infection after the administration of neuraxial anesthesia. However, published studies of neuraxial anesthesia in patients with chorioamnionitis were small and retrospective. Given the infrequent occurrence of CNS infection among noninfected patients undergoing neuraxial anesthesia, none of these studies was sufficiently large to exclude the possibility that chorioamnionitis increases the risk for meningitis or epidural abscess. Moreover, the retrospective study design introduces the possibility of selection bias; anesthesia providers may have avoided neuraxial anesthesia in the sickest patients with chorioamnionitis.

Recommendations

In our judgment, the anesthesiologist may safely administer spinal or epidural anesthesia to healthy patients at risk for bacteremia. The anesthesiologist need not avoid administration of neuraxial anesthesia in patients at risk for transient, low-grade bacteremia after the administration of anesthesia. Moreover, appropriate antibiotic therapy may lessen the risk for meningitis or epidural abscess in patients with established infection. In our practice, we administer spinal or epidural anesthesia to patients with evidence of systemic infection, provided that appropriate antibiotic therapy has begun. Thus, it often is appropriate for the anesthesia provider to request the initiation of antibiotic therapy before administration of analgesia/anesthesia. Finally, although the choice of anesthesia must be individualized, it seems prudent to avoid spinal or epidural anesthesia in untreated patients with overt clinical signs of sepsis.

Chestnut reviewed this subject and concluded[195]:

> *We do not give regional [neuraxial] anesthesia in the absence of other relevant information. Rather, we provide care for febrile patients who require anesthesia for labor, delivery, or emergency surgery. When one considers the risks of infection with regional anesthesia, one should ask: What are the alternatives? What are the consequences of withholding regional anesthesia in a febrile patient? For example, what is the greater risk in a febrile parturient: meningitis or epidural abscess after spinal or epidural anesthesia, or failed intubation and aspiration during general anesthesia?*

Finally, both physicians and patients should recognize that most cases of meningitis and epidural abscess occur spontaneously. Eng and Seligman[191] concluded, "Even if an appropriate temporal sequence…is documented…one cannot differentiate spontaneous meningitis from lumbar puncture–induced meningitis in the individual patient."

GENITAL HERPES INFECTION

Herpes simplex virus type 2 (HSV-2) causes locally recurring disease that is characterized by asymptomatic periods interrupted by episodes of viral reactivation from sites in the sensory ganglia.[221] Genital herpes infection typically presents as painful vesicular or papular lesions on the skin or mucous membranes of the genital tract, including the labia, vulva, perineum, cervix, and urethra.[222] Primary maternal HSV-2 infection is associated with transient viremia,[222] and up to 2% of pregnant women will be primarily infected during gestation.[221] Epidemiologic evidence suggests that HSV-1, formerly associated only with perioral lesions (herpes labialis), is now the predominant cause of new genital herpes infections in some populations.[223] Patients with primary infection may have systemic symptoms, including fever, headache, and lymphadenopathy, although asymptomatic primary infection is common. Hepatitis, aseptic meningitis, encephalitis, and cauda equina syndrome are uncommon complications of primary genital herpes infection. During recurrent (i.e., secondary) infection, maternal antibodies prevent the recurrence of viremia. Thus systemic symptoms are less severe—or do not occur at all—during episodes of recurrent infection. However, recurrent infection may result in severe symptoms localized to the site of the lesions on the external genitalia. Prodromal symptoms, including vulvar pain or burning, often

precede development of recurrent lesions. Unfortunately, asymptomatic shedding of the virus also may occur in the genital tract.[221,222]

Interaction with Pregnancy

During the first 20 weeks of pregnancy, primary genital herpes infection may be associated with an increased risk for pregnancy loss,[224] although contemporary cohort studies have disputed the risk for fetal death.[225] However, the major obstetric concern is the potential for transmission of the virus to the infant at the time of birth. The infant may become infected in one of two ways.[222] First, infection can occur as the fetus comes in direct contact with the virus during vaginal delivery. Second, intrauterine infection can occur by ascent of the organism after rupture of membranes. Neonatal HSV infection is a life-threatening infection with the potential for permanent CNS sequelae.[221,222,224,226] The severity of the neonatal infection may be reduced by the early initiation of antiviral therapy. Meta-analysis of seven randomized trials of antepartum antiviral therapy with acyclovir or valacyclovir demonstrated a reduction in the presence of active genital lesions at delivery (RR, 0.28) and requirement for cesarean delivery (RR, 0.30).[227] However, these trials could not demonstrate a reduction in neonatal herpes infection (there were no cases in any trial), and failure of suppressive therapy to prevent such transmission has been reported.[226]

Retrospective studies suggest that the risk for neonatal HSV infection associated with a primary maternal infection is much greater than that associated with recurrent maternal infection or asymptomatic shedding of the virus.[224,228-230] The risk for transmission in the setting of active recurrent herpes has been estimated at 3% and in infected women without genital lesions at delivery at 2 per 10,000.[221] Most likely there is a greater risk that the infant will be exposed to the virus during episodes of primary maternal infection; in recurrent herpes there is evidence that passive transfer of antibodies to HSV from the mother to the fetus is protective.

Obstetric Management

A large epidemiologic study of 58,362 women provided direct evidence that cesarean delivery dramatically reduces the overall risk for HSV transmission to the neonate when HSV cultures of the cervix and external genitalia taken at the time of labor were positive (OR, 0.14).[228] Other risk factors included maternal HSV seronegativity, positive cervical culture, use of invasive obstetric monitoring, and HSV-1 (compared with HSV-2) infection.[228]

The ACOG has reviewed the obstetric management of parturients with HSV infections and has concluded the following[221]:

> *Cesarean delivery is indicated in women with active genital lesions or prodromal symptoms, such as vulvar pain or burning at delivery, because these symptoms may indicate an impending outbreak. The incidence of neonatal disease is low when there is recurrent maternal disease, but cesarean delivery is recommended because of the potentially serious nature of the disease.…In patients with active HSV infection and ruptured membranes at or near term, a cesarean delivery should be performed as soon as the necessary personnel and equipment can be readied. There is no evidence that there is a duration of rupture of membranes beyond which the fetus does not benefit from cesarean delivery.…In pregnancies remote from term, especially in women with recurrent disease, there is increasing support for continuing the pregnancy to gain benefit from time and use of corticosteroids. There is no consensus on the gestational age at which the risks of prematurity outweigh the risks of HSV.*

Of interest, the mothers of most infants infected with HSV have no history of HSV infection and no obvious lesions at the time of delivery.[221,230] Previously, it was thought that antenatal viral cultures could predict asymptomatic viral shedding at the time of delivery and reduce the incidence of neonatal infection. Unfortunately, there is little correlation between antepartum HSV culture results and viral shedding at the time of delivery, even in women with a history of previous HSV infection.[230] Thus, the ACOG concluded that there was no evidence for cost-effectiveness of various antenatal screening protocols.[221]

Anesthetic Management

There are at least five published retrospective studies of the use of neuraxial anesthesia in patients with genital HSV infection. These studies reported no serious neurologic sequelae related to the use of neuraxial anesthesia.[231-235] However, most of the patients in these studies had recurrent (secondary) infection. Two studies[232,233] were limited to patients with recurrent infection, and a third report[231] did not indicate whether the patients had primary or recurrent infection. Bader et al.[234] reported outcomes for 169 women with genital herpes infection who underwent cesarean delivery. Five of the 169 women in this study had primary infections, and three of these women received spinal anesthesia. Of the three women, one had transient, postoperative weakness of the left leg. The authors[234] stated, "None of the cases of primary infection had associated systemic symptoms; it is therefore possible that some of these cases were actually misdiagnosed recurrent infections. The safety of regional anesthesia in patients with primary HSV infection remains unclear."

Viremia may accompany primary episodes of genital herpes infection. However, viremia rarely complicates recurrent episodes of genital herpes infection. It is unlikely that a spinal or epidural needle could introduce virus into the CNS in patients with recurrent genital herpes infection. Thus, a consensus exists that it is safe to administer spinal or epidural anesthesia to women with recurrent genital herpes infection and no systemic symptoms. There are insufficient data to allow a definitive recommendation regarding the safety of neuraxial anesthesia in patients with primary infection who may be viremic. If the anesthesia provider is confronted with a patient with primary infection, the theoretical risk for

CNS infection should be weighed against the risks of alternative methods of analgesia and anesthesia.

Finally, several studies have suggested that spinal or epidural administration of morphine, commonly administered for postcesarean delivery analgesia, increases the incidence of **recurrence of oral HSV infection**. This phenomenon was confirmed in randomized prospective trials for both epidural[236] and intrathecal[237] morphine. The cause is unknown, but some investigators have speculated that pruritus and scratching play a role in reactivation of oral lesions. Boyle[238] concluded that facial pruritus is a marker of the migration of morphine to the trigeminal nucleus but not the cause of HSV recrudescence. He suggested that immunologic modulation by the opioid within this ganglion is the primary cause of the viral reactivation. Substantial evidence now supports this mechanism.[239] A case of HSV-1 meningitis after unintentional dural puncture and passage of an intrathecal catheter has been reported.[240] The patient underwent cesarean delivery with spinal bupivacaine, fentanyl, and morphine; the authors suggested reactivation of HSV-1 due to morphine and the presence of the intrathecal catheter may have contributed to the infection.[240] To our knowledge, there are no reports suggesting that epidural or intrathecal administration of opioids increases the risk for recurrent *genital* herpes infection or neonatal herpes infection.

KEY POINTS

- Fever may be produced by endogenous pyrogens released from immune effector cells in response to infection.
- Fetal temperature typically is slightly higher than maternal temperature.
- Modest maternal fever does not seem to adversely affect the fetus, but maternal infection and other inflammatory states may cause fetal neurologic injury.
- Pyelonephritis and chorioamnionitis are the antepartum infections most likely to result in maternal and perinatal morbidity and mortality. Septic shock is an uncommon but devastating complication of maternal infection that demands aggressive hemodynamic support, broad-spectrum antibiotic therapy, and, in some cases, surgical intervention.
- Epidural analgesia increases the risk for maternal fever during labor in a subset of women. The mechanism is unclear but most likely related to a noninfectious inflammatory process. It is unknown whether epidural analgesia–associated fever places the fetus at risk for neurologic injury; however, no study has directly linked maternal fever associated with epidural analgesia to adverse effects on the fetus or neonate. Epidural fever may prompt neonatologists to evaluate neonates for possible sepsis.
- The anesthesiologist may safely administer epidural or spinal analgesia or anesthesia to patients at risk for transient bacteremia.
- The anesthesiologist may safely administer epidural or spinal anesthesia to patients with established infection, provided there is no evidence of frank sepsis. However, it seems prudent to begin antibiotic therapy before the administration of anesthesia.
- Recurrent genital herpes infection does not contraindicate the administration of neuraxial anesthesia.
- Spinal and epidural morphine administration is associated with reactivation of oral herpes simplex virus.

CHAPTER 38

Antepartum and Postpartum Hemorrhage

Barbara M. Scavone, MD

CHAPTER OUTLINE

Obstetric hemorrhage is the most common cause of maternal mortality worldwide, accounting for 25% of maternal deaths.[1] The World Health Organization estimates that severe hemorrhage complicates 10.5% of live births globally and carries with it a case-fatality rate of 1%.[1] The rates of maternal death and death due to hemorrhage vary widely throughout various regions of the world (see Chapter 40).[1-3] In the United States, hemorrhage accounts for 12.5% of pregnancy-related deaths (1.8 pregnancy-related deaths due to hemorrhage per 100,000 live births).[4] Data from the United Kingdom indicate death from peripartum hemorrhage occurs in 0.39 per 100,000 maternities.[5] Hemorrhage is the most common cause for admission of an obstetric patient to an intensive care unit and is a risk factor for myocardial ischemia and infarction and stroke.[6-8] A 2010 investigation demonstrated that organ dysfunction complicates 16% of cases of major obstetric hemorrhage (defined as transfusion of 5 or more units of packed red blood cells [PRBCs]).[9]

Evidence indicates hemorrhage rates and severe morbidity due to hemorrhage are increasing in the United States and other high-resource countries, owing primarily to increases in postpartum, rather than antepartum, hemorrhage.[10-13] The explanation for this acceleration is not entirely clear but appears to be related to rising rates of postpartum uterine atony as well as increases in abnormal placentation coincident with the rise in cesarean delivery rates.[10,11,14,15]

The majority of hemorrhage-related adverse outcomes are considered preventable.[5,16,17] Common provider-related shortcomings include failure to recognize risk factors, failure to accurately estimate the extent of blood loss, and failure to initiate treatment in a timely fashion. It is essential that clinicians develop an appreciation for the rapidity with which obstetric patients can become unstable, and that anesthesiologists—often the only physicians on the labor and delivery unit with specific training in resuscitation and critical care—become involved early in the care of bleeding patients. Timely and effective communication among all obstetric caregivers is imperative.

MECHANISMS OF HEMOSTASIS

Uterine contraction, stimulated by endogenous oxytocic substances released after delivery, represents the primary mechanism for controlling blood loss at parturition. Uterine tetany creates shearing forces that cleave the placenta from the uterine wall through the layer of the uterine decidua (see Figure 4-3). In addition, uterine contraction constricts the spiral arteries and placental veins spanning the myometrium and supplying the placental bed.

After disruption of vascular integrity, mechanisms of coagulation include (1) platelet aggregation and plug formation, (2) local vasoconstriction, (3) clot polymerization, and (4) fibrous tissue fortification of the clot. Platelet activation and aggregation occur rapidly after endothelial damage. Activated platelets release adenosine diphosphate (ADP), serotonin, catecholamines, and other factors that promote local vasoconstriction and hemostasis. These factors also activate the coagulation cascade. The

end result of the cascade is conversion of fibrinogen to fibrin and stabilization of the blood clot (see Chapter 44).

Anesthesia providers, obstetricians, midwives, and labor nurses frequently underestimate blood loss at delivery.[18] Heavy bleeding is associated with larger errors in estimated blood loss, and this underestimation may lead to inadequate replacement of intravascular volume.[18] Tachycardia and hypotension are late signs of hypovolemia, particularly in healthy young patients (Table 38-1); therefore, constant vigilance is necessary to ensure accurate estimation of blood loss and adequate resuscitation. Fluid and transfusion therapy is best guided by continual reassessment of maternal vital signs, urine output, hemoglobin concentration, and acid-base balance.

ANTEPARTUM HEMORRHAGE

Antepartum vaginal bleeding may occur in as many as 25% of pregnant women; fortunately, only a fraction of these patients experience life-threatening hemorrhage.[19] The majority of cases occur during the first trimester. The causes of antepartum hemorrhage range from cervicitis to abnormalities in placentation, including placenta previa and placental abruption. The greatest threat of antepartum hemorrhage is not to the mother but to her fetus. Several decades ago, vaginal bleeding during the second and third trimesters was associated with perinatal mortality rates as high as 80%. More recent data suggest that antepartum bleeding secondary to placenta previa and placental abruption is responsible for perinatal mortality rates of 2.3% and 12%, respectively.[20-22]

Placenta Previa

Placenta previa is present when the placenta implants in advance of the fetal presenting part. Further classification can be made on the basis of the relationship between the placenta and the cervical os. A **total placenta previa** completely covers the cervical os. A **partial placenta previa** covers part but not all of the os. A **marginal placenta previa** lies within 2 cm of, but does not cover, the cervical os (Figure 38-1).

Epidemiology

The incidence of placenta previa is 4.0 per 1000 pregnancies.[23,24] The exact cause is unclear, but prior uterine trauma (e.g., scar from prior cesarean delivery) is a common element. The placenta may implant in the scarred area, which typically includes the lower uterine segment. Conditions associated with placenta previa

TABLE 38-1 **Advanced Trauma Life Support (ATLS) Classification of Shock**

	Class 1	Class 2	Class 3	Class 4
Blood loss (%)*	< 15	15-30	30-40	> 40
Heart rate (beats/min)	< 100	> 100	> 120	> 140
Systolic blood pressure (mm Hg)	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14-20	20-30	30-40	> 35
Mental state	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic

include multiparity, advanced maternal age, smoking history, male fetus, previous cesarean delivery or other uterine surgery, and previous placenta previa.[23] The presence of placenta previa increases the likelihood that the patient will require a peripartum hysterectomy.[25]

Diagnosis

Transvaginal ultrasonography has become the gold standard for diagnosis of placenta previa; the distance from the placental edge to the internal os is measured and predicts the likelihood of antepartum hemorrhage and need for cesarean delivery.[26,27] Advances in ultrasonography have made the **double setup examination** (i.e., vaginal examination with all personnel ready for immediate cesarean delivery) nearly obsolete in modern obstetric practice. Magnetic resonance imaging (MRI) is also useful for the diagnosis of placenta previa, but its use is not practical in most cases of antepartum hemorrhage.

The classic clinical sign of placenta previa is painless vaginal bleeding during the second or third trimester. The first episode of bleeding typically occurs preterm and is not related to any particular inciting event. The lack of abdominal pain and/or absence of abnormal uterine tone helps distinguish this event from placental abruption. The absence of these factors does not exclude abruption, however, and patients with placenta previa are at risk for coexisting placental abruption.[24]

Obstetric Management

Obstetric management is based on the severity of vaginal bleeding and the maturity and status of the fetus. Active labor, persistent bleeding, a mature fetus (≥ 36 weeks' gestational age), or nonreassuring fetal status should prompt delivery.[28] The fetus is at risk from two distinct pathophysiologic processes: (1) progressive or sudden placental separation that causes uteroplacental insufficiency and (2) preterm delivery and its sequelae. The first episode of bleeding characteristically stops spontaneously and rarely causes maternal shock or fetal compromise. Expectant management in the hospital has been shown to prolong pregnancy by an average of 4 weeks after the initial bleeding episode.[28] Maternal vital signs are assessed frequently, and the hemoglobin concentration is checked at regular intervals. Fetal evaluation involves frequent performance of a nonstress test or biophysical profile, ultrasonographic assessment of fetal growth, and fetal lung maturity studies as indicated. Hemorrhage may be prevented by limitations on physical activity and avoidance of vaginal examinations and coitus, although the evidence supporting these measures is limited.

Outpatient management has resulted in good outcome in carefully selected patients.[29] Outpatient management is reserved for stable patients without bleeding in the previous 48 hours who have both telephone access and the ability to be transported quickly to the hospital. Expectant management requires immediate access to a medical center with 24-hour obstetric and anesthesia coverage and a neonatal intensive care unit.[28]

In most cases of placenta previa diagnosed between 24 and 34 weeks' gestation, a corticosteroid (e.g., betamethasone) is administered to accelerate fetal lung maturity.[28] A significant number of patients with placenta previa have preterm labor, which may provoke bleeding. Obstetricians may administer tocolytic therapy to decrease preterm contractions, with the goal to stabilize antepartum bleeding. Ritodrine has been shown to prolong pregnancy in women with placenta previa, but no studies have confirmed any decrease in the frequency or severity of vaginal bleeding.[28,30] Obstetricians must balance the potential cardiovascular consequences of tocolytic therapy in the event of maternal hemorrhage against the consequences of preterm delivery. Tocolytic therapy is not recommended for patients with uncontrolled hemorrhage or those in whom placental abruption is suspected. Although expectant management reduces the risk for prematurity, it does not eliminate it, and prematurity remains the most common cause of neonatal mortality and morbidity, especially if bleeding begins before 20 weeks' gestation.[31]

Fetuses of women with placenta previa may be at risk for other complications, including asymmetric fetal growth restriction (also known as intrauterine growth restriction).[32] Several factors may account for the association between placenta previa and fetal growth restriction. First, the lower uterine segment may be less vascular than normal sites of placental implantation. Second, the placenta often is adherent to an area of fibrosis tissue. Third, patients with placenta previa have a higher incidence of first-trimester bleeding, which may promote a partial placental separation, reducing the surface area for placental exchange. Fourth, although the blood loss from placenta previa is almost entirely maternal, trauma to the placenta with vaginal examination or coitus may result in some fetal blood loss, which could retard fetal growth.[32] Some studies have reported a higher incidence of congenital anomalies in the fetuses of women with placenta previa.[20]

Anesthetic Management

All patients admitted with antepartum vaginal bleeding should be evaluated by an anesthesia provider on arrival. Special consideration should be given to the airway examination, intravascular volume assessment, and history of previous cesarean delivery or other procedures that create a uterine scar. Volume resuscitation should be initiated using a non–dextrose-containing balanced salt solution (e.g., lactated Ringer's, normal saline). Women with placenta previa may remain hospitalized for some time prior to delivery, and at least one intravenous catheter should be maintained if bleeding is recurrent or imminent delivery is anticipated. For women without recurrent bleeding, consideration may be given to either deferring venous access entirely or placing a peripherally-inserted central catheter (PICC) for drug administration so that other peripheral veins are preserved for large-bore intravenous catheter access in the event of hemorrhagic emergency. Hemoglobin concentration measurement may be indicated after a bleeding episode. A blood type and screen, and for women who are actively bleeding, a blood type and crossmatch, should be maintained. The American Association of Blood Banks (AABB) recommends repeating such tests every 3 days in pregnant women owing to the small but finite risk for developing a new alloantibody

during pregnancy.[33] This recommendation is written into the U.S. Code of Federal Regulations.[34] The use of lower-extremity sequential compression devices may decrease the risk for venous thromboembolism in patients on bed rest. Pharmacologic prophylaxis is not commonly used because of the risk for bleeding.

Double Setup Examination. The accuracy of ultrasonography for the identification of placenta previa has almost eliminated the need for double setup examination, but a few patients still require it (e.g., morbidly obese patients who cannot be adequately evaluated with ultrasonography). The examination is performed in the operating room. All members of the obstetric care team, including the anesthesia provider, obstetrician, and pediatrician, make full preparation for cesarean delivery. Full preparation consists of application of maternal monitors, insertion of two large-bore intravenous cannulas, administration of a nonparticulate antacid, and sterile preparation and draping of the abdomen. The obstetrician subsequently performs a careful vaginal examination. A cesarean delivery is performed if significant bleeding occurs or if the obstetrician confirms the presence of total placenta previa in a woman with a mature fetus.

Cesarean Delivery. Experts recommend that women with a placental edge-to-internal os distance greater than 1 cm be offered a trial of labor; the risk for antepartum hemorrhage and need for cesarean delivery during labor are low in this setting.[26] Parturients with total previa, placental edge-to-internal os distance less than 1 cm, and/or significant bleeding will require abdominal delivery, as will some patients with nonreassuring fetal status. The choice of anesthetic technique depends on the indication and urgency for delivery, the severity of maternal hypovolemia, and the obstetric history (e.g., prior cesarean delivery).

Surveys of obstetric anesthesiologists show that neuraxial anesthesia is preferred in patients with placenta previa without active bleeding or intravascular volume deficit.[35] Patients who have placenta previa—without active preoperative bleeding—remain at risk for increased intraoperative blood loss for at least three reasons. First, the obstetrician may injure an anteriorly located placenta during uterine incision. Second, after delivery, the lower uterine segment implantation site, lacking uterine muscle compared with the fundus, does not contract as well as the normal fundal implantation site. Third, a patient with placenta previa is at increased risk for placenta accreta, especially if there is a history of previous cesarean delivery (Table 38-2).[25] For these reasons, two large-bore intravenous cannulas should be placed before the start of either elective or emergency cesarean delivery. No consensus exists on the need for blood product availability in these patients, but it seems prudent to order at least a blood type and screen. If preoperative imaging indicates the possibility of a placenta accreta, preparation for massive blood loss should be undertaken (see later discussion).

A randomized controlled trial comparing epidural with general anesthesia for cesarean delivery in women with placenta previa in the absence of active bleeding demonstrated that epidural anesthesia was associated with (1) more stable blood pressure after delivery and (2) lower transfusion rates and transfusion volumes with similar hematocrit measurements the day after surgery.[36] Operative times, estimated blood loss, urine output, and neonatal Apgar scores were similar in the two groups.[36] Combined spinal-epidural anesthesia, or even single-shot spinal anesthesia, is considered acceptable for patients without active bleeding provided that there is both a low risk for placenta accreta and a low risk for difficult airway management should intraoperative conversion to general anesthesia become necessary.

Patients with placenta previa and active preoperative bleeding represent a significant challenge for the anesthesia care team. Frequently, such patients have just presented to the hospital and there is minimal time for evaluation. In these cases, patient evaluation, resuscitation, and preparation for operative delivery all proceed simultaneously. Because the placental site is the source of hemorrhage, the bleeding may continue unabated until the placenta is removed and the uterus contracts. Preoperative evaluation requires careful assessment of the parturient's airway and intravascular volume. Two large-bore intravenous catheters should be placed, and blood products should be ordered as necessary. Blood administration sets, fluid warmers, and equipment for invasive monitoring should be immediately available. Initially, non–dextrose-containing crystalloid or colloid is infused rapidly. In some cases, the patient requires transfusion before completion of the blood crossmatch, and type-specific blood or type O, Rh-negative blood must be administered.

Rapid-sequence induction of general anesthesia is the preferred technique for bleeding patients. The choice of intravenous induction agent depends on the degree of cardiovascular instability. In patients with severe hypovolemic shock, tracheal intubation may be accomplished without an induction agent, although this situation is rare. A low dose of propofol should be administered in women with ongoing hemorrhage; in the case of *severe* ongoing hemorrhage it may be best to avoid propofol. Ketamine and etomidate are useful alternative induction agents for hemodynamically unstable patients. Ketamine 0.5 to 1.0 mg/kg has an excellent record of safety and

efficacy in obstetric anesthesia practice. Emergence phenomena such as hallucinations and nightmares are uncommon when the dose does not exceed 1 mg/kg. Ketamine may cause myocardial depression, which may result in hypotension in patients with severe hypovolemia. Etomidate 0.3 mg/kg causes minimal cardiac depression and is safe for use in obstetric patients.[37] A low dose is appropriate in patients with severe hemorrhage. Disadvantages of etomidate include venous irritation, myoclonus, and possible adrenal suppression.[38]

The agent(s) chosen for maintenance of anesthesia depends on maternal cardiovascular stability. In patients with modest bleeding and no fetal compromise, 50% nitrous oxide in oxygen can be administered with a low concentration of a volatile halogenated agent before delivery to prevent maternal awareness. The concentration of nitrous oxide can be reduced or omitted in cases of severe maternal hemorrhage or fetal compromise. In these cases, scopolamine or a benzodiazepine such as midazolam may be administered to ensure amnesia.

Oxytocin should be administered by intravenous infusion immediately after delivery. The relatively amuscular lower uterine segment implantation site does not contract as efficiently as the uterine fundus. If bleeding continues, it may be best to discontinue the volatile halogenated agent after delivery and to substitute 70% nitrous oxide and an intravenous opioid or ketamine. These drugs, along with small doses of midazolam, can be administered without causing significant uterine relaxation or cardiovascular depression. A low-dose infusion of propofol and/or ketamine may be considered, with the caution that propofol causes decreased uterine contractility in a dose-dependent manner.[39,40] Some anesthesia providers contend that bispectral index (BIS) monitoring may be useful in lowering the risk for intraoperative awareness in cases in which the volatile anesthetic agent has been discontinued, although this issue is a matter of some dispute.

If the placenta does not separate easily, a placenta accreta may exist. In such cases, massive blood loss and the need for cesarean hysterectomy should be anticipated (see later discussion). The need for invasive hemodynamic monitoring varies among patients. An indwelling arterial catheter is useful for patients with hemodynamic instability or for those who require frequent determination of hematocrit and blood gas measurements. Coagulopathy rarely occurs with placenta previa.

Placental Abruption

Placental abruption is defined as complete or partial separation of the placenta from the decidua basalis before delivery of the fetus. Maternal hemorrhage may be revealed by vaginal bleeding or may be concealed behind the placenta. Fetal compromise occurs because of the loss of placental surface area for maternal-fetal exchange of oxygen and nutrients.[41]

Epidemiology

Placental abruption complicates 0.4% to 1.0% of pregnancies, and the incidence is increasing, particularly among African-American women in the United States.[21,42-44] The causes are not well understood, but several conditions are known risk factors for abruption (Box 38-1).[42,43] Patients hospitalized for both acute and chronic respiratory diseases are at risk for placental abruption for unclear reasons.[45]

BOX 38-1 Conditions Associated with Placental Abruption

Obstetric Conditions

- Advanced maternal age
- Multiparity
- Preeclampsia
- Premature rupture of membranes
- Chorioamnionitis

Maternal Comorbidities

- Hypertension
- Acute or chronic respiratory illness
- Substance abuse
- Maternal cocaine use
- Maternal or paternal tobacco use

Trauma

- Direct (i.e., blunt abdominal)
- Indirect (e.g., acceleration/deceleration injury)

Diagnosis

The classic presentation of abruption consists of vaginal bleeding, uterine tenderness, and increased uterine activity; however, not all of these symptoms are always present. In cases of concealed abruption, vaginal bleeding may be absent and gross underestimation of maternal hypovolemia can occur. Bleeding may be painless.[41] In some cases, abruption may manifest as idiopathic preterm labor. Patients may have a variety of nonreassuring fetal heart rate (FHR) patterns, including bradycardia, late or variable decelerations, and/or loss of variability.[41] The diagnosis of placental abruption is primarily clinical, but in a subset of cases, ultrasonography may help confirm it. Ultrasonography is highly specific for placental abruption (96%), but it is not very sensitive (24%).[46] It is also useful for determining placental location, which can exclude placenta previa as a cause of vaginal bleeding.[41] The ultrasonographic examination can ascertain whether retroplacental or subchorionic hematoma is present. Normal findings do not exclude the diagnosis of placental abruption.

Pathophysiology

Complications of placental abruption include hemorrhagic shock, coagulopathy, and fetal compromise or demise. One third of coagulopathies in pregnancy are attributable to abruption, and coagulopathy is associated with fetal demise.[47] Placental tissue displays tissue factor and other procoagulant substances on cell membranes, and it is surmised that when bleeding at the decidual-placental interface (i.e., abruption) occurs, these

thromboplastic substances are released into the central circulation, resulting in consumptive coagulopathy and disseminated intravascular coagulation (DIC).[48]

Although some cases of abruption occur acutely (e.g., in the setting of trauma), many abruptions complicate chronic, long-standing placental abnormalities. Investigators have noted strong associations between abruption, fetal growth restriction, and preeclampsia, and all three conditions share similar risk factors.[49] Naeye et al.[50] prospectively studied more than 53,000 deliveries and found that decidual necrosis at the placental margin and large placental infarcts were the most common abnormalities among patients who suffered placental abruption and fetal demise. Infants who died had 14% less placental weight, 8% less body weight, and 3% shorter body length than surviving control infants of the same gestational age. In addition, histologic evidence of shallow trophoblastic invasion of the spiral arteries supports the conclusion that "ischemic placental disease" may underlie chronic placental hypoxia, leading to preeclampsia, fetal growth restriction, and abruption.[49]

The major risks for the fetus are hypoxia and prematurity. Fetal oxygenation depends on adequate maternal oxygen-carrying capacity, uteroplacental blood flow, and transplacental exchange. Separation of all or part of the placenta reduces gas exchange surface area and can lead to fetal death. The risk for intrauterine fetal demise increases as the detachment area increases, particularly when the location of bleeding is retroplacental rather than subchorionic.[41,51,52] Inadequate transplacental oxygen exchange is exacerbated by maternal hypotension, which decreases uteroplacental blood flow. Ananth and Wilcox[21] reviewed outcomes for 7.5 million pregnancies in the United States; the perinatal mortality rate associated with placental abruption was 12%. The high mortality rate is due in large part to the fact that infants of mothers with placental abruption are five times more likely to be delivered preterm.[21]

Obstetric Management

If the diagnosis of abruption is suspected, the practitioner should insert a large-bore intravenous catheter and obtain blood for assessment of hematocrit, coagulation status, and type and crossmatch. When assessing volume status, the clinician must remain aware of the possibility of hemorrhage concealed behind the placenta. Placement of a urethral catheter to monitor urine output may help the physician assess the adequacy of renal perfusion. The definitive treatment is delivery of the infant and placenta, but the degree of maternal and fetal compromise and estimated gestational age determine the timing and route of delivery.[41] If the fetus is at or near term and both maternal and fetal status are reassuring, vaginal delivery may be appropriate. If the patient is preterm, the extent of abruption is minimal, and the mother and fetus show no signs of compromise, the patient may be hospitalized and the pregnancy allowed to continue to optimize fetal maturation. The obstetrician may administer a corticosteroid to promote fetal lung maturity. If the mother develops hemodynamic instability or coagulopathy, or fetal status becomes nonreassuring, urgent cesarean delivery may become necessary. Vaginal delivery is preferred for patients with intrauterine fetal demise.[41]

Anesthetic Management

The anesthesia provider should consider the severity of the abruption and the urgency of delivery in planning anesthetic management.

Labor and Vaginal Delivery. Neuraxial labor analgesia may be offered in the setting of abruption provided that hypovolemia has been treated and coagulation status is normal. The appropriateness of neuraxial analgesia with its accompanying sympathectomy in patients at risk for extension of abruption and further hemorrhage has been questioned; however, the risk that neuraxial analgesia will worsen hemorrhage-associated tachycardia and hypotension can be mitigated by appropriate intravascular volume replacement and use of vasopressors. Close monitoring is required for evidence of further bleeding and changes in intravascular volume status. A coagulopathic patient may present for vaginal delivery, particularly in the setting of fetal demise. In this case, intravenous patient-controlled opioid analgesia should be offered.

Cesarean Delivery. Similar anesthetic considerations pertain to the administration of neuraxial anesthesia for cesarean delivery. Spinal, combined-spinal epidural, or epidural anesthesia may be administered in stable patients in whom intravascular volume status is adequate and coagulation studies are normal. General anesthesia is preferred for most cases of urgent cesarean delivery accompanied by unstable maternal status, a nonreassuring FHR pattern, or both. Propofol may precipitate severe hypotension in patients with unrecognized hypovolemia; ketamine and etomidate may represent better options for the patient with unknown or decreased intravascular volume.

Aggressive volume resuscitation is critical. Either crystalloid or colloid may be used; the choice is less important than adequate restoration of intravascular volume. In cases of severe hemorrhage, insertion of an intra-arterial catheter may aid prompt recognition of hypotension and allow for frequent blood sampling and assessment of anemia and coagulation status. Patients with abruption are at risk for persistent hemorrhage after delivery from uterine atony or coagulopathy; after delivery, oxytocin should be infused promptly to prevent uterine atony. Persistent uterine atony requires the administration of other uterotonic drugs (see later discussion). Red blood cells (RBCs) and coagulation factors should be replaced as indicated by laboratory studies. Experts recommend aggressive monitoring and early replacement of coagulation factors, especially fibrinogen, to minimize the developing coagulopathy.[53]

Most parturients recover quickly and completely after delivery. A minority of postpartum patients, notably those who have prolonged hypotension or coagulopathy, and who need massive blood volume and blood product replacement, are best monitored in a multidisciplinary intensive care unit.

BOX 38-2 Conditions Associated with Uterine Rupture

Obstetric Conditions

- Prior uterine surgery
- Induction of labor
- High-dose oxytocin induction
- Prostaglandin induction
- Grand multiparity (> 5)
- Morbidly adherent placenta
- Congenital uterine anomaly (e.g., bicornuate uterus)

Maternal Comorbidities

- Connective tissue disorder (e.g., Ehlers-Danlos syndrome)

Trauma

Obstetric

- Forceps application/rotation
- Internal podalic version
- Excessive fundal pressure

Nonobstetric

- Blunt
- Penetrating

Uterine Rupture

Epidemiology

Rupture of the gravid uterus can be disastrous for both the mother and the fetus. Fortunately, it does not occur often. Previous uterine surgery (e.g., cesarean delivery or myomectomy) increases the risk, but the incidence of true uterine rupture after cesarean delivery is still low, occurring at a rate of less than 1%.[54,55] Uterine rupture is rare in the primigravid woman or the woman with an unscarred uterus, but it does occur.[55] Box 38-2 lists additional conditions that have been associated with uterine rupture.[55,56] Very rarely, uterine rupture occurs without explanation.[57]

Rupture of a previous uterine scar may occur in the absence of labor. In a review of records from a large multistate hospital system, nearly half of all true uterine ruptures occurred in the absence of a history of cesarean delivery, and 22% of ruptures occurred in the absence of labor.[58] Lydon-Rochelle et al.[59] undertook a population-based retrospective analysis of more than 20,000 women who had undergone one previous cesarean delivery. The risk for rupture among nonlaboring women was 1.6 per 1000. Among women in spontaneous labor the risk increased approximately threefold to 5.2 per 1000; among women undergoing induction of labor the risk increased nearly fivefold to 7.7 per 1000; and among women undergoing prostaglandin induction the risk increased almost 16-fold to 24.5 per 1000. Additional risk factors for uterine rupture during a trial of labor after cesarean (TOLAC) include post-term gestation (≥ 42 weeks), birth weight greater than 4000 g, maternal age older than 35 years, and maternal height greater than 164 cm.[54]

Because of variation in nomenclature and severity, accurate determination of maternal and fetal morbidity secondary to uterine rupture is difficult. The most common variety of uterine scar disruption is separation or dehiscence, some cases of which are asymptomatic. **Uterine scar dehiscence** is defined as a uterine wall defect that does not result in excessive hemorrhage or FHR abnormalities and does not require emergency cesarean delivery or postpartum laparotomy. In contrast, **uterine rupture**, less common than dehiscence, refers to a uterine wall defect with maternal hemorrhage and/or fetal compromise sufficient to require emergency cesarean delivery or postpartum laparotomy.

The rupture of a classical uterine incision scar (a vertical incision involving the muscular uterine fundus) is associated with greater morbidity and mortality than rupture of a low transverse uterine incision scar because the anterior uterine wall is highly vascular and may include the area of placental implantation. Lateral extension of the rupture can involve the major uterine vessels and is typically associated with massive bleeding. Maternal death secondary to uterine rupture is rare, although there were three deaths attributed to uterine rupture in the 2006 to 2008 triennial report from the United Kingdom.[5] In Sweden between 1983 and 2001, Kaczmarczyk et al.[54] estimated that the neonatal mortality rate associated with uterine rupture was approximately 5%.

Diagnosis

The variable presentation of uterine rupture may cause diagnostic difficulty. Abdominal pain and an abnormal FHR pattern are the two most common presenting signs of uterine rupture,[60] but neither is 100% sensitive. One retrospective study reported the occurrence of abdominal pain in 17% of patients; an FHR abnormality was the first sign of uterine rupture in 87% of patients (see Chapter 19).[61] Other presenting signs include vaginal bleeding, uterine hypertonia, cessation of labor, maternal hypotension, loss of the fetal station, decrease in cervical dilation, or a change in fetal presentation. Breakthrough pain during neuraxial labor analgesia may also indicate uterine rupture.[62]

Obstetric Management

Treatment options for uterine rupture include repair of the uterus, arterial ligation, and hysterectomy. Uterine repair is appropriate for most cases of separation of a prior low transverse uterine scar and for some cases of rupture of a classical incision. However, the risk for rupture in a future pregnancy remains. A disadvantage of arterial ligation is that it may not control the bleeding and may delay definitive treatment. Hysterectomy may be required for some cases of uterine rupture.[56]

Anesthetic Management

Patient evaluation and resuscitation are initiated while the patient is being prepared for emergency laparotomy. If rupture has occurred antepartum, fetal compromise is likely. General anesthesia is often necessary, except in some stable patients with preexisting epidural labor analgesia. Aggressive volume replacement is essential,

and transfusion may be necessary. Urine output should be monitored. Invasive hemodynamic monitoring may be appropriate if there is uncertainty about the intravascular volume status.

Vasa Previa

Vasa previa is defined as the velamentous insertion of the fetal vessels over the cervical os (i.e., the fetal vessels traverse the fetal membranes ahead of the fetal presenting part). Thus, the fetal vessels are not protected by the placenta or the umbilical cord. Rupture of the membranes is often accompanied by tearing of a fetal vessel, which may lead to exsanguination of the fetus.

Epidemiology

Vasa previa occurs rarely (1 in 2500 to 1 in 5000 deliveries).[28] Because it involves the loss of fetal blood, vasa previa is associated with a high fetal mortality rate (nearly 60% if vasa previa is unrecognized).[63] The blood volume of the fetus at term is approximately 80 to 100 mL/kg. Therefore, the amount of blood that can be lost without fetal death is small. In addition, the vulnerable fetal vessels may be compressed by the fetal presenting part, resulting in fetal hypoxia and death. Risk factors for vasa previa include the presence of placenta previa or low-lying placenta in the second trimester, placental accessory lobes, *in vitro* fertilization, and multiple gestation.[28]

Diagnosis

Ultrasonography can be used to visualize the velamentous insertion of the vessels, and transvaginal color Doppler imaging can confirm the diagnosis.[28,63] Vasa previa should be suspected whenever bleeding occurs with rupture of membranes, particularly if the rupture is accompanied by FHR decelerations or fetal bradycardia. Hemorrhage can also occur without rupture of membranes, making the diagnosis more difficult. Rarely, vasa previa can be diagnosed via digital cervical examination or amnioscopy. The diagnosis of vasa previa can be confirmed through examination of the shed blood for evidence of fetal hemoglobin (e.g., Kleihauer-Betke test); however, when bleeding occurs, the emergency nature of vasa previa usually precludes such diagnostic confirmation.

Obstetric Management

Prenatal diagnosis confers a neonatal survival benefit. Oyelese et al.[63] conducted a retrospective study of 155 pregnancies complicated by vasa previa. Neonatal mortality was 3% when the vasa previa was diagnosed antenatally and 56% when it was not. The authors recommended ultrasonographic examination with transvaginal color Doppler in patients at risk for vasa previa. The management of vasa previa is directed solely toward ensuring fetal survival. Some authors advocate hospitalization of the patient between 30 and 32 weeks' gestation to ensure prompt delivery if rupture of membranes should occur; consideration should be given to the administration of a corticosteroid to promote fetal lung maturity.[28] Timing of delivery reflects a balance between the risks of preterm delivery and the risk for vessel rupture if the pregnancy is allowed to continue. Robinson and Grobman[64] compared delivery timing strategies for women with vasa previa and calculated that the best fetal outcomes occurred with elective delivery between 34 and 35 weeks' gestation. They further determined that confirmation of fetal lung maturity via amniocentesis was not necessary.[64]

Ruptured vasa previa is a true obstetric emergency that requires immediate delivery of the fetus, almost always by the abdominal route. Neonatal resuscitation requires immediate attention to neonatal volume replacement with colloid, balanced salt solutions, and blood.

Anesthetic Management

The choice of anesthetic technique depends on the urgency of the cesarean delivery. In many cases, general anesthesia is necessary for prompt delivery.

POSTPARTUM HEMORRHAGE

Conflicting definitions of postpartum hemorrhage exist; however, the most commonly accepted definition is more than 500 mL blood loss after vaginal delivery or more than 1000 mL after cesarean delivery.[1,65] These values may have low clinical utility because they are only slightly higher than the average blood loss for each type of delivery. Postpartum hemorrhage can also be inferred clinically (albeit retrospectively) from a 10% decrease in hematocrit from admission to the postpartum period or the need to administer PRBCs owing to postpartum blood loss.

Postpartum hemorrhage is the most common cause of maternal mortality worldwide and an important contributor to maternal death in the United States.[1,2,4] The incidence of postpartum hemorrhage varies widely throughout different regions of the world[2]; in the United States the current rate of postpartum hemorrhage is approximately 3%.[10,11] Postpartum hemorrhage, severe postpartum hemorrhage, and the attendant morbidity and mortality from hemorrhage are increasing in incidence.[10,11] Between 1994 and 2006 the transfusion rate for postpartum hemorrhage more than doubled.[10] The explanation for this acceleration is not entirely clear but appears to be related to rising rates of postpartum uterine atony as well as increases in the incidence of abnormal placentation, both coincident with the rise in cesarean delivery rates.[10,11,14,15] Other factors may include the rising rates of obstetric interventions, such as induction and augmentation of labor,[66-68] and the increasing prevalence of obesity,[69-71] multiple gestation,[67,72] hypertensive diseases of pregnancy,[73] and advanced maternal age.[12,74] However, the rising prevalence of these risk factors does not entirely explain the upward trend in postpartum hemorrhage that has been observed.[10,11]

Primary postpartum hemorrhage occurs during the first 24 hours, and secondary postpartum hemorrhage occurs between 24 hours and 6 weeks after delivery.[75] Primary postpartum hemorrhage is more likely to result in maternal morbidity or mortality. Figure 38-2 provides

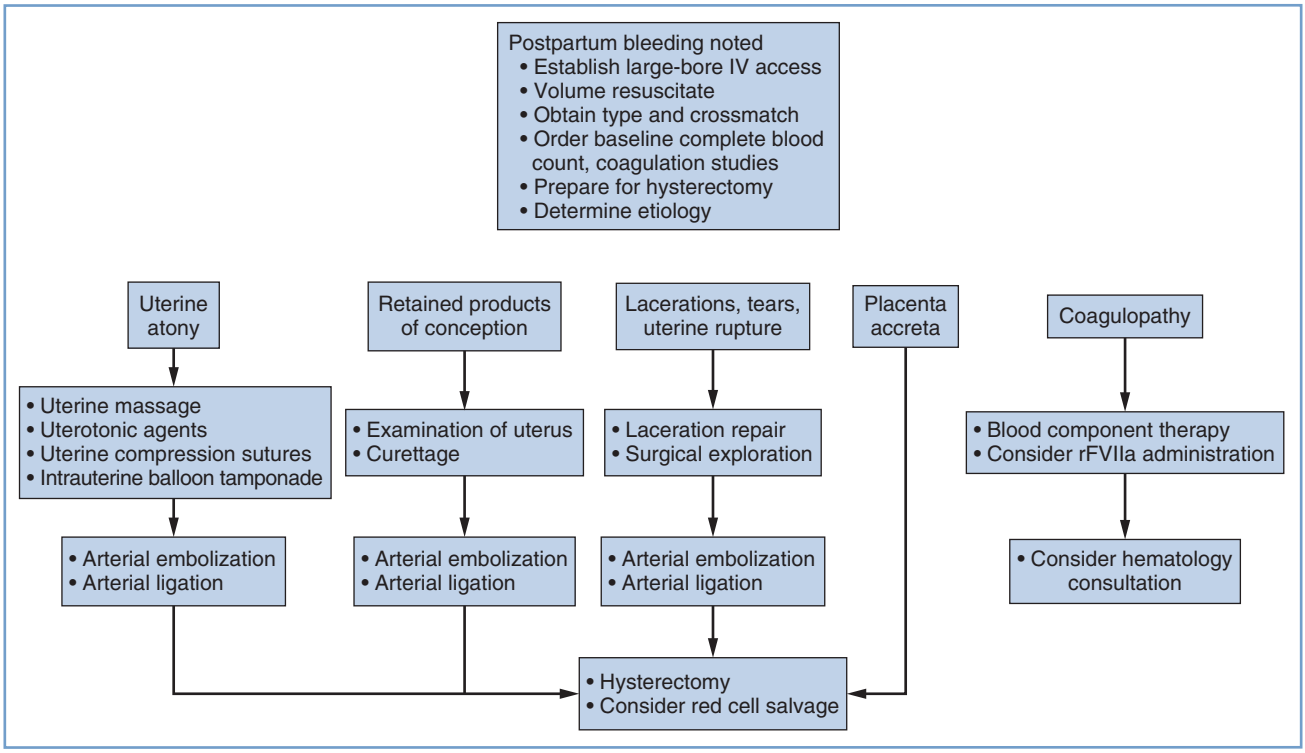

FIGURE 38-2 ■ Management options for postpartum hemorrhage. *IV,* intravenous.

an overview of the obstetric management of postpartum hemorrhage.

Uterine Atony

Epidemiology

Uterine atony is the most common cause of severe postpartum hemorrhage, accounting for approximately 80% of cases.[10,11] In addition to normal hemostatic mechanisms, postpartum hemostasis involves the release of endogenous uterotonic agents—primarily oxytocin and prostaglandins—that contract the uterus and constrict uterine vessels. Uterine atony represents a failure of this process. In addition, parturients with obstetric hemorrhage may have uterine arteries that are relatively unresponsive to vasoconstrictor substances.[76] Box 38-3 lists conditions associated with uterine atony.

Diagnosis

A soft, poorly contractile uterus and vaginal bleeding are the most common findings in patients with uterine atony. The absence of vaginal bleeding does not exclude this disorder because the atonic, engorged uterus may contain more than 1000 mL of blood. Unrecognized bleeding may manifest initially as tachycardia; worsening hypovolemia eventually leads to hypotension (see Table 38-1).

Obstetric and Anesthetic Management

Prophylaxis. The American College of Obstetricians and Gynecologists (ACOG) recommends prophylactic administration of uterotonic agents to prevent uterine atony.[75] **Active management of the third stage of labor**, including uterine massage and oxytocin administration, decreases blood loss and transfusion requirements compared with expectant management.[77,78]

BOX 38-3 Conditions Associated with Uterine Atony

Obstetric Management
- Cesarean delivery
- Induced labor
- Augmented labor

Obstetric Conditions
- Multiple gestation
- Macrosomia
- Polyhydramnios
- High parity
- Prolonged labor
- Precipitous labor
- Chorioamnionitis

Maternal Comorbidities
- Advanced maternal age
- Hypertensive disease
- Diabetes

Other
- Tocolytic drugs*
- High concentration of volatile halogenated anesthetic agent

*β-adrenergic agonists, magnesium sulfate.

Oxytocin is the first-line drug for prophylaxis and treatment of uterine atony after delivery of a third-trimester pregnancy. The number of high-affinity receptors for oxytocin increases greatly near term; alternative uterotonics are more effective in the first and second trimesters of pregnancy. Endogenous oxytocin is a 9-amino acid polypeptide produced in the posterior pituitary. The exogenous form of the drug (Pitocin, Syntocinon) is a synthetic preparation with a rapid onset and short half-life. Unfortunately, exogenous oxytocin can be associated with serious side effects, including tachycardia, hypotension, myocardial ischemia, and, rarely, death, especially in hypovolemic or other hemodynamically compromised women[79-83]; many of these adverse effects are directly related to the dose of oxytocin.[84,85] Preeclamptic women may be less able to tolerate high doses of oxytocin than healthy women.[86] In addition, high doses of oxytocin administered concomitantly with large volumes of intravenous fluids, especially those containing free water, can lead to hyponatremia, seizures, and coma because of oxytocin's structural similarity to vasopressin.[87]

The dose of oxytocin required to generate satisfactory uterine tone after delivery is lower than previously thought (see Chapter 26). In a study of nonlaboring women undergoing elective cesarean delivery, the ED_{90} of bolus dose oxytocin for satisfactory uterine tone within 3 minutes of delivery was 0.35 international units (IU)[88]; The ED_{90} was approximately 3 IU in laboring women undergoing cesarean delivery for labor arrest after labor augmentation with oxytocin.[89] The ED_{90} of oxytocin administered via infusion without a bolus dose in nonlaboring women was approximately 0.3 IU/min for 1 hour.[90] Munn et al.[91] randomized women undergoing a cesarean delivery during labor to receive a prophylactic infusion of oxytocin at 2.67 IU/min or 0.33 IU/min for 30 minutes after delivery; the higher dose was associated with less need for secondary uterotonics (19% versus 39%, respectively; $P < .001$); however, the high dose may be associated with clinically significant tachycardia and hypotension (see later discussion).

Oxytocin is rapidly metabolized by hepatic oxytocinases and cleared in the urine and bile, resulting in a half-life of less than 6 minutes. Consequently, a prolonged intravenous infusion may be more effective than bolus administration in preventing uterine atony. In an international randomized, controlled trial, Sheehan et al.[92] found that the addition of a 4-hour maintenance infusion of 0.17 IU/min (after an initial 5-IU bolus dose) decreased the need for secondary uterotonics compared with a 5-IU bolus dose alone.[92] King et al.[93] studied women at high risk for postcesarean uterine atony and demonstrated that administering a 5-IU bolus of oxytocin before a 1.3-IU/min infusion did not provide benefit compared with an infusion without a bolus. Administration of phenylephrine with oxytocin can mitigate the adverse hemodynamic consequences of oxytocin,[94] but phenylephrine may not be necessary as long as an oxytocin bolus dose is avoided and the infusion rate is maintained below 1 IU/min, the threshold at which hemodynamic consequences become apparent.[84]

Data demonstrating lower oxytocin dose requirements than previously assumed and awareness of the dangers of high-dose administration call into question the common practice of injecting 10 to 40 IU of oxytocin into a 1-liter crystalloid solution and infusing the solution at an unspecified rate, often "wide open" (i.e., gravity-dependent flow). The doses administered with this method may approach those achieved with bolus administration. At my institution, my colleagues and I administer prophylactic oxytocin at a rate of 0.3 IU/min (the ED_{90}) and increase the rate to 0.6 IU/min (twice the ED_{90}) if there is inadequate response. The maximum beneficial oxytocin infusion rate to treat persistent uterine atony is unknown.

Carbetocin is an alternative synthetic oxytocin-receptor agonist available in Canada, the United Kingdom, and other developed countries but not the United States. A meta-analysis comparing carbetocin with oxytocin suggests that carbetocin reduces the need for secondary uterotonics[95]; this difference may reflect the fact that equipotent dosing regimens have not been determined. Carbetocin has a longer duration of action than oxytocin; therefore, prolonged infusion is not necessary.

Treatment. Despite preventive measures, postpartum uterine atony may occur. A multidisciplinary response to atony is imperative. General resuscitative measures include (1) additional large-bore intravenous access, (2) intravenous administration of crystalloid and colloid solutions and vasopressors, (3) laboratory determination of hemoglobin concentration or hematocrit and assessment of coagulation status, and (4) blood bank preparation of blood products for transfusion. Bimanual compression and massage of the uterus and continued infusion of oxytocin may be helpful in restoring uterine tone. Unfortunately, few high-quality data exist to guide therapy if these management strategies fail; current practice relies on expert opinion and clinical judgment. In the case of inadequate response to oxytocin, additional uterotonic agents should be employed. Three classes of drugs are currently available for the treatment of uterine atony: oxytocin, ergot alkaloids, and prostaglandins (Table 38-3).

The **ergot alkaloids** comprise one class of drugs used for the treatment of uterine atony. The natural ergot alkaloids are produced by a fungus that commonly infests rye and other grains. Ergonovine and methylergonovine (a semisynthetic preparation) are the two ergot alkaloids currently available for use; their pharmacologic profiles are identical. Ergot alkaloids are unstable unless they are refrigerated.[96] Both drugs are dispensed in ampules containing 0.2 mg. They have a rapid onset when administered via the intramuscular route. Bolus intravenous administration is **not** recommended. The uterotonic effect usually lasts for 2 to 4 hours.

Both drugs rapidly produce tetanic uterine contractions and for this reason are restricted to postpartum use. The mechanism of action is poorly understood, but the uterotonic effect is most likely mediated by alpha-adrenergic receptor stimulation.[97] Parenteral administration of an ergot alkaloid is associated with a high incidence of nausea and vomiting.[98] Administration by any route may cause serious cardiovascular system derangements, including vasoconstriction, hypertension,[98] myocardial ischemia and infarction due to

TABLE 38-3 **Drug Therapy for Uterine Atony**

Agent	Dose and Route	Relative Contraindications	Side Effects	Notes
Oxytocin	0.3-0.6 IU/min IV infusion	None	Tachycardia Hypotension Myocardial ischemia Free water retention	Short duration of effect
Ergonovine or methylergonovine	0.2 mg IM	Hypertension Preeclampsia Coronary artery disease	Nausea and vomiting Arteriolar constriction Hypertension	Long duration of action May be repeated once after 1 h
15-Methylprostaglandin $F_{2\alpha}$	0.25 mg IM	Reactive airway disease Pulmonary hypertension Hypoxemia	Fever Chills Nausea and vomiting Diarrhea Bronchoconstriction	May be repeated every 15 min up to 2 mg
Misoprostol	600-1000 μg per rectum, sublingual, or buccal	None	Fever Chills Nausea and vomiting Diarrhea	Off-label use

IM, intramuscular; *IV,* intravenous.

coronary vasospasm,[99-101] cerebrovascular accidents,[102] seizures,[102] and even death.[99,103] Patients at greatest risk are those with preexisting hypertension; however, sudden and marked hypertension may also occur in previously normotensive patients. The combination of an ergot alkaloid followed by a vasopressor has been reported to lead to exaggerated hypertension.[104] Relative contraindications to the use of ergot alkaloids include hypertension, preeclampsia, peripheral vascular disease, and ischemic heart disease. Treatment of ergot-induced vasoconstriction and hypertension may require administration of a potent vasodilator such as nitroglycerin or sodium nitroprusside. Blood pressure and the electrocardiogram should be monitored closely after administration.

Prostaglandins of the E and F families have gained wide acceptance as escalation therapy when high-dose oxytocin is inadequate. Concentrations of endogenous prostaglandins increase during labor, but levels do not peak until the time of placental separation. It is hypothesized that uterine atony may represent a failure of prostaglandin concentrations to increase during the third stage of labor in some women.[105,106] Prostaglandins increase myometrial intracellular free calcium concentration,[107] ultimately leading to an increase in myosin light-chain kinase activity. Common side effects noted after administration of prostaglandins include fever, chills, diarrhea, nausea, and vomiting.[108,109]

A prostaglandin commonly used for the treatment of refractory uterine atony is **15-methyl prostaglandin $F_{2\alpha}$,** or carboprost; its administration may succeed in controlling hemorrhage when all other pharmacologic treatments have failed.[108,110] The recommended dose is 0.25 mg (250 μg) administered intramuscularly, which may be repeated every 15 to 30 minutes; the total dose should not exceed 2 mg (eight doses). Unfortunately, this valuable agent may precipitate bronchospasm, abnormal ventilation-perfusion ratio, increased intrapulmonary shunt fraction, and hypoxemia in susceptible patients.[111,112]

Misoprostol is a prostaglandin E_1 analogue that has been used successfully for cervical ripening and induction of labor. Misoprostol is thermostable in tropical conditions and does not require intravenous access for administration; prophylactic misoprostol administration reduced the incidence of postpartum hemorrhage compared with placebo.[113] These characteristics make it an attractive alternative to oxytocin and ergot alkaloids in low-resource areas, where the rate of maternal mortality from hemorrhage is high[1,2,113]; however, parenteral oxytocin is more effective for postpartum hemorrhage prophylaxis than misoprostol (relative risk [RR] of hemorrhage, 1.34; 95% confidence interval [CI], 1.16 to 1.55).[113]

Whether misoprostol can also decrease bleeding in patients with postpartum uterine atony unresponsive to conventional uterotonics is unclear.[114] A large international randomized controlled trial failed to identify any benefit of misoprostol 600 μg administered sublingually in addition to oxytocin for treatment of postpartum hemorrhage.[109] A second randomized controlled trial suggested that misoprostol may be less effective than the combined administration of ergometrine and oxytocin for the treatment of postpartum hemorrhage.[115] A dose of 600 to 1000 μg per rectum is commonly administered; administration via the oral, buccal, and sublingual routes has been described.[75,113,114] Like other prostaglandins, misoprostol may be associated with fever, chills, nausea, vomiting, and diarrhea.[109,113,114] Misoprostol may have a more favorable side effect profile than ergonovine or 15-methyl prostaglandin $F_{2\alpha}$ in patients with hypertension and/or reactive airway disease.

If hemorrhage and atony persist despite aggressive administration of multiple classes of uterotonic drugs, invasive techniques must be considered. Invasive techniques include intrauterine balloon tamponade, uterine compression sutures, embolization of the arteries supplying the uterus, surgical ligation of arteries, and cesarean hysterectomy (see later discussion).

Genital Trauma

The most common childbirth injuries are lacerations and hematomas of the perineum, vagina, and cervix. Most

injuries have minimal consequence, but some puerperal lacerations and hematomas are associated with significant hemorrhage, either immediate or delayed.[116] Prompt recognition and treatment can minimize morbidity and mortality.[116] Genital tract lacerations should be suspected in all patients who have vaginal bleeding despite a firm, contracted uterus. The cervix and vagina must be inspected carefully in these patients. Computed tomography (CT) and/or MRI may be useful in detecting the presence, location, and extent of suspected hematoma.[117] Pelvic hematomas may be divided into four types: vaginal, vulvar, vulvovaginal, and retroperitoneal.[116]

Vaginal hematomas result from soft tissue injury during delivery, and they may involve bleeding from the descending branch of the uterine artery.[116,118] The use of forceps or vacuum extraction increases the risk.[118] A study in Sweden of all cases of vaginal hematoma from 1987 to 2000 found a prevalence of approximately 1 in 1240 deliveries.[119] The investigators identified nulliparity, advanced maternal age, and neonatal birth weight exceeding 4000 g as risk factors for vaginal hematoma. Other risk factors may include prolonged second stage of labor, multiple gestation, preeclampsia, and vulvovaginal varicosities.[116]

Vulvar hematomas commonly involve branches of the pudendal artery.[116] Injury is usually suggested by extreme pain or clinical manifestations of hypovolemia secondary to blood loss.[116] Small vaginal or vulvar hematomas that are not enlarging may be observed and treated conservatively with ice packs and oral analgesics. Large hematomas should be incised and evacuated. Bleeding vessels should be ligated. Often no specific bleeding source can be identified. The successful use of arterial embolization to decrease bleeding and aid in surgical management of genital tract hematomas has recently been reported.[118] Volume resuscitation and transfusion may be necessary.[116]

Retroperitoneal hematomas are the least common and most dangerous hematomas associated with childbirth. A retroperitoneal hemorrhage occurs after laceration of one of the branches of the hypogastric artery. Injury typically occurs during cesarean delivery or rarely after rupture of a low transverse uterine scar during labor. These hematomas may be large and may extend as far as the kidneys.

The symptoms of concealed bleeding depend on the size of the hematoma and the rate at which it forms. In some instances, abrupt hypotension may be the first sign of bleeding. The diagnosis of a retroperitoneal hematoma must be considered whenever a postpartum patient has an unexpected decrease in hematocrit or unexplained tachycardia and hypotension. Other signs and symptoms are restlessness, lower abdominal pain, a tender mass above the inguinal ligament that displaces a firm uterus to the contralateral side, and vaginal bleeding with hypotension out of proportion to the external blood loss. Ileus, unilateral leg edema, urinary retention, and hematuria also may occur.[116] A high index of suspicion is needed; in obese women it may be especially difficult to examine the abdomen for signs of retroperitoneal hematoma.

Occasionally, a retroperitoneal hematoma may be self-limiting and need no surgical intervention. Life-threatening hematomas require exploratory laparotomy and ligation of the hypogastric vessels. Fliegner[120] reported that 38 of 39 patients with a broad ligament hematoma received a blood transfusion. The average amount administered was 4000 mL. Eight (21%) of the patients required a hysterectomy.

Anesthetic Management

Choice of anesthetic technique for the repair of genital lacerations and evacuation of pelvic hematomas depends on the affected area, surgical requirements, volume/hemodynamic status of the patient, and urgency of the procedure. Local infiltration and a small dose of intravenous opioid suffice for drainage of some vulvar hematomas; however, repair of extensive lacerations and drainage of vaginal hematomas require significant levels of analgesia or anesthesia. Pudendal nerve block may not be technically feasible because of anatomic distortion or severe pain from the hematoma. Low doses of ketamine (10-mg boluses, not exceeding a total dose of 0.5 mg/kg) may suffice to produce sedation and analgesia with minimal risk for altering airway reflexes. Spinal or epidural anesthesia may be necessary, although the clinician should exercise caution initiating (or extending) a neuraxial block in a hypovolemic patient. In some cases, general anesthesia with tracheal intubation may be necessary. Exploratory laparotomy for a retroperitoneal hematoma typically requires the administration of general anesthesia.

Retained Placenta

Retained placenta is defined as failure to deliver the placenta completely within 30 minutes after delivery of the infant and occurs in approximately 3% of vaginal deliveries.[121,122] Retained placenta is a leading cause of both primary and secondary postpartum hemorrhage. The risk for postpartum hemorrhage increases significantly if the interval between delivery of the infant and the placenta exceeds 30 minutes.[121] The severity of bleeding ranges from minimal to severe and can be life-threatening and require transfusion.[122] Risk factors for retained placenta include history of retained placenta, preterm delivery, oxytocin use during labor, preeclampsia, and nulliparity.[121,122]

Obstetric Management

Treatment of retained placenta during the early postpartum period often involves manual removal and inspection of the placenta. Curettage may be required. After removal of the placenta, uterine tone should be augmented with oxytocin and the patient should be observed for evidence of recurrent hemorrhage.

Anesthetic Management

Choice of anesthetic technique depends on the degree of hemorrhage. In some cases, the administration of small amounts of sedatives and analgesics is adequate to allow examination and manual placental extraction by a skilled obstetrician. Neuraxial anesthesia may be considered in patients who are not bleeding severely and who are

hemodynamically stable. This may be accomplished with either administration of additional local anesthetic through an existing labor epidural catheter or initiation of spinal anesthesia. General anesthesia sometimes becomes necessary, particularly in patients who are hemodynamically unstable.

In some cases, the obstetrician requires uterine relaxation to facilitate manual removal of the placenta. Historically, anesthesia providers have performed rapid-sequence induction of general anesthesia, followed by the administration of a high dose of volatile halogenated agent to relax the uterus. Equipotent doses of halothane, sevoflurane, and desflurane depress uterine contractility equally and in a dose-dependent manner. In a study of isolated human uterine muscle, an equi-anesthetic concentration of isoflurane was a less effective uterine relaxant than the other volatile agents.[123] Uterine contractility is decreased by 50% with administration of approximately 1.5 minimum alveolar concentration (MAC) of a volatile anesthetic agent.[123] The induction of general anesthesia and administration of a volatile halogenated agent results in rapid onset of uterine relaxation, and discontinuation of the volatile agent results in rapid offset when uterine relaxation is no longer necessary. However, induction of general anesthesia in a parturient entails risk for failed ventilation, failed tracheal intubation, and/or aspiration of gastric contents.

Alternatively, **nitroglycerin** may be administered for uterine relaxation. Nitroglycerin provides a rapid onset of reliable smooth muscle relaxation and a short plasma half-life (2 to 3 minutes).[124,125] Nitroglycerin has been administered for various obstetric emergencies without clinically significant side effects.[125] Peng et al.[126] described successful removal of retained placenta in 15 parturients after administration of intravenous nitroglycerin 500 μg. DeSimone et al.[127] used a substantially smaller dose of nitroglycerin (50 to 100 μg) with similar results; all patients were managed successfully without the need for induction of general anesthesia. Nitroglycerin may also be administered sublingually via spray or tablet. A double-blind, randomized, controlled study compared sublingual nitroglycerin with placebo for management of retained placenta[128]; the placenta was delivered successfully within 5 minutes in all 12 of the parturients who received nitroglycerin, compared with only 1 of the 12 who received placebo. Nitroglycerin most likely produces uterine smooth muscle relaxation by releasing nitric oxide; it may require the presence of placental tissue to be effective.[129]

Uterine Inversion

Epidemiology

Uterine inversion, or the turning inside-out of all or part of the uterus, is a rare but potentially disastrous event. It is associated with severe postpartum hemorrhage, and hemodynamic instability may be worsened by concurrent vagal reflex–mediated bradycardia. Inversions may be acute or chronic, but only acute peripartum inversions involve the obstetric anesthesia provider. The reported incidence of this disorder varies widely; recent reports suggest an incidence of approximately 1 in 2500 deliveries.[130]

Risk factors for uterine inversion include uterine atony, a short umbilical cord, uterine anomalies, and overly aggressive management of the third stage of labor, including maneuvers such as inappropriate fundal pressure or excessive umbilical cord traction.[130] Uterotonic therapy can convert a partial inversion to a complete inversion. An abnormally implanted placenta (i.e., placenta accreta) may be first recognized when uterine inversion occurs.

Diagnosis

Many cases of uterine inversion are obvious because of hemorrhage and a mass in the vagina, but others may not be readily apparent. Inversion should be suspected in all cases of postpartum hemorrhage. Ultrasonographic examination may show characteristic findings, such as an echolucent zone within an echogenic mass filling the uterine cavity on transverse view.[131] Historically, obstetricians have stated that the shock is out of proportion to the blood loss, but an underestimation of obstetric hemorrhage is more likely. An incomplete inversion not protruding through the introitus is more likely to result in missed or delayed diagnosis.[116]

Obstetric Management

Immediate replacement of the uterus, even before removal of the placenta, is the treatment goal, but it may be difficult to achieve. The appropriate technique for correcting an inversion has been described.[130] All uterotonic drugs should be discontinued immediately. The obstetrician should attempt to right the inversion by applying pressure through the vagina to the uterine fundus; ring forceps may be used on the cervix to apply countertraction. Early diagnosis and prompt correction may reduce the morbidity and mortality associated with uterine inversion.

Anesthetic Management

Often, uterine tone precludes replacement of the uterus, and uterine relaxation is necessary for successful uterine reduction.[130] The use of nitroglycerin to facilitate relaxation and replacement of the uterus has been reported.[132,133] Fairly large intravenous doses (200 to 250 μg) may be required, and the anesthesiologist typically will need to support the circulation with intravenous fluids and vasopressors. Administration of general anesthesia with a volatile halogenated agent may become necessary, not only for uterine relaxation but also to prepare for laparotomy should it become necessary to correct the inversion. Once the uterus has been replaced, a firm, well-contracted uterus is desired.[130] Oxytocin should be infused, and additional uterotonic drugs may be needed.

Placenta Accreta

Placenta accreta is defined as a placenta that in whole or in part invades the uterine wall and is inseparable from it.[134] Three types of placenta accreta occur (Figure 38-3).

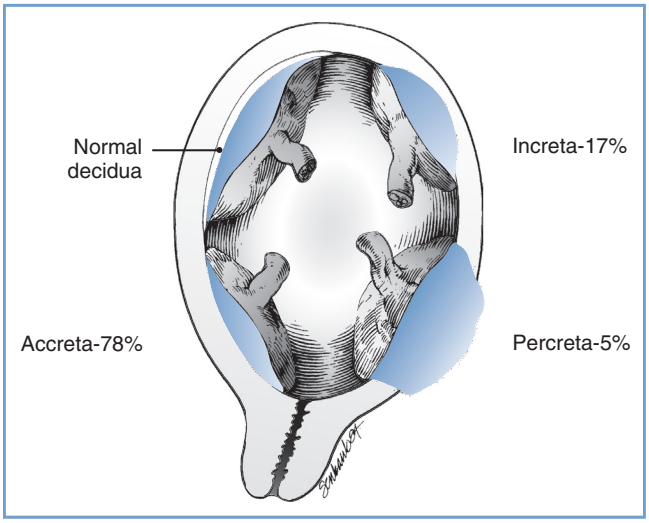

FIGURE 38-3 ■ Uteroplacental relationships found in abnormal placentation. (From Francois KE, Foley MR. Antepartum and postpartum hemorrhage. In Gabbe SG, Niebyl JR, Simpson JL, et al., editors. Obstetrics: Normal and Problem Pregnancies. 6th edition. Philadelphia, Elsevier Saunders, 2012:424.)

Placenta accreta vera is defined as adherence of the basal plate of the placenta directly to uterine myometrium without an intervening decidual layer. **Placenta increta** refers to a placenta in which chorionic villi invade the myometrium. **Placenta percreta** represents invasion through the myometrium into serosa and sometimes into adjacent organs, most often the bladder.[134]

Epidemiology

Evidence suggests that the incidence of placenta accreta is rising, primarily because of the increasing cesarean delivery rate. Between 1994 and 2007 the rate of peripartum hysterectomy for abnormal placentation increased by 20% in the United States, an increase entirely explained by adjustment for the rising prevalence of previous cesarean delivery among childbearing women.[15] The percentage of U.S. cesarean deliveries increased from 20.7% in 1997 to 32.9% in 2009, owing to increases in both primary and repeat cesarean deliveries and a decrease in the TOLAC rate.[135-137] Fortunately, the cesarean delivery rate remained stable between 2009 and 2012.[138]

Previous cesarean delivery or other uterine surgery increases the risk for both placenta previa and accreta. The combination of placenta previa with previous cesarean delivery synergistically increases the risk for coexisting placenta accreta, particularly if the placenta is anterior and overlies the uterine scar. In a prospective multicenter observational study, Silver et al.[25] determined the relationship between placenta accreta, placenta previa, and previous cesarean delivery. Placenta previa with no prior uterine surgery conferred a 3% risk for placenta accreta. In women with placenta previa and one previous cesarean delivery, the risk for placenta accreta was 11%. In patients with placenta previa and a history of two previous cesarean deliveries, the incidence of placenta accreta was increased to 40%. The incidence of placenta accreta was over 60% in women with placenta previa and a history of three or more previous cesarean deliveries (see Table 38-2). Another study noted a relationship between the extent of uterine wall invasion and the number of previous cesarean deliveries.[139]

Diagnosis

In some cases of placenta accreta the condition is first suspected at vaginal delivery, when the obstetrician notes difficulty in separating the placenta. The definitive diagnosis is then made at laparotomy. Antenatal diagnosis of placenta accreta facilitates effective planning. Antenatal diagnosis is associated with less maternal and neonatal morbidity, including decreased blood loss at delivery and transfusion of fewer units of blood products.[140] Ultrasonography is a useful screening tool in patients with placenta previa and/or previous cesarean delivery and is the primary imaging modality used for making the diagnosis of placenta accreta. However, among women at risk for placenta accreta, ultrasonography has imperfect sensitivity and specificity.[134] Some evidence suggests that MRI may help confirm the diagnosis in at-risk patients with inconclusive ultrasonographic examinations.[141]

Obstetric Management

The ACOG advises that providers working at small hospitals without adequate blood bank supplies consider transferring patients with placenta accreta to a tertiary care facility.[134] Patients treated at institutions with a 24-hour in-house obstetrician and anesthesiologist, immediate availability of a gynecologic oncologist, a fully stocked blood bank, and interventional radiology services suffer less morbidity than those treated at hospitals without these services.[142] Planned delivery with all of the necessary multidisciplinary collaborators present compared with emergency delivery is associated with less maternal morbidity, including fewer transfusions, complications, and intensive care unit admissions. Some cases of vaginal bleeding remote from term resolve spontaneously, and expectant management may prolong the duration of pregnancy, at least into the third trimester. However, the risk for severe antenatal bleeding increases as gestational length increases.[142] Timing of delivery therefore involves balancing this risk against the neonatal risks of preterm delivery. Institutions that manage women with suspected placenta accreta expectantly must have the capacity to mobilize the entire perioperative team at any time.

Most patients with known placenta accreta should undergo planned preterm cesarean delivery and hysterectomy with the placenta left *in situ* because attempts to remove the placenta are likely to initiate hemorrhage. Because the positive predictive value of ultrasonography may be low, the ACOG advises that it is reasonable to await spontaneous placental delivery in some cases, but manual removal of the placenta should be avoided.[134] Preoperative placement of ureteral stents may minimize urinary tract injury.[134] A midline vertical skin incision may provide optimal surgical exposure; it may be necessary to modify the uterine incision to avoid cutting through the placenta.

The preoperative insertion of **internal iliac artery balloon catheters** is controversial. Optimally, the

balloons are inflated after delivery as a means to provide a less bloody surgical field and decrease blood loss and transfusion requirements. Retrospective cohort studies have reported conflicting data regarding effects of balloon catheter placement on estimated blood loss, transfusion requirements, and duration of the surgical procedure.[143-146] The largest of these studies compared 59 patients who had placement of preoperative balloon catheters with 58 who did not and determined there was lower mean estimated blood loss, fewer cases with estimated blood loss greater than 2500 mL, and fewer massive transfusions in the balloon group.[146]

Multiple complications can arise from the placement of these devices, some of them involving serious disruptions of the vasculature and lower extremity ischemia.[144,146-148] Introduction of the arterial catheters (without inflation) can cause fetal bradycardia, necessitating emergency delivery.[149] If employed, therefore, internal iliac artery balloon catheters should be placed in the operating room to avoid dislodgement during transport and to allow for rapid delivery should fetal compromise occur. Authors of a recent review of the literature opined that current evidence, confined to case reports, case series, and small retrospective studies, is inadequate to guide clinical decision-making.[150] The Society of Maternal-Fetal Medicine (SMFM) recommends reserving the use of prophylactic intra-arterial balloon catheters for well-counseled women with a strong desire for fertility preservation, those who decline blood products, and those with unresectable placenta percreta.[151]

Two forms of conservative therapy for placenta accreta have been described. In selected patients with a partial placenta accreta, small focal areas of placental invasion may be managed by curettage and oversewing. Alternatively, it may be possible to leave the intact placenta *in situ*, close the uterus and abdomen, and await spontaneous placental involution.[152-154] However, conservatively managed patients often require additional therapies such as internal iliac artery balloon inflation, embolization, or methotrexate. Some patients treated in this way have subsequently had successful pregnancies[152]; however, complications have been reported, including secondary hemorrhage, subsequent need for hysterectomy, and sepsis.[152,154] The ACOG considers planned peripartum hysterectomy to be the management of choice for patients with placenta accreta and cautions the obstetrician to reserve uterine conservation strategies for hemodynamically stable patients who strongly desire future fertility.[134]

Anesthetic Management

Anesthetic management is similar to other cases of severe postpartum hemorrhage and peripartum hysterectomy (see later discussion). Preoperative suspicion for placental implantation abnormalities should alert the anesthesia provider to the potential for massive blood loss. One group of investigators reported that estimated blood loss exceeded 2000 mL in 66% of cases of placenta accreta, 5000 mL in 15%, 10,000 mL in 6.5%, and 20,000 mL in 3% of cases.[155] Initial blood loss may be minimal but can rapidly become torrential if the placental bed is disturbed or if the surgeons encounter unavoidable placental tissue during the course of the hysterectomy.

Invasive Treatment Options

Regardless of the cause of obstetric hemorrhage, first-line conservative measures may fail to control bleeding. In these cases, invasive procedures must be performed promptly to avoid severe morbidity and mortality. Second-line options include intrauterine balloon tamponade, uterine compression sutures, angiographic arterial embolization, and uterine artery and/or internal iliac artery ligation, performed in an attempt to avoid hysterectomy. Unfortunately, no randomized controlled trials assessing relative efficacy and safety of these options exist to guide management.[156,157]

Intrauterine balloon tamponade is a conservative method for controlling postpartum hemorrhage, especially when uterine atony or lower uterine segment bleeding is suspected.[75] A 2007 systematic review reported the technique is successful (no need for additional therapy) 84% of the time,[156] and a prospective evaluation reported a success rate of 81%.[158] A variety of devices have been used, including a balloon specifically designed for this purpose.[159] An intrauterine balloon can be deployed quickly, requires minimal analgesia for both insertion and removal, and preserves fertility. Failure is easily recognized and commonly attributed to prolapse though a partially open cervix; in such cases, the balloon may be replaced and secured by applying bilateral ring forceps to the cervix[160] or by placing a cervical cerclage.[161] Few complications have been reported, although concerns for infection exist.[156,157] A case report described uterine rupture after curettage and subsequent tamponade balloon placement.[162]

Uterine compression sutures (e.g., B-Lynch suture[163]) are most useful in cases of refractory uterine atony but have also been used in cases of retained placenta and accreta.[156,157] A systematic review—based mostly on case reports and case series and therefore subject to reporting bias—estimated a 92% success rate for this procedure,[156] but the success rate (avoidance of hysterectomy) in a prospective population-based trial was more modest (75%).[164] The suture may slip off of the uterine fundus and fail to provide compression.[157] Placement of compression sutures may preserve fertility; however, data are lacking on the long-term effects on fertility and pregnancy outcomes. Complications include infection, uterine necrosis, and suture erosion.[157]

Angiographic arterial embolization may be appropriate if moderate blood loss continues and if the patient is stable for transport to the interventional radiology suite. The uterine arteries, which are branches of the anterior trunk of the internal iliac arteries, provide the primary blood supply to the uterus. The ovarian and vaginal arteries also make a sizable contribution to uterine blood flow during pregnancy. During angiography the radiologist can identify the vessels responsible for bleeding and embolize these vessels effectively with gelatin sponge pledgets (Gelfoam). A small percentage of cases may require placement of a metallic coil in addition to gelatin sponges. The gelatin sponge is a temporary

occlusive agent, and flow through these vessels returns over time, preserving both the uterus and fertility.[165] Published success rates in emergently controlling postpartum hemorrhage with this approach vary between 70% and 100%.[156,157] Successful treatment of acute postpartum hemorrhage with this modality requires rapid access to an angiography facility and a skilled interventional radiologist. The patient must be observed and monitored carefully while undergoing the procedure. Ischemic complications of embolization therapy have been reported, but the risk is reduced with the use of selective techniques.[156,166,167]

Bilateral surgical ligation of the uterine arteries (O'Leary sutures) may be used to control bleeding at laparotomy. In the case of failure to control bleeding, the surgeon may proceed with a more complex procedure that involves ligation of the tubo-ovarian and ascending and descending uterine arteries. Internal iliac artery ligation may also be considered, although it is more difficult to perform.[157] Reported success rates are highly variable, and it appears that arterial ligation is being used less often than in the past.[75] The rich collateral circulation of the uterus at term most likely contributes to failure to control bleeding, as does the challenging nature of the procedure itself. Engorgement of pelvic viscera, variability in vascular anatomy, and the increased blood flow during pregnancy contribute to the risk of complications when this approach is used. Successful surgical ligation permits preservation of fertility. Ischemic complications and neuropathy have been reported.[156]

Peripartum Hysterectomy

Peripartum hysterectomy is the definitive treatment for postpartum hemorrhage unresponsive to medical and other invasive therapies. The two most common indications for this procedure are uterine atony and placenta accreta.[15] Between 1994 and 2007 the overall rate of peripartum hysterectomy increased by 15% in the United States, because of a 130% increase in hysterectomy for atony and a 23% increase in hysterectomy for placental implantation abnormalities.[15] The increase in hysterectomy for placental abnormalities is almost entirely explained by an increase in the cesarean delivery rate.[15] Parturients with a history of previous cesarean delivery are more than five times as likely to require a peripartum hysterectomy than those without this history, and risk for hysterectomy rises progressively with an increasing number of previous cesarean deliveries.[15,25] The incidence of peripartum hysterectomy due to uterine rupture has declined in the United States because the rate of TOLAC has declined.[15] Elective peripartum hysterectomy may also be undertaken for concurrent gynecologic abnormalities, especially malignancies.

Peripartum hysterectomy is a technically challenging operation; the uterus is enlarged, exposure may be difficult, the vessels are engorged, and the pregnant uterus receives a rich collateral blood supply. The presence of dense adhesions from previous surgeries can further complicate the surgery. A 2010 systematic review of emergency postpartum hysterectomy for hemorrhage revealed a perioperative morbidity rate of 56% and a mortality rate of 2.6%.[168] Compared with nonobstetric hysterectomy, patients undergoing obstetric hysterectomy are more likely to suffer postoperative hemorrhage and require blood transfusion, have intraoperative urinary tract injury, and experience perioperative complications such as wound infection, venous thromboembolism, and cardiovascular and other medical complications.[169] Mortality is more than 25 times higher in peripartum than nonperipartum hysterectomy.[169]

Transfusion is required in 44% or more of patients.[168] Emergency peripartum hysterectomy is associated with increased blood loss, worse coagulopathy, and increased transfusion rates compared with elective peripartum hysterectomy.[170] A multicenter review showed that the mean blood loss for emergency obstetric hysterectomy was 2526 mL, with a mean transfusion requirement of 6.6 units of PRBCs; in elective procedures, the mean blood loss was 1319 mL and the average replacement was 1.6 units of PRBCs (Table 38-4).[170]

Owing to the challenging technical aspects of the procedure, the obstetrician may elect to perform a subtotal hysterectomy, wherein the cervix is left *in situ*. Subtotal approaches are associated with fewer urinary tract and other operative injuries and a shorter length of stay,[168,169] but greater mean transfusion requirements and more frequent rates of reoperation than total hysterectomy.[169] Subtotal hysterectomy is not appropriate for patients with bleeding from the cervix, lower uterine segment, or both (e.g., implantation of the placenta on the lower uterine segment).

Manual compression of the aorta can be a lifesaving procedure in the event of catastrophic obstetric hemorrhage.[171] Effective aortic compression against a vertebral body in the upper abdomen should decrease blood flow to the pelvis, thereby allowing hemodynamic and hemostatic resuscitation and surgical control.[172] An aortic cross-clamp requires vascular surgery expertise and retroperitoneal dissection but may be necessary to achieve hemostasis. Mild cardiac and renal dysfunction have been noted in nonobstetric patients if the aortic cross-clamp time exceeds 50 minutes[173]; if a prolonged clamp time is required, the anesthesiologist should prepare for lactic acidosis and hemodynamic instability at the time the clamp is released. Advanced surgical techniques to control friable, engorged blood vessels include felt or Teflon pledgets to buttress sutures, the rapid application of straight clamps, and the application of high-pressure surgical sealants.[172,174]

Anesthetic Management. Anesthesia for peripartum hysterectomy is frequently challenging because massive blood loss may occur unpredictably.[175] An experienced, skilled team is invaluable and critical to a successful outcome. An experienced team may elect neuraxial anesthesia in a properly prepared patient. Intraperitoneal manipulation, dissection, and traction may exceed similar maneuvers required with cesarean delivery alone, leading to pain, nausea, and vomiting. Maintenance of a T4 sensory level of anesthesia and judicious sedation may reduce the need for intraoperative conversion to general anesthesia. In a multicenter study of peripartum hysterectomy, none of the 12 patients who received continuous

epidural anesthesia for elective or emergency hysterectomy required intraoperative induction of general anesthesia.[170]

Single-shot spinal anesthesia is unlikely to provide anesthesia of sufficient duration for an unanticipated hysterectomy. Indications for induction of general anesthesia at the beginning of a cesarean hysterectomy include anticipated difficult airway management, antepartum hemorrhage with hemodynamic instability, and known placenta percreta, which may increase the risk for massive hemorrhage and complex surgery.

Patients who have delivered vaginally with preexisting epidural labor analgesia may be managed successfully with extension of epidural blockade, but careful consideration of hemodynamic status should precede the administration of local anesthetics into the epidural space. Animal models suggest that sympatholysis established before the onset of hemorrhage reduces excessive catecholamine response to blood loss and may improve survival.[176] However, the induction of sympatholysis during hemorrhage may compromise end-organ perfusion and even precipitate cardiopulmonary arrest.

As the magnitude of blood loss increases, general anesthesia becomes the anesthetic technique of choice. First, severely hypotensive patients may require tracheal intubation for airway protection. Second, large fluid shifts and massive transfusion may adversely affect oxygenation so that control of ventilation via an endotracheal tube becomes necessary. Third, these same fluid shifts increase airway edema, potentially making failed ventilation/failed tracheal intubation more likely as the surgery proceeds. Fourth, the massive transfusion of blood products often results in the need for coadministration of potent vasopressors and calcium chloride and, thus, central venous access; the placement of a central venous catheter may be more easily accomplished after the induction of general anesthesia. In all cases, patients at risk for peripartum hysterectomy managed with neuraxial anesthesia should be informed in advance that intraoperative discomfort or severe hemorrhage may mandate the intraoperative induction of general anesthesia.

The induction of general anesthesia in the setting of severe hemorrhage requires careful use of small doses of nondepressant induction agents such as ketamine or etomidate. The circulation should be supported with replacement of intravascular volume and vasopressors as needed. A review of maternal deaths from postpartum hemorrhage in France revealed that 5 of 38 deaths followed cardiac arrest on induction of general anesthesia.[177]

Regardless of the anesthetic technique used, two or more large-bore intravenous catheters should be inserted. Invasive blood pressure monitoring may aid in the prompt recognition of hypotension and provide access for frequent blood draws. The blood bank should be alerted to the possible need for massive transfusion. At least 4 units of PRBCs should be immediately available, with additional blood products, including plasma and cryoprecipitate, readily available without delay. The ACOG recommends consideration of intraoperative blood salvage in cases of placenta accreta (see later discussion).[75,134] Vasoactive drugs (e.g., phenylephrine, epinephrine) should be available. Fluid warmers, a forced-air body warmer, and

equipment for rapid infusion of fluids and blood products should be accessible if the care team is anticipating and managing significant blood loss. Teamwork and precise communication are indispensable.

RESPONSE TO HEMORRHAGE

Prevention of Mortality

Data from the U.K. Confidential Enquiry into Maternal and Child Health and the French Confidential Enquiry into Maternal Death reveal that maternal deaths from hemorrhage in high-resource settings are often preventable and associated with substandard care.[5,177] Berg et al.[16] reported that whereas only 40% of all pregnancy-related deaths in the state of North Carolina between 1995 and 1999 were considered preventable, a staggering 93% of deaths due to hemorrhage were judged preventable. The most important factor in preventability of deaths from hemorrhage was management that did not meet the expected standard of care the review committee believed should have been available.[16]

Delays in diagnosis and treatment of postpartum hemorrhage increase the severity of hemorrhage.[17,178,179] In a retrospective structured chart review of 63 women who suffered severe obstetric hemorrhage (defined by > 3 units blood transfused and intensive care unit admission), Della Torre et al.[17] identified clinically significant delays in the diagnosis of hemorrhage in 23% of cases and delays in treatment in 38% of cases. A multicenter cohort study in France evaluated all women who developed postpartum hemorrhage due to uterine atony after vaginal birth to determine risk factors for progression to severe postpartum hemorrhage (defined by a decrease in hemoglobin concentration > 4 g/dL).[179] Patients were more likely to develop severe hemorrhage if oxytocin administration, manual exploration of the uterus, or both were delayed. Delays of more than 10 minutes in summoning either an obstetrician or an anesthesiologist also increased the odds of severity, presumably by delaying treatment. Interestingly, epidural labor analgesia protected against severe hemorrhage, in all likelihood by allowing for more rapid and thorough uterine exploration.[179]

Delays in care most likely result from several factors, including difficulties in accurately estimating blood loss and in diagnosing maternal hypovolemia and shock, lack of aggressive monitoring and treatment of coagulopathy, and poor coordination of team responses.

Practitioners often underestimate the amount of blood loss, with the degree of underestimation increasing as blood loss volume increases (Figure 38-4).[180-183] Accuracy of blood loss estimation can be improved with the use of calibrated collection drapes.[18,184] Clinician education using simulated scenarios with known blood volumes enhances estimation accuracy.[181,183,185] Separation of nonblood fluids (i.e., switching the suction canister after evacuation of amniotic fluid) and weighing pads and bedding may improve assessment. It is imperative that clinicians have a low threshold for the diagnosis of postpartum hemorrhage.

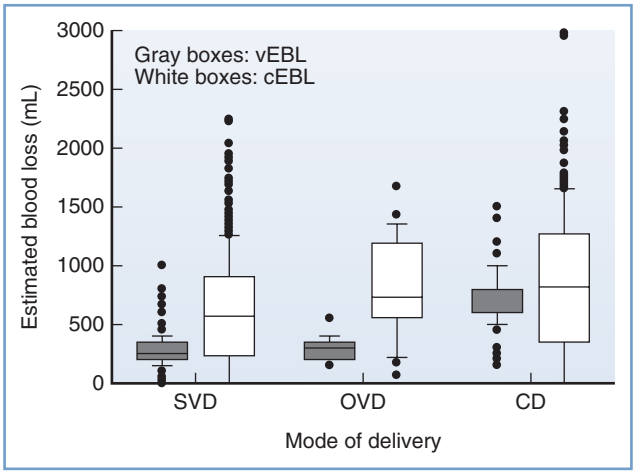

FIGURE 38-4 ■ The visually estimated blood loss (vEBL) and calculated estimated blood loss (cEBL) by mode of delivery. The boxes illustrate the 25th, 50th, and 75th percentiles and the whiskers illustrate the 10th and 95th percentiles. Calculated estimated blood loss was derived by multiplying the calculated maternal blood volume by the percent of blood volume lost, where calculated maternal blood volume = 0.75 × {[maternal height in inches × 50] + [maternal weight in pounds x 25]} and percent of blood volume lost = {predelivery hematocrit – postdelivery hematocrit}/predelivery hematocrit. vEBL was statistically different from cEBL for each degree of laceration and for all modes of delivery, demonstrating an underestimation of vEBL with increasing cEBL. *SVD,* spontaneous vaginal delivery; *OVD,* operative vaginal delivery; *CD,* cesarean delivery. (From Stafford I, Dildy GA, Clark SL, Belfort MA. Visually estimated and calculated blood loss in vaginal and cesarean delivery. Am J Obstet Gynecol 2008; 199:519.e1-7.)

A second potential explanation for delays in diagnosis and treatment relates to difficulties in diagnosing hypovolemic shock in healthy young patients. The American College of Surgeons Trauma Committee's Advanced Trauma Life Support (ATLS) system defines four stages of hypovolemic shock based on degree of blood loss (see Table 38-1).[186] Obstetric patients are often mildly tachycardic, and worrisome rates of tachycardia (> 120 beats per minute) may not develop until the patient has lost 30% to 40% of her total blood volume. Similarly, hypotension and mental status changes are late signs. Findings such as these have led to the use of a modified early obstetric warning system (MEOWS) to detect impending adverse events (Table 38-5).[187] Physiologic variables such as vital signs, oxygenation, and mental status are monitored regularly, and thresholds that trigger clinical evaluation are defined. MEOWS is not specific to hemorrhage. It has a positive predictive value of 39% and a negative predictive value of 98% in predicting maternal morbidity.[187] It is not known whether hemorrhage-specific modifications to the MEOWS would improve outcomes in the setting of obstetric hemorrhage.

Another issue that may lead to delays in care is the speed with which coagulopathy develops in the setting of obstetric hemorrhage. The rapid consumption of coagulation factors, especially fibrinogen, during obstetric hemorrhage has prompted experts to recommend early monitoring for, and aggressive treatment of, coagulopathy, especially hypofibrinogenemia.[53,188] Postpartum hemorrhage and other placental bed bleeding such as

TABLE 38-5 Trigger Thresholds for MEOWS Parameters

	Red Trigger*	Yellow Trigger*
Temperature (°C)	< 35 or > 38	35-36
Systolic blood pressure (mm Hg)	< 90 or > 160	150-160 or 90-100
Diastolic blood pressure (mm Hg)	> 100	90-100
Heart rate (beats/min)	< 40 or > 120	100-120 or 40-50
Respiratory rate (breaths/min)	< 10 or > 30	21-30

MEOWS, modified early obstetric warning system.
*A trigger is defined as a single markedly abnormal observation (red trigger) or the simultaneous combination of two mildly abnormal observations (yellow trigger). A trigger prompts urgent medical assessment.
†*Pain scores:* 0 = no pain at rest or movement; 1 = no pain at rest, slight pain on movement; 2 = intermittent pain at rest, moderate pain on movement; 3 = moderate pain at rest, severe pain on movement.
‡*Neurologic responses:* Alert: patient is alert and conscious; Verbal: patient responds to verbal stimulation; Pain: patient responds to painful stimulation; Unresponsive: patient is unresponsive to any stimulus.
From Singh S, McGlennan A, England A, Simons R. A validation study of the CEMACH recommended modified early obstetric warning system (MEOWS). Anaesthesia 2012; 67:12-8.

abruption appear to trigger a coagulopathy disproportionate to the amount of blood loss or dilution of coagulation factors (see later discussion). Once coagulopathy develops, the requirement for additional resources (e.g., blood products) accelerates. The institutional system(s) by which personnel and resources are rapidly activated must be clearly defined in advance.[171,189]

Protocols and Team Approach

Because early delays in care during postpartum hemorrhage worsen outcomes, protocols have been introduced that focus on early recognition and treatment; specifically, protocols emphasize team responses, the accurate estimation of blood loss, recognition of early signs of hypovolemic shock, early monitoring for anemia and coagulopathy, and appropriate transfusion of blood products. A number of protocols have been implemented and published, including a detailed obstetric hemorrhage "kit" by the California Maternal Quality Care Collaborative.[190]

The combination of protocols and team practice drills that emphasize these elements has been shown to decrease the severity of hemorrhage and, in some cases, mortality.[191-193] Shields et al.[193] introduced a postpartum hemorrhage protocol with practice drills and subsequently performed a follow-up study to determine whether introduction of the protocol reduced severity of hemorrhage and/or need for transfusion. All obstetric patients were assessed on admission to the hospital for risk for bleeding, and patients deemed at increased risk had blood samples sent to the blood bank for type and screen or type and crossmatch. Blood loss after delivery was estimated by weighing all absorbent material, adding the liquid contents of fluid collection devices, and subtracting the nonblood fluid volume (e.g., amniotic fluid). After delivery, each patient was assigned to one of four stages of increasing acuity, depending on estimated blood loss and changes in hemodynamic status. Higher stages of acuity directed the team of caregivers to summon help, to advance progressively through pharmacologic and surgical interventions to control the source of bleeding, and to simultaneously intensify hemodynamic and hemostatic support. In the preprotocol period, only 33% of patients were successfully treated in the earliest stage of hemorrhage (stage 1), compared with 82% in the postprotocol period ($P = .02$). Similarly, among patients who progressed to moderate hemorrhage (stage 2), 8% were successfully treated at that stage in the preprotocol period, compared with 50% in the postprotocol group ($P = .02$). Transfusion rates declined and there was a trend toward less DIC in the postprotocol period.[193]

Introduction of these types of protocols and drills has positive effects on sentinel events and malpractice payments.[194] Additionally, *in situ* drills may uncover latent systems errors that can subsequently be corrected.[195,196] The Joint Commission has called for clinicians to identify triggers that warn of excessive blood loss and hemodynamic instability early in the course of hemorrhage and to develop protocols for responding to such triggers; they recommend drills for obstetric hemorrhage, noting that these team exercises can be used for training staff as well as identifying and fixing systems problems.[197]

TRANSFUSION THERAPY

Despite advances in the prevention, diagnosis, and treatment of the hemorrhagic complications of pregnancy, the potential for significant blood loss remains. All physicians who provide care for pregnant women should understand the indications, risks, and benefits of transfusion. Transfusion may be indicated for treatment of severe anemia after moderate obstetric hemorrhage or to preserve life during massive hemorrhage.

The AABB recommends restrictive transfusion strategies after moderate hemorrhage in otherwise hemodynamically stable adults.[198] This advice is based on consideration of the risks of anemia compared to the risks of transfusion. Randomized controlled trials have failed to demonstrate benefits for liberal compared with restrictive RBC transfusion strategies. Additional considerations arise from concern about resource utilization and the costs associated with transfusion.

Risks and Benefits

Risk of Anemia

Blood oxygen content and oxygen delivery to the tissues are a function of hemoglobin concentration; however, compensatory physiologic responses offset the negative

effect of anemia on oxygen transport, especially if euvolemia is maintained with crystalloid or colloid intravascular volume expansion after moderate hemorrhage. Tachycardia and increased stroke volume combine to increase cardiac output, and blood viscosity and systemic vascular resistance decrease, augmenting blood flow to the tissues. Additionally, tissue oxygen extraction increases. Experience with patients who refuse transfusion indicate that these compensatory mechanisms are usually adequate to compensate for moderate blood loss; no increase in mortality is observed as long as hemoglobin concentration remains greater than 5.0 g/dL.[199] Weiskopf et al.[200] studied the effects of acute normovolemic hemodilution on oxygen delivery and extraction. As hemoglobin concentration fell, systemic vascular resistance decreased and heart rate, stroke volume, and cardiac index increased. Oxygen transport rate and mixed venous oxyhemoglobin saturation did not decrease until hemoglobin concentration levels reached 5.0 g/dL. Plasma lactate did not accumulate, leading the authors to conclude that transport of oxygen was not compromised during anemia of this magnitude. These measurements were made in healthy, nonpregnant patients and volunteers who were at rest; extrapolation of these results to sick or pregnant patients may not be warranted. Anemia carries increased risks in patients with cardiovascular disease.[201]

Postpartum anemia is associated with fatigue. However, fatigue is transient, and within 1 week fatigue and health-related quality of life scores are similar between postpartum patients who were anemic at discharge and those who were not.[202] Transfusion of 1 or 2 units of PRBCs to moderately anemic parturients has no effect on length of hospital stay.[203] Jonsson et al.[204] investigated the correlation between postoperative hematocrit and wound tissue oxygenation and wound collagen deposition. There was no correlation until the hematocrit fell below 15%, most likely because compensatory responses to anemia mitigate the effects of low oxygen content. The effect of moderate anemia on breastfeeding is unknown.

Risks of Transfusion

Blood product transfusion is associated with known risks (see Table 55-2). **Transfusion-associated circulatory overload** (TACO) occurs in 1% to 6% of transfused patients.[205-207] TACO sometimes develops in young patients and may follow the transfusion of as little as 1 unit of PRBCs.[208] The likelihood of TACO increases with larger amounts of plasma transfused[205] and may occur during the correction of the coagulopathy that accompanies severe hemorrhage and massive transfusion.

Transfusion-related acute lung injury (TRALI) is defined as a new acute lung injury (ALI) that occurs within 6 hours of transfusion in a patient without an alternative risk factor for ALI. It is accompanied by hypoxemia and radiographic evidence of pulmonary edema in the absence of circulatory overload (Box 38-4).[209] TRALI results when human leukocyte antigen (HLA) class I and II neutrophil or possibly monocyte antibodies in donor plasma prime and activate recipient white blood cells (WBCs) to cause an ALI. This WBC activation leads to increased pulmonary microvascular permeability and interstitial and alveolar edema and extravasated neutrophils in the alveolar spaces.[210] Multiparous female donors are more likely to carry the offending antibodies.[211] In 2006, U.S. blood collection agencies instituted male-only donor plasma transfusion policies, and the TRALI rate has fallen to approximately one third of its prior level (approximately 1 case per 12,000 transfused units).[211] Multicomponent apheresis collection techniques also decreased the risk for TRALI.[210]

BOX 38-4 Recommended Criteria for TRALI and Possible TRALI

TRALI Criteria

- Acute lung injury
  - Acute onset
  - Hypoxemia
    Research setting: $PaO_2/FIO_2 \leq 300$ or $SpO_2 < 90\%$ on room air
    Nonresearch setting: $PaO_2/FIO_2 \leq 300$ or $SpO_2 < 90\%$ on room air or other clinical evidence of hypoxemia
  - Bilateral infiltrates on frontal chest radiograph
  - No evidence of left atrial hypertension (i.e., circulatory overload)
- No preexisting acute lung injury before transfusion
- Occurs during or within 6 h of transfusion
- No temporal relationship to an alternative risk factor for acute lung injury

Possible TRALI Criteria

- Acute lung injury
- No preexisting acute lung injury before transfusion
- Occurs during or within 6 h of transfusion
- A clear temporal relationship to an alternative risk factor for acute lung injury

TRALI, transfusion-related acute lung injury.
From Kleinman S, Caulfield T, Chan P, et al. Toward an understanding of transfusion-related acute lung injury: statement of a consensus panel. Transfusion 2004; 44:1774-89.

Allogeneic RBC administration also risks **transfusion-related immunomodulation** (TRIM). The mechanisms for development of TRIM are incompletely understood, but subsequent to RBC transfusion, the host develops immune tolerance and a period of generalized immune suppression. Consequences of immune tolerance and suppression include an increased incidence of nosocomial infection, postoperative infection, and cancer recurrence.[212] In addition, microchimerism, whereby donor cells/DNA persist in the host for several years, occurs and predisposes the recipient to autoimmune illnesses.[212] There is some suggestion that TRIM increases the lifetime risk for nonsolid cell malignancies.[213] These consequences are more likely to manifest as time passes and therefore may be more likely to affect young obstetric patients than older patients. Leukoreduction may have a modest role in mitigating TRIM.[210]

The risk for **viral transmission** because of allogeneic blood transfusion continues to decrease with thorough donor screening and use of nucleic acid amplification testing (nucleic acid technology [NAT]).[214] The residual risk for transmission after both NAT and serologic testing

of donor blood is approximately 1 in 2 million for both human immunodeficiency virus (HIV) and hepatitis C virus (HCV).[198,214,215] NAT is not routinely used to test for hepatitis B virus (HBV). Instead, donor screening for hepatitis B surface antigen (HBsAg) and anti-core (HBc) antibody have greatly reduced the risk for transmission of HBV; the current risk for transmission with a blood transfusion is 1 in 350,000.[198,214] The transfusion transmission of Creutzfeldt-Jakob disease has been reported. Because of the long incubation period of this prion, symptoms may not be evident for several years after transfusion.[216] Levels of infectivity are believed to be very low.[214] The first case of West Nile virus transmitted via a blood transfusion was identified in 2002; since 2003, routine blood screening has been implemented, virtually eliminating this risk.[214] Cytomegalovirus (CMV) is carried in the monocytes of asymptomatic donors and may be transmitted to uninfected recipients of blood transfusions.[217] Most of the subsequent infections are asymptomatic or mild, but CMV infection of an immunocompromised patient and/or fetus or neonate can lead to serious sequelae. The transmission rate may be as high as 30% without preventive techniques. The risk for transmission of CMV is reduced to 1.3% if seronegative blood is transferred[218] and to 2.5% with the use of leukodepleted PRBCs.[219] In 2000, a Canadian consensus conference concluded that these two methods of preventing post-transfusion CMV infection can be used interchangeably.[217]

Bacterial contamination occasionally occurs. Because platelets may undergo conformational changes at temperatures below 18° C, they are stored at 20° C to 24° C. This warmer storage temperature (compared with that used for PRBCs) increases the risk for bacterial proliferation. In 2004, the AABB mandated testing of all platelets for bacterial contamination. Use of culture-negative platelets has resulted in a reduction in the risk of septic transfusion to 1 in 75,000.[220]

Hemolytic transfusion reaction is a rare complication; it occurs most commonly as a result of accidental administration of ABO-incompatible blood.[198] Acute intravascular hemolysis typically results in fever, chills, nausea, flushing, and chest and flank pain. These symptoms are masked by general anesthesia. Signs that may manifest during general anesthesia include hypotension, tachycardia, DIC, and hemoglobinuria.[221] Immediate supportive care consists of discontinuation of the transfusion, treatment of hypotension and hyperkalemia, administration of a diuretic, and alkalinization of the urine. Assays for urine and plasma hemoglobin concentration and antibody screening confirm the diagnosis. A second crossmatch must be performed.

The biochemical and additional changes that occur during blood storage can lead to complications in the recipient, particularly when blood products are infused rapidly, as during massive transfusion for severe hemorrhage. The anticoagulant used for blood collection and storage contains citrate, which binds ionized calcium. Citrate is rapidly metabolized in the liver and typically does *not* lead to significant **hypocalcemia**. In patients who are hypothermic, have liver disease, or require rapid infusion of multiple units of blood products, however, citrate may accumulate and cause a decrease in ionized calcium. The concentration of citrate is seven times higher in fresh frozen plasma (FFP) and platelets than in PRBCs.[222] Hypocalcemia results in reduced cardiac contractility, hypotension, and elevated central venous pressure.[223]

Plasma potassium concentration increases in stored blood. Transfused potassium usually moves intracellularly or is excreted in the urine. However, rapid infusion of multiple units of blood can lead to **hyperkalemia**, particularly in the hypothermic acidotic patient.[223] Blood maintained at 4° C also can contribute to **hypothermia**, especially if the patient is anesthetized in a cold operating room. The decreased pH of stored blood is caused by the addition of citrate-phosphate-dextrose and the accumulation of lactic and pyruvic acids as a result of RBC metabolism and glycolysis. Despite the lower pH, transfusion of large amounts of stored blood rarely causes acidosis as long as tissue perfusion remains normal.[223]

Transfusion Strategies

Several randomized controlled trials have compared the use of restrictive and liberal transfusion practices, based on lower or higher hemoglobin triggers.[224] These trials uniformly failed to demonstrate benefit to a liberal strategy and suggested that using higher hemoglobin triggers may cause harm.[224-227] A 2012 meta-analysis that examined the effect of restrictive compared with liberal transfusion triggers on various outcomes[228] found that the use of lower hemoglobin triggers reduced the risk of receiving an RBC transfusion (RR, 0.61; 95% CI, 0.52 to 0.72), reduced the volume of RBC transfused, and did not impact the rate of adverse events such as myocardial infarction, other cardiac events, or stroke. Furthermore, restrictive strategies were associated with a reduction of in-hospital mortality (RR, 0.77; 95% CI, 0.62 to 0.95) and a trend toward lower 30-day mortality (RR, 0.85; 95% CI, 0.70 to 1.03). There are no published randomized controlled trials examining low versus high transfusion triggers in obstetric patients. Among a series of 117 women with major obstetric hemorrhage (5 units or more of packed PRBCs transfused), a hematocrit nadir below 20% was associated with end organ injury.[9]

The indications for, and appropriateness of, RBC transfusion have been recently reevaluated because of (1) concerns for transfusion-related complications, (2) appreciation of the body's mechanisms for compensating for anemia, and (3) the results of the randomized trials indicating no benefit to early transfusion. The AABB recommends that RBC transfusion not be considered in euvolemic, hemodynamically stable patients until the hemoglobin concentration reaches 7 g/dL, or 8 g/dL in patients with cardiovascular disease.[198] The AABB further advises that transfusion be guided by symptoms and not by hemoglobin concentration triggers alone.[198]

Practices vary widely[229] and often deviate from these guidelines. In a retrospective chart review, Butwick et al.[230] found no specific documented indication for transfusion in 34% of obstetric patients who received a transfusion. Additionally, 18% had a pretransfusion hemoglobin concentration greater than 8 g/dL. Parker

et al.[231] documented that 31% of obstetric transfusions administered over a 1-year period occurred despite a hemoglobin concentration greater than 7 g/dL in the absence of ongoing bleeding or symptomatic anemia. Similarly, Fong et al.[232] reported that 24% of transfusions administered to patients undergoing cesarean delivery were inappropriate, based on a preadministration hemoglobin concentration higher than 7 mg/dL. Finally, in a review of 33,795 obstetric-related admissions from 1994 to 2002, Silverman et al.[233] found that 32% of RBC transfusions were not appropriate when judged against institutional guidelines.

The AABB guidelines do not address transfusion in parturients.[198] Similarly, the ACOG is silent on this issue. Given current evidence in nonobstetric patients and the lack of data in obstetric patients (who are generally young and healthy), it seems reasonable that transfusion should be considered in obstetric patients with a hemoglobin concentration less than 7 g/dL or clinical evidence of inadequate oxygen-carrying capacity. Moreover, ongoing blood loss should prompt transfusion in some patients with a hemoglobin concentration greater than 7 g/dL.

The need to obtain a blood type and screen for all parturients on admission is controversial. Some clinicians suggest that this test is not necessary in patients with no identifiable risk factors for peripartum hemorrhage. Ransom et al.[234] found that only 0.8 per 1000 low-risk patients undergoing cesarean delivery required a blood transfusion. They concluded that a routine type and screen in low-risk patients is not cost-effective. However, many anesthesia providers believe that the potential need for transfusion, and the occasional patient who develops an antibody from fetal antigen exposure during pregnancy, warrants the routine performance of a blood type and screen. The American Society of Anesthesiologists (ASA) Practice Guidelines for Obstetric Anesthesia state that the decision to perform a type and screen should be based on maternal history, anticipated hemorrhagic complications, and local institutional policies.[235] It is not necessary for all parturients to undergo a type and crossmatch, although it may be prudent to obtain a crossmatch for patients with risk factors for bleeding.[235] In addition, patients with a positive antibody screen should have a blood sample sent for crossmatch to avoid a delay in obtaining blood products should the need arise.

If blood is required quickly and the results of antibody screening are not available, the safest option is to administer ABO- and Rh-specific blood. If the blood type is unknown and blood products are required immediately, type O Rh-negative blood can be administered.

Blood Conservation Techniques

Iron deficiency is common in childbearing women because erythropoiesis occurs in the fetus at the expense of maternal iron stores. Oral iron therapy is a mainstay of anemia prevention and treatment in pregnant women. Unfortunately, oral therapy is not well-tolerated and therefore many patients may be noncompliant; others may have reduced gastrointestinal absorption.[236] Vitamin C enhances iron absorption.[236] In cases of malabsorption, intravenous iron administration may be required. Intravenous therapy more quickly and reliably corrects anemia than oral iron therapy,[237] including anemia in postpartum women.[238] Low-molecular-weight iron dextran is recommended for this purpose because it is associated with few serious adverse effects, in contrast to older iron preparations.[239] Erythropoietin stimulates bone marrow erythropoiesis but has been associated with venous thromboembolism in vulnerable populations.[240] Its use is not well studied in pregnancy.

The potential advantages of autologous blood transfusion include avoiding the risks of some transfusion-related adverse events and reduction of demands on the blood supply. The three methods of autologous transfusion are (1) preoperative (antepartum) donation, (2) normovolemic hemodilution, and (3) intraoperative blood salvage. Preoperative autologous donation causes anemia, may not reduce the risk of allogeneic transfusion, cannot be used in emergencies, and is not cost-effective because of difficulties in predicting transfusion need in obstetric patients, even those with traditional risk factors for hemorrhage.[241,242] Normovolemic hemodilution may also induce anemia and may not reduce the risk of allogeneic transfusion.[242,243] Experts do not endorse the routine use of either of these two techniques in obstetric patients.[242]

Intraoperative blood salvage is a technique of scavenging blood lost during surgery, processing it by centrifugation, washing and filtering, and administering the scavenged, autologous RBCs back to the patient. Red blood cells that are salvaged, processed, and transfused have an excellent survival rate. This procedure, which can rapidly provide large quantities of autologous blood, is widely used in cardiovascular and general surgery and is acceptable to many Jehovah's Witness patients.[244] Employment of cell salvage diminishes the need for allogeneic transfusion and postoperative anemia after cesarean delivery.[245]

Contamination of salvaged blood with bacteria, fat, bowel contents, or various pharmacologic agents represents a relative contraindication to the technique.[246] In the past, the use of intraoperative blood salvage in obstetric patients has been limited, in part, by concern that blood processing may not adequately remove amniotic fluid, fetal debris, or fetal cells and that reinfusion might precipitate amniotic fluid embolism. However, modern salvaging processes efficiently remove these contaminants.[246,247] *In vitro* studies demonstrate that washing and filtration remove tissue factor, which is implicated in the pathophysiology of amniotic fluid embolism, from salvaged products.[248] In addition, combining these processes with the use of a leukocyte-depletion filter greatly reduces fetal squames and other fetal debris.[249,250] Waters et al.[250] demonstrated that fetal squamous cell concentration in postfiltration scavenged blood is equal to that in maternal venous blood. In all cases of potential contamination, a double suction setup is recommended.[246,247] In this setup, one suction line, connected to the general suction system, removes grossly contaminated fluid immediately after amniotomy and delivery, before a second suction line delivers blood to the salvaging system.

The cell scavenging system does not distinguish between maternal and fetal red cells, and the transfusion of washed blood is likely to expose the mother to a greater

amount of fetal RBCs than commonly occurs during delivery.[249,250] In one series, the median fetal red cell transfusion (contamination) volume was 0.8 mL, ranging from 0.2 to 12.9 mL.[251] Isoimmunization of the mother is possible, and anti-D immune globulin should be administered as guided by Kleihauer-Betke testing.[246,247]

Reports of clinical experience with cell salvage in obstetric patients have accumulated over recent years; more than 650 cases have been published describing its use in obstetric patients without adverse sequelae.[251-253] Few controlled trials have been published. Rebarber et al.[254] performed a retrospective, multicenter study of 139 patients in whom autologous blood transfusion was performed during cesarean delivery between 1988 and 1997. The volume of autotransfused blood ranged from 200 to 11,250 mL. The investigators identified no cases of acute respiratory distress syndrome or amniotic fluid embolism, and the incidence of other complications (e.g., DIC) in these patients was not different from the incidence in 87 control patients who underwent similar surgical procedures without autotransfusion in the same hospitals. In a randomized study of women undergoing cesarean delivery, Rainaldi et al.[245] observed that 34 patients who underwent intraoperative salvage and re-infusion of autologous blood (mean ± SD volume, 363 ± 153 mL) required less allogeneic blood and had a shorter hospital stay than the control group. The authors of one case report attributed maternal death to cell salvage-induced amniotic fluid embolism.[255] Many authorities do not accept the cause of death as amniotic fluid embolism because the patient was quite ill with severe preeclampsia, HELLP syndrome, and coagulopathy and the postmortem examination was inconclusive concerning the diagnosis of amniotic fluid embolism.

Intraoperative blood salvage during cesarean delivery is widely regarded as safe in the United Kingdom[242,247] and is gaining acceptance in the United States. The ACOG has stated that in cases of suspected placenta accreta, "cell saver technology should be considered if available."[75] The ASA Practice Guidelines for Obstetric Anesthesia recommend that "in cases of intractable hemorrhage when banked blood is not available or the patient refuses banked blood, intraoperative cell salvage should be considered if available."[235]

Many authorities advocate this technique as a potential solution to the worsening shortage of banked blood, increased cost of allogeneic blood transfusion, and concern about transfusion-related infections and clerical errors.[246,247,249] Waters et al.[256] performed an economic analysis of the use of cell salvage in obstetrics and calculated that its cost-effectiveness may depend, in part, on an institution's case volume and the expected volume of blood lost per case. Fong et al.[232] have suggested that the use of intraoperative blood salvage might reduce exposure to allogeneic blood in almost half of obstetric patients who require transfusion and might eliminate exposure to allogeneic blood altogether in 14% to 25% of patients.

Treatment of Massive Blood Loss

In the initial resuscitation of the hemorrhaging patient, warmed non–dextrose-containing crystalloid (e.g., lactated Ringer's solution, normal saline) and/or colloid (e.g., 5% albumin) solutions are acceptable choices for volume replacement. During massive hemorrhage, blood replacement therapy becomes necessary. A coagulopathy can develop rapidly in the bleeding obstetric patient, because of hemostatic factor consumption, exsanguination, dilution, or hyperfibrinolysis. Dilutional coagulopathy results from the replacement of blood loss with crystalloid and PRBCs, which dilutes coagulation factors and platelets. Sustained hemorrhage may also lead to DIC with simultaneous accelerated consumption and fibrinolysis, resulting in worsening hemorrhage (see later discussion). Pregnancy-related pathologic processes commonly associated with DIC include amniotic fluid embolism, placental abruption, uterine infection, intrauterine fetal demise, and severe postpartum hemorrhage.

Blood Products

Allogeneic blood can be transfused as whole blood or component products. Whole blood would be an ideal choice for maintaining intravascular volume in the setting of massive hemorrhage. Alexander et al.[257] performed a population-based observational study of 1540 obstetric patients who required transfusion. The authors compared outcomes among patients who received only whole blood (43%), only PRBCs (39%), or multicomponent therapy (19%). Whole blood was associated with lower rates of acute tubular necrosis than the two other transfusion practices. However, few donor units are kept as whole blood in the modern blood bank. The high demand for blood components such as platelets, FFP, and cryoprecipitate necessitates that more than 90% of donor blood be fractionated into blood components. Blood component therapy provides the patient with only those products that are required and helps extend the shelf-life of each unit of donor blood because derivatives from one unit of blood can be used to treat several patients. Characteristics of commonly administered blood products are summarized in Table 38-6. During massive resuscitation, care must be taken to avoid hypothermia, acidosis, and hypocalcemia, because these conditions contribute to coagulopathy.

PRBC units are prepared by removing plasma from whole blood and replacing it with additives to improve red cell survival. These units are packaged with preservatives and anticoagulant (citrate, phosphate, dextrose, adenine) and have a 42-day shelf-life. Each unit has volume of approximately 300 mL with a hematocrit of 70%. Transfusion of 1 unit of PRBC increases the hemoglobin concentration by approximately 1 mg/dL in the absence of ongoing bleeding.

A unit of **fresh frozen plasma** has a volume of approximately 250 mL and contains coagulation factors. Transfusion of FFP is indicated when replacement of coagulation factors is necessary to achieve hemostasis, as may occur during massive transfusion or in the presence of DIC. Administration of FFP may be considered for correction of microvascular bleeding if the prothrombin time (PT) is more than 1.5 times normal, the international normalized ratio (INR) is greater than 2.0, or the activated partial thromboplastin time (aPTT) is more

TABLE 38-6 **Characteristics of Blood Components**

Component	Dose	Volume Per Dose	Shelf Life	Storage Conditions	Expected Response
Packed red blood cells	1 unit	250-325 mL	21-42 days	1°C to 6°C	1 g/dL increase in hemoglobin concentration
Fresh frozen plasma	Factor replacement: 10-15 mL/kg	200 mL	Frozen: 1 yr Thawed: 24 h	Frozen: ≤ –18°C Thawed 1°C to 10°C	Correction of PT, aPTT, INR by replacement of coagulation factors
Platelets	4-6 units of pooled whole blood–derived platelets or one unit of apheresis platelets	200-250 mL	5 days	20°C to 24°C with continuous and gentle agitation	Increase in platelet count of 30,000-60,000/mm^3
Cryoprecipitate	10 pooled units	100 mL	Frozen: 1 yr Thawed/pooled: 4 h	Frozen: ≤ –18°C Thawed: 1°C to 10°C	Increase in levels of fibrinogen, von Willebrand factor, factor VIII, factor XIII

aPTT, activated partial thromboplastin time; *INR,* international normalized ratio; *PT,* prothrombin time.
Modified from Sanford K, Roseff S. A surgeon's guide to blood banking and transfusion medicine. In: Spiess BD, Spence RK, Shander A, editors. Perioperative Transfusion Medicine, 2nd edition. Philadelphia, Lippincott Williams and Wilkins, 2006: 179-98.

than two times normal.[221] FFP should not be used to treat hypovolemia or as a protein supplement. One unit of FFP per 20 kg of body weight (or 10 to 15 mL/kg body weight) is an appropriate initial dose.[221] The prophylactic use of FFP is not effective for decreasing blood loss in patients at risk for massive blood loss.[222]

Cryoprecipitate is prepared from thawed FFP and contains fibrinogen, factor VIII, von Willebrand factor, fibronectin, and factor XIII. In the setting of postpartum hemorrhage, cryoprecipitate is used to replace fibrinogen, which is rapidly consumed during obstetric hemorrhage. Normal pregnancy is a hypercoagulable state,[258,259] and coagulation activity peaks at the time of parturition[260,261] because of an increase in circulating tissue factor concentration and enhancement of the tissue factor–dependent coagulation pathway.[262] It is postulated that tissue factor and other procoagulant substances are released from the placental implantation site at the time of placental separation, augmenting thrombin formation and serving an important hemostatic function after delivery.[48] In the setting of continued bleeding from the placental bed, these thromboplastic substances may continue to enter the circulation and, in severe cases, may lead to a consumptive coagulopathy and DIC.[48]

The consumption of fibrinogen appears to play a central role in the pathophysiology of peripartum hemorrhage.[263] Charbit et al.[188] prospectively identified 128 patients who had postpartum hemorrhage and classified the hemorrhage as severe (decrease in hemoglobin concentration of ≥ 4 g/dL, transfusion of ≥ 4 units PRBCs, or invasive hemostatic intervention required) or nonsevere.[188] At the time postpartum hemorrhage was diagnosed, patients who subsequently developed severe hemorrhage had lower fibrinogen, prothrombin, factor V, and antithrombin levels compared with patients without severe hemorrhage. These early differences were most marked for fibrinogen. A fibrinogen concentration less than 200 mg/dL at the time hemorrhage was diagnosed had a 100% positive predictive value for severe hemorrhage; a fibrinogen concentration greater than 400 mg/dL had a 79% negative predictive value for severe hemorrhage. The coagulation changes were consistent with a consumptive coagulopathy because they were accompanied by increases in thrombin-antithrombin complexes and D-dimer levels, both markers of excessive coagulation. Furthermore, because the fall in fibrinogen concentration was twice the fall in hemoglobin concentration, it was believed that dilution did not account for the difference in fibrinogen levels between the two groups. Other investigators have confirmed that decreases in fibrinogen correlate better than other hemostatic measures with the severity of hemorrhage.[264,265]

The alarmingly rapid consumption of coagulation factors, especially fibrinogen, during obstetric hemorrhage has prompted experts to recommend early monitoring for, and aggressive treatment of, hypofibrinogenemia with rapid central laboratory or point-of-care testing.[266-268] During active hemorrhage, clinicians should attempt to maintain the fibrinogen concentration higher than 150 to 200 mg/dL.[268] Each *dose* of cryoprecipitate supplied by most blood banks contains 5 to 10 single-donor units of cryoprecipitate, and each unit of cryoprecipitate contains approximately twice the fibrinogen of 1 unit of FFP. Therefore, the most efficient method to replace fibrinogen during obstetric hemorrhage may be to administer cryoprecipitate.[269] In a multicenter prospective cohort study of trauma victims (n = 1175), administration of cryoprecipitate compared with large doses of FFP was associated with a decreased risk for multiorgan failure.[270] In a small case series of obstetric hemorrhage associated with hypofibrinogenemia, fibrinogen concentrate was used to restore fibrinogen levels.[271] This product is currently approved for the treatment of acute bleeding in individuals with congenital hypofibrinogenemia. Further study is required to clarify its role in the treatment of the acquired hypofibrinogenemia associated with obstetric hemorrhage.[263,270]

Thrombocytopenia may develop after massive transfusion secondary to dilution or in association with obstetric comorbidities such as HELLP syndrome. **Platelet**

transfusion may be necessary if hemorrhage is accompanied by a platelet count less than 50,000/mm^3.[221] In nonbleeding patients, a transfusion trigger of 20,000/mm^3 has traditionally been suggested, although many clinicians prefer to administer platelets before the platelet count decreases to this value.[272] Platelet dysfunction associated with bleeding may also necessitate platelet administration.[221] One unit of donor platelets increases the platelet count by 5000 to 10,000/mm^3 in the average adult. The blood bank typically provides pooled random-donor platelets or single-donor apheresis platelets obtained from an ABO- and Rh-compatible donor, although ABO compatibility is not essential. One unit of apheresis platelets is equivalent to 4 to 6 units of pooled platelets.

The optimal **FFP:PRBC transfusion ratio** remains a topic of research and debate. Borgman et al.[273] sought to characterize the relationship between this ratio and survival in a retrospective review of combat victims in Iraq between 2003 and 2005. The investigators identified 246 patients who required massive transfusion and separated them into low (median ratio 1:8), medium (median ratio 1:2.5), and high (median ratio 1:1.4) FFP:PRBC ratio groups. A high FFP:PRBC ratio was independently associated with increased odds of survival after correcting for confounders (odds ratio, 8.6; 95%, CI 2.1 to 35.2). After publication of these data, some experts recommended a 1:1 FFP:PRBC ratio during massive hemorrhage. However, many authors,[274] including Borgman et al.,[273] pointed out the well-known limitations of retrospective data, which include the potential existence of unidentified confounders. These authors have articulated the fact that deaths in the low-ratio group occurred much earlier than deaths in the high-ratio group, raising the possibility that those in the low-ratio group had more severe injuries and died before FFP could be thawed and administered (e.g., survivor bias). Indeed, if the analysis is adjusted for survivor bias, the survival benefit associated with high FFP:PRBC ratio disappears.[274,275] Furthermore, a study in civilian trauma victims identified a FFP:PRBC ratio of 1:2 to 1:3 as optimal for survival.[276] However, the extrapolation of data from young male trauma victims to bleeding parturients seems fraught with potential for error.

A 2013 publication described the retrospective review of records from 142 women who had postpartum hemorrhage and required transfusion within 6 hours of delivery.[277] Patients were divided into two groups based on their response to sulprostone therapy: those in whom bleeding was controlled with sulprostone alone and those who required advanced interventional procedures. Propensity score analysis revealed that a high FFP:PRBC ratio (> 1:2) was associated with fewer requirements for interventional procedures. Retrospective studies such as these can only demonstrate an association between the FFP:PRBC ratio and outcome and cannot infer cause and effect. Investigators have uniformly called for high-quality randomized trials to adequately define the optimal FFP:PRBC ratio during resuscitation for massive hemorrhage.[273,275-278]

Many blood banks have in place **massive transfusion protocols** whereby blood products are delivered to the operating room in fixed ratios, sometimes in a cooler or refrigerator.[279] Such protocols allow the blood bank to more quickly provide component products[280] and may encourage clinicians to more effectively prevent and/or treat coagulopathy. A massive transfusion protocol for postpartum hemorrhage has been described (Figure 38-5).[281]

Recombinant Activated Factor VII

A number of reports have described the administration of recombinant activated factor VII (rFVIIa) for hemorrhage and coagulopathy unresponsive to conventional blood product resuscitation.[282] Factor VIIa binds not only to tissue factor but also with low affinity to the thrombin-activated platelet. This low-affinity binding to the activated platelet allows direct activation of factor X to Xa on the surface of the activated platelet, bypassing the normal need for factors VIIIa and IXa. Activation of factor X leads to a small thrombin burst. This thrombin, in turn, activates more platelets. Additionally, rFVIIa enhances platelet aggregation and adhesion. Recombinant activated factor VII is currently approved in the United States for the treatment and prophylaxis of bleeding in patients with hemophilia A and B with inhibitors to factors VIII and IX, acquired hemophilia, and congenital factor VII deficiency. However, its use has been reported off-label for multiple clinical scenarios, including the following: platelet disorders; severe liver disease; major trauma; cardiac, prostate, and liver surgery; stroke; and postpartum hemorrhage.[236,283] Greater numbers of patients are being treated with rFVIIa each year, and the majority of treated patients are receiving the drug for off-label indications.[284]

No randomized controlled trials investigating the use of rFVIIa in the setting of obstetric hemorrhage have been published; most recommendations are therefore based on case report or case series data. Franchini et al.[285] compiled 9 reports of 272 obstetric patients who received rFVIIa. A 10th report described a registry of 105 patients who received rFVIIa for postpartum hemorrhage in Australia and New Zealand.[286] Of the 377 patients included in these 10 reports, 82% were judged by their practitioners to have had a positive treatment response (bleeding decreased or stopped) after one or more doses of rFVIIa. These data are difficult to interpret. Variation in underlying pathology existed; 49% of patients underwent cesarean delivery, and 51% underwent vaginal delivery. Nineteen percent had vaginal or uterine lacerations, 25% had placental abnormalities, and 8% had retained placenta. Additionally, the doses were not standardized and there were no criteria for the administration of rFVIIa, nor were there criteria for what constituted a positive response. Most patients received simultaneous therapy with other traditional therapies such as FFP and cryoprecipitate administration. These circumstances make judgments regarding response to rFVIIa unreliable and uncontrolled; thus, a high likelihood for bias exists. Several authors have called for randomized placebo-controlled trials of rFVIIa use for postpartum hemorrhage, but such a trial will be difficult to undertake given the low incidence and unpredictability of massive obstetric hemorrhage.

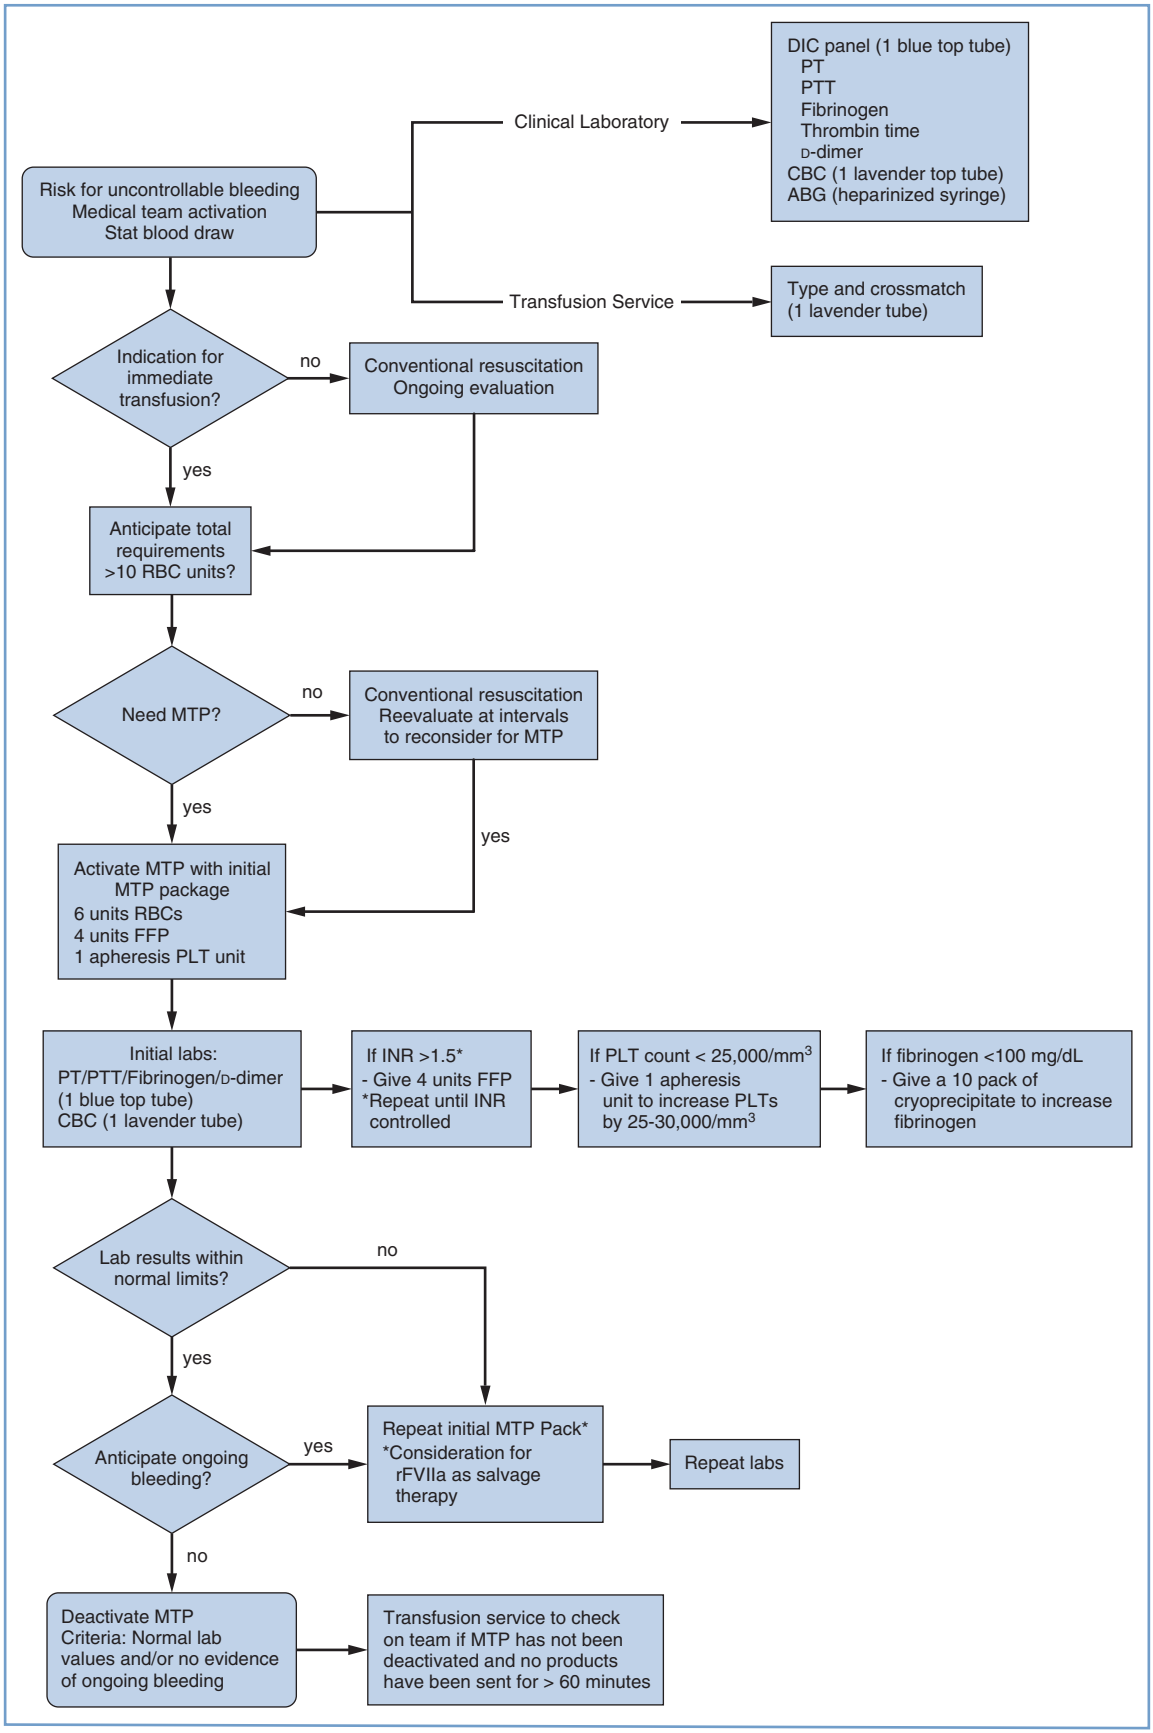

FIGURE 38-5 ■ Sample algorithm for a massive transfusion protocol for the labor and delivery unit. *ABG,* arterial blood gas; *CBC,* complete blood cell count; *DIC,* disseminated intravascular coagulation; *FFP,* fresh frozen plasma; *INR,* international normalized ratio; *MTP,* massive transfusion protocol; *PLT,* platelet; *PT,* prothrombin time; *RBC,* red blood cells; *rFVIIA,* recombinant activated factor VII. (Modified from Burtelow M, Riley E, Druzin M, et al. How we treat: management of life-threatening primary postpartum hemorrhage with a standardized massive transfusion protocol. Transfusion 2007; 47:1564-72.)

There is concern that rFVIIa may increase the likelihood of thromboembolic events. The true incidence is not known. Arterial events (e.g., myocardial infarction, cerebral thrombosis) are more likely than venous events[287,288] and are dose[287] and age dependent.[288] Among the 377 reported cases of rFVIIa administered for postpartum hemorrhage, eight patients developed venous thromboembolism, one suffered myocardial infarction, and one had a thrombotic cerebrovascular accident, suggesting a thrombotic complication frequency of 2.7% in the postpartum period. However, severe obstetric hemorrhage and peripartum hysterectomy are known to increase the risk for thrombotic complications; thus, this frequency cannot support or refute any causal relationship with rFVIIa. Leighton et al.[289] advise against rFVIIa administration in the setting of amniotic fluid embolism because tissue factor may play a role in its pathophysiology and thrombotic complications may be increased.

Given the unknown efficacy and safety of rFVIIa, as well as its high cost, rFVIIa is not recommended for routine use in obstetric practice. In 2005, an American panel, based on type II evidence (obtained from well-designed, nonrandomized trials or cohort or case-control analytic trials), judged the use of rFVIIa for treatment of postpartum hemorrhage as appropriate only when bleeding continued despite clotting factor replacement.[290] The ASA guidelines recommend consideration of rFVIIa therapy if "traditional well-tested options for treating microvascular bleeding (i.e., coagulopathy) have been exhausted."[221] In addition, maintenance of normothermia and correction of acidosis are necessary for optimal rFVIIa activity; optimization of platelet count, fibrinogen, and serum calcium are also advisable as rFVIIa requires these substances to be effective.

Antifibrinolytic Therapy

It has been suggested that antifibrinolytic therapies such as tranexamic acid may be useful in treating postpartum hemorrhage–associated coagulopathy.[291] A meta-analysis of six randomized trials comparing tranexamic acid with placebo administered shortly after birth demonstrated that tranexamic acid was associated with a nonsignificant reduction in blood loss of 33 mL.[292] In five of the six trials, tranexamic acid was administered prophylactically. The sixth trial enrolled women who had lost at least 800 mL after vaginal delivery; tranexamic acid reduced the total blood loss over the subsequent 6 hours by 50 mL (170 mL versus 221 mL, $P = .04$).[293] A large international placebo-controlled trial of tranexamic acid therapy in the setting of postpartum hemorrhage is ongoing.[294] Tranexamic acid may be most beneficial for women who demonstrate hyperfibrinolysis based on hemostatic monitoring such as thromboelastography.[263,268]

KEY POINTS

- Obstetric hemorrhage is the most common cause of maternal mortality worldwide and a leading contributor to maternal mortality in developed nations.
- Most severe morbidity and mortality that occurs secondary to obstetric hemorrhage is considered preventable and is due to delays in recognition and treatment.
- The visual estimate of vaginal bleeding often underestimates true blood loss; training clinicians, separation of amniotic fluid, use of calibrated drapes, and weighing pads and bedding improves estimation accuracy.
- Hypotension and tachycardia are late signs in hypovolemic shock.
- Antepartum hemorrhage usually represents a greater threat to the fetus than to the mother.
- Postpartum hemorrhage is increasing in both rate and severity in the developed world, mostly due to an increase in the incidence of uterine atony.
- Uterine atony is the most common cause of postpartum hemorrhage.
- The incidence of placenta accreta is increasing as a result of the higher cesarean delivery rate.
- Peripartum hysterectomy is increasing in frequency because of an increase in the incidence of both uterine atony and placenta accreta.
- Patients with placenta accreta are at high risk for massive hemorrhage and should be managed only in facilities with multidisciplinary specialists, including interventional radiologists and a well-staffed blood bank.
- Team responses that emphasize the accurate estimation of blood loss, early warning signs of shock, and rapid response to blood loss and coagulopathy are associated with less maternal morbidity.
- Coagulopathy develops quickly during bleeding from the placental bed, and may be out of proportion to blood loss or dilution because of the rapid consumption of fibrinogen.
- Intraoperative blood salvage may be lifesaving in cases of intractable hemorrhage, if banked blood is not available, or if the patient refuses banked blood.
- The safety and efficacy of recombinant activated factor VII therapy has not been fully evaluated in the treatment of obstetric hemorrhage.

CHAPTER 39

Embolic Disorders

Paloma Toledo, MD, MPH • Andrew M. Malinow, MD

CHAPTER OUTLINE

Embolic disease during pregnancy includes amniotic fluid embolism, venous thromboembolism, and venous air embolism. Each of these entities varies in its incidence, clinical course, and consequences. Embolic events account for almost one fifth of all maternal deaths in the United States.[1] Early recognition, diagnosis, and treatment are necessary to reduce associated morbidity and to avoid mortality.

AMNIOTIC FLUID EMBOLISM

Death attributable to an amniotic fluid embolism (AFE) was first reported by Meyer in 1926.[2] Early reports described a syndrome of fatal peripartum shock attributed to emboli of amniotic fluid mechanically obstructing the maternal pulmonary circulation.[3] Although the pathophysiology of this disease remains poorly understood, current evidence suggests that emboli alone are insufficient to precipitate this infrequent, idiosyncratic, and devastating condition. Rather, fetal material in the maternal circulation has the potential to trigger a massive cascade of inflammatory and hemostatic reactions that culminate in cardiopulmonary collapse and disseminated intravascular coagulation.

Epidemiology

The incidence of amniotic fluid embolism is difficult to establish because (1) AFE is a diagnosis of exclusion, (2) there is no universally accepted definition for identifying cases of AFE, and (3) differing ascertainment methods yield divergent rates of AFE. Registry data from the United Kingdom suggest an event rate between 0.8 and 2 per 100,000 deliveries.[4,5] Cross-sectional analyses of administrative data in Australia and the United States suggest higher rates—3.3 and 7.7 per 100,000 deliveries, respectively.[6,7] A systematic review published in 2009 estimated that the pooled incidence of AFE in North America was approximately 1:15,200 (95% confidence interval [CI], 1:13,900 to 1:16,700), whereas the incidence in Europe was three times lower at 1:53,800 (95% CI, 1:48,800 to 1:59,900).[8] This heterogeneity likely reflects variations in ascertainment procedures, rather than true differences by continent of origin. One limitation of analyses of secondary databases is that the diagnosis of AFE may not have been validated. For example, one regional surveillance system in Australia has developed the capacity to systematically review records for all cases identified from administrative data. By only counting those women who experienced one of the cardinal symptoms of AFE, with no other potential explanation, the reported incidence decreased from 6.3 to 3.3 cases per 100,000 pregnancies.[9]

Risk Factors

Maternal demographic factors such as older age and race or ethnicity have been associated with AFE in population-based studies.[5,7] Other obstetric factors such as abnormal placentation, placental abruption, eclampsia, multiple gestation, induction of labor, artificial or spontaneous rupture of membranes, and operative delivery have also been associated with AFE.[5,7,10-12] Because nonreassuring fetal heart rate (FHR) tracings can complicate AFE in labor, cesarean delivery may be a consequence,

rather than cause, of intrapartum AFE. Nonetheless, a strong association between cesarean birth and postpartum AFE persists among women in the United Kingdom Obstetric Surveillance System (UKOSS) dataset (adjusted odds ratio, 8.8).[5] The proportion of excess postpartum AFE events associated with cesarean delivery (the population-proportional attributable risk for cesarean delivery) from the UKOSS dataset was estimated to be 62%.[5]

Pathophysiology

In 1941, Drs. Steiner and Lushbaugh, two pathologists from the University of Chicago, described a case series of eight autopsies after fatal intrapartum shock.[3] Examination of lung tissue from these cases revealed embolic material of squamous cells, mucin, meconium, and amorphous eosinophilic material.[3] Because all of these patients were described as having tumultuous labors with stronger than usual uterine contractions, it was presumed that the forceful contractions loosened or tore the placenta and forced the emboli into the maternal circulation.[3] Yet, periods of uterine tachysystole are the least likely times for maternoplacental exchange of embolic material to occur as uterine blood flow ceases.[13] The tachysystole is probably a result of endogenous norepinephrine release and, therefore, is likely temporally related to, but not causative for, embolic material transfer.[13]

Large intravenous boluses of human meconium suspended in human amniotic fluid can precipitate cardiovascular collapse in rabbits and dogs,[3] but injection of autologous amniotic fluid fails to reproduce the AFE syndrome in many animal models.[14] The passage of fetal squames, lanugo hair, and mucin into the maternal pelvic vasculature appears to be a common event at term,[15] and fetal material has been identified in pulmonary arterial samples aspirated from critically ill women who did not have AFE.[16-18]

The exact trigger for the reaction in women with AFE is not known but may be a rare pathologic fetal antigen or a common antigen presented in an unusual way—in amount, timing, or frequency of entry into the maternal circulation.[19] AFE appears to be a systemic inflammatory response associated with the inappropriate release of endogenous inflammatory mediators.[20] Whatever the trigger, several maternal endogenous mediators appear to play an important role in the initial reaction, including arachidonic acid metabolites (i.e., thromboxane, prostaglandins, leukotrienes, endothelins).[20]

Approximately 40% of women in a United States national AFE registry had a history of allergy or atopy, leading some authors to suggest an anaphylactoid mechanism.[12] In support of this theory, the symptoms of AFE could be blocked by the administration of a leukotriene inhibitor in a rabbit model.[21] However, a series of case reports now suggests that levels of tryptase and histamine are not dramatically or universally elevated among women experiencing the AFE syndrome.[22,23] Although mast cell degranulation may contribute to the pathophysiology of AFE, this effect may be a secondary product of the inflammatory cascade, rather than causal, and thus the term *anaphylactoid syndrome of pregnancy* may be a misnomer.[23]

Other immune-mediated mechanisms have also been implicated in AFE. A case-control study demonstrated low levels of the complement components C3 and C4 among women diagnosed with AFE compared with controls, suggesting that complement activation may also contribute to the inflammatory cascade.[22] Whether complement plays a primary[19] or secondary role[24] in the AFE syndrome is unknown. A heat-stable pressor agent in meconium has been suggested as another possible mediator of AFE; in a goat model this agent caused a circulatory response similar to that seen in human AFE.[25]

Alternatively, the hemodynamic consequences of AFE could derive from activation of the coagulation system, mediated through platelet activation. Fetal squamous cells and syncytiotrophoblasts display high concentrations of tissue factor and phosphatidylserine.[26-28] Tissue factor irreversibly aggregates platelets,[29] leading to platelet degranulation, which releases thromboxane, serotonin, and additional mediators that amplify the immunologic systems. Serotonin is a potent pulmonary vasoconstrictor that produces vasodilation in the systemic vasculature and may lead to early right-sided heart failure in the AFE syndrome.[27,30,31]

Coagulopathy develops in the majority of women who survive the initial cardiovascular collapse.[12,32] One proposed mechanism involves tissue factor. As pregnancy progresses, increasing amounts of tissue factor, a potent procoagulant, accumulates in the amniotic fluid.[27,28] Tissue factor binds factor VII, thus activating the extrinsic pathway and triggering clotting by activating factor X, with the subsequent development of a consumptive coagulopathy.[27] A second possible mechanism is that amniotic fluid has a thromboplastin-like effect, which induces platelet aggregation, releases platelet factor III, and activates the clotting cascade.[33] Other components of amniotic fluid, the amniochorion, and the placenta have also been implicated in contributing to the coagulopathy. Uterine atony, whether due to a specific myometrial depressant or from uterine hypoperfusion, may exacerbate hemorrhage and consumptive coagulopathy in AFE.[34]

There is conflicting evidence regarding whether the bleeding seen in AFE is due primarily to a consumptive coagulopathy versus massive fibrinolysis. In one *in vitro* study, investigators added 10 to 60 μL of clear autologous amniotic fluid to 330 μL of blood from volunteers undergoing uneventful cesarean delivery.[35] Thromboelastographic analysis of the specimens revealed accelerated clot formation but no evidence of fibrinolysis. However, because of the rapid and severe hypofibrinogenemia observed during AFE, some investigators have suggested that severe hyperfibrinolysis is also present.[36] Future work is necessary to further refine our understanding of the coagulopathy that accompanies AFE.

Clinical Presentation

Whereas the classic presentation of AFE includes acute respiratory distress, cardiovascular collapse, and coagulopathy near the time of delivery, a broad range of AFE syndromes have been described in situations in which other diagnoses were excluded (Table 39-1).[12,20,37]

Currently, the UKOSS provides the most comprehensive prospective surveillance for amniotic fluid embolism in the world. All hospitals in the United Kingdom with a consultant-led maternity unit report all suspected cases of AFE, along with monthly delivery volume data, for central review and reporting.[5,38] Cases of AFE are defined using either *clinical criteria* that include acute hypotension, cardiac arrest, acute hypoxemia, and/or coagulopathy in the absence of any other potential explanation for the symptoms and signs observed, or *pathologic evidence* indicating the presence of fetal squames or hair in the maternal lungs. All women in the UKOSS registry demonstrated at least one cardinal feature of AFE, including shortness of breath, hypotension, coagulopathy, maternal hemorrhage, or premonitory symptoms (see Table 39-1).[5]

A national registry in the United States accepted voluntary submissions of medical records for patients with suspected AFE beginning in 1988. The diagnosis of AFE was confirmed based on meeting all entry criteria outlined in Box 39-1. Data for 46 confirmed cases of AFE were last published in 1995.[12]

AFE most often occurs during labor; intrapartum events comprise 56% of cases in the UKOSS registry[5] and 70% in the U.S. registry.[12] In the U.S. registry, seizure and dyspnea were the two most common presenting symptoms in women who collapsed before delivery.[12] Maternal symptoms may precede FHR changes, as shown in Figure 39-1. Fetal bradycardia, or the abrupt onset of variable decelerations that progress to fetal bradycardia, may also herald AFE in labor.[12]

AFE can present after abdominal trauma,[39] after first-trimester abortion,[40] in the second trimester,[41] at the time of delivery,[12] and in the postpartum period.[42] Although acknowledging that AFE has been reported up to 48 hours postpartum,[34] both the U.S. and U.K. registries require the diagnosis of AFE to be made within 30 minutes of delivery.[4,12]

Close inspection of hemodynamic data reveals a biphasic cardiovascular response during AFE. During the

TABLE 39-1 Features of Amniotic Fluid Embolism at Presentation

	Percent Exhibiting Feature (n = 60)*	Percent Exhibiting Feature as First Symptom or Sign (n = 60)*
Maternal hemorrhage†	65%	2%
Hypotension†	63%	8%
Shortness of breath†	62%	20%
Coagulopathy†	62%	0%
Premonitory symptoms† (i.e., restlessness, agitation, numbness, tingling)	47%	30%
Acute fetal compromise	43%	20%
Cardiac arrest	40%	8%
Dysrhythmias	27%	5%
Seizure	15%	7%

*Some women had multiple features; therefore, the totals are greater than 100%.
†Cardinal feature of amniotic fluid embolism. Twenty-seven percent of women experienced at least four of the five cardinal features.
Data from Knight M, Tuffnell D, Brocklehurst P, et al. Incidence and risk factors for amniotic-fluid embolism. Obstet Gynecol 2010; 115:910-7.

BOX 39-1 United States Amniotic Fluid Embolism Registry Entry Criteria

1. Acute hypotension or cardiac arrest
2. Acute hypoxia (dyspnea, cyanosis, respiratory arrest)
3. Coagulopathy (laboratory evidence or hemorrhage without an alternative explanation)
4. Onset of the above during labor, cesarean delivery, dilation and evacuation, or within 30 minutes postpartum
5. Absence of an alternative explanation for the observed signs/symptoms

Modified from Clark SL, Hankins GD, Dudley DA, et al. Amniotic fluid embolism: analysis of the national registry. Am J Obstet Gynecol 1995; 172:1158-67.

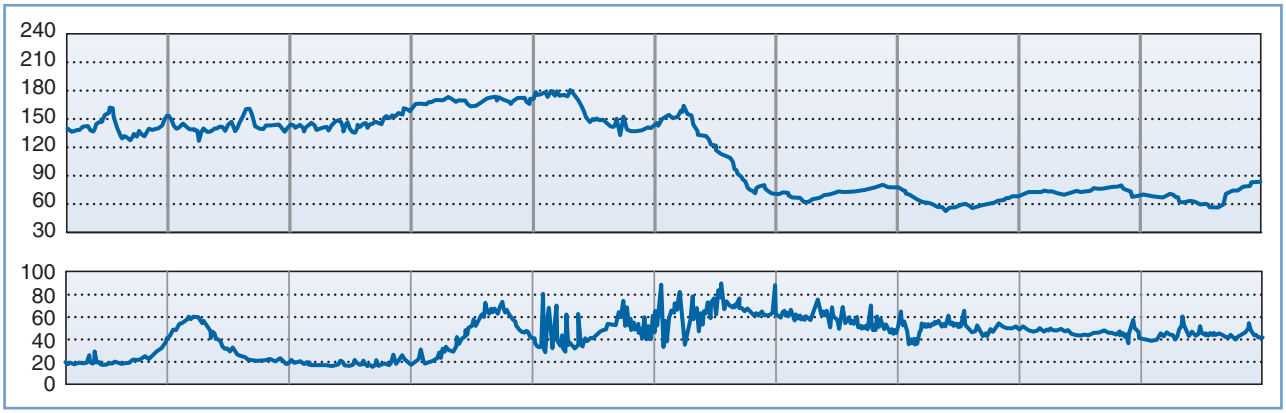

FIGURE 39-1 ■ Fetal heart rate tracing in a patient with amniotic fluid embolism. Maternal symptoms began just before the onset of spontaneous uterine hypertonus and fetal bradycardia. (Modified from Clark SL, Hankins GDV, Dudley DA, et al. Amniotic fluid embolism: analysis of the national registry. Am J Obstet Gynecol 1995; 172:1158-67.)

initial phase, acute pulmonary hypertension results in right ventricular dilation, a decrease in cardiac output, and ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch resulting in oxygen desaturation. Early arterial blood gas analysis may demonstrate evidence of profound shunt.[12] In the U.S. registry, 11 of 17 patients with a blood gas sample drawn within 30 minutes of the acute event demonstrated an initial Pao_2 less than 30 mm Hg while breathing an Fio_2 of 100%.[12] Release of endogenous catecholamines may produce a brief period of systemic hypertension and uterine tachysystole that precedes hypotension or cardiac arrest.[12] Electrocardiographic findings are nonspecific and vary from ST-wave and T-wave abnormalities to arrhythmias or asystole. A chest radiograph may show diffuse bilateral heterogeneous or homogenous areas of opacity.

Echocardiography typically demonstrates a dilated, akinetic right ventricle, pulmonary hypertension, and a normally-contracting left ventricle with a nearly obliterated cavity.[43,44] Initially, right ventricular failure leads to right ventricular dilation, which compresses the left ventricle and impedes left ventricular filling and cardiac output.[43,44] A second phase commences when right ventricular function improves,[44] typically 15 to 30 minutes after the initial event. At this point, left ventricular failure may persist due to ischemic injury to the left ventricle,[45] or direct myocardial depression,[34] and is accompanied by decreased systemic ventricular resistance, decreased left ventricular stroke index, and pulmonary edema.[46,47] Women who survive to the second phase may also experience hemorrhage and disseminated intravascular coagulopathy. Laboratory analysis may reveal anemia, thrombocytopenia, prolonged prothrombin time or activated partial thromboplastin time (aPTT) or both, and decreased fibrinogen levels.[12,34] In a minority of cases there is massive hemorrhage and disseminated intravascular coagulopathy without preceding cardiopulmonary collapse.[37]

Because many of the signs and symptoms are nonspecific, the differential diagnosis for AFE is extensive and should include nonobstetric, obstetric, and anesthetic causes (Box 39-2). Even though the time course and clinical presentation of many of these competing diagnoses are similar, only amniotic fluid embolism and placental abruption result in a relatively sudden onset of consumptive coagulopathy after maternal collapse. However, partial AFE syndromes have been described in the literature.[20] Therefore, the absence of coagulopathy should not exclude the possibility of AFE.

BOX 39-2 Differential Diagnosis of Amniotic Fluid Embolism

Nonobstetric
- Myocardial infarction
- Pulmonary embolism
- Aspiration
- Sepsis
- Anaphylaxis
- Venous air embolism

Obstetric
- Placental abruption
- Eclampsia
- Uterine rupture or laceration
- Uterine atony

Anesthetic
- High neuraxial blockade ("total spinal")
- Local anesthetic systemic toxicity
- Medication error

Confirmatory Tests

To date, there is no definitive test to confirm the diagnosis of AFE, although the UKOSS considers the finding of fetal material in the maternal pulmonary vasculature at autopsy to be pathognomonic for AFE.[5] However, fetal squamous cells and trophoblasts are commonly found in the maternal circulation of healthy parturients. Furthermore, differentiating between maternal and fetal cells histologically is challenging.[18] Clinicians should therefore not place invasive monitors solely for the purpose of aspirating cells of fetal origin.

Several biochemical markers have been suggested. Although some of these may be promising based on preliminary data and theoretical understanding of AFE, studies of test performance are limited by delayed sample acquisition and small sample size owing to the rarity and unpredictability of the AFE syndrome.

Several markers suggest an anaphylactic/anaphylactoid mechanism. Mast cells release tryptase and histamine during degranulation; tryptase has been used as a marker for anaphylaxis because its half-life is longer than that of histamine. Elevations in serum tryptase have been reported in some parturients with AFE.[23] However, a case series found normal tryptase and urinary histamine levels in nine women with presumed AFE.[22] Pulmonary mast cell counts have also been suggested; however, this measurement can only be obtained using immunohistochemistry at autopsy and therefore is of limited applicability in the clinical setting. In one observational study, the mean pulmonary mast cell count per fixed area for parturients who died of AFE was similar to that of parturients who died of anaphylactic shock but was higher than the mean counts in both pregnant and nonpregnant control patients.[48] These data, together with the finding of minimal to no elevation in serum tryptase, suggest that pulmonary mast cell degranulation may be a secondary process in AFE.[23]

Complement activation may cause mast cell degranulation, and there is some evidence supporting widespread complement activation, and depressed C3 and C4 levels, in AFE.[22] However, because complement is activated during acute respiratory distress syndrome and other inflammatory states, results are not specific for AFE. Zinc coproporphyrin[49] and sialyl Tn antigen[22] are two biomarkers that are components of meconium and have been associated with the AFE syndrome. Sialyl Tn is a mucinous glycoprotein that originates in the fetal gastrointestinal tract and is also associated with mucinous gastrointestinal tumors. Most recently, insulin-like

growth factor–binding protein-1 (IGFBP-1) was identified as a sensitive and specific biomarker for AFE in a case-control study conducted in 13 delivery centers in France.[50] IGFBP-1 levels exceeded 104.5 µg/L in 23 of 25 women with AFE and remained below 95 µg/L in all patients with postpartum hemorrhage due to atony, thrombotic pulmonary embolism, or uncomplicated labor. A single false-positive result was found in a woman with acute fatty liver of pregnancy. Based on the median concentration of IGFBP-1 in the amniotic fluid and blood samples, the investigators estimated that 6 to 92 mL of amniotic fluid passed into the maternal circulation in women who experienced the AFE syndrome.[50]

Management

Although no single intervention has been shown to reliably reverse the AFE syndrome, prompt recognition and aggressive resuscitation may improve maternal and fetal outcomes. Maternal resuscitation should focus on three priorities: (1) maintenance of oxygenation; (2) hemodynamic support; and (3) correction of coagulopathy (Box 39-3).

On diagnosis of AFE, 100% oxygen should be delivered to the patient. Given the risk for coagulopathy and hemorrhage, large-bore intravenous access is warranted. An arterial line and central venous pressure catheter may facilitate hemodynamic monitoring, blood sampling, and vasopressor administration. Transesophageal echocardiography may be useful to guide volume resuscitation and selection of appropriate vasopressor therapy.

In addition to standard resuscitative measures, other management strategies have been reported for AFE. The use of cardiopulmonary bypass, extracorporeal membrane oxygenation, continuous hemofiltration, and exchange transfusions have all been described in the literature.[5,43,51] It is speculated that these technologies may filter amniotic fluid or vasoactive mediators from the systemic circulation. Strategies for management of the early right-sided heart failure seen in AFE include inhaled nitric oxide, prostacyclin, right ventricular assist devices, and vasopressors such as vasopressin, dobutamine, and milrinone.[52,53] The use of extracorporal membrane oxygenation and intra-aortic balloon counterpulsation has also been reported for management of left-sided heart failure.[54]

In AFE, intact neonatal survival is related to the time interval from the onset of maternal compromise to delivery.[12] In the event of maternal cardiopulmonary arrest, the American Heart Association recommends that delivery of the fetus should occur within 5 minutes to increase the probability of good outcomes for both the mother and her neonate.[55] Although the operating room may provide a more favorable environment for surgery and resuscitation, simulation studies have suggested that resuscitation quality and the arrest-to-delivery interval both suffer with maternal transport[56,57]; therefore, strong consideration should be given to performing a bedside perimortem cesarean delivery.

Because coagulopathy will likely ensue for the majority of AFE survivors, the obstetric and anesthesia providers should activate a massive transfusion protocol as soon as AFE is suspected. Blood and component therapy should be guided by the clinical presentation (see Chapter 38). Close communication with the blood bank is paramount because large quantities of blood products may be needed. Analysis of the U.K. registry demonstrated that patients who developed a coagulopathy received between 12 and 106 units of blood products.[4] Potential pharmacologic therapies for the coagulopathy associated with AFE include antifibrinolytic agents (e.g., tranexamic acid, aprotinin), recombinant factor VIIa (rVIIa), prothrombin complex concentrate, and fibrinogen concentrate.[36,58,59]

The use of rVIIa to treat intractable hemorrhage in the AFE syndrome is controversial. The use is off-label in obstetric hemorrhage (see Chapter 38). Recombinant factor VIIa binds to tissue factor and initiates clotting via the extrinsic pathway. Although individual case reports have described improvement in hemostasis, rVIIa has been associated with thrombotic complications. A meta-analysis of 25 trials involving 3849 nonobstetric bleeding patients without hemophilia found a significant increase in arterial thromboembolic events among patients who received rVIIa (relative risk [RR], 1.45; 95% CI, 1.02 to 2.05).[60]

A case-controlled study based on a systematic review of case reports of women with the AFE syndrome identified a twofold increase in risk for death or permanent

BOX 39-3 Management of Amniotic Fluid Embolism

Airway

- Administer 100% oxygen.
- Intubate the trachea and support ventilation as needed.

Cardiovascular Support

- Start chest compressions if indicated.
- Ensure left uterine displacement to relieve aortocaval compression if appropriate.
- Administer fluids and vasopressors.
- Establish large-bore intravenous access.
- Consider invasive pressure monitoring.

Fetus

- Monitor fetal well-being.
- Expedite delivery for nonreassuring status in a viable fetus or in the event of maternal cardiopulmonary arrest in the second half of pregnancy (i.e., perimortem cesarean delivery).

Hemostatic Support

- Activate the obstetric hemorrhage protocol and massive transfusion protocol.*
- Send blood for serial laboratory assessment to monitor for coagulopathy and electrolyte disturbances.
- Provide blood component therapy as indicated.
- Ensure normothermia.

Postresuscitation Care

- Notify the intensive care unit of the potential admission.

*See Chapter 38.

disability among 16 women treated with rVIIa compared with 28 control patients who underwent surgery to control bleeding but did not receive rVIIa.[58] Among survivors, treatment with rVIIa was associated with more permanent disability (risk ratio, 4.0; 95% CI, 1.5 to 10.4), largely attributed to thrombosis in major organs.[58] An unmeasured increase in severity of disease in the treatment group compared with the control group could explain these dismal results because the population of patients who did not survive to the time of operation was excluded from the analysis. In this case-controlled study of case reports,[58] 50% of parturients treated with rVIIa survived, whereas in the 2010 UKOSS dataset,[5] 93% of the parturients treated with rVIIa survived (n = 14). However, the UKOSS data did not report neurologic outcomes or thromboembolic complications.[5] The differences in outcomes between these two studies may be explained in part by differing definitions of AFE and differences in case ascertainment. Only five cases in the case-controlled study[58] were peer-reviewed publications; the remainder were obtained from abstracts presented at national meetings and from registry data.

Maternal and Perinatal Outcomes

The maternal mortality ratio associated with AFE has been reported between 0.5 and 1.7 deaths per 100,000 live births.[8] AFE accounted for 7.5% of pregnancy-related deaths in the United States between 1998 and 2005.[1] The case-fatality rate from the UKOSS data was 20% (95% CI, 11 to 32),[5] significantly lower than the reported fatality rate of 61% in the 1988 to 1994 analysis of the U.S. AFE registry.[12] In the UKOSS dataset, patients who died of AFE were more likely to be from ethnic minority groups than were survivors, even after adjusting for confounders such as age, socioeconomic status, obesity, and parity (adjusted odds ratio [aOR], 11.8; 95% CI, 1.4 to 99.5).[5] Similar racial/ethnic disparities were seen in the United States.[1] Improvements in the management of critically ill parturients may have contributed to the decline in the case-fatality rate observed in the two studies, but the disparity in outcomes by race or ethnicity suggests further systems improvements are necessary.

Cardiac arrest complicated 87% of AFE cases reported to the U.S. registry but only 40% of cases identified by UKOSS.[5,12] This difference may reflect more comprehensive ascertainment in the United Kingdom that captures less severe cases; alternatively, improvements in early recognition and management of AFE over the past 15 years may explain improved outcomes recently reported from the United Kingdom compared with those previously published from the U.S. registry.

Neurologic outcomes for survivors are poor. The 1995 analysis of the U.S. registry reported a 15% overall rate of intact neurologic survival, with only 8% neurologically intact after cardiac arrest.[5,12] Neonates have a high overall survival rate, with approximately 80% of infants surviving,[5,12] but also have low rates of intact neurologic survival, with only 39% of survivors neurologically intact.[12] Intact neurologic survival for infants is related to the cardiac arrest-to-delivery interval; delays of greater than 15 minutes are associated with worse outcomes.[12]

Recurrent AFE has not been reported.

THROMBOEMBOLIC DISORDERS

Incidence

Venous thromboembolic events (VTE) in pregnancy refer to deep vein thrombosis (DVT) and pulmonary thromboembolism (PTE). The incidence of pregnancy-related thromboembolic events is 1.0 to 1.7 events per 1,000 pregnancies.[61-63] The range of reported incidences may reflect differing study designs and diagnostic criteria for thromboembolism, in addition to biologic differences among populations. Analysis of administrative data from a nationally representative sample of United States hospital admissions that included 9,058,162 pregnancy admissions and 73,834 postpartum admissions demonstrated 1.36 cases of DVT and 0.36 cases of PTE per 1,000 deliveries.[61] Fifteen to 24 percent of pregnant women with an untreated DVT develop a PTE.[61,64,65]

There is a fivefold greater odds of thromboembolic events during pregnancy (odds ratio [OR], 4.6; 95% CI, 2.7 to 7.8), and a 60-times greater odds in the postpartum period (95% CI, 26.5 to 135.9) than in nonpregnant patients.[66] Study results conflict as to whether there is an increased risk by trimester. A meta-analysis of 12 studies that evaluated the period of risk for DVT in pregnancy found that 21.9% of antepartum DVTs develop in the first trimester (95% CI, 17.4 to 27.3), 33.7% in the second trimester (95% CI, 28.1 to 39.8), and 47.6% in the third trimester (95% CI, 39.2% to 56.2%).[67] The highest risk for thromboembolic events occurs postpartum. Analysis of data from a 30-year population-based cohort (n = 50,080 births) revealed that the risk for both DVT and PTE was highest in the first week postpartum (incidence rate, 3573 per 100,000 woman-years [95% CI, 2475 to 4993 per 100,000]), with a progressive decline thereafter.[68]

Overall, the incidence of DVT appears to be stable or decreasing while the incidence of PTE appears to be increasing.[63,68] Despite the increased incidence of PTE, mortality from venous thromboembolism is decreasing.[1,62,69,70] From 1985 to 2005, the leading cause of direct maternal deaths, as reported by the Confidential Enquiries into Maternal Deaths in the United Kingdom (CMACE), was PTE.[69] In the most recent report (2006-2008), the overall rate of maternal death decreased compared with the previous triennium, largely as a result of the decreased rate of deaths due to PTE; PTE was no longer the leading cause of direct maternal deaths.[69] This change is likely the result of early recognition of at-risk patients, as well as the increasing use of protocols for peripartum thromboprophylaxis. Ten percent of all maternal deaths in the Centers for Disease Control and Prevention (CDC) Pregnancy Mortality Surveillance System from 1998 to 2005, and 15% of all direct deaths in the 2006 to 2008 CMACE report, were attributable to PTE.[1,69]

Risk Factors

The two most important risk factors for thromboembolic events in pregnancy and the postpartum period are a previous history of thromboembolism and a diagnosis of thrombophilia.[61,63,70] Essentially all known thrombophilias increase risk for VTE in pregnancy, with the greatest risk increase noted in women homozygous for the factor V Leiden mutation.[71] Antenatal immobilization and obesity are the most important modifiable risk factors for VTE,[72] and their combination has a multiplicative effect.[73] In the most recent CMACE report, 81% of the 16 patients who died of PTE were either overweight or obese.[69] Compared with vaginal birth, cesarean delivery essentially doubles the risk for postpartum venous thromboembolism, with greater increases noted for unplanned, as opposed to elective, cesarean delivery.[61-63] The American College of Chest Physicians has defined major and minor risk factors for postcesarean VTE (Box 39-4).[74]

BOX 39-4 Risk Factors for Venous Thromboembolism in the Postpartum Period

Major Risk Factors: presence of at least *one* risk factor*

- Immobility (strict bed rest for ≥ 1 week in the antepartum period)
- Previous venous thromboembolism
- Preeclampsia with fetal growth restriction
- Thrombophilia
  - Antithrombin III deficiency
  - Factor V Leiden (homozygous or heterozygous)
  - Prothrombin G20210A (homozygous or heterozygous)
- Medical conditions
  - Systematic lupus erythematous
  - Heart disease
  - Sickle cell disease
- Postpartum hemorrhage ≥ 1000 mL *and* surgery
- Blood transfusion
- Postpartum infection

Minor Risk Factors: presence of at least *two* risk factors*

- Body mass index > 30 kg/m^2
- Emergency cesarean delivery
- Multiple pregnancy
- Postpartum hemorrhage > 1000 mL
- Smoking > 10 cigarettes/day
- Fetal growth restriction
- Thrombophilia
  - Protein C deficiency
  - Protein S deficiency
- Preeclampsia

*The presence of at least one major risk factor or two minor risk factors is an indication for prophylactic therapy for venous thromboembolism (see text).

Modified from Bates SM, Greer IA, Middeldorp S, et al. VTE, thrombophilia, antithrombotic therapy, and pregnancy: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest 2012; 141(2 Suppl):e691S-736S.

Pathophysiology

Virchow's triad describes three factors that contribute to an increased risk for thromboembolism: (1) **venous stasis**, (2) **vascular damage**, and (3) **hypercoagulability**. The incidence of each factor is increased during pregnancy or in the postpartum period. Venous stasis occurs due to venocaval compression and possibly decreased mobility later in pregnancy. Separation of the placenta from the uterine wall traumatizes the endometrium, which accelerates the coagulation cascade. Finally, pregnancy is a relatively hypercoagulable state, associated with enhanced platelet turnover, coagulation, and fibrinolysis.[75,76] Thrombin generation and the concentration of clotting factors increase during pregnancy, including factors I (fibrinogen), V, VII, VIII, IX, X, and XII.[75] Platelet count typically remains unchanged or is decreased during pregnancy. Fibrinolytic activity decreases during the 48 hours after delivery and enhances clot stability in the early postpartum period.[75]

The prognosis of PTE depends on the following factors: (1) the size and number of emboli; (2) concurrent cardiopulmonary function; (3) the rate of clot fragmentation and lysis; (4) the presence or absence of a source for recurrent emboli; and (5) the location of the embolism (proximal or main pulmonary artery embolism is more symptomatic than segmental embolization).[77] Massive PTE can occlude the pulmonary vasculature and precipitate cardiopulmonary arrest; smaller emboli may also lead to cardiopulmonary failure by triggering pulmonary arterial vasospasm[78] and secondary pulmonary edema.[79] Local platelets embedded in the clot release serotonin, adenosine diphosphate, and thrombin, factors that promote both vasoconstriction and bronchoconstriction.[80] Redistribution in pulmonary blood flow leads to "hyperperfusion" of otherwise low $\dot{V}/\dot{Q}$ zones in unaffected areas of the lung; the resulting intrapulmonary shunts can generate hypoxemia disproportionate to the cross-sectional area occluded by clot.[81] At the same time, regional hypoxic pulmonary vasoconstriction exacerbates pulmonary hypertension initiated by mechanical and humoral factors. Intracardiac shunting may develop when elevated right ventricular pressure forces blood across a probe-patent foramen ovale. Elevated pulmonary venous pressure and aggressive intravenous volume replacement may disrupt capillary integrity and exacerbate pulmonary edema.[79]

The increase in right ventricular pressure leads to right ventricular dilation, with increased wall tension and oxygen demand, and a leftward shift of the interventricular septum.[78] Compression of the left ventricle combined with a decrease in preload impairs left ventricular function, cardiac output, and coronary arterial perfusion, with eventual myocardial ischemia and cardiopulmonary failure.

Deep Vein Thrombosis

Clinical Presentation

The signs and symptoms of DVT are nonspecific and often mimic normal symptoms of pregnancy, specifically lower leg edema and pain. A systematic review of the

anatomic distribution of DVT in symptomatic pregnant patients (six studies, pooled n = 124) identified left leg thrombus in 88% of pregnant women in whom the side of the DVT was reported.[82] Most thrombi were proximally located in the iliac or femoral veins or both. This distribution is different from the anatomic distribution seen in nonpregnant patients, who are more likely to have thrombi in the distal calf vessels.[82] A prospective observational study of serial ultrasonographic examinations in pregnant women (n = 24) found an increase in vessel diameter and a decrease in flow velocity in the proximal deep leg veins with increasing gestation; this finding was most notable in the common femoral vein.[83] The flow velocity was slower in the left leg than in the right leg, presumably owing to uterine compression of the left iliac vein where it crosses the right iliac artery.[83]

TABLE 39-2 **Physical Findings in Pulmonary Embolism**

Finding	Patients Affected (%)
Tachypnea	85
Tachycardia	40
Fever	45
Accentuated second heart sound	50
Localized rales	60
Thrombophlebitis	40
Supraventricular dysrhythmia	15

Modified from Spence TH. Pulmonary embolization syndrome. In Civetta JM, Taylor RW, Kirby RR, editors. Critical Care. Philadelphia, JB Lippincott, 1988:1091-102.

Diagnosis

For patients with new-onset signs or symptoms suggestive of DVT, the American College of Obstetricians and Gynecologists (ACOG) recommends compression ultrasonography of proximal veins as the initial diagnostic test.[84] If the test is negative, and involvement of the iliac vessels is not suspected, no further action other than routine surveillance is necessary. A positive result warrants treatment (see later discussion). If the results are negative or equivocal, and iliac vein thrombosis is suspected, clinicians may opt for magnetic resonance imaging or presumptive anticoagulation.[84]

The D-dimer test is useful in nonpregnant patients because it has a high sensitivity and a high negative predictive value. Unfortunately, D-dimer levels are increased in pregnancy, making interpretation of elevated levels difficult in pregnant women. In one prospective, longitudinal study, serial D-dimer levels were evaluated in 89 healthy pregnant women; values exceeded the normal nonpregnant reference range in all but one woman in the third trimester.[85] Therefore, the D-dimer test is not currently recommended for diagnosis of DVT in pregnancy[84]; however, future work may delineate pregnancy-specific thresholds.

Pulmonary Thromboembolism

Clinical Presentation

Clinical suspicion for PTE is critical to ensure timely diagnosis and treatment (Table 39-2). Physical signs and symptoms may be subtle and limited to symptoms (e.g., shortness of breath) that mimic normal pregnancy. Palpitations, anxiety, chest pain that may be pleuritic, cyanosis, diaphoresis, and cough with or without hemoptysis may all indicate PTE. Physical examination of the patient commonly reveals tachypnea, crackles, decreased breath sounds (more common than rhonchi or wheezing), and tachycardia. Signs of right ventricular failure, including an accentuated or split second heart sound, jugular venous distention, a parasternal heave, and hepatic enlargement, may be apparent. The electrocardiogram may show signs of right ventricular strain, including a right-axis shift, P pulmonale, ST-segment abnormalities, and T-wave inversion, as well as supraventricular arrhythmias. One or more of the signs of DVT (calf or thigh edema, erythema, tenderness, palpable cord) generally accompanies the pulmonary or cardiovascular findings.[64,77] Despite the observation that pulmonary shunt is a common feature of PTE, as many as 30% of all patients with a pulmonary embolus have an arterial Pao_2 greater than 80 mm Hg, and the diagnosis of PTE cannot be excluded on the basis of an apparently normal Pao_2.[77]

Invasive hemodynamic monitoring typically demonstrates (1) normal to low (< 15 mm Hg) pulmonary artery occlusion pressure, (2) increased mean pulmonary artery pressure (although typically < 35 mm Hg), and (3) increased (> 8 mm Hg) central venous pressure.[79] Calculated pulmonary vascular resistance typically is more than 2.5 times normal resistance; right ventricular failure occurs when the mean pulmonary artery pressure exceeds 35 to 45 mm Hg.[79] Left ventricular failure may occur secondary to poor left ventricular filling and arterial hypoxemia.

Diagnosis

There are no validated risk criteria, such as the Wells or Geneva criteria, for pregnant patients, which makes diagnosis of PTE in pregnancy challenging. If the pregnant patient has signs or symptoms suggestive of DVT in addition to the signs or symptoms of PTE, compression ultrasonography should be done. If the results are positive, treatment should ensue; however, if results are negative, further imaging is necessary. In the absence of symptoms of DVT, or if compression ultrasonography of the legs is negative, the choice of the next diagnostic test to be performed is controversial. Factors such as the likelihood of a nondiscriminatory test and the radiation exposure to both mother and fetus must be considered in decision-making.

The American Thoracic Society developed an evidence-based guideline for the evaluation of suspected PTE, which has been endorsed by the ACOG.[86] A diagnostic algorithm for suspected PTE is shown in Figure 39-2. If there are no signs or symptoms of DVT, a chest radiograph should be performed, both to exclude

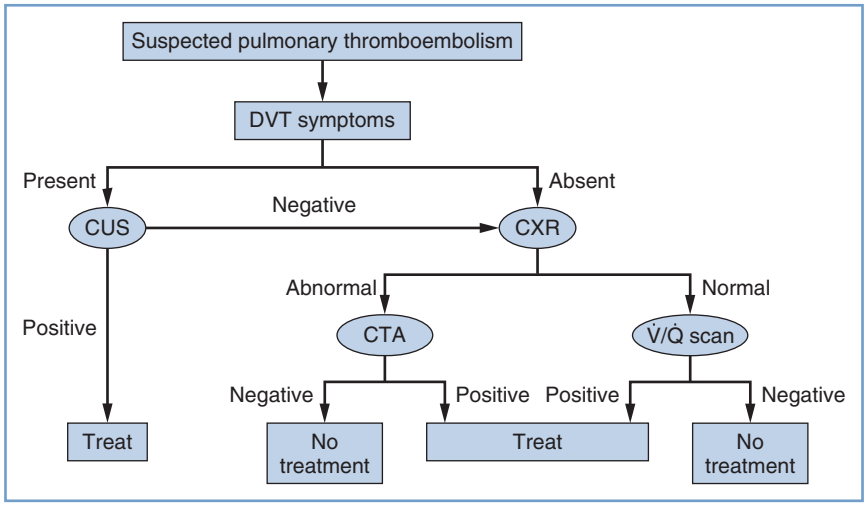

FIGURE 39-2 ■ Diagnostic algorithm for workup of suspected pulmonary thromboembolism during pregnancy. *CTA,* computed tomography pulmonary angiography; *CUS,* compression ultrasonography; *CXR,* chest radiograph; *DVT,* deep vein thrombosis; *V̇/Q̇ scan,* ventilation-perfusion scan.

alternative diagnoses, and to guide decision-making for the next most appropriate test. If the chest radiograph is normal, V̇/Q̇ scanning should be performed.[86] A retrospective study of 304 women who underwent computed tomographic angiography (CTA) or V̇/Q̇ scanning at a single institution between 2001 and 2006 demonstrated that pregnant women with a normal chest radiograph have a fivefold higher rate of a nondiagnostic result from a CTA compared with a V̇/Q̇ scan (RR, 5.3; 95% CI, 2.1 to 13.8).[87] The use of chest radiography as a screening procedure may also minimize the amount of radiation to which a pregnant woman and her fetus are exposed if the pregnant patient is a candidate for V̇/Q̇ scanning.[86] If the chest radiograph is abnormal, CTA is the next appropriate test because the proportion of nondiagnostic V̇/Q̇ scans in the presence of an abnormal chest radiograph has been reported to be as high as 48%.[88] If either the V̇/Q̇ scan or CTA is positive, anticoagulation should ensue. The use of magnetic resonance pulmonary angiography has not been validated in the pregnant population. A new diagnosis modality, V̇/Q̇ single-photon emission computed tomography (SPECT), has recently been introduced[89,90]; however, to date, the V̇/Q̇ SPECT has not been evaluated in pregnant women.

Perhaps the greatest concern with diagnostic imaging for PTE is maternal and fetal exposure to ionizing radiation. The teratogenic effects of ionizing radiation are discussed in Chapter 17).[91] Both V̇/Q̇ scanning and CTA are associated with low-doses of fetal radiation exposure (< 1 mGy). V̇/Q̇ scanning delivers a higher *fetal* dose of radiation than CTA; however, the *maternal* radiation exposure is higher with CTA, particularly radiation to the breast tissue. A patient's lifetime breast cancer risk may increase as much as 14% after CTA.[92]

Management of Thromboembolic Disorders

Anticoagulation

All women with a new-onset thromboembolic event in pregnancy should be therapeutically anticoagulated.[84] Patients with a previous history of thrombosis, certain high-risk populations, such as patients with acquired or inherited thrombophilias, or patients with a mechanical heart valve should be anticoagulated during pregnancy as well as the postpartum period. The ACOG practice bulletin on thromboembolism in pregnancy outlines which patients should receive prophylactic or therapeutic anticoagulation.[84]

Although the exact dose and regimen for anticoagulation remain controversial, two classes of drugs are typically used to initiate anticoagulation: **low-molecular-weight heparin (LMWH)** and **unfractionated heparin (UFH)** (see Chapter 44). Table 39-3 lists anticoagulation regimens commonly used in pregnancy. The ACOG does not make a distinction between UFH and LMWH for initiation of anticoagulation[84]; however, the American College of Chest Physicians recommends LMWH for prophylactic and therapeutic anticoagulation for pregnant women instead of UFH.[74]

LMWH has an enhanced ratio of antithrombotic (anti–factor Xa) to anticoagulant (anti–factor IIa) activity when compared with UFH and does not affect aPTT measurement.[93] A 2005 systematic review (64 studies, pooled n = 2777) evaluated the efficacy and safety of LMWH in pregnancy. The rate of VTE was 0.9% (95% CI, 0.6% to 1.3%), the rate of significant maternal bleeding was 2.0% (95% CI, 1.5% to 2.6%), and there were no reported cases of heparin-induced thrombocytopenia when LMWH was used for any indication in pregnancy.[93]

TABLE 39-3 Commonly Used Anticoagulation Regimens during Pregnancy

Drug	Dose
Prophylactic LMWH	Enoxaparin 40 mg SC once daily Dalteparin 5000 units SC once daily Tinzaparin 4500 units SC once daily
Therapeutic LMWH (weight-adjusted treatment dose)	Enoxaparin 1 mg/kg q12h Dalteparin 200 units/kg once daily Tinzaparin 175 units/kg once daily Dalteparin 100 units/kg q12h
Prophylactic UFH	UFH 5000-10,000 units SC q12h
Therapeutic UFH (weight-adjusted treatment dose)	UFH 10,000 units or more SC q12h adjusted to target aPTT (1.5-2.5 times the normal range 6 h after injection)
Postpartum anticoagulation	Prophylactic LMWH/UFH for 4-6 wk *or* Vitamin K antagonists for 4-6 wk (target INR 2.0-3.0). Therapy must overlap with LMWH/UFH until INR ≥ 2.0 for 2 days

aPTT, activated partial thromboplastin time; *INR,* international normalized ratio; *LMWH,* low-molecular weight heparin; *SC,* subcutaneous; *UFH,* unfractionated heparin.

Modified from American College of Obstetricians and Gynecologists. Thromboembolism in pregnancy. ACOG Practice Bulletin No. 123. Washington, DC. (Obstet Gynecol 2011; 118:718-28.)

An older systematic review (1999) did not find any significant increase in osteoporosis in pregnant women treated with LMWH compared with nonpregnant controls.[94]

The pharmacokinetics of LMWH are altered during pregnancy[95]; however, dose adjustment is not routinely required for prophylactic therapy.[84] When LMWH is used for therapeutic anticoagulation, dosing can be adjusted based on anti–factor Xa activity; the desired peak level is 0.6 to 1.0 U/mL measured 4 hours after injection.[84] Thromboelastography provides an alternative method to assess LMWH activity. Carroll et al.[96] demonstrated that the delta reaction time (ΔR) measured by thromboelastography correlates with anti–factor Xa levels in the pregnant woman and allows LMWH doses to be adjusted to ensure anticoagulation or, conversely, confirms the absence of anticoagulation. LMWH is cleared by the kidney; therefore, dose reduction may be required in patients with renal failure.

UFH therapy may be used to initiate anticoagulation or to maintain therapy as the patient nears delivery (see later discussion). UFH exerts its anticoagulant activity by binding to antithrombin III and potentiates inactivation of other coagulation factors, including thrombin (IIa), factors IXa, Xa, XIa, and XIIa, and kallikrein. Typically, UFH is administered as a subcutaneous injection for both prophylactic and therapeutic therapy. Intravenous therapy becomes necessary when PTE causes hemodynamic instability; it is initiated with a bolus dose and maintained by infusion titrated to a therapeutic aPTT value. The aPTT measured 6 hours after an injection or dose adjustment should be maintained at 1.5 to 2.5 times the normal range.[84] In pregnancy, the bioavailability of UFH decreases owing to an increase in heparin-binding proteins, increased plasma volume, increased renal clearance, and increased degradation by plasma heparinases.[97] Based on pharmacodynamic studies, 5000 units of subcutaneous heparin are often inadequate to achieve *prophylactic* serum anti–factor Xa levels in the second half of pregnancy.[98] Thus, for therapeutic anticoagulation, the ACOG currently recommends UFH 10,000 units subcutaneous twice daily, with aPTT monitoring and dose adjustment.[84]

In patients who develop heparin-induced thrombocytopenia, or severe cutaneous reactions to heparin, fondaparinux is the preferred anticoagulant owing to minimal cross-reactivity with UFH.[84] Anticoagulation with other classes of drugs such as vitamin K antagonists, thienopyridines, direct factor Xa inhibitors, and direct thrombin inhibitors is possible in pregnancy, but the use of these medications is less common. Additionally, animal studies with rivaroxaban, a direct factor Xa inhibitor, and dabigatran, a direct thrombin inhibitor, have found teratogenic effects, reduced fetal viability, hemorrhagic changes, and placental abnormalities; thus, their use in pregnancy is not recommended.[99]

Antithrombotic Therapy and Anesthetic Implications

The greatest concern with neuraxial procedures in anticoagulated patients is spinal or epidural hematoma. A meta-analysis of the incidence of epidural hematoma in obstetric patients (8 studies, pooled n = 1.1 million) found an incidence of 1:183,000.[100] Notwithstanding the very low incidence, the consequences of a spinal-epidural hematoma can be devastating. The American Society of Regional Anesthesia and Pain Medicine (ASRA) guidelines include a summary of 16 cases of spinal hematoma after neuraxial anesthesia in obstetric patients; approximately half of the cases had some form of permanent motor or sensory dysfunction.[101]

A case report and literature review published in 2005 described six published cases of spontaneous epidural hematoma in pregnancy.[102] One proposed cause is that a pressure differential exists between the low-pressure epidural space and central venous pressure and that an increase in central venous pressure relative to the pressure in the epidural space leads to spontaneous rupture of the venous wall.[102] Case reports of spontaneous epidural hematoma in anticoagulated pregnant women, including patients with preeclampsia, have been reported.[103,104]

In 2010, ASRA published updated guidelines for regional anesthesia in patients receiving antithrombotic or thrombolytic therapy.[101] Among other topics, the updated guidelines address antithrombotic therapy during pregnancy. Owing to the relative paucity of outcome data in pregnant women, the ASRA suggests following the guidelines for surgical patients when developing clinical policy for obstetric patients with regard to initiation of neuraxial procedures and postpartum thromboprophylaxis (Table 39-4).[101] The ASRA guidelines do not make recommendations for patients receiving doses of more than 10,000 units of UFH daily or for patients

TABLE 39-4 Time Interval for Administration of Neuraxial Anesthesia after Anticoagulation

Therapy	American Society of Regional Anesthesia and Pain Medicine[101]	European Society of Anaesthesiology[105]
SC UFH, prophylactic	No delay*	4-6 h[†‡]
SC UFH, therapeutic	No recommendation*[‡]	8-12 h[‡§]
LMWH, prophylactic	10-12 h	12 h
LMWH, therapeutic	24 h	24 h

LMWH, low-molecular weight heparin; *SC,* subcutaneous; *UFH,* unfractionated heparin.
*No contraindication to neuraxial procedures with twice-daily dosing *and* total daily dose < 10,000 units.
[†]UFH ≤ 15,000 units/day.
[‡]Check platelet count if UFH therapy for more than 4 days (American Society of Regional Anesthesia and Pain Medicine) or more than 5 days (European Society of Anaesthesiology).
[§]Check activated partial thromboplastin time (aPTT) or activated clotting time (ACT) before initiation of neuraxial procedure.

receiving UFH more than twice daily. These guidelines differ somewhat from those of the European Society of Anaesthesiology.[101,105]

For patients being treated with UFH for more than 4 days, a platelet count should be assessed before initiation of neuraxial anesthesia procedures.[101] Measurement of aPTT is not necessary in patients receiving prophylactic UFH (≤ 5000 units twice a day) but may be indicated in patients receiving a large dose. Protamine reversal of UFH to facilitate more rapid administration of neuraxial anesthesia is not recommended. Further, protamine reversal of LMWH also is not recommended because it is unpredictable in reversing LMWH-induced anti–factor Xa activity.[101] If anticoagulant dosing is provided outside the ranges specifically addressed by the ASRA guidelines, individualized risk-benefit assessment is necessary to ascertain the best timing for initiation of neuraxial procedures. In some cases, confirmation of coagulation parameters (e.g., aPTT, anti–factor Xa level) within the normal range before initiation of neuraxial anesthesia may help to clarify the relative risk/benefit ratio for an individual patient.[101]

Other anticoagulant medications sometimes administered to pregnant women include aspirin, warfarin, and newer anticoagulant medications. In patients receiving warfarin therapy, the ASRA recommends discontinuing warfarin therapy for 4 to 5 days and waiting for normalization of the international normalized ratio (INR). Neuraxial catheters are *not* recommended in patients receiving fondaparinux, and neuraxial techniques are *not* recommended in patients anticoagulated with direct thrombin inhibitors. Treatment with thrombolytics is an absolute contraindication to neuraxial anesthesia.[101] By contrast, there is no contraindication to neuraxial anesthesia in patients who have received nonsteroidal anti-inflammatory drugs or aspirin if these drugs are used alone.[101]

If a patient is not a candidate for neuraxial anesthesia, noninvasive analgesic methods (e.g., intravenous opioids) should be offered for labor, and general anesthesia should be performed for operative procedures, including cesarean delivery.

The following anticoagulation strategies will help to facilitate safe and timely neuraxial analgesia/anesthesia for parturients[101]:

1. Women taking oral anticoagulants should transition to LMWH or UFH no later than 36 weeks' gestation.
2. LMWH should be discontinued 36 hours before planned delivery; the patient should be converted to UFH if necessary.
3. Intravenous UFH should be discontinued 4 to 6 hours before planned delivery.

Postpartum, prophylactic anticoagulation with LMWH or UFH can begin 12 hours after vaginal delivery or 2 hours* after neuraxial catheter removal, whichever occurs later. A 24-hour delay is required for the first dose of UFH or LMWH if (1) the patient underwent a cesarean delivery, (2) therapeutic dosing is required (regardless of the mode of delivery), or (3) blood was present during needle or catheter placement.[101] The ASRA postpartum dosing recommendations differ from the guidelines of the ACOG and other international guidelines, including those of the Royal College of Obstetricians and Gynaecologists.[84,106] Therefore, a multidisciplinary institutional review of anticoagulation policies is advisable.

Because of the risk for epidural hematoma—even in the absence of neuraxial procedures—anesthesiologists, obstetricians, and nursing staff must remain vigilant for signs and symptoms of epidural hematoma. These include (1) severe, unremitting backache; (2) neurologic deficit, including bowel or bladder dysfunction or radiculopathy; (3) tenderness over the spinous or paraspinous area; and (4) unexplained fever.[107] Suspicion of epidural hematoma should lead to immediate diagnostic imaging of the spinal cord and neurosurgical consultation for possible spinal cord decompression. Neurologic recovery is a function of the severity of preoperative deficits, the duration of maximum deficit, and the interval between symptom onset and surgery; better outcomes are associated with a shorter symptom onset-to-surgery interval.[108] A high index of suspicion is necessary because neurologic dysfunction may mimic local anesthetic-induced effects.[109]

Risks of general anesthesia in the anticoagulated patient include airway bleeding. Laryngoscopy and tracheal intubation should be as atraumatic as possible. The anesthesia provider should be aware that placement of nasopharyngeal and oropharyngeal airways, gastric tubes, and other devices (e.g., temperature probes, stethoscopes)

*The U.S. Food and Drug Administration recommends waiting at least 4 hours after removal of a neuraxial catheter before administering a postprocedure dose of LMWH. (U.S. Food and Drug Administration. Low molecular weight heparins: drug safety communication—recommendations to decrease risk of spinal column bleeding and paralysis. November 6, 2013. Available at http://www.fda.gov/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm373918.htm. Accessed November 2013.)

carries the tangible risk for traumatic hemorrhage. Emergency surgery may necessitate the administration of protamine or the transfusion of blood products (e.g., plasma, platelets) to reverse anticoagulation and reduce the risk for hemorrhage during and after surgery.

Prevention of Thromboembolic Events

Given the morbidity and mortality associated with thromboembolic events, there is great interest in identifying and implementing strategies to reduce their occurrence. Several risk-stratification strategies have been proposed to prevent thromboembolic events, although these are based on expert opinion.[74,106,110] A meta-analysis published in 2010 found that there was insufficient evidence on which to base recommendations for thromboprophylaxis in pregnancy and the postpartum period.[111] The American College of Chest Physicians recommends the following for postcesarean delivery thromboprophylaxis based on the risk factors outlined in Box 39-4[74]:

- For patients without any risk factors for VTE, no thrombosis prophylaxis other than early mobilization should be used.
- For women at increased risk for VTE because of the presence of one major or at least two minor risk factors, pharmacologic thromboprophylaxis with prophylactic LMWH should be used; mechanical prophylaxis should be initiated in women with contraindications to anticoagulants.
- For women at very high risk for VTE who have multiple additional risk factors for VTE in the puerperium, prophylactic LMWH should be combined with elastic stockings and/or intermittent pneumatic compression over LMWH alone.
- For women in whom significant risk factors persist after delivery, extended prophylaxis (up to 6 weeks postpartum) is recommended.

One decision-analysis study modeled the safety and efficacy of thromboprophylaxis with intermittent pneumatic compression stockings at cesarean delivery compared with universal subcutaneous heparin prophylaxis. The use of the pneumatic compression stockings was the preferred strategy because universal heparin prophylaxis would be associated with 13 cases of heparin-induced thrombocytopenia or hemorrhage for each VTE prevented.[112] The reduction in VTE risk was similar between pneumatic compression stockings and universal heparin use.[112] Casele and Grobman[113] found intermittent pneumatic compression stockings to be cost-effective when compared with no thromboprophylaxis after cesarean delivery. Regardless of whether thromboprophylaxis is initiated in the hospital or not, women are at the highest risk for thrombotic events in the first week postpartum.[68] Therefore, careful postdischarge planning and evaluation of VTE risk are equally important to inpatient management.

VENOUS AIR EMBOLISM

Venous air embolism (VAE) is a recognized complication of many surgical procedures.[114] The first study of VAE during cesarean delivery was published in 1987.[115] Subsequent research has revealed that VAE is a common occurrence during cesarean delivery. Most air emboli are small, but volumes greater than 200 to 300 mL, or 3 to 5 mL/kg, may be lethal.[114] Early recognition and appropriate management are necessary for avoiding adverse outcomes.

TABLE 39-5 Methods to Detect Venous Air Embolism

Method of Detection	Sensitivity	Volume of Air Detected (mL/kg)
Transesophageal echocardiography	High	0.02
Precordial Doppler	High	0.05
Pulmonary artery catheter	High	0.25
Expired CO_2	Moderate	0.5
Expired nitrogen	Moderate	0.5

Modified from Mirski MA, Lele AV, Fitzsimmons L, Toung TJK. Diagnosis and treatment of vascular air embolism. Anesthesiology 2007; 106:164-77.

Incidence

The reported incidence of VAE during cesarean delivery varies depending on the method used to ascertain the presence of air (Table 39-5). The most sensitive monitors detect volumes of air as low as 0.02 mL/kg.[114] Studies that have used precordial Doppler monitoring in patients undergoing cesarean delivery with neuraxial anesthesia have found incidence rates ranging from 10% to 65%.[115-119] One study used precordial Doppler monitoring to detect VAE and correlated the Doppler findings with transthoracic echocardiographic evidence of intracardiac air. Of the 42 patients who underwent cesarean delivery with neuraxial anesthesia, 11 (26%) had evidence of VAE, with perfect agreement between the Doppler and the echocardiographic monitoring (kappa = 1.0).[117] One study of healthy parturients undergoing elective cesarean delivery under general anesthesia found that 29 of 30 parturients had evidence of intraoperative VAE.[120] The authors defined VAE as a 0.1% increase from the baseline of expired nitrogen concentration (equivalent to 0.25 to 1.0 mL/kg venous air).[120] Although the volume of entrained air may be lower with general anesthesia using positive-pressure ventilation than spontaneous ventilation,[121] the use of prophylactic positive end-expiratory pressure has not been shown to decrease the incidence of VAE in a neurosurgical population.[122]

The incidence of VAE does not appear to vary with maternal position. The Trendelenburg position could produce a pressure gradient between the right side of the heart and open venous sinuses in the surgical field. A meta-analysis of two randomized controlled trials, which compared 5 to 10 degrees reverse Trendelenburg position with supine positioning for cesarean delivery (pooled n = 130) found no difference in the incidence of air embolism (RR, 0.95; 95% CI, 0.65 to 1.26).[123]

The majority of VAE episodes are subclinical. The true incidence of fatal VAE in the obstetric population is

unknown. One estimate using data on maternal deaths from the National Center for Health Statistics from 1974 to 1978 found that 25 of 2475 deaths were attributable to air embolism.[124] More recent published estimates in the United States have not reported VAE as a cause of maternal death.[1] In the most CMACE report from the United Kingdom, only 1 of 261 deaths was attributed to VAE.[69] This death occurred during intercourse 2 weeks postpartum.[69] This case highlights that VAE may occur in the nonoperative setting. Venous air embolism has been reported during pregnancy during vaginal examinations and during orogenital sex.[125,126]

Pathophysiology

A pressure gradient as small as −5 cm H_2O between the surgical field and the heart allows a significant amount of air to be entrained into the venous circulation. Immediately after placental separation, the raw endometrial surface appears to be a location of significant air entrainment; almost all episodes of VAE during cesarean delivery are noted after the delivery of the placenta.[118] In the noncesarean delivery setting, pressurized air in the vagina is believed to traverse the cervical canal, dissect around fetal membranes (if present), and enter the maternal circulation via subplacental sinuses.[127]

Small volumes of air can precipitate pulmonary vasospasm via a pathophysiology that mimics that of other embolic phenomena. Vasoactive mediators or mechanical obstruction of small vessels appear to induce pulmonary vasoconstriction that leads to $\dot{V}/\dot{Q}$ mismatch, hypoxemia, right-sided heart failure, arrhythmias, and hypotension. Fluid resuscitation and increased hydrostatic pressure may provoke interstitial pulmonary edema. A paradoxical air embolus into the arterial circulation (by means of a patent foramen ovale) can lead to cardiovascular and neurologic sequelae and morbidity. Large volumes of air (> 3 mL/kg) can generate cardiovascular collapse by creating an "air lock" that causes right ventricular outflow tract obstruction.

Clinical Presentation

Most air emboli are subclinical with no sequelae; however, massive VAE can manifest as a sudden, dramatic, and devastating event with hypotension, hypoxemia, and even cardiac arrest.[128] In awake patients receiving neuraxial anesthesia, transient episodes of hypoxemia, dyspnea, or chest pain during uterine repair suggest VAE.[115,116,118,119] In the patient receiving general anesthesia, evidence of VAE may be limited to hypoxemia and a slight decrease in end-tidal CO_2.[114] VAE may be more frequent when the uterus is exteriorized than when it is repaired within the abdomen, either owing to vertical elevation relative to the heart or traction on the uterus that opens venous sinuses.[118,119] Clinically significant air emboli may be associated with hypotension, heart rate or rhythm changes, evidence of right-sided heart strain on the electrocardiogram, an increase in central venous pressure, and/or an increase in pulmonary artery pressure. Electrocardiographic changes consistent with myocardial ischemia (e.g., ST-segment depression) are relatively common during cesarean delivery,[129,130] but the clinical significance of ST-segment depression and its relationship to VAE remain unclear.

A precordial stethoscope may detect a pathognomonic "millwheel murmur." Transesophageal echocardiography may detect air in the right atria or the pulmonary artery. However, several small case series failed to identify VAE using echocardiography at the time of ST-segment depression during cesarean delivery.[129] More recent evidence suggests that ST-segment depression in the immediate postdelivery period may be associated with rapid oxytocin administration.[131,132]

Management

The clinician should consider VAE in women who complain of intraoperative chest pain or dyspnea or experience sudden hypoxemia, hypotension, or arrhythmia during cesarean delivery. Although continuous precordial Doppler monitoring has been recommended by some experts,[114] the rarity of hemodynamically significant VAE suggests that targeted use in high-risk patients (e.g., women with a known intracardiac shunt) may be more appropriate than routine application. Transthoracic or transesophageal echocardiography may help to confirm a diagnosis of VAE, to exclude alternative causes of hemodynamic instability, and to guide appropriate clinical management. Regardless, clinical suspicion of VAE should prompt appropriate management (Box 39-5).

Currently, there are no data to support central line insertion for air aspiration from the right side of the heart, but central line placement may be indicated to deliver potent vasopressors.[114] Position changes to limit air entrainment are recommended. However, in a canine study of resuscitation positioning after a 2.5 mL/kg VAE,[133] repositioning animals to direct air to the dependent portion of the right side of the heart did not improve cardiac function or survival; thus, this maneuver is not

BOX 39-5 Resuscitation of the Obstetric Patient with Massive Venous Air Embolism

Air
- Prevent further air entrainment (e.g., flood the surgical field with saline solution, lower the surgical field relative to the heart if tolerated).

Airway
- Administer 100% oxygen; discontinue nitrous oxide; intubate the trachea and support ventilation as needed.

Cardiovascular Support
- Support circulation with chest compressions, intravascular volume expansion, and vasopressors as needed.

Fetus
- Expedite delivery.

Postresuscitation Care
- Evaluate for intracerebral air and consider hyperbaric oxygen therapy if indicated.

recommended. The use of the Valsalva maneuver and positive-end expiratory pressure should be avoided because an increase in right atrial pressure may result in a paradoxical embolism. In patients with delayed emergence from anesthesia, computed tomography or magnetic resonance imaging may be considered to evaluate for intracerebral air. Hyperbaric oxygen may improve neurologic outcomes if instituted within 6 hours of intracerebral air embolism.[134]

KEY POINTS

- Embolic disorders are a major cause of maternal morbidity and mortality.
- Early recognition, diagnosis, and therapy may reduce the incidence of morbidity and mortality associated with embolic disorders.
- Amniotic fluid embolism is a diagnosis of exclusion. It may occur at any time during labor or delivery, as well as antepartum or postpartum.
- During pulmonary embolic phenomena, hemostatic and immunologic mediators may trigger a cascade of physiologic derangements disproportionate to the cross-sectional area of occluded lung tissue.
- Pregnant patients are at fivefold higher risk than nonpregnant patients for pulmonary thromboembolism. The third trimester and first postpartum week are the periods of highest risk.
- Several prophylactic and therapeutic anticoagulation regimens exist for patients with venous thromboembolism or those at increased risk for thromboembolism; anesthesia providers should be aware of the safety implications of anticoagulation therapy on the timing of initiation of neuraxial anesthesia and neuraxial catheter removal.
- Venous air embolism is a common occurrence during cesarean delivery. Most of the emboli are small, transient, and benign. Massive venous air embolism is rare during vaginal or cesarean delivery but can be fatal.

CHAPTER 40

Maternal Mortality

Jill M. Mhyre, MD

CHAPTER OUTLINE

GLOBAL MATERNAL MORTALITY

Globally in 2010, 287,000 women died while pregnant or within 42 days of the end of pregnancy.[1] This number corresponds to a ratio of 210 maternal deaths per 100,000 live births and to a 1-in-180 lifetime risk for maternal death for each girl entering her childbearing years (Table 40-1).[1] According to the World Health Organization (WHO), "No issue is more central to global well-being than maternal and perinatal health. Every individual, every family and every community is at some point intimately involved in pregnancy and the success of childbirth."[2]

Definitions for maternal death are listed in Table 40-2, and measures of maternal mortality are listed in Table 40-3. More than 99% of maternal deaths occur in developing countries, with 85% in either sub-Saharan Africa or South Asia (see Table 40-1). As part of the Millennium Development Goals,[1] the international community committed to reduce the **maternal mortality ratio (MMR)** by 75% between 1990 and 2015,[1] from 400 to less than 100 per 100,000 live births. Between 1990 and 2010, the global MMR fell by 47%, with the greatest reductions demonstrated in East Asia (69%), North Africa (66%), and South Asia (64%).[1] Although the MMR declined 41% in sub-Saharan Africa, the lifetime risk for maternal death remains unacceptably high, at 1 in 39.[1] There is considerable regional variation. Within sub-Saharan Africa, the highest MMRs are in Chad (1100) and Somalia (1000) and represent rates that are 10-fold higher than the lowest ratios in the region.[1]

Leading Causes

Hemorrhage, hypertensive disorders of pregnancy, and **sepsis** account for more than half of global maternal deaths and for slightly more than a third of deaths in the developed world.[3] Hemorrhage is the leading cause of maternal death in both Africa and Asia (Table 40-4). Hypertensive disorders represent the leading cause in Latin America and the Caribbean.[3] Infection and sepsis may be substantially underestimated in regions where laboratory diagnostic tests are unavailable.[4] In one Malawi hospital with full laboratory capabilities, infection played a primary role in almost three fourths of all maternal deaths.[5]

Anemia and **obstructed labor** each cause approximately one tenth of maternal deaths in Asia.[3] Anemia is associated with (1) iron and other micronutrient deficiencies, (2) pregnancy intervals of less than 1 year, (3) adolescent pregnancy, (4) hemoglobinopathy, (5) urinary tract infection, (6) human immunodeficiency virus (HIV) infection, (7) parasitic infections including malaria, and (8) recurrent antepartum hemorrhage.[6-8] Anemia can cause lethal congestive heart failure in pregnancy[7] and also increases the risk for maternal death from other complications, particularly hemorrhage and infection.[6]

Obstructed labor is an important cause of maternal death in communities in which early adolescent pregnancy is common, childhood malnutrition leads to small maternal pelves, and operative delivery is unavailable.[9] Maternal mortality from obstructed labor is largely the result of uterine rupture or ascending genital tract infection.[9,10] Prolonged pressure on the pelvic outlet can lead to tissue necrosis and obstetric fistula, which is thought to affect between 2 and 3.5 million women worldwide.[11,12]

HIV/acquired immune deficiency syndrome (AIDS) increases vulnerability to both nonobstetric infection (e.g., tuberculosis, malaria) and obstetric complications (e.g., hemorrhage, pregnancy-related sepsis, septic abortion).[13,14] The WHO attributed 6.5% of

TABLE 40-1 Estimates of Maternal Mortality Ratio (MMR), Number of Maternal Deaths, and Lifetime Risk by United Nations Millennium Development Goal Regions, 2010

Region	MMR[a]	Range of MMR Uncertainty		No. of Maternal Deaths[a]	Lifetime Risk for Maternal Death,[a] 1 in:

Reproduced from World Health Organization. Trends in Maternal Mortality 1990-2010: Estimates Developed by WHO, UNICEF, and UNFPA. Geneva, Department of Reproductive Health and Research, 2012.

maternal deaths in 2010 to HIV/AIDS.[1] In contrast, the Institute of Health Metrics and Evaluation estimated that one in five maternal deaths in 2011 would not have occurred in the absence of the HIV epidemic, based on statistical models that account for the prevalence of HIV within a population.[15,16] In countries most severely affected, including Botswana, Malawi, Namibia, South Africa, Swaziland, and Zimbabwe, MMRs increased between 1990 and 2000, but they have since begun to decline as antiretroviral therapy becomes increasingly available.[1,15,16]

Maternal deaths attributed to **unsafe abortion** account for 13% of maternal deaths worldwide (47,000 in 2008).[17] The WHO defines *unsafe abortion* as "a procedure for terminating an unintended pregnancy either by individuals without the necessary skills or in an environment that does not conform to minimum medical standards, or both."[17,18] Worldwide, 49% of abortions were unsafe in 2008, compared with 44% in 1995.[19] The case-fatality rate (460 maternal deaths per 100,000 unsafe abortions) and the absolute number of maternal deaths per year (28,500) are highest in sub-Saharan Africa.[17,20]

Early marriage (before age 18 years) has been identified as a major health risk for girls, increasing their exposure to domestic violence, coercion, pregnancy, and sexually transmitted diseases such as HIV/AIDS.[21-23] Girls younger than 15 years are five times more likely to die in childbirth than women in their 20s,[24] and pregnancy is among the leading causes of death worldwide for girls ages 15 to 19.[25] Early childbearing also increases the likelihood of **high parity birth** (≥ 5) later in life. With a threefold increase in the MMR, high parity is the most important demographic risk for maternal death because it remains so common, accounting for 29% of births globally between 1990 and 2005.[26] **Advanced maternal age** is less common globally but increases individual risk

TABLE 40-2 Glossary of Terms Used in Discussions of Maternal Mortality

Source	Term	Definition*
World Health Organization	Maternal death	Death of women while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management but not from accidental or incidental causes. ICD-10 A34, O00-O95, O98-O99[1]
	Direct maternal death	Death resulting from obstetric complications of the pregnant state (pregnancy, labor, and the puerperium), from interventions, omissions, incorrect treatment, or from a chain of events resulting from any of the above. A34, O00-O95[1]
	Indirect maternal death	Deaths resulting from previous existing disease or disease that developed during pregnancy and which was not due to direct obstetric causes but was aggravated by physiologic effects of pregnancy. O98-O99[1]
	Late maternal death	The death of a woman from direct or indirect obstetric causes more than 42 days but less than 1 year after termination of pregnancy. O96-O97[1]
	Pregnancy-related death	Deaths occurring in women while pregnant or within 42 days of termination of pregnancy, irrespective of the cause of death.
U.S. Centers for Disease Control and Prevention, Pregnancy Mortality Surveillance System[2]	Pregnancy-associated death	Death of a woman while pregnant or within 1 year of termination of pregnancy, irrespective of cause.
	Pregnancy-related death	Death of a woman while pregnant or within 1 year of termination of pregnancy, irrespective of the duration and site of the pregnancy, from any cause related to or aggravated by her pregnancy or its management, but not from accidental or incidental causes.
	Non–pregnancy-related death	Death of a woman while pregnant or within 1 year of termination of pregnancy, due to a cause unrelated to pregnancy.

*Numbers after some definitions indicate cause of death codes.

for maternal death as much as fourfold for women aged 35 years or older and as much as eightfold after age 40.[27]

Anesthesia providers working in the developing world must contend with profound limitations in staffing, equipment, and other resources.[14,28-33] In addition, patients who labor at home may face a variety of social and environmental obstacles to reach a facility with the capacity to provide comprehensive emergency obstetric care,[34-36] and many arrive at these facilities in septic or hemorrhagic shock.[37,38] Cesarean delivery is the most common major surgical procedure in Africa,[39] and perioperative maternal mortality is estimated to be between 1.2% and 2%.[40-42] As many as one third of deaths that occur within 24 hours of surgery have been attributed to anesthesia, mainly because of airway problems with general anesthesia or hemodynamic collapse with neuraxial anesthesia.[14,28,29,43] Peripartum deaths have also been attributed to limited availability or affordability of blood products.[32,40,43,44] The number of maternal perioperative deaths likely pales in comparison with maternal deaths that result from the unmet need for lifesaving obstetric procedures, including cesarean delivery.[45]

Strategies to reduce global maternal mortality include (1) improvement in family planning services and a reduction in the performance of unsafe abortion[46,47]; (2) community-based education focused on safe birth practices and indications for transfer to a higher level of care[48-51]; and (3) development of the infrastructure needed to provide timely emergency obstetric care, including the performance of indicated cesarean delivery (and safe administration of anesthesia) by trained care providers, who can also provide resuscitation of women in whom shock develops secondary to hemorrhage or infection.[52-57] Limited human, political, and economic capital mandate ongoing rigorous evaluation of the effectiveness of future programmatic efforts.[58,59] Cluster randomized trials to evaluate these strategies are beginning to appear[48,49,51] and suggest that certain interventions succeed only when deployed as part of an integrated, context-specific and culturally sensitive program.[55] For example, training traditional birth attendants to identify and manage complications may only improve maternal and perinatal outcomes if accompanied by ongoing training, resource support, and effective referral pathways to emergency obstetric care.[60]

MATERNAL MORTALITY IN THE DEVELOPED WORLD

In developed regions of the world, the reported MMR has traditionally fluctuated around 10 per 100,000 live births.[61] As of 2010, the WHO has reported an MMR of 16 (95% confidence interval [CI], 14 to 18). This apparent increase reflects increases documented primarily in the United States, as well as expansion of the developed world to include Cyprus, Israel, the Republic of Moldova, Belarus, the Russian Federation, and Ukraine.[1]

The most comprehensive maternal surveillance system in the world is the **Confidential Enquiry into Maternal Deaths (CEMD)** in the United Kingdom.* Triennial reports of CEMD in England and Wales extend back to 1952 and have covered the entire United Kingdom since the 1985 to 1987 report. By government mandate, all maternal deaths are subject to this enquiry, and health professionals have a duty to provide all requested information.[62,63] Once a case is identified, practitioners are asked to provide (1) a full account of the circumstances leading up to the woman's death, (2) all supporting records, (3) any clinical or other lessons that have been learned, and (4) details of any actions that may have been taken as a result.[62,63] Regional assessors review the files to ensure completeness before removing identifying information. Central assessors compile the cases and produce the triennial reports. The reports focus on both medical and nonmedical recommendations for action to improve safety for future pregnant women.

The CEMD reports include both the internationally defined MMR and the U.K.-defined maternal mortality rate (see Table 40-3). The numerator for the U.K.-defined maternal mortality rate includes all deaths that in the opinion of the central assessors are related to pregnancy, including some causes that are not internationally coded as maternity related (e.g., suicide attributed to postpartum depression). The denominator includes all pregnancies that resulted in a live birth or stillbirth after 20 weeks' gestation. The international MMR is calculated strictly from data coded on death certificates; the U.K. maternal mortality rate includes all deaths identified through active surveillance. As a result, the 2006 to 2008 internationally defined MMR for the United Kingdom (6.69 per 100,000 live births) is significantly lower than the 2006 through 2008 maternal mortality rate (11.39 per 100,000 maternities).[63,64]

National confidential enquiry reports are now published by many other countries, including Australia,[65] France,[66] the Netherlands,[67] New Zealand,[68] and South Africa.[14]

In the United States, the **National Center for Health Statistics (NCHS)** has provided maternal death counts since 1900 and MMRs since 1915.[69] Accuracy is limited because (1) the system relies on death certificates rather than active surveillance, (2) the certification of death is the legal responsibility of individual states, and (3) the process of maternal death ascertainment varies by state.

The U.S. MMR reported by the NCHS declined from more than 600 deaths per 100,000 live births in 1915 to fewer than 10 deaths per 100,000 live births by 1980 (Figure 40-1).[69] Throughout the 1980s and 1990s, the MMR oscillated between 6.6 and 9.2. Then in 1999, the MMR began to increase, reaching 16.6 in 2009 (Figure 40-2).[70] Improvements in ascertainment explain

*The Confidential Enquiries into Maternal Death have been overseen by a series of organizations in recent years, including The Confidential Enquiry in Maternal and Child Health (CEMACH), the Center for Maternal and Child Enquiries (CMACE), and, most recently, Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the United Kingdom (MBRRACE-UK), led by the National Perinatal Epidemiology Unit (NPEU) at the University of Oxford. Future reports are planned on an annual basis starting in 2014.

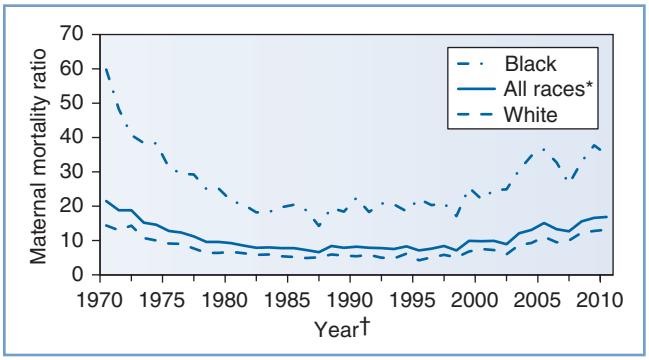

FIGURE 40-2 ■ U.S. maternal mortality ratios by race, 1970 to 2010.[69,70,155-158] *Includes races other than white and black. †Beginning in 1989, race for live births tabulated according to race of mother, not child.

BOX 40-1 Pregnancy Questions, U.S. Standard Certificate of Death, 2003 Revision

If female:
- Not pregnant within the past year
- Pregnant at the time of death
- Not pregnant, but pregnant within 42 days of death
- Not pregnant, but pregnant 42 days to 1 year before death
- Unknown if pregnant within the past year

Reprinted from National Center for Health Statistics. United States Standard Certificate of Death—Rev. 11/2003. Available at www.cdc.gov/nchs/data/dvs/DEATH11-03final-acc.pdf. Accessed June 2012.[159]

some of the increase. In 1999, the *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* (ICD-10) replaced the ICD-9 as the coding system for U.S. death certificates and liberalized the criteria by which pregnancy could be linked with death. Growing numbers of states perform electronic matches among women's death certificates, live birth certificates, and fetal death files. In addition, increasing numbers of states have adopted the 2003 revision of the U.S. Standard Certificate of Death, which introduced questions about pregnancy status at the time of death (Box 40-1). By 2005, 19 states had adopted the standard pregnancy questions; the MMR calculated from vital records in these states was 17.3, compared with 10.7 from states without any questions about pregnancy on the state death certificate.[71]

In 1987, the Centers for Disease Control and Prevention (CDC) partnered with state health departments and the American College of Obstetricians and Gynecologists (ACOG) to form the **Pregnancy Mortality Surveillance System (PMSS).**[72] To capture maternal deaths more completely, the PMSS recommended that states develop an active surveillance system and collect death certificates and matching live birth or fetal death certificates for all pregnancy-associated deaths (defined in Table 40-2). These certificates are forwarded to the CDC, where clinically experienced epidemiologists manually review the certificates to identify all pregnancy-related deaths (defined in Table 40-2). Similar surveillance enhancement procedures have been estimated to improve case ascertainment by between 22% and 93%.[73] The pregnancy-related mortality ratio (PRMR) includes deaths that took place up to a year after the end of pregnancy and, according to the PMSS, increased from 10.3 in 1991 to 16.8 in 2003 before returning to 15.4 in 2005.[74,75] Documentation of pregnancy on the death certificate increases ascertainment further. In 2005, among the 19 states with death certificates that include the standard pregnancy questions, the combination of data from the NCHS and the PMSS suggests an MMR of 19.7 and a PRMR of 22.3.[71]

Leading Causes

According to a 2006 systematic review of data from Europe, North America, Australia, New Zealand, and Japan, **hypertensive disorders of pregnancy, embolic disorders,** and **hemorrhage** together account for slightly less than half of maternal deaths in the developed world (see Table 40-4).[3] **Indirect deaths** account for another 14%.[3]

Indirect deaths have exceeded direct deaths in the United Kingdom since 1997, with cardiac disease being the most common category of death. Similar patterns are seen in the United States, where the combination of cardiovascular conditions and cardiomyopathy comprised 23% of all pregnancy-related deaths between 1998 and 2005 and cerebrovascular accidents and noncardiovascular medical conditions represented another 20%.[75] Cause-specific mortality ratios are shown in Table 40-e1 (available online at expertconsult.com). Cardiomyopathy, including both peripartum and other types of cardiomyopathy, is the leading diagnosis underlying maternal cardiac death in both the United States and the United Kingdom.[63,75]

Venous thromboembolism was the leading direct cause of maternal death in the United Kingdom for many years (see online Table 40-e1), but a national campaign to improve venous thromboembolism prophylaxis heralded a 60% reduction in the cause-specific mortality ratio to 0.79 per 100,000 in the 2006 to 2008 CEMD report.[63,76,77]

During this period, **sepsis** due to **genital tract infection** emerged as the leading cause of direct obstetric death in the United Kingdom and was largely attributed to community-acquired group A streptococcal disease.[63,64] Current recommendations focus on early warning scoring systems to identify vital sign derangements that could indicate systemic infection, standardized management according to the *Surviving Sepsis Campaign*, and early involvement of anesthesiologists and intensivists.[63,78] More detail is provided in Chapters 37 and 55.

In the United States between 1998 and 2005, seven conditions each accounted for 10% to 13% of all pregnancy-related deaths, including hemorrhage, hypertensive disorders of pregnancy, sepsis, thrombotic pulmonary embolism, cardiomyopathy, other cardiovascular disorders, and noncardiovascular medical disorders (see online Table 40-e1).[75]

Injury-related deaths are considered pregnancy-associated but not pregnancy-related; they are discussed in Chapter 55.

Risk Factors

Detailed descriptions of hypertensive disorders of pregnancy, obstetric sepsis, maternal hemorrhage, embolic disorders, and cardiovascular diseases in pregnancy are provided in Chapters 36, 37, 38, 39, and 42, respectively. Common clinical and sociodemographic factors that increase the risk for maternal death from all of these complications are discussed in this chapter (see later discussion).

Advanced maternal age increases maternal risk,[79] with a linear trend evident for each 5-year increase in maternal age beyond 34 years.[63] In the United States between 1998 and 2005, the PRMR among women 40 years of age and older was 166.9 for black women (compared with 24.8 for black women 20 to 24 years of age) and 40.0 for white women (compared with 7.5 for white women 20 to 24 years of age).[75] Based on data from the PMSS for the years 1991 through 1999, the association between age and mortality persisted after data were controlled for parity, prenatal care, race, and education.[79] Among older black women (≥ 40 years), the excess risks were greatest for hypertensive disorders of pregnancy, infection, cerebrovascular accident, and other medical conditions. Among older white women, the greatest excess risks for death were due to hemorrhage, cardiomyopathy, embolic disorders, and other medical conditions.[79]

In the United States, **black or African-American race** significantly correlates with the risk for death. Non-Hispanic black women experience a PRMR that is 3.5-fold higher than non-Hispanic white women. Based on death certificate data (1999 to 2009), disparities are most dramatic for deaths associated with ectopic pregnancy (black-to-white ratio of 4.8), cardiomyopathy (4.2), and deaths from complications of anesthesia (2.9).[70] In a case series of anesthesia-related maternal deaths in Michigan published in 2007, six of eight deaths occurred among non-Hispanic black women in Detroit, suggesting a profound concentration of maternal risk.[80] The disparity in maternal mortality between black and white women persists after data are controlled for maternal age, income, and receipt of prenatal care[81] and appears to be related to a higher case-fatality rate.[82]

Other racial and ethnic groups also experience increased risk.[63] In the United States between 1999 and 2009, in comparison with non-Hispanic white women, the MMR was 80% higher for American Indian or Alaska Native women.[70] In England, black African, black Caribbean, Indian, Pakistani, and Chinese women have higher relative risks of death than white women.[63,83]

Immigrants, asylum seekers, and non-native speakers appear to be particularly vulnerable to both maternal death and substandard care, based on data from the United Kingdom and the Netherlands.[63,67,83,84] In the United States, Hispanic and Asian/Pacific Islander immigrants face increased risk compared with women of these same racial/ethnic groups born in the United States.[85] Significant regional variation has been identified in France, with increased risk noted for women delivering in Paris (adjusted odds ratio [AOR], 1.6; 95% CI, 1.2 to 2.0) and the overseas districts (AOR, 3.5; 95% CI, 2.4 to 5.0) compared with continental France.[86] Differences in behavior, biology, environmental conditions, social circumstances, and the quality of clinical care may contribute to disparities in outcomes for sociodemographically vulnerable populations.[63,86,87]

Maternal obesity increases the risk for maternal death from a variety of causes, including pulmonary embolism, infection, preeclampsia, and anesthesia-related complications. Remarkably, there are limited epidemiologic data to establish this connection. Obesity is a common feature in case series of maternal deaths. In the 2006 to 2008 CEMD report from the United Kingdom, 49% of women who died were overweight or obese.[63] Among the subset of women experiencing severe obstetric complications (including eclampsia, pulmonary embolism, amniotic fluid embolism, acute fatty liver of pregnancy, and antenatal stroke), obesity (body mass index ≥ 30 kg/m^2) was associated with maternal death [AOR, 5.26; 95% CI, 1.15 to 6.46].[83]

Multifetal pregnancies increase maternal risk for a variety of complications, including preeclampsia, venous thromboembolism, heart failure, myocardial infarction, peripartum hemorrhage, and maternal death.[63,88-91] Compared with twin pregnancies, triplet and higher-order multiple pregnancies further increase maternal risk for preeclampsia, hemorrhage, and emergency peripartum hysterectomy.[89,90] In the United States between 1979 and 2000, the relative risk of death associated with a multifetal pregnancy was 3.6 (95% CI, 3.1 to 4.1) with threefold to fourfold increases in the cause-specific relative risk of death for embolism, hemorrhage, hypertensive disorders of pregnancy, infection, cardiomyopathy, and other medical conditions.[91]

Cesarean delivery has also been associated with an increased risk for maternal death; however, the association does not always reflect a causal relationship. Death can be a consequence of the indication for the operation rather than the mode of delivery itself. In an attempt to estimate the relative risk of death due to cesarean delivery, a population-based case-control study from France

focused on 65 maternal deaths after singleton births among low-risk women in whom complications developed only after delivery.[92] Cases were identified by the French National Confidential Enquiry on Maternal Deaths from 1996 through 2000.[92] These cases were compared with 10,244 singleton births to low-risk women identified through the French National Perinatal Survey conducted in 1998. After data were controlled for maternal age, nationality, parity, and preterm delivery, the AOR for increased risk for death with cesarean delivery was 3.64 (95% CI, 2.15 to 6.19). The increased risk was most dramatic for intrapartum cesarean deliveries (AOR, 4.58; 95% CI, 2.30 to 9.09) but persisted when cesarean delivery preceded labor (AOR, 2.42; 95% CI, 1.14 to 5.13).[92] Among women who underwent cesarean delivery, there was an increased risk for cause-specific maternal mortality from venous thromboembolism, puerperal infection, and complications of anesthesia. There was no difference in risk for death from postpartum hemorrhage or amniotic fluid embolism.

A cohort study of deliveries in Canada between 1991 and 2005 compared 46,766 planned cesarean deliveries for breech presentation with 2,292,420 planned vaginal deliveries in which labor was either spontaneous or induced.[93] Planned cesarean delivery increased the risk for postpartum cardiac arrest (AOR, 5.1; 95% CI, 4.1 to 6.3), major puerperal infection (AOR, 3.0; 95% CI, 2.7 to 3.4), anesthetic complications (AOR, 2.3; 95% CI, 2.0 to 2.6), and puerperal venous thromboembolism (AOR, 2.2; 95% CI, 1.5 to 3.4), but did not increase the risk for in-hospital maternal death ($P = .87$).[93]

A medical record review of all in-hospital maternal deaths that occurred in a sample of U.S. hospitals between 2000 and 2006 sought to identify evidence for a causal connection between mode of delivery and the mechanism of maternal death.[94] Among 1,461,270 live births, there were 95 maternal deaths (6.5 per 100,000). Although 61% of the deaths were associated with cesarean delivery, one third of these were perimortem cesarean deliveries in which the surgical procedure followed maternal cardiac arrest. Four deaths were thought to have been directly caused by cesarean delivery (attributed to hemorrhage or infection), with an additional seven deaths attributed to pulmonary thromboembolism after cesarean delivery. Two deaths were thought to have been causally related to vaginal delivery (one case of uterine inversion and one case of rupture of an unrecognized cerebral berry aneurysm during labor), and two deaths were attributed to pulmonary thromboembolism after vaginal delivery. Another 16 deaths were thought to have been potentially preventable had a cesarean delivery or an earlier cesarean delivery been performed (12 due to preeclampsia, 3 due to hemorrhage, and 1 due to sepsis).[94] The investigators concluded that a policy of universal thromboprophylaxis for all patients undergoing cesarean delivery would eliminate the increased risk for maternal death caused by cesarean delivery as opposed to vaginal delivery.[94]

Regardless of mode of delivery, risk appears to be particularly concentrated in women with preexisting medical conditions; pulmonary hypertension, malignancy, systemic lupus erythematosus, sickle cell disease, and major cardiovascular and renal disease all confer substantially increased risk for maternal death or end-organ injury.[95,96] Given the preponderance of indirect deaths documented in recent CEMD reports, central assessors have repeatedly recommended both preconception counseling and intensive multidisciplinary antepartum and intrapartum care for women with serious medical or mental health conditions that may be aggravated by pregnancy.[62,63] These conditions include congenital or acquired cardiac disease, obesity with a body mass index of 30 kg/m^2 or higher, epilepsy, diabetes, asthma, autoimmune disorders, renal or liver disease, HIV infection, and a personal or family history of severe mental illness.[62,63] The Joint Commission has advanced a similar proposal in the United States.[97]

Some **health system characteristics** have been associated with a higher risk for maternal death; they include (1) low maternal-fetal medicine specialist density[98] and (2) a single physician functioning as both the obstetrician and the anesthesia provider.[99]

Severe and Near-Miss Morbidity

Death is considered the extreme outcome of the following continuum of adverse pregnancy events: normal pregnancy → morbidity → severe morbidity → near-miss → death.[100] Approximately half of women experience some **morbidity** during pregnancy, most commonly anemia, urinary tract infection, mental health conditions, hypertensive disorders, and pelvic or perineal trauma.[101] Research has focused on severe morbidity, near-miss events, and maternal deaths to elucidate the patient, provider, and health system factors that lead to these adverse outcomes.

Severe maternal morbidity includes those complications that have the potential to evolve toward end-organ injury or maternal death; its estimated incidence depends on the health system evaluated, the method of ascertainment, and the definition of severe morbidity used.[102-105] Waterstone et al.[102] evaluated pregnancies in France between 1997 and 1998 for the presence of severe preeclampsia, severe hemorrhage, or sepsis; the combined incidence for these three conditions was 12.0 per 1000 deliveries (95% CI, 11.2 to 13.2). Zhang et al.[103] applied the same criteria across Western Europe and identified a combined European incidence for these three conditions of 9.5 per 1000 deliveries (95% CI, 9.1 to 9.9). Analyses of administrative codes (ICD-9 or ICD-10) for conditions that indicate severe obstetric morbidity in population-level data suggest rates of 8.1 per 1000 hospitalizations in the United States from 2004 to 2005, 13.8 per 1000 in Canada from 2003 to 2007, and 13.8 per 1000 deliveries in Australia in 2004.[106-109]

Near-miss morbidity occurs when a woman survives a life-threatening complication that occurred during pregnancy, childbirth, or within 42 days of termination of pregnancy.[110] The concept of a near-miss event evolved from early studies of pregnant patients who required intensive care.[111-113] Mantel et al.[114] proposed a definition that requires evidence of severe organ dysfunction,

intensive care unit admission, emergency hysterectomy, or an anesthetic accident such as failed intubation. On the basis of these criteria, a meta-analysis of 11 studies suggests a ratio of 4.2 near-misses per 1000 deliveries (95% CI, 4.0 to 4.4).[115] Geller et al.[116] validated a five-factor scoring system consisting of organ system failure (5 points), intensive care unit admission (4 points), transfusion of more than 3 units of blood products (3 points), extended intubation (2 points), and surgical intervention (1 point); a total score higher than 7 points defines a near-miss event. According to this scoring system, the incidence of a near-miss event was approximately 0.2 per 1000 deliveries in a perinatal tertiary care center in Chicago between 1995 and 2001.[116]

Maternal near-miss morbidity has also been defined using administrative data by combining ICD-9 codes for diagnoses indicating end-organ injury with either a prolonged length of stay (> 99th percentile) or transfer to a second health care facility.[95] Based on this administrative data definition, the incidence of near-miss maternal morbidity or maternal death in the United States between 2003 and 2006 was 1.3 per 1000 hospitalizations for delivery.[95]

The WHO Working Group on Maternal Mortality and Morbidity Classification determined that end-organ injury represents the most epidemiologically sound way to identify near-miss morbidity.[117] In 2009 the WHO proposed a panel of clinical, laboratory-based, or management-based criteria to identify maternal end-organ injury (see Box 40-e1 available at expertconsult.com).[110,118] Cecatti et al.[119] applied the WHO near-miss criteria to all ICU admissions in a tertiary care facility in Brazil between 2002 and 2007 and found a near-miss morbidity ratio of 14.7 events per 1000 live births, a MMR of 125 deaths per 100,000 live births, and a maternal near-miss-to-mortality ratio of 10.7:1.

Preventability has emerged as an important concept in maternal mortality and near-miss morbidity reviews because the opportunities for prevention identified from these reviews can be used to prioritize changes in clinical policy and health system improvements.[64,97,120] The Perinatal and Maternal Mortality Review Committee in New Zealand proposed a comprehensive list of contributory factors, including those attributed to the health care organization, personnel, technology and equipment, the environment and geography, and patient-level barriers to accessing or engaging with care.[68] Although contributory factors may be identified in the majority of maternal deaths, multiple reviews suggest that only 20% to 45% were likely preventable.[66,68,116,121,122] In a case-control study of maternal death, near-miss events, and severe morbidity, Geller et al.[122] identified a higher proportion of preventability among deaths and near-miss events compared with cases of severe morbidity (41% and 45% versus 17%) and suggested that provider-level improvements in medical care among women who develop severe morbidities represent the most frequent opportunities to prevent both near-miss events and maternal deaths. Across various reviews, the highest rates of preventability are noted among ethnic minorities[63,67] and among deaths attributed to hemorrhage, hypertensive disorders of pregnancy, and sepsis or infection.[63,123]

Anesthesia-Related Maternal Mortality

Anesthesia-related maternal mortality has been defined as "death attributable to anesthesia, either as the result of medications used, method chosen, or the technical maneuvers performed, whether iatrogenic in origin or resulting from an abnormal patient response."[124] A death may be considered anesthesia-related if it can be uniquely attributed to an anesthetic complication.[80] Actual case reports often include layers of comorbidities, anesthetic complications, and problems with nonanesthetic care; these cases may be considered anesthesia-related if optimal anesthetic care would likely have averted the death.[80] If optimal anesthetic care in combination with improvements in obstetric or medical management would likely have saved the woman's life, then the death may be considered anesthesia-contributing.[80] In some cases, the anesthetic complication is tragic but incidental (e.g., failed intubation during advanced cardiac life support for massive pulmonary embolism).

Anesthesia-related maternal death is extremely rare in the developed world. Table 40-5 shows recent MMRs attributed to anesthesia in the United States and the United Kingdom. Comparable ratios reported elsewhere in recent years include 1.4 per million live births in France for the years 2001 through 2006 and 1.0 per million in the Netherlands for the years 1993 through 2005.[66,67] Active surveillance in the United Kingdom may

TABLE 40-5 Anesthesia-Related Maternal Mortality Ratios in the United States and the United Kingdom, 1979-2008*

Triennium	United States (95% CI)	United Kingdom (95% CI)
1979-1981	4.3 (3.1-5.7)	8.7 (5.5-13.2)†
1982-1984	3.3 (2.3-4.5)	7.2 (4.3-11.4)†
1985-1987	2.3 (1.5-3.4)	2.6 (1.2-5.8)
1988-1990	1.7 (1.1-2.7)	1.7 (0.7-4.4)
1991-1993	1.4 (0.8-2.2)	3.5 (1.8-6.8)
1994-1996	1.1 (0.6-1.9)	0.5 (0.1-2.6)
1997-1999	1.2 (0.7-2.0)	1.4 (0.5-4.2)
2000-2002	1.0 (0.5-1.7)	3.0 (1.4-6.6)

2006-2008	Not available	3.1 (1.5-6.4)

CI, confidence interval.

*Reported rates refer to the risk for anesthesia-related death during pregnancy or up to 1 year after delivery per million live births in the United States or per million maternities in the United Kingdom.

†Rates for England and Wales only.

U.S. data from Hawkins JL, Chang J, Palmer SK, et al. Anesthesia-related maternal mortality in the United States: 1979-2002. Obstet Gynecol 2011; 117:69-74; U.K. data from Cantwell R, Clutton-Brock T, Cooper G, et al. Saving Mothers' Lives: Reviewing Maternal Deaths to Make Motherhood Safer: 2006-2008. The Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom. Br J Obstet Gynaecol 2011; 118(Suppl 1):1-203.

BOX 40-e1 The WHO Maternal Near-Miss Criteria

Clinical Criteria

- Acute cyanosis
- Gasping[a]
- Respiratory rate > 40 or < 6/min
- Shock[b]
- Oliguria nonresponsive to fluids or diuretics[c]
- Clotting failure[d]
- Loss of consciousness lasting ≥ 12 hours[e]
- Loss of consciousness *and* absence of pulse/heart beat
- Stroke[f]
- Uncontrollable fit/total paralysis[g]
- Jaundice in the presence of preeclampsia[h]

Laboratory-Based Criteria

- Oxygen saturation < 90% for ≥ 60 minutes
- Pa_{O_2}/F_{IO_2} < 200 mm Hg
- Creatinine ≥ 300 µmol/L or ≥ 3.5 mg/dL
- Bilirubin > 100 µmol/L or > 6.0 mg/dL
- pH < 7.1
- Lactate > 5
- Acute thrombocytopenia (< 50,000 platelets)
- Loss of consciousness *and* the presence of glucose and ketoacids in urine

Management-Based Criteria

- Hysterectomy after infection or hemorrhage
- Use of continuous vasoactive drugs[i]
- Transfusion of ≥ 5 units of red blood cells
- Intubation and ventilation for ≥ 60 minutes not related to anesthesia
- Dialysis for acute renal failure
- Cardiopulmonary resuscitation

[a] *Gasping* is a terminal respiratory pattern and the breath is convulsively and audibly caught.

[b] *Shock* is a persistent severe hypotension, defined as a systolic blood pressure < 90 mm Hg for ≥ 60 minutes with a pulse rate at least 120 despite aggressive fluid replacement (> 2 L).

[c] *Oliguria* is defined as a urinary output < 30 mL/h for 4 h or < 400 mL/24 h.

[d] *Clotting failure* can be assessed by the bedside clotting test or absence of clotting from the IV site after 7 to 10 minutes.

[e] *Loss of consciousness* is a profound alteration of mental state that involves complete or near-complete lack of responsiveness to external stimuli. It is defined as a Coma Glasgow Scale < 10 (moderate or severe coma).

[f] *Stroke* is a neurologic deficit of cerebrovascular cause that persists beyond 24 hours or is interrupted by death within 24 hours.

[g] Condition in which the brain is in a state of continuous seizure.

[h] *Preeclampsia* is defined as the presence of hypertension associated with proteinuria. *Hypertension* is defined as a blood pressure of at least 140 mm Hg (systolic) or at least 90 mm Hg (diastolic) on at least two occasions and at least 4 to 6 h apart after the 20th week of gestation in women known to be normotensive before pregnancy. *Proteinuria* is defined as excretion of 300 mg or more of protein every 24 hours. If 24-h urine samples are not available, proteinuria is defined as a protein concentration of 300 mg/L or more (≥ 1+ on dipstick) in at least two random urine samples taken at least 4 to 6 hours apart.

[i] For instance, continuous use of any dose of dopamine, epinephrine, or norepinephrine.

TABLE 40-6 **Case-Fatality Rates per Million Anesthetics for Cesarean Delivery in the United States (95% CI)**

Year of Death	General	Neuraxial	Risk Ratios
1979-1984	20.0 (17.7-22.7)	8.6 (7.8-9.4)	2.3 (1.9-2.9)
1985-1990	32.3 (25.9-49.3)	1.9 (1.8-2.0)	16.7 (12.9-21.8)
1991-1996	16.8 (8.9-28.7)	2.5 (1.2-4.5)	6.7 (3.0-14.9)
1997-2002	6.5 (2.1-15.3)	3.8 (2.3-6.1)	1.7 (0.6-4.6)

CI, confidence interval.
Data from Hawkins JL, Chang J, Palmer SK, et al. Anesthesia-related maternal mortality in the United States: 1979-2002. Obstet Gynecol 2011; 117:69-74.

be particularly effective at comprehensive identification of anesthesia-related maternal deaths.

A number of clinical and sociodemographic factors commonly appear among cases of anesthesia-related maternal death and may play a causal role in the mechanism of death. These include (1) maternal obesity; (2) patient refusal of neuraxial anesthesia; (3) remote anesthetic location; (4) delay in anesthesia provider consultation; (5) insufficient multidisciplinary planning, communication, and coordination; and (6) inadequate supervision of care.[62,63,80,124-126] In the United States, the relative risk of anesthesia-related maternal death appears to be increased for African-American women.[80,124,127]

Anesthesia-related maternal deaths are distributed throughout the perioperative period and follow both neuraxial and general anesthesia, primarily administered for cesarean delivery, but occasionally for vaginal delivery or another obstetric or nonobstetric surgical procedure.[62,80,126, 127] Case-fatality rates according to mode of anesthesia for cesarean delivery are presented in Table 40-6. To generate these estimates, the authors identified cases from death certificate data collected by the PMSS and estimated the total number of anesthetics delivered based on the national incidence of cesarean delivery and the proportions of cesarean deliveries completed with neuraxial and general anesthesia according to national surveys of anesthesia providers.[127,128]

Anesthesia-related maternal deaths are almost always preventable,[62-64,80,126,129] as evidenced by both individual case analysis and review of historical trends. The relative risks of general and neuraxial anesthesia for cesarean delivery in the United States have shifted over time, reflecting three major safety initiatives in anesthesia practice (see Table 40-6).[130] The first initiative addressed the hazard of **local anesthetic systemic toxicity (LAST),** identified as a major problem in a series of editorials published in the early 1980s.[131,132] In response, in 1984, the U.S. Food and Drug Administration recommended that bupivacaine 0.75% not be used for epidural anesthesia in obstetric patients. Also, anesthesiologists developed a series of safety procedures to avoid the unintentional intravascular administration of a toxic dose of local anesthetic through an epidural catheter. Case-fatality rates for neuraxial anesthesia subsequently declined 78% between the years 1979 through 1984 and 1985 through 1990 (see Table 40-6). Despite this improvement in prevention, LAST remains a rare and potentially lethal complication in obstetric anesthesia, with recent events attributed to drug error by nonanesthesia providers, cumulative dosing above the toxic threshold, epidural catheter migration, and single-shot transversus abdominis plane (TAP) blocks.[62,133-135] Lipid emulsion is now recommended as part of a comprehensive resuscitation strategy.[136,137]

The second initiative involved a shift toward **greater use of neuraxial anesthesia for cesarean delivery.**[128] Between 1985 and 1990, the relative risk of general anesthesia compared with neuraxial anesthesia for cesarean delivery was 16.7 (see Table 40-6), and much of the increase in risk was attributed to failed intubation or aspiration of gastric contents during induction of general anesthesia or both. In response, anesthesia providers now reserve general anesthesia for specific indications, including (1) emergency cesarean delivery with insufficient time to establish neuraxial anesthesia; (2) medical conditions that make neuraxial anesthesia unsafe, such as maternal coagulopathy, hemorrhagic shock, and septic shock; and (3) failed neuraxial anesthesia with intraoperative pain.[138]

The third initiative introduced a series of **protocols and devices to improve the safety of general anesthesia.**[130] Pulse oximetry and capnography have been widely credited with the decline in the incidence of unrecognized esophageal intubation.[139] Failed intubation algorithms, extraglottic airway devices (particularly the laryngeal mask airway), and a heightened focus on simulation and practice have impelled a transformation in airway management toward a clear focus on effective oxygenation and ventilation as well as ongoing preparation for airway emergencies.[64,140,141] Consequently, the case-fatality rate for general anesthesia decreased by 80% between the years 1985 through 1990 and 1997 through 2002 (see Table 40-6).[127] Nevertheless, recent series continue to report deaths from difficult intubation, unrecognized esophageal intubation, pulmonary aspiration of gastric contents (both with anesthetic induction and emergence), postextubation airway obstruction, and postoperative respiratory arrest attributed to opioids or other respiratory depressants.* Strategies to limit the risk for airway misadventure are discussed in Chapters 29 and 30.

The relative risk of general anesthesia in comparison with neuraxial anesthesia has fallen since 1990 and was estimated to be 1.7 (95% CI, 0.6 to 4.6) between 1997 and 2002.[127] In contemporary anesthesia practice, both general anesthesia and neuraxial anesthesia carry remote, but tangible risks for maternal death.

Why do women die of neuraxial anesthesia? **High neuraxial block** was the leading cause of anesthesia-related maternal death among women receiving neuraxial anesthesia for cesarean delivery in the United States between 1997 and 2002.[127] It was also the leading cause

*See references 62, 63, 80, 125, 127, 142.

of legal claims for maternal death or permanent brain injury filed between 1990 and 2003 (n = 15/25; 60%), with the majority of these attributed to unrecognized intrathecal catheters intended for the epidural space.[142] Single-shot spinal anesthesia administered after failed epidural anesthesia for cesarean delivery represents a second clinical scenario associated with high neuraxial block.[143] More details on high neuraxial block and its management may be found in Chapters 23 and 26.

Potentially lethal **infectious complications of neuraxial block** include meningitis, encephalitis, and neuraxial abscess.[144-146] The CEMD 2006 to 2008 report included a case of acute hemorrhagic disseminated leukoencephalitis attributed to thoracolumbar spinal canal empyema.[63] Current guidelines stress the importance of strict aseptic technique during neuraxial block administration, as well as appropriate monitoring and management for any infectious complications that may develop.[147,148] Further details are available in Chapter 32.

Other series suggest that neuraxial cardiac arrest and hypotensive arrest may be important mechanisms by which neuraxial anesthesia can lead to maternal death.[14,149] Prevention likely depends on careful attention to intravascular volume status, as well as the prompt, aggressive treatment of maternal hypotension to prevent reflex-mediated bradycardia and cardiovascular collapse.[150] Finally, perioperative respiratory arrest can result from neuraxial opioids or intravenous opioids or other respiratory depressants administered during or after neuraxial anesthesia.[62,80]

Further efforts to improve maternal safety must include a comprehensive approach to **high-quality perioperative patient care.** Timely preanesthesia evaluation and ongoing communication with obstetric providers are essential to limit the number of patients who require emergency administration of anesthesia without sufficient evaluation and preparation. Problems with **postoperative care** have long been recognized[151] but appear to account for a growing proportion of perioperative maternal deaths,[61,62,125,126] particularly those attributed to respiratory events, hemorrhage, and maternal sepsis.[67,68,87,143,145] The physiology of pregnancy and the compensatory physiologic responses that occur in young pregnant women may obscure early signs of septic or hemorrhagic shock. **Early warning scoring systems** may facilitate the early identification of women who have, or are beginning to develop, a critical illness.[62,63,97,126,152] Postanesthesia and postpartum care are commonly provided by labor and delivery nurses (as opposed to perianesthesia care nurses[153]) with limited training and experience with major anesthetic complications, noninvasive ventilation, and advanced cardiopulmonary life support.[154]

Fortunately, severe morbidity and mortality are rare in obstetrics; as an unfortunate consequence of this rarity, individual clinical experience with serious adverse events will always be limited. Simulation may be an effective strategy for all obstetric and anesthesia providers to prepare for a wide variety of obstetric emergencies, including postoperative airway obstruction, failed intubation, eclampsia, anaphylaxis, maternal cardiac arrest, and maternal hemorrhage. Chapter 11 details additional strategies to enhance patient safety.

KEY POINTS

- Ninety-nine percent of maternal deaths worldwide occur in developing countries. More than half of global maternal deaths are attributed to direct obstetric causes, including maternal hemorrhage, hypertensive disorders of pregnancy, and infection.
- In the developed world, 16 women die per 100,000 live births. In the United States, the maternal mortality ratio is increasing; in 2009, 16.6 women died per 100,000 live births.
- Advanced maternal age, maternal obesity, multiple gestation, cesarean delivery, and nonwhite race increase the risk for maternal death.
- Hypertensive disorders of pregnancy, embolic disorders, and hemorrhage together account for just under half of maternal deaths in the developed world but appear to be eclipsed by indirect deaths in some countries.
- Death is considered the extreme outcome of the following continuum of adverse pregnancy events: normal pregnancy → morbidity → severe morbidity → near-miss → death.
- In the developed world, the anesthesia-related maternal mortality ratio is estimated to range between 1 and 3 per million live births.
- Anesthesia safety for obstetric patients depends on the provision of high-quality perioperative patient care.

PART X

THE PARTURIENT WITH SYSTEMIC DISEASE

Donald Caton, MD

John Snow, the London physician who twice anesthetized Queen Victoria for childbirth, made the first notes of an anesthetic administered to a parturient with systemic disease. On February 12, 1852, he was called to anesthetize a 23-year-old pregnant woman with osteosarcoma of the left shoulder. Her labor had begun 6 hours earlier. As Snow describes it, "the chloroform was not given to the extent of causing unconsciousness but it removed the suffering and caused fits of laughter in the patient after each time of inhaling it for the first half hour." The child was stillborn, "ill-nourished and small." From the child's condition, Snow believed that it had been dead for some time. He noted that the woman died a few weeks later.[1]

Snow wrote extensively about anesthesia. He was acutely aware that systemic disease affected the patient's response to anesthesia. In his last book, published posthumously, he described in detail various physical conditions that influenced a patient's response. Snow stated, "The comparative strength of debility of the patient has considerable influence on the way in which chloroform acts. Usually the more feeble the patient is, whether from illness, or from any other cause, the more quietly does he become insensible."[2] Snow's approach to patients with systemic disease was the same as that used today. The management of the parturient with severe diseases did not become a significant clinical problem until the twentieth century, when medical care had improved to the point that such a patient could survive into adulthood and become pregnant with a reasonable chance of carrying a child into the third trimester. Snow's experience with this seriously ill patient was probably unique for his day.[3]

CHAPTER 41

Autoimmune Disorders

Phil Popham, BSc, MBBS, FRCA, MD • Robert W. Reid, MD

CHAPTER OUTLINE

In the late 19th century Ehrlich proposed the dictum of *horror autotoxicus*, the belief that immunity is directed against foreign material and never against one's own body. The demonstration of autoantibodies in the 1950s disproved the theory and demonstrated the failure of self-tolerance.[1] Autoimmunity has been described in more than 40 disorders, and it may result in chronic illness and severe disability.

The cause of autoimmunity involves genetic and environmental factors, and consequently the classification of autoimmune diseases has been controversial. The traditional clinical classification recognizes immune responses that are directed against a particular antigen and are limited to a particular organ or cell type (**organ-specific disease**), and those that are directed against a range of antigens that produce multisystem involvement (**systemic disease**). Some examples are shown in Box 41-1. Classification now incorporates a "spectrum of autoimmunity" from low-level (possibly beneficial to self) to high-level (clearly detrimental to self) autoimmunity.[2]

The pathogenesis of autoimmunity is complex. A genetic predisposition underlies abnormal reactivity of B cells and immunoglobulins, T-cell receptors, and genes within the major histocompatibility complex (MHC).[3] Specific allotypes within the MHC are associated with certain diseases; for example, HLA-DR2 is strongly positively associated with **systemic lupus erythematosus (SLE)** but negatively associated with **diabetes mellitus type 1,** HLA-DR4 is associated with **rheumatoid arthritis** and **diabetes mellitus type 1,** and HLA-B27 is associated with **ankylosing spondylitis.** Recent work using genome-wide association studies has identified genetic associations between single nucleotide polymorphisms (SNPs) and autoimmune conditions[4] and may lead to a new classification of autoimmune disease.[5] Meta-analyses of HLA subclasses show similar associations with autoimmunity.[6]

Environmental factors may predispose to autoimmunity. Parasitic infection may reduce the incidence of autoimmunity, whereas bacterial infection with *Klebsiella* may predispose to ankylosing spondylitis. Drug-induced SLE is well described.

Sex hormones, notably the androgen-estrogen balance and its effect on cytokine production, have been implicated in the development of autoimmunity.[7] Autoimmune disorders are more common in women than men, with the highest incidence of several conditions occurring during the childbearing years; occasionally, the initial diagnosis is made during pregnancy. During normal pregnancy, altered immune function allows

BOX 41-1 Classification of Some Autoimmune Diseases

Organ-Specific Disease

- ***Neurologic:*** Myasthenia gravis, autoimmune peripheral neuropathy, Hashimoto's encephalopathy, temporal arteritis
- ***Hematologic:*** Autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, cold agglutinin disease
- ***Skin:*** Vitiligo, pemphigus vulgaris, alopecia areata, autoimmune urticaria, psoriasis
- ***Gastrointestinal:*** Crohn's disease, celiac disease, autoimmune hepatitis, primary biliary cirrhosis, ulcerative colitis
- ***Endocrine***: Hashimoto's thyroiditis, Addison's disease, diabetes mellitus type 1, Graves' disease
- ***Skeleton***: Ankylosing spondylitis, psoriatic arthropathy
- ***Cardiovascular***: Autoimmune cardiomyopathy
- ***Renal***: Goodpasture's syndrome

Systemic Disease

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Multiple sclerosis
- Sjögren's syndrome
- Dermatomyositis
- Scleroderma
- Polymyositis
- Mixed connective tissue disease
- Wegener's granulomatosis

maternal tolerance of the fetal allograft. Both mother and fetus produce immunologic factors that inhibit maternal cell-mediated immunity,[8,9] prevent rejection of the fetus, and limit the expression of autoimmunity. Conversely, the high estrogen environment of pregnancy may enhance immune function.[10] Although this may protect the mother and fetus from peripartum infection, it increases the likelihood of autoimmune conditions.

Systemic lupus erythematosus, lupus anticoagulant, scleroderma, and **polymyositis/dermatomyositis** are discussed in this chapter. Other autoimmune disorders are discussed elsewhere in this text, including **diabetes mellitus type 1** (see Chapter 43) **autoimmune thrombocytopenic purpura** and **autoimmune hemolytic anemia** (see Chapter 44), **rheumatoid arthritis** and **ankylosing spondylitis** (see Chapter 48), and **myasthenia gravis** (see Chapter 49).

SYSTEMIC LUPUS ERYTHEMATOSUS

Definition and Epidemiology

Systemic lupus erythematosus (SLE) is a multisystem inflammatory disease of unknown etiology that is characterized by the production of autoantibodies against nuclear, cytoplasmic, and cell membrane antigens. Although SLE may occur at any age, it is recognized most commonly in women during their childbearing years, with a female-to-male ratio of 9:1. African-Americans, Asians, and Native Americans are affected more often than whites.[11] An estimated 1 in 1200 deliveries occur in women with SLE.[12]

BOX 41-2 Diagnostic Criteria for Systemic Lupus Erythematosus

- Malar rash (butterfly rash over malar region)
- Discoid rash (erythematous, raised patches with scaling)
- Photosensitivity
- Oral ulceration
- Arthritis
- Serositis (pleuritis or pericarditis)
- Renal disorder (persistent proteinuria or cellular casts)
- Neurologic disorder (seizures or psychosis)
- Hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
- Immunologic disorder (anti-DNA, anti-Sm nuclear antigen, anticardiolipin antibodies, lupus anticoagulant, or false-positive syphilis test)
- Antinuclear antibody

From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1982; 25:1271-7; and Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1997; 40:1725.

Pathophysiology

The etiology of SLE remains unclear. The principal mechanism is thought to be an immune complex disease involving IgG antibodies to double-stranded DNA and other nuclear proteins. Intracellular autoantigens are released by necrotic and apoptotic cells, leading to aberrant sensitization against these antigens. Impaired clearance of apoptotic cells and prolonged exposure to nuclear autoantigens may be involved.[13] Affected individuals have both hyperactivity of the antibody-producing B cells and defects of the helper and suppressor T cells.[14] Genetic defects of immune regulation and possibly environmental triggers including viruses and bacteria lead to a proliferation of B cells capable of producing autoantibodies. More than 30 classes of antigens have been identified as targets of these antibodies. A variety of antigen-antibody immune complexes are formed, followed by secondary inflammatory responses. Deposition of immune complexes and continued inflammation within the glomerulus may lead to irreversible renal injury. Deposits also occur within the skin, choroid plexus, and other endothelial surfaces, with or without an inflammatory response. However, SLE is not simply an immune complex disorder because some autoantibodies actively bind to erythrocytes, granulocytes, lymphocytes, and macrophages, leading to their removal from the circulation.[11]

Diagnosis

Clinical manifestations of SLE are diverse, owing to the widespread antigenic targets. Box 41-2 outlines objective criteria for the diagnosis of SLE.[15,16] Although epidemiologic studies require the presence of four or more of these criteria, the clinical diagnosis may be suspected if fewer features are present without another explanation. Typically, the diagnosis of SLE is made

before conception, but in 20% of cases the initial diagnosis is made during pregnancy.[17]

Effect of Pregnancy

Although pregnancy does not worsen the long-term course of SLE,[18,19] disease activity may increase during pregnancy.[20,21] A preconception history of nephritis predicts adverse maternal outcome.[22] The risk for significant disease activity during pregnancy is increased sevenfold if active disease is present in the 6 months before conception.[23] Assessments using the SLE Disease Activity Index found that 50% to 65% of women with active disease had deterioration during pregnancy in both retrospective[24] and prospective[25] studies. Such flares occur most commonly in the second and third trimesters and the puerperium and are not more severe than those in nonpregnant patients; most respond to conservative management.

Effect on the Mother

Most women with SLE do not have renal impairment at conception, possibly because renal insufficiency impairs fertility. If lupus nephritis does preexist, deterioration in renal function may occur during pregnancy. This is generally mild and reversible, but 12% of pregnant women with SLE suffer irreversible progression of renal dysfunction.[26,27] Long-term glomerular filtration rate may be preserved.[28]

The presence of hypertension, edema, and proteinuria in both lupus nephritis and preeclampsia makes distinguishing between the two difficult. It is not clear whether preeclampsia is more common in patients with SLE, but a large meta-analysis suggests an association between lupus nephritis and preeclampsia.[29] The distinction is critical because treatments are different (immunosuppressive therapy for lupus nephritis versus delivery for preeclampsia). Increased serum uric acid concentration, proteinuria without active urinary sediment, and liver enzyme abnormalities suggest preeclampsia rather than SLE.

SLE may cause thrombocytopenia. When thrombocytopenia occurs in a pregnant woman, preeclampsia, HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome, and disseminated intravascular coagulation must also be considered. Anemia, a common manifestation of SLE, must be differentiated from nutritional anemia and the physiologic anemia of late pregnancy.

Ligamentous relaxation often occurs during late pregnancy and may worsen the pain of lupus arthritis. Patients with SLE occasionally require joint replacement, most commonly of the femoral head. These prostheses may become painful, dislocated, or infected during pregnancy.[30] Neurologic complications of SLE are rare during pregnancy but include seizures, chorea gravidarum, and stroke.

Effect on the Fetus

Maternal SLE impairs fetal survival and increases the risk for preterm delivery. A systematic review of papers published between 1980 and 2009 showed that preterm delivery occurred in 39.4% of 2751 pregnancies in 1842 patients.[29] In the Hopkins Lupus Pregnancy Cohort, preterm birth occurred in 38 of 57 (67%) pregnancies in women with moderate to severe active SLE, compared with 68 of 210 (32%) pregnancies in women with inactive or mild active SLE.[31] Improved perinatal management and control of disease activity has reduced the rate of fetal loss from 43% (between 1960 and 1965) to 17% (between 2000 and 2003).[32] Data from California showed a preterm delivery rate in SLE that was six times higher than that found in the general population.[33]

Neonatal lupus erythematosus (NLE) is a syndrome that results from maternal autoantibodies against Ro (SS-A) or La (SS-B) crossing the placenta and binding to fetal tissue. These autoantibodies are found in up to 87% of patients with SLE,[34] but NLE occurs in only a small proportion of patients. The condition is generally benign and self-limiting, and reversible manifestations such as cutaneous lupus, elevation in aminotransferase levels, and thrombocytopenia resolve as maternal antibodies disappear from the neonatal circulation within 8 months of birth. Anti-Ro/anti-La antibodies may bind to fetal cardiac conduction cells *in utero*, leading to cell death and irreversible fetal heart block. Neonatal congenital heart block occurs in 2% of neonates when anti-Ro antibody is detected in the mother.[35] Fetal echocardiography reveals atrioventricular dissociation, cardiac dilation, and pericardial effusion. Treatment includes prompt delivery, newborn cardiac pacing, antepartum administration of dexamethasone, and consideration of apheresis to remove maternal antibodies.[36]

Medical Management

Optimally, women with SLE should delay pregnancy until their disease has been quiescent for at least 6 months, and they should be taking "acceptably safe" medications at the time of conception.[21,23,27,37] Medications with acceptable safety are used to minimize disease activity during gestation.

Disease-modifying antirheumatic drugs (DMARDs) and immunosuppressive agents form the mainstay of treatment. Antimalarial drugs are frequently used to reduce SLE activity.[38] Discontinuation of **hydroxychloroquinine** just before conception or in early pregnancy leads to a significant increase in disease activity.[39] A systematic review of English literature (1982-2007) found that antimalarial drugs, particularly hydroxychloroquinine, prevent lupus flares; increase long-term survival; contribute to protection against irreversible organ damage, thrombosis, and bone loss; and have low toxicity.[40] Hydroxychloroquinine should be continued in all women who were taking it before conception and may be used to treat flares during gestation. In contrast, **mycophenolate mofetil** should be discontinued before conception owing to the risk for teratogenicity. **Azathioprine** is an acceptable substitute and should be continued if used before conception.[21,23] The fetal liver does not express the enzyme necessary to convert azathioprine to its active form,[41] but maternal use of azathioprine has been associated with reversible neonatal lymphopenia, depressed serum immunoglobulin levels, and decreased thymic size in the newborn.[41,42]

Corticosteroids may be used to treat flares of SLE disease activity. Antenatal exposure to low-dose **prednisone** (< 20 mg daily) appears to be safe, and most children develop normally. However, there is concern that prolonged fetal exposure to other corticosteroids such as **dexamethasone** or **betamethasone** may lead to fetal growth restriction and abnormal neuronal development.[43] Corticosteroid therapy may precipitate gestational diabetes, and patients should be monitored for evidence of glucose intolerance. Striae, gastrointestinal ulceration, and bone demineralization may complicate long-term corticosteroid therapy. Affected patients should receive postprandial and bedtime antacids.[44] The pediatrician should be alerted to the possibility of neonatal adrenal suppression.

Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and stronger analgesics may be used to manage lupus arthritis. Although there is no evidence of teratogenicity with these agents,[41] concern exists that NSAIDs may cause premature closure of the fetal ductus arteriosus,[45] impairment of maternal and neonatal hemostasis,[46] and adverse effects on maternal renal function.

Obstetric Management

Patients with SLE are at increased risk for intrauterine fetal death and preterm delivery. Estimation of the gestational age is obtained with ultrasonography at the first prenatal visit and again at 20 weeks' gestation. Continued surveillance consists of nonstress testing, biophysical profile measurement, and/or umbilical artery Doppler velocimetry beginning at 26 to 28 weeks' gestation and performed weekly until delivery.[27]

The coexistence of antiphospholipid antibodies predicts a much higher maternal and fetal risk. Maternal serologic markers are checked regularly, together with platelet count, creatinine clearance, 24-hour urine protein level, and presence or absence of anti-Ro/anti-La antibodies.[47] Platelet count measurement is repeated monthly. If anti-Ro/anti-La antibodies are detected or the fetal heart rate is 60 beats per minute without variability in the second trimester, fetal echocardiography and fetal heart rate testing are performed to check for signs of congenital heart block or failure.[48] Thromboprophylaxis is important in patients with **antiphospholipid syndrome** (see later discussion). In normal pregnancy, serial complement levels gradually increase. However, declining levels of C3 and C4 suggest active disease and lupus nephritis.[21] Aspirin resistance may predict adverse maternal and neonatal outcome.[49] Regular assessment of blood pressure, weight gain, and proteinuria is performed to detect the development of preeclampsia.

The timing and route of delivery are individualized. Although vaginal delivery is preferred, the cesarean delivery rate in parturients with SLE is 40%.[12]

Anesthetic Management

The obstetrician, rheumatologist, and anesthesiologist should formulate a joint plan for delivery. Maternal organ system involvement, current disease severity, and particularly the presence of flares must be assessed.[50]

Pericarditis is common in patients with SLE and is typically asymptomatic. A history of dyspnea on exertion or unexplained tachycardia may suggest pericarditis or **myocarditis. Cardiac tamponade** has been reported.[51] Prolongation of the PR interval or nonspecific T-wave changes may be seen on the electrocardiogram. Coronary artery vasculitis, accelerated atherosclerosis leading to **myocardial ischemia,** and even **myocardial infarction** in young women have been reported.[52,53]

An echocardiographic study in 69 patients with SLE showed a high incidence of **valvular abnormalities,** including valvular thickening in 51%, vegetations in 43%, regurgitation in 25%, and stenosis in 4%.[54] Current American Heart Association guidelines recommend antibiotic prophylaxis only for patients at highest risk for infective endocarditis in whom there is both significant risk and consequence of infection.[55] Prophylactic antibiotics are not recommended for women with common valvular lesions undergoing genitourinary procedures, including vaginal delivery, but are specifically indicated for those with previous infective endocarditis, unrepaired cyanotic congenital heart disease, implanted prosthetic material or devices, or a history of cardiac transplantation with cardiac valvulopathy.

The prevalence and progression of **pulmonary hypertension** in 28 patients with SLE has been studied.[56] The prevalence increased from 14% at initial evaluation to 43% 5 years later. Epidural anesthesia for cesarean delivery in parturients with pulmonary hypertension has been reported (see Chapter 42). The abrupt onset of sympathetic blockade and decreased venous return may cause precipitous systemic hypotension and hypoxemia. One report described the administration of general anesthesia in a parturient with SLE and pulmonary hypertension, with coexisting SLE-related restrictive lung disease, pulmonary edema, and orthopnea.[57] In one report of three parturients with pulmonary hypertension secondary to SLE and antiphospholipid syndrome, two died of right-sided heart failure within 48 hours of delivery.[58]

Subclinical **pleuritis** is common, but significant **pleural effusions** occur rarely. Patients may suffer from **infectious pneumonia** or **lupus pneumonitis.** The latter condition is characterized by fleeting hemorrhagic infiltrates that may become consolidated. **Pulmonary embolism** and **diaphragmatic dysfunction** have been reported.[52]

Central and peripheral sensorimotor and autonomic neuropathies are observed in as many as 25% of patients with SLE.[59] **Vocal cord palsy** has been reported in SLE.[50,60] These deficits should be documented before the administration of either neuraxial or general anesthesia. **Migraine headache** and **cerebral vasculitis** resulting from SLE must be considered in the differential diagnosis of a postpartum headache. **Psychological disorders** and frank **psychosis** can occur during disease flares.[11,61] **Seizures** can occur, especially if chronic anticonvulsant medications are discontinued inadvertently.

Hematologic abnormalities, including **anemia, thrombocytopenia,** and **coagulopathy,** should be documented. An abnormality of the activated partial thromboplastin time (aPTT), which is not corrected with a 1 : 1 control plasma mix, suggests the presence of either lupus

anticoagulant (a coexistent but separate disease entity) or, more rarely, true autoantibodies against specific coagulation factors (e.g., VIII, IX, XII). Lupus anticoagulant is a laboratory artifact that does *not* cause clinical coagulopathy. True coagulation factor autoantibodies (or inhibitors) may result in a significant bleeding diathesis, which contraindicates the administration of neuraxial anesthesia.

Long-term use of NSAIDs leads to qualitative platelet abnormalities but has rarely been associated with epidural or subdural hematoma, and the role of NSAIDs in causing spinal epidural hematoma remains conjectural.[62,63] In a prospective study of 924 patients undergoing orthopedic procedures with spinal or epidural anesthesia, preoperative antiplatelet medications were taken by 39% of these patients; no cases of spinal epidural hematoma were observed.[64] The same investigators similarly studied 1035 patients undergoing epidural steroid injection.[65] NSAID use was reported by 32% of patients undergoing chronic pain management; there were no cases of spinal hematoma. In the CLASP study, a large, multicenter randomized trial, 9364 pregnant women received either low-dose aspirin (60 mg daily) or placebo for prevention and treatment of preeclampsia.[66] Of 5000 enrollees, at least 1069 patients received epidural analgesia, and no cases of epidural hematoma were observed.[67] Determination of the bleeding time before neuraxial injection in patients taking aspirin or NSAIDs is no longer indicated. Measurement of thromboelastography has been suggested as an alternative but is not widely available.[68]

Atypical blood antibodies may complicate crossmatching of blood for patients with SLE. Additional time should be allowed for this possibility.

Prosthetic orthopedic joints should be positioned carefully during vaginal or cesarean delivery. Lupus arthritis rarely involves the cervical spine. Women who have undergone long-term corticosteroid therapy should receive a peripartum stress dose of a corticosteroid.

ANTIPHOSPHOLIPID SYNDROME

Definition and Epidemiology

The antiphospholipid syndrome (APS, also known as Hughes' syndrome) was first recognized in the early 1980s[69-71] and classified by international consensus in 2005.[72] It is a *prothrombotic* disorder characterized by the presence of two autoantibodies, lupus anticoagulant and anticardiolipin antibody. Affected patients are at risk for both arterial and venous thrombosis. Patients with SLE may show lupus anticoagulant (34%) and anticardiolipin antibody (44%).[73] However, APS is a distinct and separate entity from SLE. A long-term cohort study found that among patients with APS, only 11 of 128 (8%) had SLE.[74]

The population prevalence of APS is unclear. In 1990, commenting on the volume of publications on APS, Harris[75] remarked that the syndrome "probably occurs less frequently than the number of papers published on the subject." But in 2007, with greater clinical recognition, Hughes predicted that the prevalence of APS will exceed that of SLE.[70]

Pathophysiology

APS is characterized by two important misnomers. First, the antiphospholipid antibodies do not bind directly to phospholipids but to phospholipid-binding plasma proteins such as β_2-glycoprotein I, prothrombin, and annexin V. Second, the lupus anticoagulant has no true anticoagulant activity *in vivo* but is a laboratory artifact that affects phospholipid-dependent coagulation assays: the aPTT, the kaolin clotting time (KCT), the tissue thromboplastin inhibition (TTI) test, and the dilute Russell viper venom time (dRVVT). These times remain prolonged even when the tests are repeated with a 1:1 mixture of the patient's plasma and control plasma. The prothrombin time (PT) typically is normal. Lupus anticoagulant appears to block *in vitro* assembly of prothrombinase (a phospholipid complex), thus preventing the conversion of prothrombin to thrombin. True bleeding associated with lupus anticoagulant is extremely rare and, in most cases, is caused by an underlying factor deficiency or inhibitor.[76]

Contrary to expectation, lupus anticoagulant and anticardiolipin antibody are associated with both arterial and venous **thrombotic events.** The current model by which this thrombotic tendency occurs involves antiphospholipid antibodies binding to β_2-glycoprotein I, which then bind to glycoprotein Ibα on platelets, monocytes, and endothelial cells. These complexes cause platelet adhesion, expression of prothrombotic molecules, and local complement activation.[76,77]

Diagnosis

The diagnosis of APS depends on a clinical history of unexplained recurrent venous or arterial thrombosis, pregnancy loss, and laboratory evidence of anticardiolipin antibody or lupus anticoagulant.[72] The latter is demonstrated by (1) evidence of abnormal phospholipid-dependent coagulation (elevated aPTT), (2) evidence that this abnormality is caused by an inhibitor rather than a factor deficiency (elevated aPTT with 1:1 mix), and (3) proof that the inhibitor is directed against phospholipid rather than specific coagulation factors. Antibodies should be demonstrable on two occasions separated by 12 weeks.[78] The presence of lupus anticoagulant, anticardiolipin (aCL), and anti-β_2-glycoprotein I (aβ2GPI) antibodies ("triple positivity") with a clinical diagnosis of APS predicts severe disease.[79] Results from different laboratories show considerable variability, and guidelines on diagnostic criteria have been published.[80] Tests for syphilis detect the antiphospholipid antibodies present in syphilis, and consequently the Venereal Disease Research Laboratory (VDRL) and Wasserman test results are often falsely positive.

Effect on the Mother

Pregnant women with APS are at risk for **venous and arterial thrombosis, pulmonary embolism, myocardial infarction, cerebral infarction** and **fetal loss.** Cohort studies suggest that contemporary management strategies may improve maternal outcome. In 130 women with APS followed over a 3-year period, 48%

experienced at least one of the following disorders: **transient ischemic attack, peripheral thrombosis** (of which one fourth occurred in pregnancy and the puerperium), **stroke, amaurosis fugax, autoimmune thrombocytopenia,** and **SLE.**[81] Women who were diagnosed with APS on the basis of recurrent pregnancy loss and evidence of antiphospholipid antibody, but without prior thrombotic events, rarely suffered thrombosis during pregnancy.[82] A history of thromboembolic events significantly worsens prognosis and increases the likelihood of future events, an effect ameliorated by the use of oral anticoagulants.[83] Thrombocytopenia, present in one fourth of patients with APS, may require splenectomy.[84] **Catastrophic APS,** an accelerated form of the condition that results in multisystem organ thrombosis and failure, may be triggered by pregnancy in 4% of cases.[85]

Effect on the Fetus

Pregnant women with APS are at high risk for intrauterine fetal death. Early studies showed that only 7.5% of pregnancies resulted in the delivery of a live newborn,[86] whereas recent reports have shown live-birth rates up to 100%.[87] Pregnant women with lupus anticoagulant, aCL, and aβ2GPI antibody titers greater than four times the upper limit of normal have a twofold increase in risk for fetal loss, when compared with women with positive titers only (35% versus 77% live-birth rate).[88] Placental infarction is the apparent mechanism of mortality, and most fetal deaths occur during mid and late pregnancy. There is no high-level evidence to guide management of pregnant women with high antibody titers.[89]

Most infants born to women with APS do not have an increased rate of neonatal or childhood complications,[90] although cases of antiphospholipid-related **fetal and neonatal thrombosis** (mainly cerebral thrombosis) have been reported.[91]

Medical and Obstetric Management

Fetal survival and maternal thrombotic risk may be improved when affected pregnant women are treated with low-dose aspirin and heparin. A 2005 meta-analysis found that combined treatment with unfractionated heparin and aspirin can reduce pregnancy loss by 54%.[92] Recommendations on investigation and management of APS have been made.[93] Women with more than three unexplained pregnancy losses before 10 weeks' gestation should be tested for antiphospholipid antibodies; women with APS and recurrent pregnancy loss should receive prophylactic doses of **heparin** and **low-dose aspirin** throughout pregnancy, and administration for 6 to 8 weeks postpartum should be considered. A history of APS with thrombosis may require full anticoagulation throughout pregnancy and the postpartum period. A meta-analysis suggested that unfractionated heparin in combination with aspirin increases the live-birth rate in women with APS, but the benefit of **low-molecular-weight heparin (LMWH)** is unclear; neither type of heparin crosses the placental barrier.[94]

Catastrophic antiphospholipid syndrome (CAPS or Asherson's syndrome) occurs in 1% of patients with APS.[85] Diagnosis requires the presence of antiphospholipid antibodies with involvement of at least three organs and rapid onset and progression of disease. Mortality is as high as 50%.[72] Aggressive treatment with full anticoagulation, antibiotic cover for a precipitating bacterial infection, intravenous corticosteroids and immunoglobulins, and plasma exchange may be required. Severe **thrombocytopenia** may respond to **rituximab.**

Anesthetic Management

Management of the patient with antiphospholipid antibodies is similar to that of the patient with SLE. Coexisting autoimmune disorders, secondary organ involvement, and thrombotic phenomena should be evaluated. The term *lupus anticoagulant* is a misnomer (as discussed earlier) and does *not* warrant withholding neuraxial anesthesia. Infrequently, antiphospholipid antibodies can cause coagulation factor deficiencies, and in such patients neuraxial anesthesia is relatively contraindicated. In the absence of an underlying coagulation deficit or anticoagulant therapy, the prolonged aPTT does *not* suggest a bleeding tendency, and neuraxial anesthesia may be administered safely.

The anesthetic management of pregnancies complicated by APS has been reviewed.[95,96] All subjects received aspirin (75 to 150 mg daily) throughout pregnancy, and aspirin therapy alone was not considered a contraindication to neuraxial anesthesia. In parturients who received thromboprophylaxis with standard unfractionated heparin, spinal or epidural anesthesia was administered 4 hours after the last dose of heparin. The use of LMWH for thromboprophylaxis precludes administration of neuraxial anesthesia until at least 12 hours have elapsed since the time of the last dose.[97] Further, therapeutic anticoagulation with high-dose LMWH precludes the administration of neuraxial anesthesia until at least 24 hours have elapsed since the time of the last dose (see Chapters 39 and 44). The use of **thromboelastography** to document clearance of heparin before administration of neuraxial anesthesia in parturients with lupus anticoagulant has been described.[98]

If fetal compromise secondary to multi-infarct placental insufficiency exists, hypotension from sympathetic blockade should be prevented. Neuraxial anesthesia with an epidural, intrathecal, or combined spinal-epidural technique is not contraindicated, provided that blood pressure is closely controlled. Parturients with APS who undergo general anesthesia are at risk for venous thrombosis. Compression stockings, warm intravenous fluids, and early ambulation should be used, whereas hypothermia and dehydration should be avoided.[95,96,99] There is no evidence that a "walking epidural" confers benefit.

SYSTEMIC SCLEROSIS (SCLERODERMA)

Definition and Epidemiology

Systemic sclerosis or scleroderma is a chronic progressive autoimmune disease of unknown etiology characterized by deposition of fibrous connective tissue in the skin and

other tissues, microvascular changes, and chronic inflammation. It is a heterogeneous disorder and may be in the form of **limited** or **diffuse cutaneous scleroderma.** A subset of patients exhibit systemic sclerosis without cutaneous involvement.[100]

The annual incidence of scleroderma in the United States is 19 per million. The prevalence is 240 per million, which is four to nine times greater than the reported global prevalence. Scleroderma is almost five times more common among women than men and occurs primarily between 30 and 50 years of age.[101]

Pathophysiology

The stimulus for fibroblasts to produce excessive collagen and other matrix constituents is unknown; however, their accumulation leads to microvascular obliteration and fibrosis in the skin and other target organs. Endothelial cells undergo vasomotor and permeability changes, producing cyclic vasoconstriction-vasodilation and edema. Patients with scleroderma produce autoantibodies against nuclear and centromere structures, although their significance is unclear. Scleroderma exhibits a strong female predilection, a steep rise in incidence after the childbearing years, and features that are similar to graft-versus-host disease after bone marrow transplantation, prompting some to postulate that microchimerism may be involved in its pathogenesis. Fetal cells gain access to the maternal circulation during gestation and may be detected in maternal blood for decades after delivery. After some unknown stimulus (that possibly includes environmental factors), these fetal cells may differentiate and initiate a reaction similar to graft-versus-host disease.[102,103]

Diagnosis

Raynaud's phenomenon, characterized by cyclic pallor and cyanosis of the digits in response to cold or emotion, is a common prodrome to scleroderma, with 1% of patients progressing to scleroderma. The triad of Raynaud's phenomenon, nonpitting edema, and hidebound skin establishes the diagnosis of scleroderma.

Limited cutaneous scleroderma, also termed **CREST syndrome,** involves calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia. Skin involvement is limited to the hands, face, and feet in this form of the disease. The more extensive clinical manifestations of diffuse cutaneous scleroderma are summarized in Box 41-3.

BOX 41-3 Manifestations of Diffuse Cutaneous Systemic Sclerosis

Skin
- Raynaud's phenomenon
- Nonpitting edema
- Hidebound skin (involves all but back and buttocks)

Gastrointestinal
- Hypomotility
- Dysphagia
- Reflux esophagitis
- Postprandial fullness
- Constipation
- Abdominal pain
- Intermittent diarrhea
- Malnutrition
- Ileus

Pulmonary
- Interstitial fibrosis
- Pleuritis
- Pulmonary hypertension

Renal
- Proteinuria
- Renal insufficiency and failure
- Malignant hypertension

Cardiac
- Chronic pericardial effusion
- Myocardial ischemia and infarction
- Conduction disturbances
- Heart failure

Musculoskeletal
- Arthritis (symmetric, small joints)
- Myopathy
- Muscle wasting

Other
- Peripheral or cranial neuropathy
- Facial pain
- Trigeminal neuralgia
- Keratoconjunctivitis sicca
- Xerostomia
- Absence of anticentromere antibodies

From LeRoy EC. Systemic sclerosis (scleroderma). In Wyngaarden JB, Smith LH, Bennett JC, editors. Cecil Textbook of Medicine. 19th edition. Philadelphia, WB Saunders, 1992:1530-5.

Effect of Pregnancy

Progression of scleroderma tends to be slow. More than 70% of patients with diffuse cutaneous scleroderma and more than 90% of those with limited cutaneous scleroderma are alive 15 years after diagnosis.[104] Renal failure and malignant hypertension are the most common causes of death. Successive reviews by Steen[105-107] indicate that improvements in management allow patients with scleroderma to have successful maternal and fetal outcomes. Maternal symptoms were unchanged in 62% of pregnancies and improved in 20%. In the other 18% of pregnancies, esophageal reflux, cardiac arrhythmias, arthritis, skin thickening, and/or renal crisis occurred or worsened.[105-107] Deterioration of renal function is of greatest concern.[108]

Effect on Pregnancy and the Fetus

The frequency of preterm births and small-for-dates infants is higher in pregnant women with scleroderma.[108] Preterm birth occurs in 25% of pregnancies (compared with 5% in control pregnancies), and most preterm deliveries occur in women with unstable diffuse scleroderma of less than 4 years' duration. Miscarriage occurs

more commonly in women with long-standing diffuse scleroderma.[105]

Medical Management

Management is symptomatic rather than curative, and is directed toward slowing end-organ damage. When lifestyle alterations (e.g., avoidance of cold, cessation of smoking) are no longer effective, management may include **calcium entry–blocking agents** for skin manifestations, **proton-pump inhibitors** and occasionally **esophageal dilation** for gastrointestinal tract symptoms, and **phosphodiesterase inhibitors** and **prostaglandins** for pulmonary arterial hypertension. No disease modification benefits have been shown by administration of **penicillamine, methotrexate,** or other immunosuppressive agents (other than the use of glucocorticoids for inflammatory myositis).[109,110]

Drugs with unproven or potential teratogenicity are relatively contraindicated during pregnancy. However, **angiotensin-converting enzyme (ACE) inhibitors** are the agents of choice for treating scleroderma-associated renal crisis and malignant hypertension, despite the potential for fetal teratogenicity, renal atresia, pulmonary hypoplasia, anhydramnios, and fetopathy.[106] ACE inhibitors provide the only effective control of hypertension during scleroderma-associated renal crisis and should be started immediately if maternal hypertension occurs. Their use should be avoided if hypertension or overt renal crisis is not present.

Nitric oxide donors and possibly **heparin** may provide some protection against placental dysfunction in pregnant women with scleroderma.[111]

Obstetric Management

Pregnant women with scleroderma should be specifically evaluated for evidence of renal, pulmonary, and cardiac dysfunction. Preterm delivery or termination of pregnancy may be required in the presence of advanced or rapidly progressive disease. Frequent assessment of renal function and intensive observation for the onset of systemic or pulmonary hypertension, cardiac dysfunction, and fetal compromise, combined with improvements in monitoring and treatment, allow most mothers to deliver healthy infants. Obstructive uropathy may result from an enlarging uterus trapped within a noncompliant abdomen.[112] Uterine and cervical wall thickening may lead to ineffective uterine contractions or cervical dystocia at delivery.[107] Even the tightest abdominal skin usually heals if cesarean delivery is necessary.[107]

Anesthetic Management

The pregnant woman with scleroderma presents several challenges to the anesthesia provider and should be assessed before labor and delivery. Early multidisciplinary involvement is required.

History and physical examination should be directed toward detection of underlying systemic dysfunction. Laboratory tests include complete blood cell count, coagulation screen, electrolyte concentrations and creatinine clearance, arterial blood gas analysis, urinalysis, and urine protein determination. An electrocardiogram and pulmonary function testing should be performed in all patients. Echocardiography is increasingly used to assess ventricular dysfunction, pericardial and pleural effusions, and pulmonary hypertension.[113] Particular attention should be paid to arterial pulses, noninvasive blood pressure measurement, peripheral venous access, extent of Raynaud's phenomenon involvement, and special positioning requirements.

Severe limitation of mouth opening caused by hidebound perioral skin may make direct laryngoscopy impossible and mandates careful airway assessment.[114] Maximal mouth opening, the ability to sublux the mandible, visualization of oropharyngeal structures, degree of atlanto-occipital joint extension, and presence of oral or nasal telangiectases should be checked and a determination made as to whether direct laryngoscopy will be difficult if general anesthesia is required.[115] The patient should be prepared for the possibility of an awake tracheal intubation. Specialized airway equipment (e.g., fiberoptic laryngoscope, videolaryngoscope, emergency cricothyrotomy set) should be immediately available. The changes in graded intubation scores that occur during labor should also be borne in mind.[116]

Epidural anesthesia has been used successfully in parturients with scleroderma.[117,118] Early administration of epidural analgesia in laboring women in whom tracheal intubation is likely to be difficult is to be encouraged. Even when severe diffuse cutaneous involvement is present, the skin of the lumbar back is spared. Spinal anesthesia for cesarean delivery complicated by precipitous hypotension in a parturient with scleroderma has been reported.[119] Recovery was uneventful in this woman, with full return of motor function within 3.5 hours. However, prolonged duration of regional anesthesia has been observed in some patients with scleroderma. An axillary block performed with 1% lidocaine with epinephrine was reported to have persisted for 24 hours,[120] a digital nerve block performed with 1% lidocaine without epinephrine persisted for 10 hours,[121] and a sciatic nerve block persisted for 16 hours.[122] Prolonged epidural anesthesia with 2% 2-chloroprocaine has also been reported.[123]

Unduly prolonged analgesia and anesthesia may be due to reduced uptake of the local anesthetic agent as a consequence of microvasculature changes. This is not a contraindication to neuraxial techniques but should prompt the use of small incremental boluses of the local anesthetic agent. The patient should be warned of the possibility of prolonged neural blockade. Because continuous infusion techniques may result in the administration of an excessive dose with prolonged neural blockade, incremental bolus or patient-controlled injection techniques may be preferable. Whether this consideration makes epidural (with the ability to titrate the dose) rather than spinal anesthesia preferable for cesarean delivery is unclear.

If cesarean delivery is required, the decision to use epidural or general anesthesia depends on the urgency of delivery, anticipated airway difficulty, and the operator skills. Gastric hypomotility increases the risk for esophageal reflux and aspiration. Diffuse cutaneous involvement

may indicate the need for central venous catheterization if venous access is difficult, and for invasive arterial monitoring if noninvasive blood pressure measurement is inaccurate. Radial artery catheterization is contraindicated in patients with Raynaud's phenomenon because of the risk for hand ischemia. Brachial artery catheterization may be necessary. Pulmonary artery catheterization may be indicated in the presence of cardiac dysfunction or pulmonary hypertension.[124] The use of noninvasive assessment of cardiac function with transthoracic echocardiography is likely to increase.[125] Warming of the patient, and especially of the extremities affected by Raynaud's phenomenon, is required. Scleroderma reduces tear production, and the eyes should be protected against corneal abrasions.

POLYMYOSITIS AND DERMATOMYOSITIS

Definition and Epidemiology

Polymyositis and **dermatomyositis** represent two members of a larger disease group, the idiopathic inflammatory myopathic diseases. Polymyositis is characterized by nonsuppurative inflammation of muscle, primarily skeletal muscles of the proximal limbs, neck, and pharynx. This inflammation leads to symmetric weakness, atrophy, and fibrosis of affected muscle groups. Dermatomyositis represents the same disorder, with the addition of a characteristic heliotrope eruption (blue-purple discoloration of the upper eyelid) and Gottron's papules (raised, scaly, violet eruptions over the knuckles). These disorders are quite rare, with a prevalence of 10 per million and an annual incidence of 5.5 per million. Women are affected twice as often as men. The age at onset is bimodal, with peaks before puberty and during the fifth decade.[126]

Pathophysiology

Both polymyositis and dermatomyositis are associated with other autoimmune disorders, notably scleroderma. The etiology of inflammatory muscle disease is unknown and probably multifactorial. An initial insult mediated by viral or other infectious agent, or exposure to environmental substances, may lead to initial muscle damage in genetically susceptible individuals. This initial process may then trigger an autoimmune response involving chronic muscle inflammation. A viral etiology is suggested by seasonal and geographic clustering of new cases. However, viral genomic material has not been identified in affected muscle tissue. Many drugs, including lipid-lowering drugs in the statin group and antiretroviral drugs, are associated with the development of myopathy. The presence of cellular infiltrates within affected muscle tissue and complement-mediated capillary damage are features of inflammatory muscle diseases. More than 12 autoantibodies have been identified within affected individuals. Underlying malignancy has been associated with both polymyositis and dermatomyositis, although causality is unclear; the association is stronger for dermatomyositis than polymyositis.[126,127]

BOX 41-4 Diagnostic Criteria for Polymyositis and Dermatomyositis

POLYMYOSITIS

- Symmetric weakness of proximal muscles
- Histologic evidence of muscle inflammation and necrosis
- Elevation of serum skeletal muscle enzymes
- Electromyographic evidence of myopathy

DERMATOMYOSITIS

- Three or four of the above, plus heliotrope eruption or Gottron's papules

From Bohan A, Peter JB. Polymyositis and dermatomyositis (second of two parts). N Engl J Med 1975; 292:403-7.

Diagnosis

The diagnostic criteria proposed by Bohan and Peter remain the standard of classification for polymyositis and dermatomyositis (Box 41-4).[128] After exclusion of other conditions that can mimic polymyositis or dermatomyositis, clinical features together with electromyographic and laboratory evidence of myositis (both through blood tests and muscle biopsy) establish the diagnosis. Serum creatine kinase concentration correlates with disease activity. Variable systemic involvement may be present. Pharyngeal muscle involvement leads to **dysphagia** and **reflux,** and most patients exhibit **impairment of gastric and esophageal motility.**[129] Pulmonary involvement is present in 50% of patients with polymyositis/dermatomyositis, and **chronic aspiration pneumonitis** and **pneumonia** are the most common pulmonary manifestations. **Pulmonary fibrosis** is present in 30% of patients and may rarely lead to **pulmonary hypertension.**[130,131] **Myositis of the respiratory muscles** may cause respiratory insufficiency. **Cardiac involvement** includes nonspecific repolarization abnormalities, conduction disturbances, arrhythmias, coronary artery vasculitis, and, rarely, heart failure.[132] **Arthritis** generally involves the small joints of the hands and fingers. Renal or hematologic involvement is rare. The onset of a pregnancy-associated form of dermatomyositis has been described postpartum.[133]

Effect of Pregnancy

Reports of polymyositis or dermatomyositis during pregnancy are rare. Ishii et al.[134] reviewed 12 reports of 29 pregnancies during a 30-year period. In 11 (40%) of the patients, the initial diagnosis was made during gestation or the immediate postpartum period. Pregnancy may be a trigger for induction of dermatomyositis in some women. Among the 18 patients with previously diagnosed disease, the disease remained inactive in 11 (61%) of the patients, and 2 (11%) had an exacerbation of disease activity.

Effect on the Fetus

Fetal survival is affected by concurrent polymyositis/dermatomyositis. In a literature review, 10 of 29 (32%)

pregnancies ended with fetal death or spontaneous abortion; eight infants (26%) were delivered preterm.[134] Fetal outcome was strongly influenced by disease activity. Of the women who had minimal disease activity, nearly 60% delivered healthy newborns at term. Silva et al.[135] observed a similar correlation between outcome and disease activity in four pregnancies in four women with polymyositis/dermatomyositis, two with active disease and fetal death and two with disease remission and uneventful outcome.

Medical and Obstetric Management

Pregnancy should be planned during periods of disease inactivity. Serum creatine kinase, glutamic oxaloacetic transaminase, and aldolase determinations can guide this decision.

Glucocorticoid treatment is the mainstay of medical management of active disease. Efficacy of steroids has not been demonstrated in controlled studies, but improvement in muscle strength and decreased creatine kinase concentration are usually seen after 1 to 2 months of either continuous or pulsed steroid therapy. **Methotrexate, azathioprine,** and **intravenous immunoglobulin** may be beneficial; there is limited evidence for their use and safety in pregnant patients.[136-138] Obstetric management involves frequent monitoring of disease activity and fetal well-being.

Anesthetic Management

Anesthetic management of the pregnant woman with polymyositis/dermatomyositis begins with the evaluation of disease activity and underlying cardiopulmonary involvement. If muscle weakness is present, spirometry should be performed to determine whether respiratory muscles are affected. Maximum breathing capacity and peak expiratory flow rate are the most helpful measurements. Pharyngeal weakness may cause chronic aspiration and pulmonary diffusion defects. Arterial blood gas analysis and a chest radiograph should be obtained in patients with a history of aspiration. An electrocardiogram should be obtained to exclude conduction abnormalities and arrhythmias.

Use of neuraxial anesthesia in a patient with muscle weakness requires caution because excessive cephalad spread may further impair intercostal muscle function and lead to ventilatory failure. Abdominal muscle paralysis may slow progress of the second stage of labor. Careful epidural administration of a dilute solution of local anesthetic should provide effective pain relief without adverse effect on the progress of labor. Intrathecal opioid administration is an attractive, alternative method of labor analgesia in these patients.

Patients with polymyositis/dermatomyositis may exhibit **atypical responses to muscle relaxants.** A short-lived thumb contracture after **succinylcholine** administration in a child with dermatomyositis has been reported.[139] Direct laryngoscopy was not impaired, the contracture resolved in 3 minutes, and normal neuromuscular recovery occurred. Plasma potassium concentration increased by 20%, although this response is similar to that seen in normal subjects after succinylcholine administration. Prolonged paralysis of 50 minutes after succinylcholine administration in a patient with dermatomyositis has been noted.[140] The patient was found to be homozygous for an atypical pseudocholinesterase. Of four other patients with dermatomyositis in whom dibucaine numbers were measured, one was heterozygous for atypical pseudocholinesterase. The occurrence of benign contractures and the possibility of atypical pseudocholinesterase do not preclude the use of succinylcholine if it is required for cesarean delivery, although newer agents such as rocuronium may provide an alternative. Neuromuscular recovery should be documented before extubation. Some investigators have advocated the avoidance of agents known to trigger malignant hyperthermia in patients with polymyositis/dermatomyositis and elevated creatine kinase levels.[141,142] This approach is speculative and is not supported by published clinical experience.

An atypical response to **nondepolarizing muscle relaxants** has been reported. A case of prolonged paralysis (9.5 hours) after administration of vecuronium in a patient with polymyositis has been reported.[143] Underlying malignancy with associated **myasthenic syndrome** can prolong neuromuscular blockade. Other reports of nondepolarizing neuromuscular blockade in patients with polymyositis/dermatomyositis have indicated a normal response and recovery.[142,144,145] Parturients who have undergone long-term corticosteroid therapy should receive a peripartum stress dose of a corticosteroid.

KEY POINTS

- Pregnancy does not worsen the long-term course of autoimmune disorders.
- Autoimmune disorders can lead to renal, cardiac, and pulmonary dysfunction.
- Systemic lupus erythematosus can result in maternal thrombocytopenia.
- Systemic lupus erythematosus is associated with a higher incidence of spontaneous abortion, intrauterine fetal demise, and preterm delivery.
- Antiphospholipid syndrome is characterized by the presence of the autoantibodies lupus anticoagulant and anticardiolipin antibody.
- The term *lupus anticoagulant* is a misnomer because it has no true anticoagulant activity *in vivo.*
- Patients with lupus anticoagulant do *not* have a bleeding tendency in the absence of an underlying coagulation disorder and can safely receive neuraxial anesthesia.
- Patients with scleroderma are at increased risk for difficult airway management.
- Scleroderma can prolong the duration of neuraxial anesthesia.
- The severity of polymyositis/dermatomyositis affects fetal survival.

- Patients with polymyositis/dermatomyositis may have an atypical response to succinylcholine.
- Neuraxial anesthesia must be administered cautiously to parturients with polymyositis/dermatomyositis and intercostal muscle weakness.

CHAPTER 42

Cardiovascular Disease

Mladen I. Vidovich, MD, FACC, FSCAI

CHAPTER OUTLINE

Evidence suggests that gender has a significant impact on cardiovascular disease. The etiology of coronary thrombosis causing acute myocardial infarction is different in women than in men. Plaque erosion, rather than plaque rupture, occurs at a higher rate in women than in men. Coronary artery diameter is smaller in women,[1] and women frequently develop more diffuse atherosclerosis than men. Female aortas appear to be stiffer due to underlying fibrosis or remodeling. Women have more microvascular coronary artery dysfunction than men and frequently demonstrate impaired coronary artery vasodilator response.

Autoimmune rheumatic diseases are associated with premature atherosclerosis; vasculitides such as Takayasu's arteritis, temporal arteritis, rheumatoid vasculitis, lupus vasculitis, and polymyalgia rheumatica are all more common in women than in men. During exercise stress testing, women more often have atypical and nonanginal pain than men, who more often have typical angina.[2] Women with acute myocardial infarction more frequently do not have chest pain, especially women who have the infarction at a younger age. In-hospital mortality for acute myocardial infarction is higher for women than for men.[3] Although women who have non–ST-segment elevation myocardial infarction have a worse risk profile than men, the infarction is frequently treated less aggressively.[4] Yet women are more likely than men to summon emergency medical services during a myocardial infarction.

Whether women have worse outcome after percutaneous coronary intervention has been a matter of debate.[5] At the time of presentation for both percutaneous and surgical coronary revascularization procedures, women are older than men and have more cardiovascular risk factors and comorbid conditions.[5] Older studies demonstrated worse overall outcome in women than in men; however, more recent studies have demonstrated a narrowing or disappearance of the gender outcome gap. Similarly, several studies have demonstrated that female gender was an independent predictor of coronary artery bypass (CABG) operative mortality. However, after extensive baseline risk adjustment, outcomes after CABG or aortic valve replacement have been reported to be similar for men and women.

The number of pregnancies has been associated with the future risk for coronary artery disease[6] and progression of atherosclerosis.[7] Hypertensive disorders of pregnancy, preeclampsia, and gestational diabetes mellitus are risk factors for future development of cardiovascular disease.[8,9] Earlier identification of these women with an increased lifetime risk for developing cardiovascular disease may present a unique opportunity for prevention of subsequent cardiovascular events.

Historically, rheumatic mitral stenosis represented the most common cardiac condition encountered in pregnant women. This disease continues to be a major problem in the developing world and in certain immigrant populations in the United States. In the industrialized countries, congenital heart disease has become the most common cardiac condition complicating pregnancy. This demographic change is a result of significant advances in the treatment of complex congenital heart conditions and survival of these patients into childbearing age. In the United States, maternal mortality due to hemorrhage and hypertensive disorders of pregnancy has declined, whereas mortality due to cardiovascular conditions has steadily increased.[10]

The optimal management of women with cardiovascular disease begins *before* conception. Normal physiologic changes of pregnancy may exacerbate preexisting cardiovascular disease. For most women with heart disease, pregnancy is associated with favorable outcome; however, even with modern advances in treatment and monitoring, there remains a high incidence of morbidity and mortality for some conditions. Thus, for some women, it may be advisable to avoid pregnancy.

There is significant individual variability in the severity of specific cardiovascular disease entities. Additionally, several cardiovascular conditions may be simultaneously present in one individual. Management may be further complicated by the presence of noncardiovascular pathologic processes. The anesthetic management of the parturient with cardiovascular disease should be individualized, and a multidisciplinary team should plan peripartum care. Some case reports and small series have described the anesthetic management of these patients, but, in general, few data justify choosing one anesthetic technique over another. Therefore, the anesthesiologist must have a thorough understanding of the normal physiologic changes of pregnancy as well as the individual parturient's pathophysiology, and then plan anesthetic management that best achieves the desired hemodynamic goals. Optimal *analgesia* is often an important part of safe childbirth in these patients.

The anesthetic care of women with cardiovascular disease does not end with labor and delivery; rather, it continues postpartum when the physiologic changes of pregnancy may be at their greatest. Inadequate postpartum analgesia may be associated with hypertension and tachycardia. Postoperative shivering increases oxygen consumption and may cause myocardial ischemia in patients with limited cardiac reserve.

CARDIOVASCULAR PHYSIOLOGIC CHANGES OF PREGNANCY

The **electrocardiogram (ECG)** typically changes during pregnancy. During the third trimester, the enlarging gravid uterus causes upward and lateral rotation of the heart, which may result in left-axis deviation of 15 to 20 degrees. Overall, however, the QRS axis is quite variable during pregnancy. At rest, nonspecific ST-segment and T-wave changes are very common during normal pregnancy.[11] Exercise in healthy pregnant women does not cause distinctive ECG changes when compared with nonpregnant subjects.

No repolarization abnormalities are observed with uncomplicated vaginal delivery. ST-segment *elevation* is never seen in normal pregnancy and should always be considered pathologic. ST-segment *depression* is seen in 25% to 81% of parturients undergoing cesarean delivery, regardless of the type of anesthesia. Oxytocin administration during the third stage of labor has been associated

with ST-segment depression.[12,13] However, these oxytocin-associated ECG changes are not associated with myocardial damage. Whether these ECG changes are caused by underlying ischemia or some other mechanism remains unclear.[14]

Left ventricular mass increases during normal pregnancy.[15,16] The increase in left ventricular mass is greater in multiple gestation than in singleton gestation.[17] Preeclampsia also results in a greater increase in left ventricular mass.[18]

Plasma lipid concentrations, including total serum cholesterol, triglycerides, and low-density lipoprotein cholesterol concentrations, increase during pregnancy.[19] Obese pregnant women have an even greater increase in plasma lipids. This increase in plasma lipids results in part from insulin resistance and an increase in estrogen levels during pregnancy. The effects of these physiologic changes in plasma lipid concentrations on long-term cardiovascular outcomes are unclear.

Brain natriuretic peptide (BNP) is a natriuretic hormone synthesized primarily in the heart ventricles. BNP levels increase as a response to increased filling pressures in patients with heart failure. Physiologically, BNP has hypotensive, diuretic, and natriuretic effects. During uncomplicated normal pregnancy, BNP levels are unchanged (< 20 pg/mL).[20] The lack of change in BNP levels during normal pregnancy suggests that the heart adapts to the increased volume load associated with pregnancy. By contrast, BNP levels are increased in preeclamptic women[20] and in pregnant women with heart disease.[21] A correlation exists between BNP and the increases in left ventricular mass and end-diastolic and end-systolic volumes observed in preeclampsia.[18] The increase in BNP with fluid administration in preeclamptic women further confirms that this hormone is secreted in response to increased intracavitary pressures. Intravenous fluid administration does not increase BNP levels in healthy women.[22,23] BNP is elevated in women with complex congenital heart disease, but it varies considerably among anomalies. Therefore, its use for individual patient management remains unclear.[24]

Cardiac enzyme levels may be altered by pregnancy or pregnancy-associated disease. Myocardial cell death is associated with elevation of sensitive and specific cardiac biomarkers—creatine kinase MB fraction (CK-MB) and cardiac troponins.[25] Cardiac troponin levels are not elevated above the upper limits of normal during uncomplicated pregnancy. Troponin levels are elevated in women with gestational hypertension or preeclampsia.[26,27] By contrast, CK-MB levels may be elevated up to two to four times the upper limit of normal owing to the presence of these enzymes in the uterus and placenta (see Figure 47-1). Thus, elevated CK-MB levels are not specific for the diagnosis of myocardial infarction during pregnancy.[27,28] In patients with preeclampsia who have concurrent myocardial infarction, the observed troponin levels are higher than expected for the underlying preeclampsia.[29] Heterophil antibody interference with the troponin assay may cause a false-positive increase in troponin levels during pregnancy. However, both CK-MB and troponin are sensitive markers for the diagnosis of myocardial infarction during pregnancy.

Cardiac output increases as early as 5 weeks' gestation and continues to increase throughout the second trimester until it is approximately 50% greater than nonpregnant values (see Figure 2-1). Cardiac output does not change from this level during the third trimester; it may actually be reported as decreased in the third trimester if measurements are made in the supine position, which causes aortocaval compression. Both an increase in heart rate and stroke volume contribute to the increase in cardiac output. Distribution of cardiac output to the uterine circulation increases from 1% in the nonpregnant state to 12% during the second half of pregnancy (see Chapter 2).

CARDIAC EXAMINATION DURING PREGNANCY

Pregnant women frequently complain of mild dyspnea at rest and exertion; on occasion, exercise tolerance is decreased. Therefore, it is important to recognize normal changes in the physical examination associated with pregnancy (Table 42-1).

Resting heart rate is higher in pregnancy, and peripheral pulses are "well filled" with rapid upstroke and collapse, primarily owing to lower systemic vascular resistance (SVR). The central venous pressure remains unchanged during pregnancy, and any elevation of jugular venous pressure is an abnormal finding. Basilar rales may be heard on lung auscultation; however, these are no longer heard after deep inspiration, a brief breath-hold, or a cough. These evanescent rales likely result from basilar atelectasis.

The heart examination during pregnancy is altered as a result of uterine enlargement. Consequently, the point of maximum impulse (left ventricular apex) is displaced superiorly and laterally during advanced pregnancy. It remains crisp, well defined, and hyperdynamic. In thin women, the right ventricular impulse may become visible owing to an increase in circulating blood volume and the proximity of this chamber to the anterior chest wall.

Recognition of normal auscultatory changes helps distinguish pathologic from physiologic changes. New murmurs are heard in more than 90% of pregnant women. The loudest murmurs are heard between 15 and 25 weeks' gestation; murmur intensity decreases toward term and increases again during labor and the early postpartum period. This peripartum increase in murmurs is followed by a gradual decrease; most of these pregnancy-associated murmurs are no longer appreciated by 6 weeks postpartum.[30] Importantly, there is no correlation between the disappearance of physiologic murmurs of pregnancy and the return of cardiac output and blood volume to prepregnancy levels.[31]

The first heart sound (S1) becomes louder and is widely split owing to early closure of the mitral valve during pregnancy. The second heart sound (S2) is unchanged. It is quite common to appreciate the third heart sound (S3), although considerable expertise and a quiet environment are necessary because of the presence of underlying tachycardia and an increased basal respiratory rate. The fourth heart sound (S4) is rarely

TABLE 42-1 **Cardiovascular Physical Examination in Pregnancy**

Feature	Normal Pregnancy	Implication of Abnormal Findings
Jugular venous pressure	Normal	Any elevation warrants further evaluation of volume status
Carotid pulse	Normal upstroke Normal volume	Decreased or delayed upstroke (aortic stenosis), bifid pulse (hypertrophic cardiomyopathy)
Peripheral pulses	Well filled	Diminished or delayed (aortic stenosis, left ventricular outflow obstruction)
Point of maximum impulse	Crisp, slightly laterally displaced	Any enlargement or more than slight lateral displacement warrants further evaluation.
S1	Louder and widely split	
S2	Unchanged	Soft/absent/paradoxically split (aortic stenosis) Loud P2, fixed split (pulmonary hypertension)
S3	Normally present	
S4	Rarely heard	
Aortic stenosis murmur	Increased	
Aortic regurgitation murmur	Decreased	Helpful to confirm physical examination findings with echocardiography
Mitral stenosis murmur	Increased	
Mitral regurgitation murmur	Decreased	
Hypertrophic cardiomyopathy murmur	Decreased	Not all hypertrophic cardiomyopathies have obstructive murmurs; helpful to confirm with echocardiography
Peripheral edema	Mild edema normally present	Asymmetric edema warrants further evaluation
Stigmata of Marfan syndrome		Risk for aortic dissection
Stigmata of Turner syndrome		Risk for aortic dissection

LV, left ventricle.

appreciated. Owing to increased cardiac output and increased flow through cardiac valves, a systolic ejection murmur, usually soft (grade 2 to 3/6), is appreciated over the upper sternal border and the right side of the heart.

The murmurs of aortic and mitral regurgitation generally decrease and may become inaudible during pregnancy owing to the decrease in SVR. However, administration of phenylephrine or development of hypertension during pregnancy, both of which increase the SVR, increases the intensity of these murmurs.[32]

The murmur associated with aortic stenosis increases in intensity during pregnancy from increased flow through the stenotic valve. A diminished carotid upstroke, soft or inaudible S2, and a grade 4/6 murmur are almost always indicative of severe aortic stenosis. An audible, physiologic split S2 almost invariably rules out severe aortic stenosis. Diastolic murmurs during pregnancy are almost always associated with an underlying pathologic process.

The murmur of hypertrophic cardiomyopathy may have decreased intensity because the pregnancy-associated increase in intravascular volume may result in decreased outflow tract obstruction. The murmur of an atrial septal defect may become more audible during pregnancy.

Mammary souffle ("soo-fuhl") is a noncardiac sound; it describes the continuous hum heard over the breasts. It becomes audible during late pregnancy and lactation, and it disappears at the end of lactation.

Most pregnant women display some degree of peripheral edema, in part owing to uterine compression of the inferior vena cava, which impedes venous return. This physiologic edema is symmetric and decreases with leg elevation and the left lateral decubitus position. The pathologic edema of preeclampsia should be differentiated from the physiologic edema of pregnancy. Asymmetric lower extremity edema is almost invariably pathologic. A tender and warm lower extremity may suggest deep vein thrombosis or cellulitis.

Funduscopic examination in pregnancy may help differentiate chronic hypertension from hypertensive disease of pregnancy (preeclampsia/eclampsia) and may identify changes due to long-standing diabetes.

It is important to look for stigmata of Marfan syndrome. Tall stature, large arm span, or other stigmata may alert the practitioner to the presence of a previously undiagnosed condition. Patients with Marfan syndrome frequently demonstrate scoliosis and may have dural ectasia. Turner syndrome is characterized by short stature and webbed neck. Both conditions predispose pregnant women to aortic dissection (see later discussion).

CARDIAC RISK PREDICTION

The New York Heart Association (NYHA)[33] and Heart Failure Stage[34] classifications describe symptoms and predict risk in the nonpregnant population (Box 42-1). Several classifications have been proposed to specifically predict cardiac risk during pregnancy (Boxes 42-2, 42-3, and 42-4).[35-38] These classifications may help predict the individual pregnant woman's cardiac risk and, combined with the clinical constellation and results of cardiac imaging, may help guide clinical management.[35,37-39] Implementation of a standardized and guideline-based approach to care, based on risk assessment, provides consistency in treating pregnant women with cardiac disease.

Maternal cardiac disease is associated with an increased incidence of **neonatal complications**. The most widely

BOX 42-1 New York Heart Association (NYHA) Functional Classification of Heart Failure

Classification of Heart Failure

Class I

No limitation of physical activity

Class II

Mild limitation of physical activity; regular physical activity causes symptoms

Class III

Marked limitation of physical activity; no symptoms at rest; minimal activity causes symptoms

Class IV

Symptoms at rest

Stages in the Development of Heart Failure

Stage A

At risk for heart failure but without structural heart disease or symptoms (e.g., hypertension, coronary artery disease, obesity)

Stage B

Structural heart disease but without signs or symptoms (e.g., previous myocardial infarction, asymptomatic valvular heart disease)

Stage C

Structural heart disease with prior or current symptoms of heart failure (e.g., known structural heart disease and symptoms)

Stage D

Refractory heart failure (e.g., marked symptoms at rest with maximal medical therapy)

Modified from Kosman CE, editor. New York Heart Association. Diseases of the Heart and Blood Vessels; Nomenclature and Criteria for Diagnosis. 6th edition. Boston, Brown and Co., 1964; and Hunt SA, Abraham WT, Chin MH, et al. Focused update incorporated into the ACC/AHA 2005 Guidelines for the Diagnosis and Management of Heart Failure in Adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: developed in collaboration with the International Society for Heart and Lung Transplantation. Circulation 2009; 119:e391-479.

BOX 42-2 CARPREG (CARdiac Disease in PREGnancy) System for Predicting Maternal Cardiovascular Events

Prior cardiac event (1 point)
- Heart failure
- Transient ischemic attack
- Cerebrovascular accident
- Arrhythmia

NYHA > class II or cyanosis (1 point)
Mitral valve area < 2 cm^2 (1 point)
Aortic valve area < 1.5 cm^2 (1 point)
Left ventricular outflow tract gradient > 30 mm Hg (1 point)
Ejection fraction < 40% (1 point)

CARPREG Points	Cardiac Complication Rate
0	5%
1	27%
2	75%

Points are added and the total score reflects the predicted cardiac event rate.
NYHA, New York Heart Association.

BOX 42-3 ZAHARA (Zwangerschap bij vrouwen met een Aangeboren HARtAfwijking) for Predicting Maternal Cardiovascular Events

History of arrhythmia (1.5 points)
Use of cardiac medications before pregnancy (1.5 points)
NYHA > class II (0.75 point)
Left-sided heart obstruction (peak gradient > 50 mm Hg or aortic valve area < 1.0 cm^2) (2.5 points)
Systemic atrioventricular valve regurgitation (moderate/severe) (0.75 point)
Pulmonic atrioventricular valve regurgitation (moderate/severe) (0.75 point)
Mechanical valve prosthesis (4.25 points)
Repaired or unrepaired cyanotic heart disease (1.0 point)

ZAHARA Points	Cardiac Complication Rate
0-0.5	2.9%
0.51-1.50	7.5%
1.51-2.50	17.5%
2.51-3.50	43.1%
≥ 3.51	70.0%

Points are added and the total score reflects the predicted cardiac event rate.
NYHA, New York Heart Association.
Modified from Drenthen W, Boersma E, Balci A, et al. Predictors of pregnancy complications in women with congenital heart disease. Eur Heart J 2010; 31:2124-32.

accepted associations are cyanosis, NYHA functional class greater than II, presence of a mechanical valve prosthesis, heparin or warfarin use during pregnancy, multiple gestation, smoking during pregnancy, left-sided heart obstruction, and use of cardiac medications before pregnancy.[35,39]

CARDIOVASCULAR IMAGING DURING PREGNANCY

Echocardiography

Echocardiography allows for safe and noninvasive assessment of heart structure and function. Both transthoracic and transesophageal echocardiography can be performed at any stage of pregnancy. Echocardiography helps predict overall cardiac risk and guides anesthetic management in pregnant women with cardiac disease. Echocardiography also allows assessment of intravascular volume

BOX 42-4 Modified World Health Organization Cardiac Risk Assessment

Class I (no increase or a mild increase in morbidity)

- Mild pulmonic stenosis
- PDA
- Mitral valve prolapse
- Repaired ASD, VSD, PDA, anomalous pulmonary venous return

Class II (small increase in maternal mortality, moderate increase in maternal morbidity)

- Unrepaired ASD or VSD
- Repaired tetralogy of Fallot
- Most arrhythmias
- Mild left ventricular dysfunction
- Hypertrophic cardiomyopathy
- Marfan syndrome without aortic dilation
- Bicuspid aortic valve with aortic diameter < 45 mm

Class III (significant increase in maternal mortality and severe increase in maternal morbidity)

- Mechanical valve(s)
- Systemic right ventricle
- Fontan circulation
- Unrepaired cyanotic heart disease
- Complex congenital heart disease
- Marfan syndrome with aortic dilation 40 to 45 mm
- Bicuspid aortic valve with aortic dilation 45 to 50 mm

Class IV (pregnancy is not recommended or is contraindicated)

- Pulmonary artery hypertension of any cause
- Severe left ventricular dysfunction
- Previous peripartum cardiomyopathy with residual left ventricular dysfunction
- Severe mitral stenosis
- Severe aortic stenosis
- Marfan syndrome with aortic dilation > 45 mm
- Bicuspid aortic valve with aortic dilation > 50 mm
- Severe unrepaired aortic coarctation

PDA, patent ductus arteriosus; ASD, atrial septal defect; VSD, ventricular septal defect.

Modified from Thorne S, MacGregor A, Nelson-Piercy C. Risks of contraception and pregnancy in heart disease. Heart 2006; 92:1520-5; and Regitz-Zagrosek V, Blomstrom Lundqvist C, Borghi C, et al. European Society of Cardiology guidelines on the management of cardiovascular diseases during pregnancy. Eur Heart J 2011; 32:3147-97.

and may obviate the need for right-sided heart catheterization to determine ventricular filling pressures.

One of the most commonly used echocardiographic assessments of left ventricular function—left ventricular ejection fraction—remains unchanged during pregnancy. Echocardiographic measurements of cardiac output increase during pregnancy owing to increases in stroke volume and heart rate. Importantly, stroke work is increased during pregnancy, which is consistent with augmented myocardial fiber function. Both the right and left ventricular chamber size are increased in end diastole and end systole, and the heart becomes more globular. This increase in chamber size results in increased left ventricular end-systolic and end-diastolic volumes and is accompanied by an increase in left ventricular wall thickness (eccentric left ventricular hypertrophy). These parameters return to baseline within 3 to 6 months postpartum.[40] Left ventricular end-diastolic and end-systolic volumes are further increased with multiple gestation; the stroke volume is increased an additional 15%. Combined with a small additional increase in heart rate, this change results in a 20% greater increase in maternal cardiac output with multiple gestation compared with singleton gestation.[17]

Left atrial size is increased during pregnancy[16]; the increase is even greater with multiple gestation than with singleton gestation.[17] Preeclampsia results in an adaptive concentric hypertrophy and an increase in left ventricular mass due to increased afterload.

In normal pregnancy, left ventricular diastolic function is increased in the first two trimesters and declines in the third trimester.[15] Twenty percent of women with preeclampsia have evidence of global diastolic dysfunction.[41] Diastolic function is most commonly assessed echocardiographically by evaluating mitral valve inflow, pulmonary venous flow, and myocardial tissue motion (tissue Doppler imaging).

Cardiac Magnetic Resonance Imaging

The risks of magnetic resonance imaging (MRI) in pregnant women are similar to those in nonpregnant patients. The *potential* risks to the fetus are teratogenicity and acoustic damage. There are no published reports of untoward fetal effects resulting from MRI in pregnant women. Owing to limited evidence on safety during organogenesis, it may be prudent to limit use of MRI during the first trimester. Cardiac magnetic resonance (CMR) imaging should be performed during pregnancy only after consideration of both the maternal and fetal benefits and risks. However, given the quality of images and diagnostic yield, CMR is preferable to any other modality that uses ionizing radiation. Gadolinium use during pregnancy should be avoided; it should be used only if absolutely required. Gadolinium is a pregnancy category C drug; it crosses the placenta and has been shown to be teratogenic in animal studies.

Left- and Right-Sided Heart Catheterization

Left-sided heart catheterization remains the gold standard for diagnosis of coronary artery disease, and it can be performed at any time during pregnancy. Radial arterial access is preferable to femoral access because it is associated with earlier ambulation, increased patient comfort, and a significant reduction in access-related bleeding complications. Additionally, during the procedure, the left lateral decubitus position can be more easily maintained with radial access. Cardiologists should strictly adhere to the ALARA principle (as low as reasonably achievable) to limit both maternal and fetal ionizing radiation exposure.

The use of pulmonary artery catheterization has significantly declined in the United States in recent

years. Similar information can be obtained noninvasively by transthoracic or transesophageal echocardiography. However, thermodilution and Fick cardiac output measurements can be obtained only with the use of a pulmonary artery catheter. Similarly, right-sided heart catheterization is required for vasoreactivity testing in patients with pulmonary hypertension. Historically, pulmonary artery catheterization has helped guide fluid management in women with severe preeclampsia and eclampsia, particularly those who develop renal failure and pulmonary edema (see Chapter 36). In the future, ventricular filling in these patients may be assessed noninvasively with the bedside use of portable, hand-held transthoracic echocardiography devices.

Iodinated Contrast Use during Pregnancy

The use of iodinated contrast media in pregnant women appears safe. To date, there have been no reports of fetal teratogenic or mutagenic effects after maternal administration of iodinated contrast media. Free iodide in the contrast medium administered to the mother may depress fetal, and subsequently neonatal, thyroid function. Therefore, it has been suggested that neonatal thyroid function be checked during the first week postpartum. Minimal amounts of iodinated contrast media are excreted in breast milk; even smaller amounts are absorbed by the neonate's gastrointestinal tract. The slight potential risk associated with absorption of contrast medium is thought to be insufficient to recommend interruption of breast-feeding after maternal administration of iodinated contrast media.

Computed Tomographic Angiography

Multidetector computed tomography (CT) allows noninvasive imaging of the coronary arteries along with cardiac structure and function. Use of contemporary CT with aggressive dose-reduction techniques can significantly limit the radiation dose. The overall radiation dose of coronary CT angiography may be equivalent to, or even lower than, radiation doses delivered with conventional invasive coronary angiography. Although soft cardiac structures not seen by conventional coronary angiography are well visualized by CT angiography, the intravenous contrast medium load is greater with CT angiography, and coronary intervention cannot be performed at the time of imaging. Thus, in pregnancy, invasive coronary angiography appears preferable under most circumstances.

Ionizing Radiation Risks to the Fetus

The ionizing radiation dose to the fetus can be limited by the use of echocardiography, intracardiac echocardiography, and markedly reduced fluoroscopy frame rates. Because the fetus is not directly within the radiation beam for cardiac procedures, the fetal exposure occurs through indirect scatter radiation. Therefore, external shielding of the fetus is ineffective. The fetal radiation dose cannot be measured and is therefore estimated. It is reassuring that the estimated fetal doses are low. Nonetheless, the safest approach is to avoid ionizing radiation during pregnancy if possible, and to assess both the maternal and fetal risks and benefits before deciding on the most appropriate imaging modality.

CARDIAC DRUGS AND PREGNANCY

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors are the mainstay of coronary artery disease treatment, left ventricular dysfunction, and hypertension in nonpregnant patients. These drugs are particularly useful in nonpregnant patients with diabetes mellitus.

In the first trimester, the use of ACE inhibitors has been associated with an increased risk for fetal cardiovascular and central nervous system malformations. Use of ACE inhibitors during the second and third trimesters of pregnancy has also been associated with adverse fetal and neonatal outcomes as a result of the ACE inhibitors' effect on fetal renal vascular tone. These drugs cause fetal kidney malfunction and decreased fetal urine output, which results in oligohydramnios. Positional limb deformities, skull ossification retardation, and lung hypoplasia are seen with ACE inhibitor–associated oligohydramnios. These effects are not thought to be caused by fetal exposure to ACE inhibitors during the first trimester. Thus, despite the exceptionally useful profile of ACE inhibitors in nonpregnant patients with cardiovascular disease, their use in pregnancy is contraindicated (pregnancy category D) (see Chapter 14).[42]

Angiotensin Receptor–Blocking Agents

Fewer data are available on the use of angiotensin receptor–blocking agents in pregnancy. Nonetheless, given the adverse outcomes associated with use of ACE inhibitors in pregnancy and the mechanism of action of angiotensin receptor–blocking agents, the use of these drugs is not recommended in pregnancy.[42]

Beta-adrenergic Receptor Antagonists

Beta-adrenergic receptor antagonists are often used for treatment of coronary artery disease, myocardial infarction, hypertension, many arrhythmias, and a wide spectrum of cardiomyopathies. There is no evidence that beta-adrenergic receptor antagonists are teratogenic. Prolonged and high-dose use of these drugs has been associated with fetal growth restriction (also known as intrauterine growth restriction); however, the overall risk is likely small.[42] Neonatal bradycardia, hypotension, and hyperglycemia are rarely encountered.

Calcium Entry–Blocking Agents

First-trimester maternal use of **verapamil** and **diltiazem** is likely not teratogenic. Both drugs appear to be safe and effective treatments for cardiac arrhythmias in the second and third trimesters.[42] The use of **amlodipine**, a

dihydropyridine calcium entry–blocking agent, appears safe during pregnancy.[42]

Other Drugs

Hydralazine is used in the treatment of cardiomyopathy and is also an excellent antihypertensive agent. It has a long track record of safe use during pregnancy.[42]

The use of **nitrates** for treatment of angina during pregnancy appears safe. Nitrates likely can be safely used long term in pregnant women with cardiomyopathy.[42]

Digoxin is quite useful for the treatment of various cardiomyopathies and some arrhythmias. Digoxin freely crosses the placenta, but its use has not been associated with congenital abnormalities or untoward fetal effects.[42] Digoxin's pharmacokinetics are altered during pregnancy, and attention to blood levels is recommended.

Eptifibatide, tirofiban, and abciximab are potent intravenous platelet aggregation inhibitors **(IIB/IIIA receptor inhibitors)** used to inhibit platelet aggregation during percutaneous coronary intervention. Both the American Society of Regional Anesthesia and Pain Medicine (ASRA) and the European Society of Anaesthesiology (ESA) guidelines strongly advise avoidance of neuraxial anesthesia until platelet function has recovered after administration of these agents.[43,44]

Statins interrupt cholesterol synthesis and result in a lowering of plasma cholesterol levels. The widespread use of statins (which are associated with exceptionally robust cardiovascular outcome data) has transformed the treatment of coronary artery disease. Nonetheless, given the critical importance of cholesterol synthesis in the normal development of the embryo and placenta, and thus their potential for teratogenicity, statins are contraindicated in pregnancy (pregnancy category X).[42]

Thiazide diuretics do not appear to be teratogenic. Long-term use may result in a reduction in uteroplacental perfusion, which may be associated with fetal growth restriction and oligohydramnios.[42] Neonatal hypoglycemia and thrombocytopenia have been reported.

Loop diuretics are likely not teratogenic.[42] Similar to thiazide diuretics, fetal growth restriction may be associated with long-term use during pregnancy. **Spironolactone** is an aldosterone antagonist frequently used in the treatment of patients with congestive heart failure and cardiomyopathy, but because of its antiandrogenic potential its use during pregnancy is not recommended.[42]

AORTIC DISEASES AND AORTIC DISSECTION

The cardiovascular changes of pregnancy may to lead to increased arterial wall tension and intimal shear forces. However, the full impact of pregnancy on changes in aortic wall structure is not fully understood. Estrogen-induced changes in collagen deposition, as well as circulating elastases and relaxin, may weaken the aortic media and thus predispose the aorta to dissection during pregnancy. Approximately half of aortic dissections and ruptures in women younger than 40 years of age are associated with pregnancy.[45] Dissection of the ascending aorta (Stanford type A or DeBakey type I or II) is a surgical emergency, whereas dissection of the descending aorta (Stanford type B or DeBakey type III) is predominantly treated medically.

Conditions that predispose women to aortic dissection during pregnancy include Marfan syndrome, Ehlers-Danlos syndrome, bicuspid aortic valve,[46] Turner syndrome, and non–Marfan syndrome–associated familial thoracic aneurysms.[47] Aortic dissection has been associated with preeclampsia and chronic hypertension in pregnancy.[48] Most aortic dissections that occur during pregnancy are type A (ascending aorta); the average aortic diameter at the time of dissection is 4.8 cm.[49] The majority of dissections occur in the third trimester of pregnancy, but aortic dissections may also occur at the time of delivery or in the early postpartum period. It has been hypothesized that contraction of the uterus causes outflow resistance, thus predisposing to aortic dissection after delivery.

Marfan Syndrome

Marfan syndrome is an autosomal-dominant connective tissue disorder. The penetrance is high, but the expression is variable. Marfan syndrome is caused by a mutation in the *FBN1* gene encoding fibrillin-1, a glycoprotein. Sporadic mutations are seen in approximately 25% of patients without a family history of this syndrome. Aortic dilation and aortic dissection contribute significantly to cardiovascular complications in these patients. In addition to aortic disease, affected patients often have valvular disease (e.g., aortic regurgitation, mitral regurgitation, mitral valve prolapse). Aortic dissection has been observed during pregnancy and in the peripartum period.[50,51] Most patients have type A aortic dissection; type B aortic dissection and abdominal aortic aneurysm are less commonly seen.

Based on observational studies, current guidelines recommend that women with Marfan syndrome who are planning pregnancy undergo replacement of the ascending aorta and the aortic root if the diameter is greater than 4.0 cm (class IIa, level of evidence C).[47,52] The aortic root dilation rate increases during pregnancy and does not return to baseline after delivery. Subsequent pregnancies further increase the aortic dilation rate.[53]

Aortic Disease Associated with a Bicuspid Aortic Valve

Bicuspid aortic valve has been associated with dissection during pregnancy.[46] Affected women are slightly younger, and the dissection occurs earlier in pregnancy than in patients with Marfan syndrome.[49] Because the disease is familial, first-degree relatives of patients with a bicuspid aortic valve should be screened for this disease.[54]

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is an inherited connective tissue disorder. Ehlers-Danlos syndrome type IV has been associated with severe complications and maternal mortality. Rupture of the bowel, aorta, vena cava, and uterus may

occur.[47] Pregnancy outcomes in patients with Ehlers-Danlos syndrome types I, II, and III are generally favorable, although these women have a higher incidence of pelvic instability, preterm delivery, perineal lacerations, and postpartum hemorrhage than the general population.[55]

Turner Syndrome

Turner syndrome is caused by complete or partial absence of an X chromosome. In addition to short stature, webbed neck, and characteristic facial features, Turner syndrome is associated with aortic coarctation and hypertension. During pregnancy, the syndrome is associated with aortic dissection.[56,57] Moreover, approximately 30% of patients with Turner syndrome have a bicuspid aortic valve, which is also a risk factor for aortic dissection. Preconception echocardiographic evaluation of patients with Turner syndrome is recommended.[47,58] Given the frequent aortic abnormalities in these patients, preconception MRI is also recommended. Cesarean delivery is frequently required in these patients because of cephalopelvic disproportion.[58]

Management

Given the inherent risk for aortic dissection, parturients with aortic disease should deliver in a center that has immediate access to a cardiothoracic surgeon with expertise in aortic endovascular repair techniques.[59] Current guidelines are based on expert opinion, case reports, and current standard of care (level C evidence) (Box 42-5; Table 42-2). The 2010 American College of Cardiology (ACC) Foundation/American Heart Association (AHA) guidelines recommend the following for pregnant women with chronic aortic dilation: (1) strict blood pressure control; (2) monthly or bimonthly echocardiographic measurement of aortic dimension; (3) cesarean delivery in women with significant aortic enlargement, dissection, or severe aortic valve regurgitation; and (4) prophylactic surgery in the setting of progressive aortic dilation and/or advancing aortic valve regurgitation.[47]

All patients with Marfan syndrome should receive beta-adrenergic receptor antagonist therapy throughout pregnancy to decrease the rate of aortic dilation.[47,60] The risk for major aortic complications during pregnancy appears low if the aortic root diameter is less than 4.0 cm.[47] In the event of a type A aortic dissection in the first or second trimester, surgical repair should be performed with the knowledge of fetal risk during hypothermic circulatory arrest. If the dissection occurs in the third trimester and the fetus is deemed viable, an urgent cesarean delivery followed by aortic surgery may be performed.

Both neuraxial[61,62] and general anesthesia[63] may be safely performed in these patients, with emphasis on meticulous blood pressure stability and control. Invasive blood pressure monitoring is recommended to facilitate tight hemodynamic control. Dural ectasia and scoliosis may complicate neuraxial anesthetic techniques in parturients with Marfan syndrome.[64] The increase in lumbar cerebrospinal fluid volume associated with dural ectasia may cause unpredictable and inadequate spread of intrathecal local anesthetic solutions; thus, it may be prudent to obtain lumbar spine MRI before planned pregnancy.

BOX 42-5 Management of Chronic Aortic Diseases in Pregnancy*

Class I†

- Women should be counseled about the risk for aortic dissection as well as the heritable nature of the disease before pregnancy.
- Strict blood pressure control, specifically to prevent stage 2 hypertension, is recommended.‡
- Monthly or bimonthly echocardiographic measurements of the ascending aortic dimensions are recommended to detect aortic expansion.
- For imaging of pregnant women, magnetic resonance imaging (without gadolinium) is recommended over computed tomography to avoid both maternal and fetal radiation exposure. Transesophageal echocardiography is an option for imaging of the thoracic aorta.
- Women should be delivered in a center where cardiothoracic surgery is available.

Class IIa†

- Cesarean delivery is reasonable for patients with significant aortic enlargement, dissection, or severe aortic valve regurgitation.

Class IIb†

- If progressive aortic dilation and/or advancing aortic valve regurgitation is documented, prophylactic surgery may be considered.

*All recommendations are *Level of Evidence C* (very limited populations have been evaluated and recommendations are based on consensus opinion of exerts, case studies, or standard of care).
†Class I: Procedure/treatment should be performed/administered; Class IIa: It is reasonable to perform procedure/administer treatment; Class IIb: Procedure/treatment may be considered.
‡Stage 2 hypertension: blood pressure ≥ 160/100 mm Hg.
Modified from Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. Circulation 2010; 121:e266-369.

CONGENITAL HEART DISEASE

Atrial Septal Defect

Patients with an atrial septal defect may remain asymptomatic until the fourth decade of life. Not infrequently, women with an atrial septal defect may become symptomatic during pregnancy. The most common defect is the secundum-type atrial septal defect (80%), whereas the primum, sinus venosus, and coronary sinus types of atrial septal defect are less common. Right ventricular overload leads to pulmonary hypertension and Eisenmenger syndrome in less than 5% of patients with an atrial septal defect. In women with both an atrial septal

TABLE 42-2 **Anesthetic Considerations for Specific Cardiovascular Pathologic Processes**

Disease	Modifier	Anesthetic Considerations	Monitoring
Ascending aortic dilation/aneurysm	Bicuspid aortic valve Marfan syndrome Turner syndrome	Meticulous attention to blood pressure control Maintain beta-adrenergic receptor antagonist therapy Possible dural ectasia (Marfan syndrome) may increase risk for failed spinal anesthesia	Low threshold for invasive blood pressure monitoring
Unrepaired ASD	PAP < 40 mm Hg	Pregnancy/labor usually well tolerated Meticulous attention to de-airing all venous access tubing Consider potential for air embolism with loss-of-resistance-to-air epidural technique	
	PAP ≥ 40 mm Hg	High-risk group Maintain preload Positive-pressure ventilation decreases preload and increases intrathoracic pressure, which is deleterious to RV function	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring
Repaired ASD	PAP < 40 mm Hg	Pregnancy well tolerated	
	PAP ≥ 40 mm Hg	High-risk group Maintain preload Positive-pressure ventilation decreases preload and increases intrathoracic pressure, which is deleterious to RV function	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring May require pulmonary vasodilators
Unrepaired or repaired VSD	PAP < 40 mm Hg	Pregnancy well tolerated	
	PAP ≥ 40 mm Hg	High-risk group	Invasive blood pressure monitoring. Central venous access/filling pressure monitoring May require pulmonary vasodilators
Patent ductus arteriosus		Pregnancy well tolerated	Echocardiographic evaluation to rule out pulmonary hypertension (rare)
Fontan repair		Meticulous attention to preload; low and high preload poorly tolerated Positive-pressure ventilation is poorly tolerated because increased intrathoracic pressure impedes venous return	Continuous telemetry monitoring indicated because of high incidence of arrhythmias
Transposition of the great arteries	Complete/repaired	Caution with preload due to propensity for RV dysfunction Meticulous attention to preload in the early postpartum period	Low threshold for central venous access/filling pressure monitoring in patients with RV dysfunction Continuous telemetry monitoring indicated because of high incidence of arrhythmias
	Congenitally corrected	Pregnancy well tolerated	Echocardiographic assessment of ventricular function is helpful
Ebstein's anomaly		Pregnancy well tolerated with normal RV function May have associated ASD detected by echocardiography (see above for ASD considerations)	Low threshold for continuous telemetry monitoring because of high incidence of arrhythmias

Continued

TABLE 42-2 **Anesthetic Considerations for Specific Cardiovascular Pathologic Processes—cont'd**

Disease	Modifier	Anesthetic Considerations	Monitoring
Tetralogy of Fallot (repaired)		Pregnancy well tolerated	Echocardiographic assessment of RV structure, function, and evidence of pulmonary hypertension
Pulmonary hypertension	Mild-moderate	Attention to preload	Low threshold for central venous access/filling pressure monitoring
	Severe	Very high-risk group Maintain SVR Maintain preload/venous return Prevent/treat pain, hypoxemia, hypercarbia, and acidosis Avoid myocardial depression	Multidisciplinary approach Echocardiography May require pulmonary vasodilators Invasive blood pressure monitoring Central venous access/filling pressure monitoring Caution with pulmonary artery catheterization without fluoroscopic guidance
Aortic stenosis	Transvalvular gradient < 25 mm Hg, valve area > 1.5 cm^2, normal LV function	Neuraxial anesthesia generally well tolerated Attentive preservation of preload and afterload Monitor closely for volume overload during the first 24 hours after delivery	Low threshold for invasive blood pressure monitoring
	Transvalvular gradient ≥ 25 mm Hg, valve area < 1.0 cm^2, LV dysfunction	High-risk group Consider risks/benefits of neuraxial versus general anesthesia Avoid myocardial depressants and vasodilators Meticulously maintain preload and afterload Avoid abrupt decrease in SVR with sympathectomy Maintain sinus rhythm Address new-onset atrial fibrillation (rate control, consider cardioversion). Monitor very closely for volume overload during first 24 hours after delivery	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring
Mitral stenosis	Valve area > 1.5 cm^2, gradient < 5 mm Hg, no pulmonary hypertension	Neuraxial anesthesia generally well tolerated Maintain sinus rhythm and prevent tachycardia Increase in preload is not well tolerated Address new-onset atrial fibrillation (rate control, consider cardioversion) Monitor closely for volume overload during first 24 hours after delivery	Low threshold for central venous access/filling pressure monitoring
	Valve area ≤ 1.5 cm^2, gradient ≥ 5 mm Hg, pulmonary hypertension	High-risk group Consider percutaneous mitral valvuloplasty prior to labor/delivery Maintain sinus rhythm and prevent tachycardia Increase in preload is not well tolerated Address new-onset atrial fibrillation (rate control, consider cardioversion) Prevent/treat pain, hypoxemia, hypercarbia, and acidosis	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring

TABLE 42-2 **Anesthetic Considerations for Specific Cardiovascular Pathologic Processes—cont'd**

Disease	Modifier	Anesthetic Considerations	Monitoring
Pulmonary stenosis	Mild-moderate	Pregnancy well tolerated	
	Severe	High-risk group Consider balloon valvuloplasty Prevent tachycardia Mitigate increase in pulmonary artery resistance (e.g., hypoxemia, positive-pressure ventilation)	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring
Hypertrophic cardiomyopathy	Without LVOT obstruction	Pregnancy well tolerated	
	With LVOT obstruction	Maintain beta-adrenergic receptor antagonist therapy Low preload and low afterload worsen outflow gradient Treat hypotension with phenylephrine Maintain sinus rhythm and prevent tachycardia Address new-onset atrial fibrillation (rate control, consider cardioversion)	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring Echocardiography helpful to follow outflow tract gradient
Cardiac tamponade		Meticulous attention to preload Maintain spontaneous ventilation Positive-pressure ventilation is deleterious to preload Volatile anesthetic agents depress ventricular function	Invasive blood pressure monitoring Central venous access/filling pressure monitoring

All patients with cardiovascular disease should labor in the lateral position to decrease aortocaval compression. Central venous pressure monitoring should be performed above the diaphragm.

ASD, atrial septal defect; *LV,* left ventricle; *LVOT,* left ventricular outflow tract; *PAP,* pulmonary artery pressure; *RV,* right ventricle; *SVR,* systemic vascular resistance; *VSD,* ventricular septal defect.

defect and Eisenmenger syndrome, pregnancy carries a significant risk for both maternal and fetal mortality, and is not recommended.[54,65] In the absence of pulmonary hypertension, pregnancy is overwhelmingly well tolerated in women with an atrial septal defect.

Cardiac complications are similar in women with unrepaired and repaired atrial septal defects. Preeclampsia, fetal demise, and small-for-gestational-age infants are more common in pregnant women with an unrepaired atrial septal defect than in the general obstetric population.[66] Pregnant women with an atrial septal defect are more likely to develop supraventricular and ventricular arrhythmias than women who are not pregnant.[67]

The risk for paradoxical embolism is increased in patients with an unrepaired atrial septal defect. It is critically important to ensure that intravenous catheters are de-aired.[54] Transesophageal echocardiography demonstrates the presence of microbubbles in the right-sided cardiac chambers within 15 seconds of the epidural injection of air or fluid.[68] Therefore, it seems prudent to avoid using the loss-of-resistance-to-air technique to identify the epidural space (see Table 42-2). Both neuraxial and general anesthesia are appropriate for patients with a repaired or unrepaired atrial septal defect.

Ventricular Septal Defect

There are four types of ventricular septal defects; the most common type is a perimembranous ventricular septal defect. Pregnancy is well tolerated in women with a repaired ventricular septal defect or a small ventricular septal defect in the absence of pulmonary hypertension. An unrepaired ventricular septal defect with Eisenmenger syndrome is associated with a high risk for maternal cardiac complications (see later discussion). Pregnancy is not recommended in patients with a ventricular septal defect and Eisenmenger syndrome.[54,65] Preeclampsia is encountered more frequently in women with an unrepaired ventricular septal defect.[69] Echocardiography allows assessment of right-sided pressures and shunt fraction.

Patent Ductus Arteriosus

Pregnancy is well tolerated in patients with patent ductus arteriosus, and complications are rare.[70] A left-to-right shunt may cause pulmonary hypertension. Pregnancy is not recommended in women with patent ductus arteriosus with Eisenmenger syndrome.[54,65]

Coarctation of the Aorta

Women with repaired coarctation of the aorta tolerate pregnancy well. Systemic arterial hypertension is often observed during labor. The coarctation may be associated with a bicuspid aortic valve in more than half the patients.[71] Prepregnancy evaluation of the coarctation, including the residual degree of obstruction[72] and associated anomalies (e.g., bicuspid aortic valve), is recommended.[54]

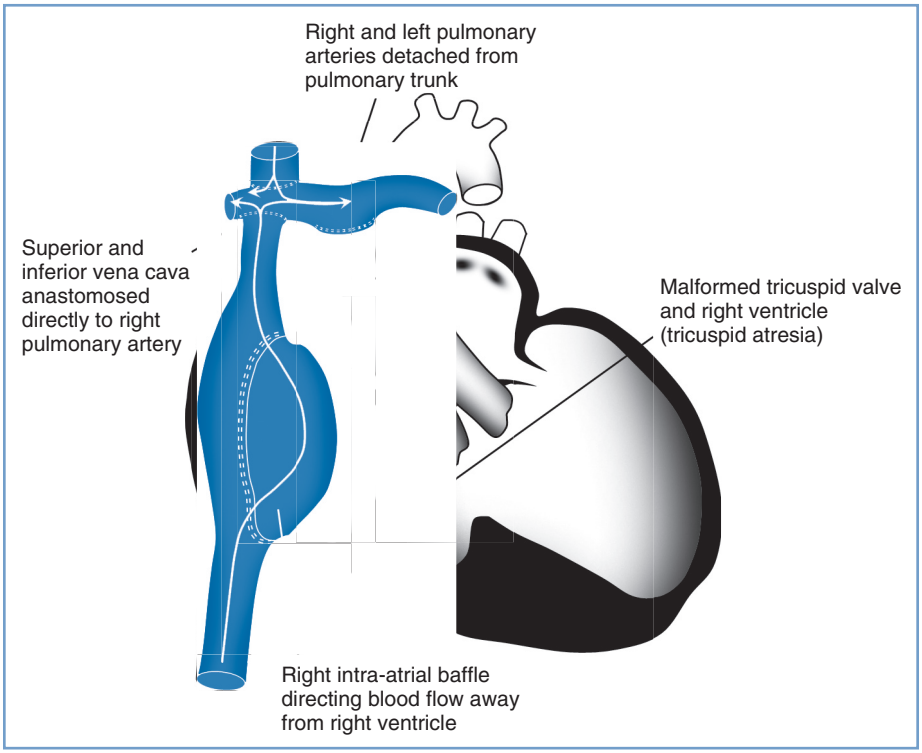

FIGURE 42-1 ■ Schematic depiction of a Fontan repair. There is no functional right ventricle. The white lines with arrows represent the pathway of venous blood returning to the heart. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

Vaginal delivery with neuraxial anesthesia is the preferred mode of delivery; cesarean delivery is reserved for obstetric indications.[73-75] Epidural anesthesia has been successfully administered in a patient with an uncorrected coarctation.[76] One report described the use of remifentanil to control blood pressure during administration of general anesthesia for cesarean delivery.[77]

Fontan Repair

The Fontan repair is a surgical procedure that establishes blood flow from the venous system to the pulmonary artery by bypassing the right ventricle (Figure 42-1). It can be performed for valvular defects such as tricuspid or pulmonic atresia, or other anomalies with a single ventricle. Because there is no functional right ventricle, blood flow from the periphery to the lungs occurs at *very low* pressure gradients. Owing to the presence of surgical scar tissue in the atrium, patients with a Fontan repair are prone to supraventricular and, less commonly, ventricular arrhythmias.[78,79] The Fontan repair is associated with the highest prevalence of arrhythmias during pregnancy of any congenital heart condition.[39] Deterioration in the NYHA functional status during pregnancy can occur.[79]

Administration of neuraxial analgesia/anesthesia for labor and vaginal delivery[80] and emergency cesarean delivery[81] has been described.[82] Administration of neuraxial anesthesia, with meticulous attention to maintenance of normal intravascular preload, appears to be the preferred anesthetic technique for cesarean delivery. Use of neuraxial anesthesia avoids the adverse effects of myocardial depression and positive-pressure ventilation on the Fontan circulation, which lacks a functioning right ventricle (see Table 42-2).[80,81]

Transposition of the Great Arteries

Transposition of the great arteries comprises two distinct groups: complete transposition of the great arteries (d-transposition) and congenitally corrected transposition of the great arteries (l-transposition). In both conditions, the aorta originates from the right ventricle and the pulmonary artery originates from the left ventricle. Complete transposition of the great arteries manifests as neonatal cyanosis.

Pregnant women born with d-transposition of the great arteries have undergone surgical correction—traditionally an *atrial* switch procedure (Senning or Mustard) or the more contemporary *arterial* switch procedure (Jatene or Rastelli). In the atrial switch procedure, the right ventricle functions as the systemic ventricle. Atrial arrhythmias, right ventricular (systemic ventricle) dysfunction, tricuspid regurgitation (systemic atrioventricular valve), atrial baffle obstruction or leaks, and pulmonary hypertension are some of the long-term complications of the traditional atrial switch surgical repair of d-transposition of the great arteries.[65] The advantage of the Jatene and Rastelli procedures is that the left ventricle functions as the systemic ventricle. However, myocardial ischemia may occur after arterial

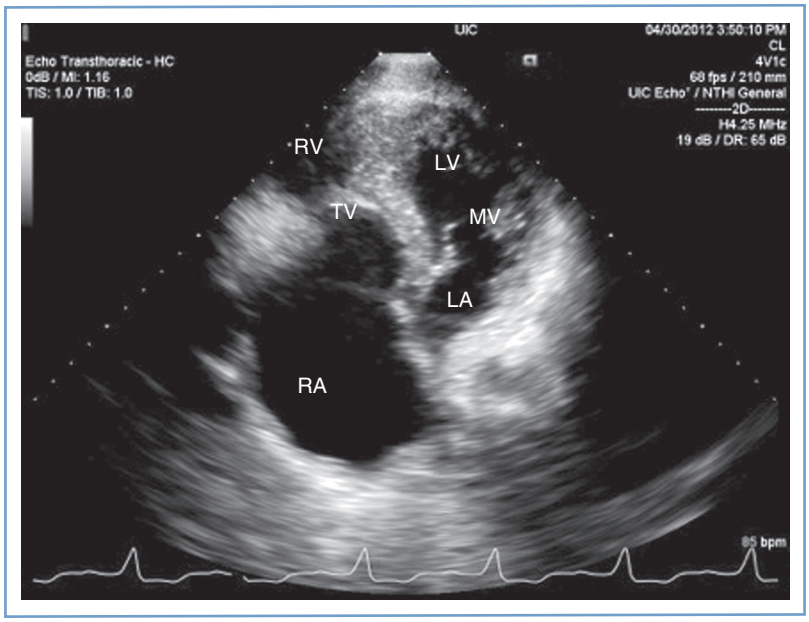

FIGURE 42-2 ■ Echocardiographic image of Ebstein's anomaly. The right atrium is markedly enlarged. *RA,* right atrium; *RV,* right ventricle; *TV,* tricuspid valve; *LA,* left atrium; *MV,* mitral valve; *LV,* left ventricle. switch operations, because the coronary arteries are reimplanted during these procedures.[83]

All women with repaired d-transposition of the great arteries require detailed echocardiography and, ideally, CMR imaging before planned pregnancy.[54,65] Owing to the propensity for arrhythmias in these patients,[39,84] continuous telemetry monitoring during labor and delivery seems appropriate. Women who have undergone the Mustard operation tolerate pregnancy well[85,86]; however, there is a risk for right ventricular dysfunction[84,87] that may be irreversible.[88] The physiologic changes of pregnancy and/or the natural progression of disease result in an increased right ventricular volume in pregnant women who have undergone a Mustard procedure.[85,88] There are limited data about pregnancy in patients who have undergone an arterial switch operation. Overall, pregnancy outcomes after arterial switch operations appear favorable.[89]

Patients with congenitally corrected transposition (l-transposition) of the great arteries tolerate pregnancy well.[90-92] Thorough echocardiographic evaluation before and throughout pregnancy is advisable.[54,65,83]

Both neuraxial and general anesthesia appear to be reasonable options for parturients with surgically corrected and congenitally corrected transposition of the great arteries (see Table 42-2). Successful cesarean delivery with general anesthesia has been reported in a parturient with d-transposition of the great arteries corrected with a Jatene procedure.[93]

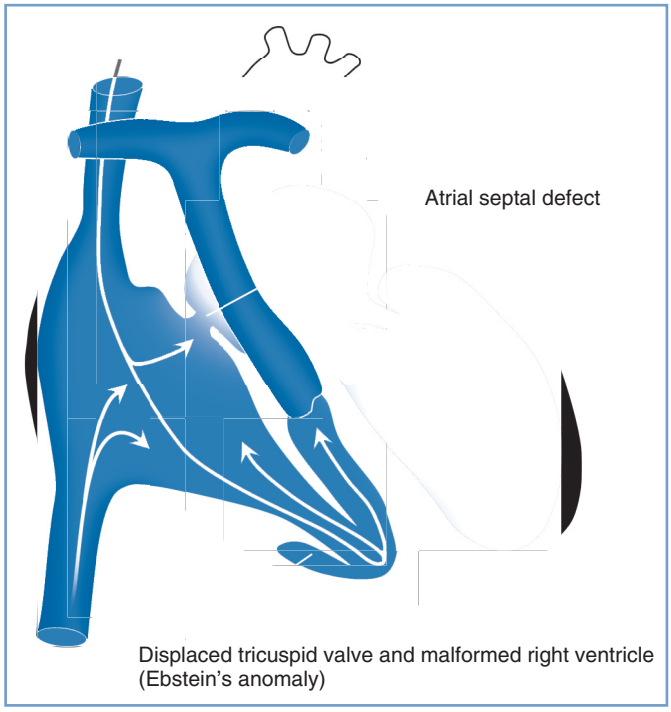

FIGURE 42-3 ■ Schematic depiction of Ebstein's anomaly and atrial septal defect. An atrial septal defect is present in more than one third of patients with Ebstein's anomaly. The white lines with arrows represent the pathway of venous blood returning to the heart. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

Ebstein's Anomaly

In Ebstein's anomaly the tricuspid valve is displaced toward the apex of the right ventricle, which results in severe tricuspid regurgitation and right atrial enlargement (Figures 42-2 and 42-3). It is commonly associated with an atrial septal defect and preexcitation syndromes. Accessory pathways result in arrhythmias in approximately 30% of patients; the most commonly observed arrhythmias include atrial tachycardia, atrial flutter, and atrial fibrillation. Pregnancy appears to be well tolerated

in patients with Ebstein's anomaly, especially in women with preserved ventricular function (see Table 42-2).[65,94,95] Patients with a concomitant atrial septal defect and cyanosis have an increased risk for fetal loss and low infant birth weight.[54]

Tetralogy of Fallot

Unrepaired tetralogy of Fallot consists of a ventricular septal defect, an aorta that overrides the ventricular septal defect, and right ventricular outflow tract obstruction (infundibular, valvular, or both), with resulting right ventricular hypertrophy.[54,65] Most women born with tetralogy of Fallot in the United States now present in pregnancy with surgically repaired tetralogy of Fallot. Unrepaired tetralogy of Fallot is rarely seen in developed countries; pregnancy is associated with significant risk in patients with unrepaired defects and is not recommended.[54,65]

During surgical repair the ventricular septal defect is closed and the right ventricular outflow obstruction is repaired. After surgery, important considerations include residual pulmonic valve insufficiency and resulting right ventricular dilation and dysfunction. The preanesthesia evaluation of these patients should include detailed echocardiographic evaluation of cardiac structure and function. Preferably, preconception CMR imaging should be performed because it provides superior imaging of the right-sided chambers. Patients with repaired tetralogy of Fallot are at risk for atrial and ventricular arrhythmias. Sudden cardiac death has been observed late after repair.[96]

Women with repaired tetralogy of Fallot and well-compensated hemodynamic function tolerate pregnancy well (see Table 42-2).[97-99] However, the presence of pulmonary hypertension, right ventricular dysfunction, right ventricular dilation, and/or pulmonic regurgitation predisposes these patients to adverse peripartum complications such as arrhythmias and right-sided heart failure.[65,99,100]

The safe management of neuraxial analgesia/anesthesia for labor and vaginal or cesarean delivery has been described in parturients with repaired tetralogy of Fallot and a wide range of residual pathologic processes.[101] In patients with unrepaired tetralogy of Fallot or tetralogy of Fallot with residual pathology, the anesthesiologist should avoid a decrease in SVR, which worsens the severity of the right-to-left shunt. It is also important to maintain adequate intravascular volume and venous return. In the presence of right ventricular compromise, high filling pressures are needed to enhance right ventricular performance and ensure adequate pulmonary blood flow. Administration of neuraxial analgesia during early labor (low-dose local anesthetic-opioid epidural analgesia or opioid-only intrathecal analgesia) may attenuate the surge of catecholamines and subsequent hemodynamic instability. It may be advisable to choose a titratable neuraxial technique for cesarean delivery (epidural or low-dose sequential spinal-epidural anesthesia [see Chapter 26]) to avoid the abrupt decrease in SVR associated with single-shot spinal anesthesia.

BOX 42-6 Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension
1′. Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
2. Pulmonary hypertension owing to left-sided heart disease
3. Pulmonary hypertension owing to lung disease and/or hypoxia
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms

Updated classification from the 4th World Symposium on Pulmonary Hypertension (Dana Point, CA, 2008). Modified from Simonneau G, Robbins IM, Beghetti M, et al. Updated clinical classification of pulmonary hypertension. J Am Coll Cardiol 2009; 54:S43-54.

PULMONARY HYPERTENSION

Box 42-6 outlines the current classification of pulmonary hypertension. Group 1 (pulmonary arterial hypertension) includes idiopathic pulmonary arterial hypertension and pulmonary hypertension due to congenital heart disease.[102] Other clinical conditions associated with group 1 pulmonary hypertension include connective tissue disease, human immunodeficiency virus (HIV) infection, portal hypertension, drugs/toxins (e.g., anorectics, methamphetamine, cocaine), and hemoglobinopathies (e.g., sickle cell disease).[102-104]

All of these conditions are associated with exceptionally high maternal mortality. Older studies reported maternal mortality rates as high as 56%[105]; however, more contemporary studies have demonstrated some improvement in maternal mortality, with rates ranging from 17% to 33%.[106] Nonetheless, pregnancy should be discouraged in women with pulmonary hypertension.

Normal mean pulmonary artery pressure (PAP) at rest is 14 ± 3 mm Hg (upper limit of normal = 20 mm Hg). Pulmonary arterial hypertension is defined as a mean PAP greater than 25 mm Hg with a *normal* pulmonary artery occlusion pressure (PAOP) (≤ 15 mm Hg) and pulmonary vascular resistance greater than 3 Wood* units.[103,104] In contrast, in "postcapillary" pulmonary hypertension due to left-sided heart failure (group 2), PAOP is *elevated* (> 15 mm Hg). Increased pulmonary vascular resistance results in right ventricular overload, which is followed by right ventricular hypertrophy. Right ventricular hypertrophy progresses to dilation of the right-sided chambers, eventually leading to right ventricular failure and death.[104]

A loud pulmonic heart sound (P2) can be heard on physical examination. The second heart sound is widely split owing to delayed closure of the pulmonic valve resulting from high right-sided pressures (pulmonary valve closes *after* the aortic valve). A right-sided

*Wood unit, unit of measure of vascular resistance (mm Hg • min/L); multiply by 80 to convert to dyne•s•cm^{-5}.

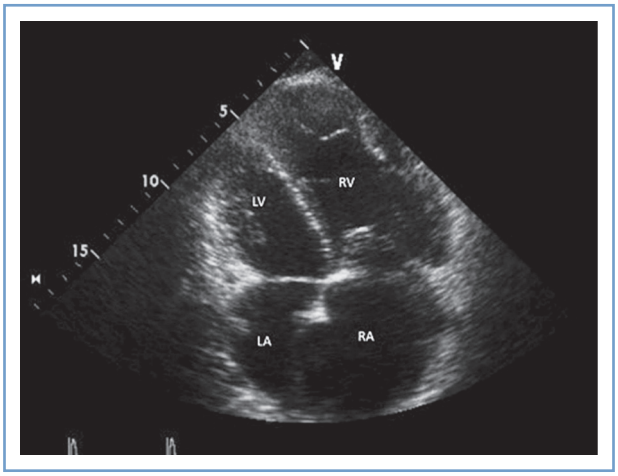

FIGURE 42-4 ■ Echocardiographic image of pulmonary hypertension with severe right-chamber enlargement. The RV basal measurement is 55 mm (upper limit of normal 42 mm); the RA minor axis dimension is 70 mm (upper limit of normal 44 mm). *RA,* right atrium; *LA,* left atrium; *RV,* right ventricle; *LV,* left ventricle. (Courtesy Dr. Mayank Kansal, University of Illinois at Chicago, Chicago, IL.)

holosystolic murmur of tricuspid regurgitation is frequently appreciated. Palpation of the precordium demonstrates the classic right ventricular heave. The most commonly encountered ECG findings in patients with pulmonary hypertension are right-axis deviation and right ventricular hypertrophy.

Echocardiography helps establish the diagnosis and prognosis of pulmonary hypertension because it demonstrates the degree of right ventricular hypertrophy and allows estimation of pulmonary artery pressure by assessing the velocity of the tricuspid regurgitant jet (Figure 42-4). Echocardiography also allows assessment of right ventricular function.

Echocardiographic assessment of right-sided pressures may be inaccurate; therefore, invasive right-sided—and frequently left-sided—heart catheterization is required for the definitive diagnosis of pulmonary arterial hypertension. Right-sided heart catheterization allows pressure measurements, thermodilution and Fick cardiac output determination, and vasoreactivity testing. Vasoreactivity testing is usually performed with inhaled nitric oxide or intravenous infusion of sodium nitroprusside, epoprostenol, or adenosine in the cardiac catheterization laboratory. Patients who achieve a decrease in mean PAP of 10 mm Hg or more and achieve a mean PAP of 40 mm Hg or less, without a decrease in cardiac output, are "positive acute responders."[103,104] Patients with a positive response have a better prognosis and may respond to oral therapy with a calcium entry–blocking agent.[103]

Eisenmenger Syndrome

In patients with an anatomic shunt between the systemic and pulmonary circulations at the atrial, ventricular, or aortopulmonary artery level, a left-to-right shunt initially causes increased pulmonary blood flow. Over time, pulmonary vascular resistance increases and pulmonary hypertension develops. The development of pulmonary hypertension results, at least in part, from endothelial dysfunction and vascular remodeling of the pulmonary vascular bed. This increase in pulmonary vascular resistance causes reversal of the shunt (from left-to-right to right-to-left), which results in hypoxemia and cyanosis. This anatomic and physiologic scenario is referred to as *Eisenmenger syndrome*.

Maternal mortality in women with Eisenmenger syndrome is exceptionally high (i.e., 30% to 50%).[105,106] The cardiovascular physiologic changes of pregnancy present a significant hemodynamic challenge for women with pulmonary hypertension and may lead to development of right ventricular failure. The peripartum period, with its rapid fluid shifts and increased oxygen demand, is particularly challenging. Death usually occurs peripartum or postpartum. In a systematic review of case reports of pulmonary hypertension associated with congenital heart disease published between 1997 and 2007 (n = 29),[106] all eight maternal deaths occurred postpartum (range, 0 to 24 days after delivery).

Women with Eisenmenger syndrome often cannot respond to the increased oxygen demands of pregnancy. The normal pregnancy-related decrease in pulmonary vascular resistance does not occur because pulmonary vascular resistance is fixed. In addition, the normal pregnancy-associated decrease in SVR tends to exacerbate the severity of the right-to-left shunt. These changes, together with the normal pregnancy-associated decrease in functional residual capacity, predispose women with Eisenmenger syndrome to hypoxemia. Maternal hypoxemia leads to a high incidence of fetal growth restriction and fetal demise. With contemporary drug therapy, cardiac imaging, and collaborative care, successful pregnancy has been described in patients with Eisenmenger syndrome.[106]

Pulmonary arterial hypertension due to congenital heart disease can be caused by a number of unrepaired congenital heart defects with a left-to-right shunt. Eisenmenger syndrome is associated with ventricular septal defect, atrial septal defect, patent ductus arteriosus, and atrioventricular septal defect (also referred to as endocardial cushion defect). More rarely encountered congenital heart defects (e.g., partial or total anomalous pulmonary venous return, transposition of the great arteries) may also lead to pulmonary arterial hypertension and Eisenmenger syndrome.[54]

Medical and Obstetric Management

Pregnant women with pulmonary hypertension should receive multidisciplinary care in a referral center. Diuretics are frequently needed to manage volume overload in patients with pulmonary arterial hypertension. Diuretics may be particularly helpful in the immediate postpartum period, when uterine contraction and autotransfusion cause an increase in ventricular preload. Dobutamine infusion may help improve right ventricular function. It is unclear whether all of these patients should receive thromboprophylaxis. Both hemorrhage and thromboembolism are causes of maternal mortality.[106]

Therapy for pulmonary arterial hypertension includes general supportive measures, assessment of vasoreactivity, and administration of vasoactive drugs.[104] Inhaled **nitric oxide** selectively dilates the pulmonary vasculature. Case reports have described the successful use of nitric oxide for vaginal and cesarean deliveries in parturients with pulmonary arterial hypertension.[107-109] Epoprostenol, treprostinil, and iloprost are **prostacyclins** used in the treatment of pulmonary hypertension. Successful pregnancy has been described in patients with pulmonary arterial hypertension treated with epoprostenol.[110-113] Similarly, sildenafil, a **phosphodiesterase type-5 inhibitor**, has been successfully used in pregnant women with pulmonary arterial hypertension.[114,115] **Endothelin receptor antagonists** (e.g., bosentan, ambrisentan) are likely teratogenic, and therefore their use is contraindicated during pregnancy.

The optimal mode of delivery in patients with pulmonary hypertension is unknown. In a systematic review that included reports from 1978 to 1996,[105] operative delivery was an independent risk factor for maternal mortality. In contrast, the mode of delivery was not identified as a risk factor for maternal death in a systematic review that included more recent cases.[106] Cesarean delivery is associated with larger changes in intravascular volume, more bleeding complications and blood loss, and a greater risk for thromboembolism; therefore, it seems reasonable to reserve cesarean delivery for obstetric indications.

Anesthetic Management

The primary goals of anesthetic management are (1) maintenance of adequate SVR; (2) maintenance of intravascular volume and venous return; (3) avoidance of aortocaval compression; (4) prevention of pain, hypoxemia, hypercarbia, and acidosis, which may increase pulmonary vascular resistance; and (5) avoidance of myocardial depression during general anesthesia (see Table 42-2).

Current evidence on choice of anesthetic technique for patients with pulmonary arterial hypertension is based on case reports and series from high-volume referral centers. The use of both general[113,116] and epidural anesthesia[117,118] has been reported.[119] Neuraxial (epidural and combined spinal-epidural) anesthesia with use of pulmonary vasodilators in highly specialized centers appears to be associated with favorable overall outcomes.[120,121] In published case reports, cautious administration of epidural anesthesia did not affect the shunt flow in parturients with Eisenmenger syndrome. Slowly titrated epidural or combined spinal-epidural anesthesia eliminates the undesirable effects of myocardial depression and positive-pressure ventilation (with its associated decrease in preload) associated with general anesthesia.

Intravascular volume assessment in patients with pulmonary arterial hypertension is of utmost importance. It is likely best achieved with central venous pressure monitoring; pulmonary artery catheterization without the use of fluoroscopy is technically challenging owing to the frequent presence of tricuspid regurgitation and right-sided chamber enlargement in these patients. Pulmonary artery catheterization has not been shown to improve outcome. Both transthoracic and transesophageal echocardiography are very helpful, and invasive blood pressure monitoring is indispensable. Because patients with pulmonary arterial hypertension frequently require systemic anticoagulation, the choice of anesthesia in these patients is best determined by a multidisciplinary team.

Because of its ease of administration, nitric oxide can be readily administered in the urgent setting. Nitric oxide has been administered during epidural anesthesia for emergency cesarean delivery using a noninvasive ventilation device.[122] Successful cesarean delivery with inhaled iloprost and slowly titrated epidural anesthesia has been reported.[123,124]

Given the high rate of postpartum mortality, patients should be monitored in an intensive care setting for a number of days postpartum.

INFECTIVE ENDOCARDITIS

Endocarditis during pregnancy is rare. It is most frequently associated with intravenous drug use or preexisting structural heart and valve abnormalities (e.g., rheumatic valvular disease, congenital heart disease). Maternal and fetal mortality rates are both high (range, 15% to 25%, respectively).[125]

Antibiotic Prophylaxis

Currently, the ACC, the AHA, and the American College of Obstetricians and Gynecologists (ACOG)[126] do not recommend antibiotic prophylaxis during vaginal or cesarean delivery in the absence of structural heart disease.[54,127,128] In patients with congenital heart disease and the *highest* risk for adverse outcomes, it is *reasonable* to administer antibiotic prophylaxis against infective endocarditis before *vaginal* delivery at the time of membrane rupture.[54] High-risk patients include those with one or more of the following: (1) a prosthetic cardiac valve or a valve repaired with prosthetic material, (2) unrepaired or palliated cyanotic congenital heart disease, and (3) surgically constructed palliative shunts and conduits (Box 42-7). In patients with one of these high-risk conditions who have an established infection (e.g., chorioamnionitis), the underlying infection should be treated. Additional antibiotics specific to endocarditis prophylaxis are not recommended.[126] Mitral valve prolapse is *not* an indication for antibiotic prophylaxis. It is important to note that the level of evidence for these recommendations is C (consensus opinion of experts, case studies, standard of care). In young women of childbearing age, there is no difference in the rate of prosthetic valve endocarditis with mechanical or bioprosthetic valves.

Diagnosis and Treatment

The diagnosis of endocarditis rests on a very high index of suspicion, physical examination, laboratory findings, and cardiac imaging. The modified Duke criteria are the most widely accepted criteria for the diagnosis of endocarditis (Box 42-8). Patients with endocarditis may have

BOX 42-7 High-Risk Cardiac Conditions for Which Antibiotic Endocarditis Prophylaxis for Vaginal Delivery at Time of Membrane Rupture is Reasonable

- Prosthetic heart valve
- Prosthetic material used for heart valve repair
- History of infective endocarditis
- Unrepaired cyanotic congenital heart disease
- Repaired congenital disease
  - Palliative shunts and/or conduits
  - Prosthetic material or percutaneously inserted devices/material during the first 6 months after the procedure
  - Residual defects in proximity to prosthetic material or percutaneously inserted device
- Cardiac transplantation recipient with valvulopathy

Modified from American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Prevention of infective endocarditis: guidelines from the American Heart Association. Circulation 2007; 116:1736-54.

BOX 42-8 Modified Duke Criteria for the Diagnosis of Bacterial Endocarditis

Major Criteria

- Positive blood culture with typical infective endocarditis microorganism
- Evidence of endocardial involvement with positive echocardiogram

Minor Criteria

- Predisposing factor: known cardiac lesion, recreational drug injection
- Fever > 38° C
- Evidence of embolism: arterial emboli, pulmonary infarcts, Janeway lesions, conjunctival hemorrhage
- Immunologic problems: glomerulonephritis, Osler's nodes
- Positive blood culture (with an atypical microorganism that does not meet a major criterion) or serologic evidence of infection with organism consistent with infective endocarditis but not satisfying a major criterion

The diagnosis of infective endocarditis is confirmed if two major criteria, one major and three minor criteria, or five minor criteria are present.

Modified from Durack DT, Lukes AS, Bright DK. New criteria for diagnosis of infective endocarditis: utilization of specific echocardiographic findings. Duke Endocarditis Service. Am J Med 1994; 96:200-9.

negative blood cultures. Therefore, absence of bacterial growth in blood cultures does not automatically rule out endocarditis.

In addition to systemic antibiotic therapy, valve replacement may be required in pregnant women with endocarditis. Alternatively, successful treatment with aggressive antibiotic therapy has been described.

Neuraxial Anesthesia in Patients with Systemic Infection

The safety of neuraxial anesthesia in patients with systemic infection has been debated for many years (see Chapter 37).[129] Neurologic complications after spinal or epidural anesthesia are rare in large observational series[130,131]; however, there is general agreement that patients with *untreated* systemic infection should *not* receive neuraxial anesthesia.

Published data and clinical experience suggest that spinal anesthesia may be safely administered in patients who have received antibiotic treatment and are responding to treatment at the time of dural puncture. Similarly, it is likely that epidural anesthesia may be safely administered to patients with treated systemic infection.[129] In patients with endocarditis, bacteremia may seed the epidural space and cause epidural abscess in the absence of neuraxial anesthesia. Similarly, meningitis is a recognized neurologic complication of endocarditis. Therefore, it may be difficult to determine whether the neuraxial procedure contributed to the development of the infection if meningitis or epidural abscess should develop in a patient with endocarditis receiving neuraxial anesthesia.

IMPLANTABLE CARDIAC DEVICES

Permanent and Temporary Pacemakers

Permanent pacemakers implanted before pregnancy are occasionally encountered. Pregnancy and labor and delivery are generally well tolerated in these patients.[132,133]

Advanced second-degree (two or more nonconducted P waves) or third-degree atrioventricular block is rare in pregnant women and is most commonly seen in patients with congenital heart disease. Recommendations are inconsistent as to whether temporary pacing is required for labor and delivery.[134-138] Some of the principal indications for pacemaker placement (e.g., symptomatic bradycardia, periods of asystole greater than 3 seconds, escape rhythms below the atrioventricular node with rates < 40 beats per minute) also appear to be appropriate indications for parturients; the decision to electively place either a temporary or permanent device should be made by a multidisciplinary team. Patients who develop hemodynamic instability due to bradycardia should receive a temporary venous pacemaker. Transcutaneous pacing is an attractive alternative, but it is uncomfortable for prolonged use. Because the majority of patients requiring temporary pacing have underlying congenital heart disease, it is critically important to understand the cardiac anatomy before placing the venous pacemaker to minimize complications such as perforation or valve injury.

Implantable Cardioverter-Defibrillators

Pacemaker and implantable cardioverter-defibrillator (ICD) implantation during pregnancy may be performed with echocardiographic guidance, thus reducing fetal radiation exposure. A wearable automatic defibrillator is an attractive option for pregnant women, because it may

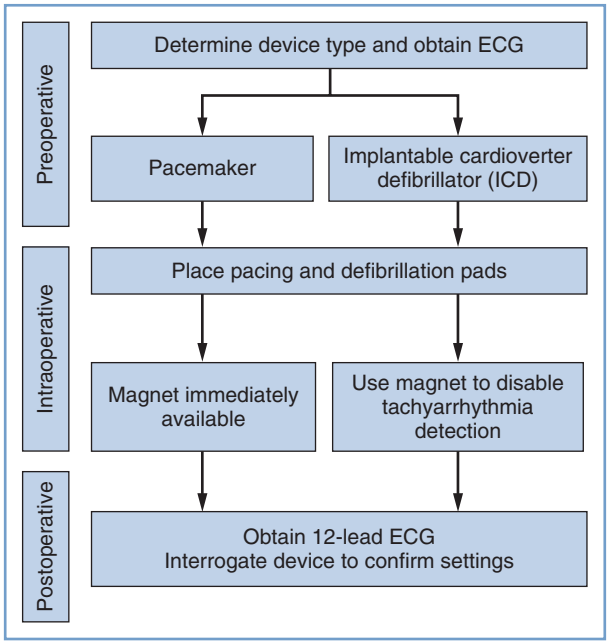

FIGURE 42-5 ■ A suggested perioperative approach to the management of implantable cardiac devices during cesarean delivery. *ECG,* electrocardiogram.

allow ICD implantation to be postponed until after delivery. In the future, ICDs that are placed entirely within a subcutaneous pocket may be offered to pregnant women and eliminate the need for fetal radiation exposure.

Women with previously placed ICDs usually tolerate pregnancy and delivery well. Pregnancy does not increase the risk for ICD-related complications, and it does not increase the number of ICD discharges. Rather, the severity of underlying structural heart disease determines the overall complication rate.[139] Case reports suggest that pregnant women tolerate ICD shocks as well as nonpregnant women.[139,140]

Peripartum Management

Pacemakers and ICDs should be interrogated before or during pregnancy and before and after labor and vaginal or cesarean delivery (Figure 42-5). The type of device, manufacturer, and model should be documented. The indication for the device, the patient's underlying rhythm, and whether the patient is pacemaker dependent should be identified. Given the complexity of contemporary pacing and ICD devices, it is imperative to perform this evaluation in collaboration with an electrophysiologist or a cardiologist familiar with device management. It is helpful to obtain a 12-lead ECG before and after delivery and before and after any change in device programming.

The response of the device to magnet placement and removal should be known. It is important to recognize that different devices may respond quite differently to magnet placement. Most pacemakers will pace in an asynchronous mode after application of an external magnet. For most ICDs, the magnet will disable tachycardia detection (i.e., the device will not deliver a shock for ventricular tachycardia or ventricular fibrillation), but the magnet will *not* alter the pacing mode and rate settings. Magnets do *not* change bradycardia pacing settings for ICDs.

Because of the variability of pacemaker design from different manufacturers, and the highly sophisticated programming settings, peripartum device management should be individualized. Management is best planned before labor and delivery using a collaborative approach. For operative obstetric procedures, electromagnetic interference is unlikely given the distance of the site of surgery from the implanted device. Because pacemaker electrical activity can occur without resulting ventricular contraction, monitoring patients with an implantable cardiac device includes continuous ECG *together with* either plethysmography (pulse oximetry) or invasive blood pressure monitoring to ascertain the presence of a pulse.

For all procedures in patients with a pacemaker, a magnet should be immediately available. Immediate availability of external pacing and defibrillation capability is mandatory for all patients regardless of the type of device and urgency of the surgery. For most obstetric surgeries, it is recommended that devices *not* be reprogrammed and that ICDs *not* be deactivated by reprogramming. If deactivation of an ICD is necessary, the patient must remain in a monitored setting with external defibrillation pads placed on the patient until it is confirmed that the ICD has been reactivated. If the ICD is not deactivated by reprogramming, a magnet should be placed over the device intraoperatively to disable tachyarrhythmia detection. Removal of the magnet will restore previous ICD settings.

In patients with a pacemaker or an ICD, central intravenous catheter placement in the upper body needs to be performed with extreme caution so as not to damage or entangle device leads; this is particularly important in leads that were recently inserted (< 3 months earlier).

ADULT ARRHYTHMIAS

The incidence of arrhythmias is increased during pregnancy in patients with and without structural heart disease. The mechanisms have been attributed to atrial[16] and ventricular stretch[40] due to increased intravascular volume as well as the increase in resting heart rate. Additionally, autonomic and hormonal changes of pregnancy have been proposed as putative mechanisms.

Palpitations are frequent during pregnancy, and Holter monitoring often reveals premature atrial and ventricular contractions. The frequency of ectopy decreases after delivery. Interestingly, there is no correlation between symptomatic palpitations and frequency of underlying arrhythmias.[141] Therefore, no treatment is needed in asymptomatic patients with **premature atrial contractions** or **premature ventricular contractions**. Substances such as caffeine, alcohol, and cocaine should be discontinued, and treatment with a beta-adrenergic receptor antagonist may be considered in symptomatic patients.

Women who have been diagnosed with an arrhythmia before pregnancy frequently develop an exacerbation of

arrhythmia during pregnancy. Recurrence of a preexisting arrhythmia is associated with adverse fetal events.[142]

Supraventricular Arrhythmias

Overall, **supraventricular tachycardia** (SVT) during pregnancy is rare, with an estimated 24 episodes/100,000 pregnancies.[143] It is unclear whether pregnancy increases the risk for new-onset supraventricular tachycardia,[144,145] although the first onset of **paroxysmal supraventricular tachycardia** during pregnancy is unusual. Symptoms of supraventricular tachycardia may be exacerbated during pregnancy.[144]

Premature atrial contractions are frequently encountered during pregnancy. Their frequency generally decreases in the postpartum period.[141] Premature atrial contractions are overwhelmingly benign and rarely cause significant palpitations. Symptomatic patients can be treated with a low dose of a beta-adrenergic receptor antagonist.

Atrial fibrillation is encountered rarely during pregnancy. Rate and/or rhythm control along with prevention of thromboembolism are the mainstays of treatment of atrial fibrillation. The ventricular rate can be successfully controlled with digoxin, a beta-adrenergic receptor antagonist, or a nondihydropyridine calcium entry–blocking agent.[146] Alternatively, quinidine, sotalol, flecainide, or amiodarone may be used to control rapid ventricular response. These drugs also allow for pharmacologic cardioversion of atrial fibrillation. Although restoration of sinus rhythm reduces the risk for thromboembolism and may provide considerable short-term hemodynamic advantages in certain patients, the impact of a rhythm-control treatment strategy on long-term outcome is unclear.

Because atrial fibrillation during pregnancy most frequently results from underlying structural heart disease (rheumatic mitral stenosis or congenital heart disease), systemic anticoagulation during pregnancy is recommended. There is extensive published experience with the use of unfractionated heparin and warfarin during pregnancy; limited data are available with low-molecular-weight heparin (LMWH).

Use of the CHADS2 score[147] facilitates risk stratification for predicting stroke and thromboembolism associated with atrial fibrillation. This risk stratification provides guidance for choice of anticoagulation.[146] Points are assigned for the presence of six risk factors: **C**ongestive heart failure (1 point), **H**ypertension (1 point), **A**ge 75 years or older (1 point), **D**iabetes mellitus (1 point), and prior **S**troke/transient ischemic accident and thromboembolism (2 points). Patients at low risk for stroke generally receive aspirin, whereas those at high risk receive oral anticoagulation with warfarin or a newer oral anticoagulant (e.g., dabigatran, apixiban, rivaroxaban). There are no published reports of the use of these newer oral anticoagulants in pregnant women.

Atrial flutter is an organized macro-reentrant arrhythmia rarely seen during pregnancy. The atrial rate is usually 300 beats per minute; ventricular rate control may be difficult to achieve medically. Electric cardioversion is recommended for unstable patients, although pharmacologic cardioversion with ibutilide during pregnancy has been reported.[148]

Atrial tachycardia most frequently results from increased automaticity of atrial cells. Incessant atrial tachycardia has been successfully ablated during pregnancy.

Ventricular preexcitation syndromes (e.g., Wolff-Parkinson-White syndrome) are rarely encountered in pregnancy; these patients are usually identified at a younger age and have undergone highly effective electrophysiologic treatment. A few case reports suggest that preexcitation syndromes may be associated with an increased rate of supraventricular arrhythmias during pregnancy.

Ventricular Arrhythmias

Ventricular arrhythmias are commonly associated with underlying structural heart disease. The diagnostic evaluation warrants a baseline ECG and echocardiography. During pregnancy, peripartum cardiomyopathy as cause of ventricular arrhythmias needs to be ruled out.

Idiopathic ventricular tachycardia is most commonly monomorphic, originating from the right ventricular outflow tract. New-onset idiopathic ventricular tachycardia during pregnancy has been reported in a very small series of patients. These reported arrhythmias were catecholamine sensitive and responsive to beta-adrenergic receptor antagonist therapy.[149] Idiopathic ventricular tachycardia may also be sensitive to treatment with verapamil[150] or isoproterenol.[151] Polymorphic ventricular tachycardia[152] and electrical storm with Brugada syndrome[153] have also been reported during pregnancy.

Sudden cardiac death due to idiopathic ventricular tachycardia has been described in pregnant women with hypertrophic cardiomyopathy.[154-156] Sustained idiopathic ventricular tachycardia, successfully treated with lidocaine infusion, has been described in patients with repaired tetralogy of Fallot.

Congenital Long QT Syndrome

The congenital long QT syndrome is caused by mutations in cardiac ion channels resulting in prolongation of ventricular repolarization. The clinical spectrum ranges from a lack of symptoms to arrhythmia-associated syncope and sudden cardiac death. Risk for cardiac events (syncope, arrhythmias, or death) is decreased in pregnant women with long QT syndrome, due at least in part to the increase in heart rate that occurs during pregnancy.[157] Compared with the 40-week prepregnancy period, the 40-week postpartum period has been associated with an increased risk for ventricular tachycardia in women with long QT syndrome.[158] Different long QT syndrome genotypes may have different risks associated with pregnancy. The LQT2 genotype is associated with a higher rate of cardiac events in the 9-month postpartum period than the LQT1 and LQT3 genotypes.[157,159] Prophylactic treatment with a beta-adrenergic receptor antagonist is recommended during pregnancy and postpartum in patients with long QT syndrome.[157,160]

Antiarrhythmic Drugs

The risk for adverse fetal effects of antiarrhythmic drugs should be assessed on an individual basis (see Chapter 14). Beta-adrenergic receptor antagonists, amiodarone, and sotalol are effective in preventing idiopathic ventricular tachycardia during pregnancy. Fetal exposure to amiodarone (pregnancy category D) has been associated with hypothyroidism and, possibly, fetal growth restriction. Sotalol is classified as pregnancy category B and appears safe. Because sotalol is a beta-adrenergic receptor antagonist, its use may be associated with neonatal bradycardia and hypoglycemia.

Electric Cardioversion

Life-threatening or hemodynamically unstable arrhythmias should be terminated by electric cardioversion.[146,160] **Defibrillation** refers to administration of electric energy to terminate ventricular fibrillation. By contrast, **synchronized cardioversion** is delivery of an electric shock synchronized to the QRS complex. Synchronized cardioversion is administered for supraventricular rhythms (i.e., atrial fibrillation, atrial flutter, atrial tachycardia) as well as for monomorphic ventricular tachycardia with a pulse.[146] Pulseless ventricular tachycardia and polymorphic ventricular tachycardia should be treated with **unsynchronized cardioversion**.

Electric cardioversion can be performed safely throughout pregnancy without apparent adverse effects on fetal hemodynamic function.[161,162] Nonetheless, it is prudent to monitor the fetal heart rate (FHR) during cardioversion.[163] Current guidelines recommend the use of a biphasic defibrillator. Ventricular fibrillation can be successfully terminated with biphasic devices that use lower energy than is required with monophasic devices. Biphasic automatic external defibrillators (AEDs) are more effective in terminating ventricular fibrillation with lower energy than older monophasic devices.

If hemodynamically significant or severely symptomatic arrhythmias develop during pregnancy, electrophysiologic interventional management may be performed. Successful **radiofrequency catheter-based ablation** has been reported in pregnant women with no or minimal ionizing radiation exposure.

Patients usually require anesthesia care for cardioversion. The risk for pulmonary aspiration of gastric contents associated with sedation (with an unprotected airway) should be weighed against the risks associated with general anesthesia and tracheal intubation. The judicious use of sedation rather than general anesthesia is usually preferred. A benzodiazepine or propofol can provide satisfactory sedation and amnesia. Regardless of whether sedation or general anesthesia is selected, a nonparticulate oral antacid should be administered; administration of a histamine-2 (H_2)-receptor antagonist to increase gastric pH should also be considered. The use of metoclopramide in these patients is controversial owing to its possible association with tachyarrhythmias.

Maintenance of Sinus Rhythm

Development of atrial fibrillation may cause significant hemodynamic compromise, particularly in pregnant women with stenotic valvular lesions (aortic stenosis or mitral stenosis) or hypertrophic cardiomyopathy with its associated diastolic dysfunction. Hemodynamic compromise results from the diminished diastolic filling time and loss of the atrial contraction contribution to ventricular filling. Maintenance of sinus rhythm and strict rate control have *not* been shown to be beneficial in older (nonpregnant) patients with paroxysmal or permanent atrial fibrillation. However, published studies are largely not applicable to pregnant women, and it seems reasonable to maintain sinus rhythm and control heart rate in this population. Rate control is particularly important in patients with stenotic valvular lesions and hypertrophic cardiomyopathy because the hemodynamic condition of these patients may quickly deteriorate in the presence of tachycardia.

MYOCARDIAL INFARCTION

The term *myocardial infarction* signifies myocardial cell death caused by ischemia.[25] Myocardial infarction is diagnosed by clinical signs and symptoms, ECG patterns, elevation of biomarkers (CK-MB fraction, troponin), and various imaging modalities (echocardiography, radionuclide imaging, CMR imaging, CT). The current Universal Classification of Myocardial Infarction recognizes five types of myocardial infarction (Box 42-9).[25]

Myocardial infarction during pregnancy is rare; the estimated incidence is 2.8 to 6.2 per 100,000 deliveries.[164,165] It occurs most commonly in the third trimester or the immediate postpartum period. Myocardial infarction during pregnancy is associated with maternal use of tobacco, dyslipidemia, family history of myocardial infarction, hypertension, African race, Hispanic ethnicity, and diabetes. Contemporary evidence suggests that the maternal mortality rate from myocardial infarction during pregnancy is approximately 5%.[165]

Acute coronary syndrome is an encompassing term used to describe unstable angina, non–ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI). Unstable angina is differentiated from NSTEMI by lack of elevation of cardiac biomarkers. Compared with unstable angina or NSTEMI, STEMI is an emergency and requires early reperfusion; a "door-to-balloon" interval of less than 90 minutes is optimal.

Only 40% of pregnant patients with myocardial infarction have evidence of coronary artery atherosclerosis (type I myocardial infarction); spontaneous coronary artery dissection (type II myocardial infarction) is observed in as many as 27% of patients. Angiographically normal coronary arteries are seen in 13% of patients[166]; in these cases, myocardial infarction likely results from coronary artery spasm or embolism. Spasm can be spontaneous, or it can be due to cocaine or ergot alkaloids. Septic and metastatic neoplastic coronary embolism after abortion have been described. Atherosclerosis is more

BOX 42-9 Universal Classification of Myocardial Infarction

Type 1—Spontaneous Myocardial Infarction

Due to atherosclerosis and plaque rupture/erosion resulting in intracoronary thrombus formation

Type 2—Myocardial Infarction due to Ischemic Imbalance

Due to conditions other than atherosclerosis (e.g., supply-demand mismatch, coronary vasospasm, coronary embolism, coronary dissection, stress of noncardiac surgery)

Type 3—Cardiac Death due to Myocardial Infarction

Cardiac death highly suggestive of myocardial infarction without the availability of biomarker confirmation

Type 4a—Myocardial Infarction related to Percutaneous Coronary Intervention

Due to distal plaque embolization, side-branch occlusion, and directly related to coronary intervention (e.g., stenting or balloon angioplasty)

Type 4b—Myocardial Infarction due to Stent Thrombosis

Detected by autopsy or angiography

Type 5—Myocardial Infarction due to Coronary Artery Bypass Grafting (CABG)

Cardiac biomarker elevation associated with surgical revascularization procedure

Modified from Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. Circulation 2012; 60:1581-98.

commonly the cause of myocardial infarction in the antepartum period than in the peripartum or postpartum period, whereas coronary artery dissection is observed more frequently in the peripartum and postpartum periods.[166] It has been hypothesized that the high rate of spontaneous coronary artery dissection is related to hormonal changes of pregnancy.

Cesarean delivery is commonly associated with ischemic-appearing ST-segment depression.[14,167-170] These changes have been attributed, at least in part, to oxytocin administration (see earlier discussion).[12,13] ST-segment elevation is *not* a normal occurrence during labor and delivery or with any type of intrapartum anesthesia. Hence, ST-segment elevation should always be considered abnormal, and ST-segment depression should be carefully evaluated.

CK-MB fraction may be elevated during normal pregnancy and labor (see Figure 47-1); thus, measurement of this enzyme is less useful for the diagnosis of myocardial infarction in pregnant women than in nonpregnant women.[28] An elevated troponin level is much more specific, although troponin may be elevated in patients with gestational hypertension and preeclampsia/eclampsia.[26,27] Both markers are quite sensitive for the diagnosis of myocardial infarction.

Percutaneous Coronary Intervention

STEMI during pregnancy should be treated with primary percutaneous coronary intervention. Although successfully used in anecdotal reports, use of thrombolytic therapy for STEMI in pregnant women should be reserved for rare instances. Radial arterial access for the percutaneous coronary intervention procedure is preferable because it has fewer bleeding complications and a lower mortality rate than femoral arterial access. Systemic anticoagulation with unfractionated heparin appears most reasonable owing to its short half-life, the availability of activated clotting time (ACT) monitoring, and the ability to rapidly reverse its anticoagulant effect. Importantly, larger doses of heparin are needed to achieve the desired level of anticoagulation in pregnant women than in nonpregnant patients. Anticoagulation for percutaneous coronary intervention can be achieved with low-molecular weight heparin, although inability to rapidly assess its anticoagulant effect and its altered pharmacokinetics during pregnancy are major disadvantages.

Percutaneous coronary interventions for treatment of myocardial infarction include conventional "plain old balloon angioplasty" and stent placement. An advantage of conventional balloon angioplasty is that it does not require dual antiplatelet therapy; however, placement of a stent is associated with a lower risk for abrupt vessel closure in the short term and a lower long-term risk for restenosis.

Dual antiplatelet therapy is mandatory after placement of a coronary artery stent to prevent stent thrombosis (Table 42-3). This therapy consists of both aspirin (81 to 325 mg daily) and clopidogrel. Clopidogrel can be substituted with a newer agent (e.g., prasugrel, ticagrelor) in specific nonpregnant patients. However, the safety and efficacy of these newer antiplatelet agents in pregnancy are unknown.

Stent Type Choice

In patients with a nonacute coronary syndrome (e.g., chronic stable angina), bare-metal stents require a minimum of 1 month of dual antiplatelet therapy, whereas drug-eluting stents require a minimum of 12 months. When either bare-metal stents or drug-eluting stents are placed in a patient with any *acute* coronary syndrome (e.g., unstable angina, NSTEMI, STEMI), 12 months of dual antiplatelet therapy is recommended. The advantage of drug-eluting stents is a decreased risk for in-stent restenosis than occurs with bare-metal stents. Drug-eluting stents elute an antiproliferative agent (everolimus, sirolimus, paclitaxel) into the arterial wall and reduce the neointimal proliferation that causes in-stent restenosis. However, the stent strut endothelialization process is slower with drug-eluting stents than with bare-metal stents; thus, a longer duration of dual antiplatelet therapy is required to prevent stent thrombosis. Overall rates of death and myocardial infarction are similar with drug-eluting and bare-metal stents. The risk for stent thrombosis may be lower with contemporary drug-eluting stents than with bare-metal stents. Newer-generation drug-eluting stents may allow for earlier discontinuation of dual antiplatelet therapy.

TABLE 42-3 **Dual Antiplatelet Therapy Recommendations**

		Percutaneous Coronary Intervention (PCI)		
		BALLOON ANGIOPLASTY	BARE-METAL STENT	DRUG-ELUTING STENT
Nonacute Coronary Syndrome	Aspirin	Indefinitely	Indefinitely	Indefinitely
	Clopidogrel	None	1 month	12 months
Acute Coronary Syndrome*	Aspirin	Indefinitely	Indefinitely	Indefinitely
	Clopidogrel	12 months	12 months†	12 months

*Acute coronary syndrome includes unstable angina, non–ST-segment elevation myocardial infarction, ST-segment elevation myocardial infarction.
†If necessary for the safe care of the obstetric patient, dual antiplatelet therapy can be discontinued 1 month after placement of a bare-metal stent.

Dual Antiplatelet Therapy

Bare-metal stents allow for discontinuation of dual antiplatelet therapy 1 month after percutaneous coronary intervention, if necessary, even in the setting of acute coronary syndrome (see Table 42-3). This may be advantageous in pregnant women who are at risk for intrapartum and postpartum hemorrhage. Therefore, most interventional cardiologists will place a bare-metal stent in a pregnant woman with acute coronary syndrome. Although it appears reasonable to continue dual antiplatelet therapy as long as feasible in a pregnant woman with acute coronary syndrome, there are little data on the optimal duration of dual antiplatelet therapy in this unique clinical setting. Continuing research is being performed to determine the optimal duration of dual antiplatelet therapy after percutaneous coronary intervention in the nonpregnant population.

It is not advisable to perform neuraxial anesthesia in patients receiving dual antiplatelet therapy.[43] After clopidogrel is discontinued, aspirin should be continued indefinitely in patients with any type of stent. Both spinal and epidural anesthesia can be performed safely in patients receiving aspirin. Clopidogrel should be discontinued 7 days before performance of neuraxial anesthesia.[43]

Aspirin crosses the placenta. A 2002 meta-analysis found no *overall* increase in the risk for congenital malformations when aspirin was administered in the first trimester; however, a twofold increase in the risk for gastroschisis was observed.[171] Another meta-analysis that evaluated the use of aspirin for prevention of preeclampsia found no evidence of increased risk for fetal growth restriction, pregnancy loss, or neonatal hemorrhage.[172] Most evidence suggests that aspirin use is safe during pregnancy.[173]

Coronary Artery Anomalies

Coronary artery anomalies occur in approximately 1% of the general population. Coronary artery anomalies are frequently associated with congenital heart disease such as d-transposition of the great arteries and tetralogy of Fallot.

There are numerous types of coronary anomalies, and most are benign. The two most common clinically significant anomalies are (1) a left main coronary artery that originates from the right coronary cusp and (2) a right coronary artery that originates from the left coronary cusp. External mechanical compression of those anomalous coronary vessels may cause myocardial ischemia and eventually lead to arrhythmias. The resulting ischemia and arrhythmias have been associated with sudden cardiac death. The effect of the physiologic changes of pregnancy in women with coronary artery anomalies has not been well studied.

VALVULAR HEART DISEASE

Pregnancy and its associated changes in cardiovascular physiology present a unique clinical challenge to women with underlying valvular heart disease. The general management principles for pregnant women with valvular heart disease are directed toward specific hemodynamic goals and the need for anticoagulation in patients with a mechanical valve.

Aortic Stenosis

The most common cause of aortic stenosis in pregnant women is a congenital bicuspid aortic valve. Less common causes/types of aortic stenosis include rheumatic, supravalvular, and subvalvular aortic stenosis.[174] Rheumatic aortic stenosis is invariably associated with some degree of mitral valve involvement. The hemodynamic implications of the various causes of aortic stenosis are similar. Calcific aortic stenosis of an anatomically normal tricuspid aortic valve occurs much later in life and is unlikely to be encountered in women of childbearing age.

Bicuspid aortic valve, the most common congenital heart defect, occurs in 0.5% to 2% of the population; women are affected four times less commonly than men. It is heritable; therefore, first-degree relatives of patients with a bicuspid aortic valve should be screened.[54] Bicuspid aortic valve is associated with accelerated and premature valve stenosis as well as aortic valve regurgitation. Symptoms of aortic stenosis (dyspnea on exertion, chest pain, syncope) generally present in the third and fourth decades of life. Importantly, patients with a bicuspid

TABLE 42-4 Severity Classification of Valvular Lesions

	Normal	Mild	Moderate	Severe
Aortic Stenosis				
Valve area (cm^2)	3.0-4.0	> 1.5	1.0-1.5	< 1.0
Mean gradient (mm Hg)		< 25	25-40	> 40
Jet velocity (m/sec)		< 3.0	3.0-4.0	> 4.0
Mitral Stenosis				
Valve area (cm^2)	4.0-6.0	> 1.5	1.0-1.5	< 1.0
Mean gradient (mm Hg)		< 5	5-10	> 10
Pulmonary artery systolic pressure (mm Hg)		< 30	30-50	> 50

Modified from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 Focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2008; 52:e1-142.

aortic valve have underlying aortic root pathology in the media that is associated with aortic root dilation, thus predisposing to ascending root dissection.[49]

The normal aortic valve area is 3.0 to 4.0 cm^2 (Table 42-4). There is no pressure gradient across a normal aortic valve with normal resting cardiac output. Patients generally develop symptoms when the valve area is less than 1.0 cm^2 and the pressure gradient across the valve is greater than 40 mm Hg. The published definition of severe aortic stenosis varies. An aortic valve area less than 1.0 to 1.5 cm^2 and a mean valve gradient of 25 to 50 mm Hg generally define the group of patients with a high risk for cardiovascular complications due to aortic stenosis.[35,36,38,60]

Classically, the aortic valve area is estimated invasively in the cardiac catheterization laboratory using the Gorlin equation. Forward cardiac output is determined by thermodilution and/or Fick methods, and left ventricular and aortic pressures are simultaneously recorded. Doppler velocity measurements during echocardiography allow noninvasive estimation of aortic valve area using the continuity equation.

Using both these methods, the estimated transvalvular *gradient* increases during pregnancy because of the physiologic increase in cardiac output. The calculated valve *area* remains unchanged, however, because both the Gorlin equation and the continuity equation take cardiac output into account. The echocardiographic dimensionless *valve index* is useful in pregnant women as well as other patients; it takes into account both left ventricular outflow velocity and the aortic velocity. Because both velocities are increased during pregnancy, the dimensionless index and estimated valve area remain unchanged during pregnancy.

The severity of aortic stenosis affects maternal risk during pregnancy. *Mild* and *moderate* aortic stenosis are associated with favorable pregnancy outcomes.[174-176] Women with *severe* aortic stenosis experience frequent cardiac complications during pregnancy (e.g., worsening NYHA functional class, pulmonary edema, congestive heart failure, arrhythmias, hospitalization). The reported rates of these complications during pregnancy vary widely (e.g., heart failure and pulmonary edema 4% to 78%, arrhythmias 2% to 33%, hospitalization rate as high as 78%). Mortality is rare, however.[174,175,177] Additionally, women with severe disease are more likely to require a cardiac intervention (balloon valvuloplasty, valve replacement) during pregnancy or immediately postpartum. Percutaneous balloon valvuloplasty of the aortic valve is a palliative procedure that allows completion of pregnancy before definitive repair.

Obstetric and Anesthetic Management

Labor and assisted vaginal delivery are preferred. Cesarean delivery is reserved for obstetric indications.

Whether general or neuraxial anesthesia is more appropriate for parturients with aortic stenosis has been a matter of debate.[178-180] Historically, neuraxial anesthesia has been thought to be relatively contraindicated in patients with aortic stenosis; the simultaneous decrease in preload and afterload associated with neuraxial anesthesia may be particularly hazardous in these patients. However, case reports have documented successful administration of neuraxial anesthesia (spinal,[181] continuous spinal,[182] combined spinal-epidural,[180,183] epidural[184]) and general anesthesia[185,186] with favorable maternal and neonatal outcomes.

The choice between neuraxial and general anesthesia should not be made based on the aortic valve gradient or aortic valve area alone. The preanesthetic assessment should include physical examination, symptom evaluation, and comprehensive assessment of the right and left ventricular structure and function, as well as the structure and function of other cardiac valves. The presence or absence of pulmonary hypertension should also be determined.

Echocardiography offers indispensable information regarding left and right ventricular ejection fraction, left ventricular wall thickness, pulmonary artery pressure, presence of aortic insufficiency, mitral valvular structure and function, and aortic root size. Serial assessment of the aortic valve area before and during pregnancy is very helpful in managing these patients. Patients with normal right and left ventricular function are more likely to tolerate fluid shifts and the depressant effects of general anesthetic agents. If left ventricular dysfunction develops in the presence of aortic stenosis, a condition referred to as **low-output**, **low-gradient aortic stenosis** may be present.

The presence of pulmonary hypertension, right ventricular dysfunction, or mitral regurgitation is associated with greater dependence on preload and may unfavorably affect the hemodynamic response to neuraxial anesthesia. Patients with a dilated aortic root will likely benefit from gradual blood pressure changes, because aortic root dilation has been associated with aortic dissection. Left ventricular hypertrophy, frequently present with aortic stenosis, is associated with significant diastolic

dysfunction and may impede left ventricular filling. The presence of left ventricular hypertrophy will render these patients more sensitive to the adverse effects of decreased preload, tachycardia, and the development of congestive heart failure, especially in the setting of acute-onset atrial fibrillation. Aortic regurgitation is quite common in patients with a bicuspid aortic value. The ventricles are exposed to both pressure and volume overload, further complicating hemodynamic management and response to anesthesia.

The goals of anesthetic management are (1) maintenance of a normal heart rate, sinus rhythm, and adequate systemic vascular resistance; (2) maintenance of intravascular volume and venous return; (3) avoidance of aortocaval compression; and (4) avoidance of myocardial depression during general anesthesia (see Table 42-2). In the absence of prospective randomized trials in this patient population, current clinical evidence suggests that either neuraxial analgesia/anesthesia or general anesthesia is safe for patients with mild or moderate aortic stenosis with normal right and left ventricular ejection fraction and the absence of other significant valvular lesions or pulmonary hypertension. Neuraxial anesthetic techniques that allow gradual titration of anesthesia seem advantageous in these patients.

In patients with severe aortic stenosis, general anesthesia remains the gold standard. Although published reports have described successful administration of neuraxial anesthesia for labor and vaginal and cesarean delivery in women with severe aortic stenosis, the influence of publication bias in these reports cannot be excluded. In contemporary obstetric anesthesiology practice, an opioid-based neuraxial labor analgesia technique, along with alternative forms of analgesia (e.g., pudendal nerve block, intravenous opioids) is well tolerated in parturients with severe aortic stenosis. A slowly dosed, low-concentration local anesthetic epidural technique, chosen to mitigate the untoward effects of sympathectomy, may be safely performed with vigilant blood pressure monitoring. The anesthesiologist may choose to avoid use of an epinephrine-containing local anesthetic solution because the unintentional intravenous injection of epinephrine can precipitate tachycardia; further, systemic absorption of epinephrine can diminish SVR and reduce venous return. General anesthesia may be the best choice for cesarean delivery in patients with severe aortic stenosis and other significant valvular lesions, pulmonary hypertension, and/or left ventricular dysfunction. Induction of anesthesia with a combination of etomidate and a moderate dose of a lipid-soluble opioid may be preferable to agents that cause myocardial depression and vasodilation (propofol, thiopental) and tachycardia (ketamine). Anesthesia can be maintained with an opioid and a low-dose volatile anesthetic technique.

Peripartum invasive arterial blood pressure monitoring is recommended for parturients with moderate and severe aortic stenosis. Pulmonary artery catheterization is unlikely to provide much clinical benefit in this patient population. Development of atrial fibrillation with rapid ventricular response is deleterious in these patients because it decreases diastolic filling time and eliminates the atrial component of left ventricular filling. If new-onset atrial fibrillation results in hypotension or pulmonary edema, sinus rhythm should be promptly restored.

Aortic Regurgitation

The most common etiology of chronic aortic regurgitation in pregnant women is a degenerated bicuspid aortic value; rheumatic aortic regurgitation occurs less frequently. Dilation of the ascending aorta and the resulting aortic leaflet separation may also result in aortic regurgitation. Most commonly, aortic root dilation results from cystic medial necrosis associated with Marfan syndrome, or it occurs in association with a bicuspid aortic value. Chronic aortic regurgitation is generally well tolerated during pregnancy, especially in patients with preserved left ventricular ejection fraction.[187,188] The physiologic changes of pregnancy (increased heart rate resulting in a shorter duration of diastole, as well as reduced SVR) contribute to an overall reduction in regurgitant aortic flow.

Although patients with chronic aortic regurgitation can compensate for the hemodynamic stress over time, patients with acute aortic regurgitation are frequently very ill and may require surgery. Endocarditis is the most common etiology of acute aortic regurgitation during pregnancy. Ascending aortic dissection may also result in severe acute aortic regurgitation. Affected patients may require valve replacement during pregnancy.

Anesthetic Management

The goals of anesthetic management are (1) maintenance of a normal to slightly elevated heart rate, (2) prevention of an increase in SVR, (3) avoidance of aortocaval compression, and (4) avoidance of myocardial depression during general anesthesia (see Table 42-2).

Antepartum echocardiography may guide decisions regarding the choice of anesthesia and monitoring. Patients with chronic, compensated aortic insufficiency and normal ejection fraction tolerate the hemodynamic changes of pregnancy well; however, patients with left ventricular dysfunction will likely require careful assessment of volume status and pulmonary artery pressures during labor and delivery. Traditionally, a pulmonary artery catheter has been used for this purpose. In the future, transthoracic echocardiography will likely be used for this purpose.

The degree of aortic insufficiency, concomitant involvement of the mitral valve, and the size of the aortic root help define hemodynamic goals. Patients with a bicuspid aortic valve may have simultaneous aortic stenosis and aortic regurgitation. Both neuraxial analgesia/anesthesia and general anesthesia can be safely performed in patients with aortic regurgitation and preserved left ventricular ejection fraction. Severe aortic insufficiency with left ventricular dysfunction is not a contraindication for neuraxial anesthesia. Initiation of neuraxial analgesia during early labor may mitigate pain-associated increases in SVR that can be deleterious in patients with aortic regurgitation. Intra-aortic balloon pump placement is contraindicated in patients with aortic regurgitation because its use increases regurgitant flow.

Mitral Stenosis

Mitral stenosis frequently becomes symptomatic during pregnancy owing to the increase in maternal blood volume and heart rate. Increased blood volume with decreased diastolic filling time can result in pulmonary edema. Additionally, mitral stenosis predisposes patients to development of atrial tachyarrhythmias (atrial fibrillation, atrial flutter) as well as thromboembolic complications, with or without atrial arrhythmias. The underlying hypercoagulable state of pregnancy also increases the risk for thromboembolic complications in patients with mitral stenosis. Therefore, systemic anticoagulation is recommended for the duration of pregnancy and postpartum.

The etiology of mitral stenosis is almost invariably rheumatic.[175,189] Severe mitral stenosis is defined as a valve area less than 1.0 cm^2 (see Table 42-4). In addition to valve area, a mean value gradient of greater than 10 mm Hg and a mean PAP greater than 50 mm Hg are used to define severe mitral stenosis. Transmitral valve gradients measured by echocardiography increase during pregnancy.[190]

Poor functional status NYHA (e.g., III to IV) portends a greater risk for adverse outcomes.[60,191,192] When possible, preconception treatment of symptomatic moderate or severe mitral stenosis is preferred.[38,60] The procedure of choice is percutaneous balloon mitral valvuloplasty. Suitability for percutaneous balloon valvuloplasty is determined by an echocardiography-based scoring system, which takes into account valve calcification and mobility as well as valvular and subvalvular thickening.[193]

For patients who require percutaneous valvuloplasty during pregnancy, the procedure is ideally performed after 12 to 14 weeks' gestation to minimize fetal radiation exposure during the period of organogenesis. If the patient can be stabilized with medical management, delaying the procedure to 26 to 30 weeks' gestation will reduce the risk for preterm birth. Open surgical mitral valve commissurotomy is associated with higher rates of fetal mortality than percutaneous valvuloplasty (38% versus 5%).[194]

Standard medical therapy during pregnancy includes a reduction in activity level (e.g., bed rest), beta-adrenergic receptor antagonist and diuretic therapy, and anticoagulation.

Obstetric and Anesthetic Management

Cesarean delivery is typically reserved for obstetric indications. Vaginal delivery is usually assisted, because the Valsalva maneuver during the second stage of labor may result in a sudden increase in central venous pressure. Regardless of the method of delivery, patients are at risk for hemodynamic compromise and pulmonary edema immediately after delivery because uterine contraction results in autotransfusion.[195] Therefore, these patients usually require postpartum intensive care.

Neuraxial analgesia/anesthesia for labor and vaginal or cesarean delivery can be safely performed in patients with mitral stenosis.[189,196] The important anesthetic goals are (1) maintenance of a low-normal heart rate and preservation of sinus rhythm; (2) aggressive treatment of atrial fibrillation, if present; (3) avoidance of aortocaval compression; (4) maintenance of venous return; (5) maintenance of adequate SVR; and (6) prevention of pain, hypoxemia, hypercarbia, and acidosis, which may increase pulmonary vascular resistance (see Table 42-2).

Parturients with mitral stenosis are at risk for both intrapartum and postpartum hemodynamic compromise and pulmonary edema. Invasive hemodynamic monitoring is often helpful, and close peripartum monitoring of filling pressures is important. Echocardiographic assessment of right-sided pressures appears to somewhat overestimate true pressures; therefore, in selected patients with severe mitral stenosis, a pulmonary artery catheter may help guide fluid management. The decision to place a pulmonary artery catheter should be guided by assessment of NYHA functional status, right ventricular function, pulmonary artery pressure, and severity of symptoms related to mitral stenosis before pregnancy.

Adequate analgesia during the first stage of labor is essential. Intrathecal administration of a lipid-soluble opioid during the first stage of labor provides excellent analgesia without causing sympathetic blockade. Neuraxial administration of an opioid with a small dose of local anesthetic may provide satisfactory analgesia for the second stage of labor. Hypotension should be treated with a direct-acting vasoconstrictor (phenylephrine).

Neuraxial anesthesia for cesarean delivery is best administered with a titratable technique (epidural anesthesia, sequential combined spinal-epidural anesthesia), judicious intravenous fluid administration, and titration of phenylephrine to maintain hemodynamic stability. During induction and maintenance of general anesthesia, tachycardia should be prevented by administration of a beta-adrenergic receptor antagonist and/or an opioid. After delivery, care should be taken with the administration of the uterotonic agent 15-methyl prostaglandin-F_{2a}, because it may increase pulmonary vascular resistance.

Mitral Regurgitation

Mitral regurgitation is generally well tolerated during pregnancy. Nonetheless, some evidence suggests that the volume overload associated with pregnancy may induce unfavorable structural alterations in women with mitral regurgitation.[197] Both neuraxial and general anesthesia are well tolerated. Chronic mitral regurgitation may be associated with left ventricular dysfunction; thus, echocardiographic assessment of left ventricular function helps guide anesthetic and fluid management. The goals of anesthetic management in patients with mitral regurgitation include (1) prevention of an increase in SVR, (2) maintenance of a normal to slightly increased heart rate, (3) maintenance of sinus rhythm, (4) aggressive treatment of acute atrial fibrillation, (5) avoidance of aortocaval compression, (6) maintenance of venous return, (7) prevention of an increase in central venous volume, (8) avoidance of myocardial depression during general anesthesia, and (9) prevention of pain, hypoxemia, hypercarbia, and acidosis, which may increase pulmonary vascular resistance (see Table 42-2).

Mitral Valve Prolapse Syndrome

Historically, prior to the contemporary understanding of the complex three-dimensional echocardiographic anatomy of the mitral valve, mitral valve prolapse tended to be overdiagnosed. Currently, the term *mitral valve prolapse* should be restricted to conditions in which the free margin of the anterior, posterior, or both leaflets of the mitral valve is displaced superior to the annular plane of the mitral valve.[198] With these diagnostic criteria, the prevalence of mitral valve prolapse in the general population is 2% to 3%, with no female preponderance.[199] Mitral valve prolapse is a heterogeneous disorder with various causes and associations, including familial and degenerative or myxomatous disorders, Marfan syndrome, Ehlers-Danlos syndrome, a redundant papillary chordal apparatus, and many other diseases.[200] Varying degrees of mitral regurgitation can be associated with this condition. There is some overlap between the strictly defined mitral valve prolapse syndrome and mitral regurgitation. Therefore, along with history and physical examination, echocardiography plays a central role in the diagnosis, treatment, and ongoing assessment of these patients.

The overall clinical course in patients with mitral valve prolapse is excellent.[201] Pregnancy and vaginal or cesarean delivery with either neuraxial or general anesthesia are well tolerated. Patients with moderate or severe mitral regurgitation and/or depressed left ventricular function are at increased risk for morbidity and mortality.[202] The recommendations for anesthetic management of parturients with mitral regurgitation and/or left ventricular dysfunction also apply to patients with these conditions associated with mitral value prolapse. Antibiotic endocarditis prophylaxis is not recommended.[127]

Tricuspid Stenosis and Regurgitation

Rheumatic **tricuspid stenosis** is rarely encountered in pregnancy; most frequently, it accompanies rheumatic mitral stenosis. Clinically, it is associated with dyspnea, pulmonary hypertension, and congestive heart failure. Successful treatment with balloon valvuloplasty has been described.

Tricuspid regurgitation is rarely found in isolation during pregnancy. Functional tricuspid regurgitation is often observed in normal pregnancy with little clinical consequence. Severe tricuspid regurgitation is often associated with congenital heart disease such as Ebstein's anomaly. Overall, pregnancy is well tolerated in the presence of tricuspid regurgitation. Affected patients may be susceptible to hypotension with a decrease in preload.[60]

Pulmonic Stenosis and Regurgitation

Pregnancy is well tolerated in patients with **pulmonic stenosis**, and isolated pulmonic stenosis has not been found to affect maternal and fetal outcomes[203] (see Table 42-2). In a small series of cases, affected patients had normal right ventricular function and only mild symptoms on initial presentation.[203] Nonetheless, valvuloplasty is recommended in asymptomatic nonpregnant patients with pulmonic stenosis and a transpulmonic valve gradient greater than 40 mm Hg and in symptomatic nonpregnant patients with a gradient greater than 30 mm Hg.[60]

Pulmonic regurgitation occurs infrequently as an isolated valvular lesion; it is most commonly associated with congenital heart disease, such as repaired tetralogy of Fallot[100] or repaired pulmonic stenosis. Physiologic pulmonic regurgitation is commonly seen during pregnancy.[204] Overall, pregnancy and labor are well tolerated in the presence of mild or moderate pulmonic regurgitation; however, severe pulmonic regurgitation is highly associated with maternal cardiac events during pregnancy.[205,206] Right-sided heart failure due to pulmonic regurgitation occurs more commonly in patients with multiple gestation, pulmonary artery stenosis distal to the left and right pulmonary arteries, preexisting right ventricular systolic dysfunction, and/or right ventricular hypertrophy.[206]

Prosthetic Heart Valves

Bioprosthetic Valves

The advantage of bioprosthetic valves is that long-term systemic anticoagulation is not required. It is unclear whether pregnancy, with its associated cardiovascular changes, accelerates bioprosthetic valve structural degeneration. Several studies observed complications related to valve deterioration, most of which required reoperation during pregnancy or shortly after delivery.[207-211] Other studies reported little or no impact of pregnancy on valve structural deterioration.[212-216] Hence, although a bioprosthetic valve simplifies the required anticoagulant regimen during pregnancy, it may expose the mother to a high risk for reoperation and associated operative mortality (ranging from 3.8%[213] to 8.7%[217]). The 10-year incidence of valve replacement or valve-related death ranges from 50% to 80% in young women of childbearing age.[213,215,217] The risk for valve failure appears higher in the mitral position than in the aortic position.[215] Bioprosthetic homografts appear to be more durable than heterografts. Autografts have a better hemodynamic profile than heterografts.

Anticoagulation for Patients with a Mechanical Valve

All patients with a mechanical valve require systemic anticoagulation. Mechanical valves have a higher risk for thromboembolism than bioprosthetic valves. Valves in the mitral position have a higher risk for thromboembolism than valves in the aortic position. A higher risk for mechanical valve thromboembolic complications has been observed during pregnancy.[218] No large prospective randomized trials have examined the use of various anticoagulation strategies for pregnant women with a mechanical valve. Additionally, newer prosthetic valve designs may have a lower risk for thromboembolism than older models. The current anticoagulation recommendations are based on expert consensus guidelines from three major professional organizations: the ACC/AHA,[60] the American College of Chest Physicians (ACCP),[173,219] and

the European Society of Cardiology (ESC).[38] Differences among these guidelines are summarized in Table 42-5.

Warfarin. In patients with a mechanical valve, anticoagulation with warfarin is associated with lower rates of thromboembolic complications and maternal death than is heparin.[220] Warfarin crosses the placenta. Use of warfarin between 6 and 12 weeks' gestation has been associated with embryopathy; therefore, consensus guidelines have recommended substitution with unfractionated heparin or LMWH during this period.[220] Additionally, the use of warfarin at any time during pregnancy has been associated with fetal wasting, central nervous system abnormalities, and fetal hemorrhagic complications.[173]

Warfarin anticoagulation effect is monitored by periodic assessment of the international normalized ratio (INR). Low-dose aspirin may be safely administered in addition to warfarin. Warfarin should be discontinued before delivery; in patients with a mechanical heart valve, heparin must be substituted.

Warfarin anticoagulation should be stopped for 4 to 5 days and the INR measured immediately before administration of a neuraxial block (see Chapter 44). Concurrent administration of other anticoagulants or antiplatelet agents increases the risk for bleeding complications. After delivery, patients with a mechanical valve typically require bridging to warfarin; the type of anesthesia and timing of neuraxial catheter removal may significantly affect the timing of anticoagulation after delivery.[43,44]

Unfractionated Heparin. Unfractionated heparin does not cross the placenta and therefore is safer for the fetus than warfarin. However, use of unfractionated heparin in the first trimester and close to term has been associated with an increased risk for valve thrombosis.[220] Unfractionated heparin can be administered subcutaneously or as a continuous intravenous infusion. Its therapeutic efficacy is monitored with the aPTT. Heparin requirements are higher during pregnancy due to underlying physiologic changes (e.g., increased levels of heparin-binding proteins, factor VIII, fibrinogen). The incidence of heparin-induced thrombocytopenia is three times higher in women than in men.

Intravenous unfractionated heparin should be discontinued 4 to 6 hours before administration of a neuraxial anesthetic technique or anticipated delivery (see Chapter 44).[43] The aPTT should be determined to verify normalization of coagulation function, and a platelet count should be checked to rule out heparin-induced thrombocytopenia. An indwelling neuraxial catheter can be removed 2 to 4 hours after the last dose of unfractionated heparin. Unfractionated heparin can be restarted 1 hour after removal of a neuraxial catheter.

Low-Molecular-Weight Heparin. LMWH does not cross the placenta and is administered subcutaneously for most indications. The pharmacokinetics of LMWH are altered in pregnancy. Use of LMWH for thromboprophylaxis during pregnancy has been associated with mechanical valve thrombosis.[221-224] The efficacy of LMWH can be monitored with anti–factor Xa levels. *Peak* anti–factor Xa levels should be checked 4 to 6 hours after LMWH administration in pregnant women with a mechanical valve. Importantly, in pregnant women with a mechanical valve, the required doses of LMWH are considered *therapeutic* and are therefore higher than those required for deep vein thrombosis prophylaxis. Additional monitoring of trough anti–factor Xa levels may allow further refinement of management. In the absence of anti–factor Xa monitoring, therapeutic use of LMWH in pregnant women with a mechanical valve is not advisable.[38]

A neuraxial block should not be performed until at least 24 hours have elapsed after the last dose of LMWH. Anti–factor Xa levels do not predict the risk for bleeding. Other anticoagulants or antiplatelet agents coadministered with LMWH increase the risk for bleeding complications. After delivery, LMWH should not be administered until at least 24 hours have elapsed after performance of the neuraxial block procedure (see Chapter 44).[43] After removal of a neuraxial catheter, at least 4 hours should elapse before administration of the next dose of LMWH (see Table 42-5).

New Anticoagulants. There are no published reports of the use of new oral anticoagulants in pregnancy. Therefore, use of oral **direct thrombin inhibitors** (dabigatran) or oral **anti–factor Xa inhibitors** (apixiban, rivaroxaban) cannot be recommended during pregnancy.

There are no published reports of the administration of **bivalirudin** during pregnancy; the use of **argatroban** during pregnancy has been described.[225] The current ASRA guidelines recommend against neuraxial anesthesia administration in patients receiving direct thrombin inhibitors.[43]

Neuraxial Anesthesia in Patients with a Mechanical Valve. No published observational or prospective randomized trials have investigated the use of neuraxial anesthetic techniques in patients with a mechanical heart valve who require systemic anticoagulation. Therefore, current clinical practice is guided by consensus guidelines.[43,44,226,227] Systemic anticoagulation may affect the choice and timing of anesthesia, and the neuraxial anesthetic technique and timing of catheter removal may influence the choice and timing of resumption of systemic anticoagulation after vaginal or cesarean delivery. Therapeutic anticoagulation is usually not resumed for at least 12 hours *after* delivery. The choice and timing of the anesthetic technique should be developed in discussion with the patient, the cardiologist, and the obstetrician, with consideration of consensus guidelines (see Table 39-4).

CARDIOMYOPATHIES

Heart Failure Nomenclature

Accurate description of patients with heart failure is important for diagnostic, therapeutic, and prognostic purposes. It is helpful to broadly describe symptoms of heart *failure* as **new-onset (acute)** or **chronic**. **Acute-on-chronic** heart failure describes patients with

TABLE 42-5 **Major Professional Society Guidelines for Anticoagulation in Pregnant Patients with Mechanical Valve(s)**

	American College of Cardiology/American Heart Association*	European Society of Cardiology†	American College of Chest Physicians‡
Warfarin	May discontinue warfarin at 6-12 weeks' gestation per patient preference and substitute UFH or LMWH	May consider continuing low-dose warfarin (< 5 mg daily) throughout pregnancy with informed patient consent	UFH or LMWH until 13 weeks' gestation, then warfarin In high-risk patients (older generation valves in mitral position, previous thromboembolism) continue warfarin throughout pregnancy
INR goal	Aortic and mitral valve: 3.0 (range, 2.5-3.5)	No recommendation	Aortic valve: 2.5 (range, 2.0-3.0) Mitral valve: 3.0 (range, 2.5-3.5)
Unfractionated heparin	Continuous infusion or dose-adjusted subcutaneous administration twice daily	In high-risk patients, continuous infusion	Subcutaneous administration twice daily
aPTT goal	aPTT 6 h after subcutaneous injection: twice control value	aPTT 4-6 h after subcutaneous injection: twice control value	Mid-interval aPTT (6 h after injection): twice control or anti–factor Xa level of 0.35-0.70 U/mL
Low-molecular-weight heparin	Subcutaneous administration twice daily	Subcutaneous administration twice daily	May give adjusted dose of LMWH throughout pregnancy, twice daily
Anti–factor Xa level goal	Maintain peak level 0.7-1.2 U/mL 4-6 h after administration	Maintain peak level 0.8-1.2 U/mL 4-6 h after administration	Maintain manufacturer's recommended peak anti–factor Xa level (approximately 1.0 U/mL) 4 h after administration
Aspirin	Low-dose aspirin (75-100 mg daily) reasonable in second and third trimesters in addition to warfarin or heparin	Not recommended	Low-dose aspirin (75-100 mg daily) added to thromboprophylactic regimen for patients with valves at high risk for thromboembolism
Peripartum§	Discontinue warfarin 2-3 weeks before planned delivery and start continuous intravenous UFH	Discontinue warfarin at 36 weeks' gestation and start dose-adjusted UFH or LMWH. Replace LWMH at least 36 h before planned delivery and substitute with UFH. Discontinue UFH 4-6 h before planned delivery	Discontinue warfarin close to delivery; replace with UFH or LMWH

§For resumption of anticoagulation in the postoperative period, the 2010 American Society of Regional Anesthesia and Pain Medicine Practice Advisory[43] recommends the following: (1) Warfarin: The indwelling neuraxial catheter should be removed when the INR is less than 1.5. (2) UFH: The indwelling neuraxial catheter should be removed 2 to 4 hours after the last dose of UFH, after checking the patient's coagulation status (aPTT). The next dose of UFH should not be given until at least 1 hour has elapsed after removal of the catheter. (3) LMWH: The first therapeutic dose should not be administered until 24 hours after the initiation of the neuraxial procedure and until at least 2 hours after removal of the indwelling neuraxial catheter. The U.S. Food and Drug Administration recommends waiting at least 4 hours after removal of a neuraxial catheter before administering a postprocedure dose of LMWH. (U.S. Food and Drug Administration. *Low Molecular Weight Heparins: Drug Safety Communication—Recommendations to Decrease Risk of Spinal Column Bleeding and Paralysis. worsening symptoms after an earlier diagnosis of heart failure.

Heart failure can be separated into **left sided** (predominantly pulmonary congestion and pulmonary edema) and **right sided** (predominantly peripheral edema). **Biventricular** heart failure describes symptoms that result from both right and left ventricular involvement.

Assessment of ventricular function allows for differentiation between **systolic** and **diastolic** heart *dysfunction*. Arbitrarily, left ventricular dysfunction is defined by a left ventricular ejection fraction less than 45% to 50%.

Left ventricular systolic dysfunction (decreased ejection fraction) is not synonymous with left-sided heart failure because patients may be largely asymptomatic, even with left ventricular ejection fraction less than 30%. Similarly, diastolic dysfunction is not synonymous with diastolic heart failure. Diastolic heart failure is more accurately described as **heart failure with preserved ejection fraction (HFpEF)**.

The NYHA classification describes patients' *functional status* (see Box 42-1), and the functional status can change over time. In contrast, the *staging classification* of heart failure recognizes that heart failure is a progressive condition and may manifest as variable symptoms over time.[34,228] Both classifications remain highly useful in clinical practice.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a unique cardiomyopathy of unknown cause that occurs during pregnancy or the postpartum period.[229-231] The *timing* of development of heart failure is important to help exclude other causes of heart failure. To make the diagnosis of peripartum cardiomyopathy, the development of heart failure should occur in the last month of pregnancy or within 5 months of delivery (Box 42-10). Other identifiable causes of heart failure should be excluded, and the absence of other recognizable cardiac disease prior to the last month of pregnancy should be verified. Echocardiographic diagnostic criteria include (1) left ventricular ejection fraction less than 45% (and/or M-mode fractional shortening < 30%) and (2) end-diastolic left ventricular dimension greater than 27 mm/m^2 body surface area.[232] Some women develop cardiomyopathy before the last month of pregnancy. This condition is referred to as *pregnancy-associated cardiomyopathy*. Its clinical signs, symptoms, and outcomes are similar to those for peripartum cardiomyopathy.[233]

BOX 42-10 Diagnostic Criteria for Peripartum Cardiomyopathy

Traditional Criteria

- Onset of heart failure during the last month of pregnancy or within 5 months of delivery
- No other identifiable cause of heart failure
- No known heart disease before pregnancy

Echocardiographic Criteria

- Left ventricular ejection fraction < 45%
- Fractional shortening < 30%
- Left ventricular end-diastolic volume ≥ 27 mm/m^2

Modified from Pearson GD, Veille JC, Rahimtoola S, et al. Peripartum cardiomyopathy: National Heart, Lung, and Blood Institute and Office of Rare Diseases (National Institutes of Health) workshop recommendations and review. JAMA 2000; 283:1183-88; and Hibbard JU, Lindheimer M, Lang RM. A modified definition for peripartum cardiomyopathy and prognosis based on echocardiography. Obstet Gynecol 1999; 94:311-6.

The incidence of peripartum cardiomyopathy varies around the world and has been reported to be as high as 1 in 300 live births in Haiti[234] and 1 per 3000 to 4000 live births in the United States.[229,235] The cause(s) for such regional variation are unclear. Risk factors for peripartum cardiomyopathy include African race, multiparity, multiple gestation, preeclampsia, gestational hypertension, use of tocolytic agents, cocaine abuse, and age older than 30 years.

The etiology of this relatively rare condition remains unclear; several possible causes have been proposed, including underlying myocarditis, apoptosis, inflammation, pathologic maternal immune response to fetal antigens, effects of prolactin, viral triggers, and hereditary/familial factors.

Patients with peripartum cardiomyopathy have typical signs and symptoms of systolic heart failure. On clinical examination, the apical impulse is displaced laterally and an S3 gallop is appreciated. Because of left ventricular enlargement (Figure 42-6) and changes in ventricular cavity geometry, functional mitral regurgitation is frequently seen. Peripartum cardiomyopathy is primarily a diagnosis of exclusion, and the symptoms may be disguised as physiologic changes of pregnancy; thus, the use of echocardiography helps confirm the diagnosis. Right-sided heart pressures can almost always be assessed by echocardiography; hence, right-sided heart catheterization is rarely necessary. Left-sided heart catheterization may be necessary to assess the coronary arteries. However, given that the risk for ischemic cardiomyopathy in pregnancy is very low, and because coronary angiography results in fetal radiation exposure, left-sided heart catheterization is infrequently used to make the diagnosis. Ischemic cardiomyopathy is typically accompanied by regional wall motion abnormalities, whereas peripartum or nonischemic cardiomyopathy typically results in a global decrease in contractility.

Medical management of peripartum cardiomyopathy rests on basic treatment paradigms for congestive heart failure and dilated cardiomyopathy (see later discussion). Compared with other forms of nonischemic cardiomyopathy (e.g., infiltrative or HIV-related), peripartum cardiomyopathy has a better prognosis, with a 94% 5-year survival rate in the United States.[236] Recovery of left ventricular function occurs in slightly more than half of the affected women.[233] Black women are 6.4 times more likely to die of peripartum cardiomyopathy than white women. In contrast, in Haiti the 2-year mortality is 15.4% and only a fourth of the patients experience normalization of left ventricular function.[234]

The risk for subsequent pregnancy is substantially higher in women who do not recover normal left ventricular function.[237] In a series of 44 women with peripartum cardiomyopathy, the maternal mortality rate in subsequent pregnancies was 19% in women with

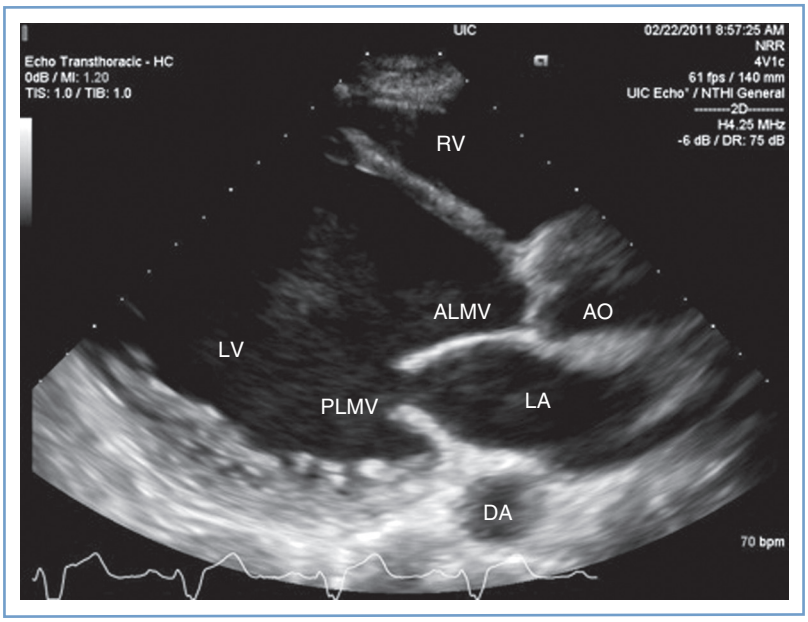

FIGURE 42-6 ■ Echocardiographic image of dilated cardiomyopathy. *RV,* right ventricle; *LA,* left atrium; *LV,* left ventricle; *ALMV,* anterior leaflet of the mitral valve; *PLMV,* posterior leaflet of the mitral valve; *AO,* aorta; *DA,* descending aorta. (Courtesy Dr. Mayank Kansal, University of Illinois at Chicago, Chicago, IL.)

persistent left ventricular dysfunction compared with 0% in women without residual dysfunction.[237] Therefore, subsequent pregnancy should be discouraged if left ventricular function has not recovered. Even in patients with normalized left ventricular function, careful counseling is advised owing to a significant risk for recurrence of left ventricular dysfunction in a subsequent pregnancy.[38]

Obstetric and Anesthetic Management

Obstetric management involves expedient delivery after stabilization of the mother; in most cases, cesarean delivery is reserved for obstetric indications. Continuous spinal anesthesia[238] and combined spinal-epidural anesthesia[239,240] have been safely administered in patients with severe peripartum cardiomyopathy. Given the intravascular fluid shifts associated with labor, delivery, and the immediate postpartum period, invasive blood pressure and central venous pressure monitoring are recommended. Neuraxial anesthesia appears ideally suited for these patients because it results in a beneficial decrease in both preload and afterload. Particular attention should be paid to the immediate postpartum period when autotransfusion combined with the regression of neuraxial anesthesia may cause worsening of heart failure.

Other Nonischemic Cardiomyopathies

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is relatively common, with a prevalence estimated at 1 in 500. It is an autosomal dominant disorder associated with various forms of left ventricular hypertrophy; the risk that an affected patient will transmit the disease to offspring is 50%. Additionally, hypertrophic cardiomyopathy mutations are highly penetrant. Preconception genetic counseling is recommended.[154]

The complications that result from hypertrophic cardiomyopathy can be separated into two categories: mechanical and electrophysiologic. The mechanical consequences relate to left ventricular outflow tract obstruction, mitral regurgitation, diastolic dysfunction, and development of heart failure. The electrophysiologic complications include atrial and ventricular arrhythmias and, most important, the risk for sudden cardiac death. The myocardial ischemia observed in patients with hypertrophic cardiomyopathy, often at ages younger than expected, is caused by supply-demand mismatch rather than coronary atherosclerosis. Hypertrophic cardiomyopathy is associated with disorganized myocardial architecture, myocardial disarray, and fibrosis (Figure 42-7).

One of the hallmarks of hypertrophic cardiomyopathy is the dynamic left ventricular outflow tract obstruction. The obstruction gradient typically increases after a premature ventricular contraction. One third of patients have left ventricular outflow tract obstruction at rest, one third have a physiologically provocable gradient, and one third have no gradient (nonobstructive form of hypertrophic cardiomyopathy). A gradient of 30 mm Hg or more is clinically significant.[241]

Pregnant women with hypertrophic cardiomyopathy may have dyspnea, fatigue, angina, palpitations, and/or syncope. Symptoms of congestive heart failure are rarely seen in patients in sinus rhythm; these symptoms are more frequently encountered when atrial fibrillation is present.

On physical examination the classic obstructive systolic murmur is heard at the apex (grade 3 to 4/6), and it radiates to the left sternal border. Although most patients will have a displaced and forceful left ventricular impulse, the presence of a murmur depends on the degree and

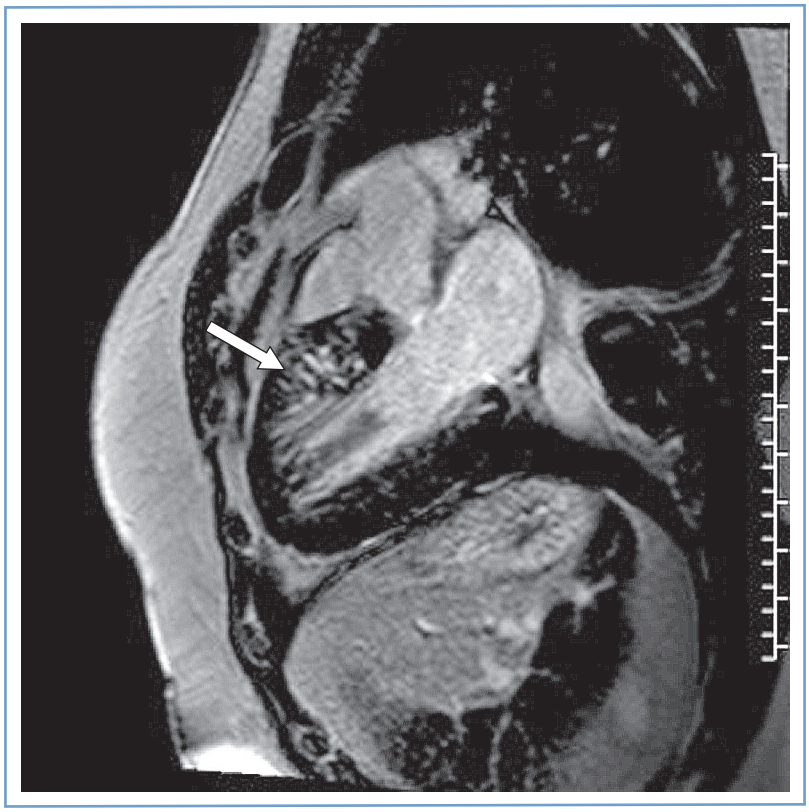

FIGURE 42-7 ■ Cardiac magnetic resonance image of hypertrophic cardiomyopathy with myocardial scar. Arrow shows scar with delayed enhancement with gadolinium in the hypertrophied myocardium. (Courtesy Dr. Afshin Farzaneh-Far, University of Illinois at Chicago, Chicago, IL.)

type of obstruction. The intensity of a hypertrophic cardiomyopathy murmur increases with a Valsalva maneuver or standing (decreased preload or afterload causes more obstruction), and it decreases with squatting (increased afterload causes less obstruction). Invasive arterial pressure monitoring allows recognition of a *bifid* arterial pulse waveform.

The ECG is abnormal in the vast majority of patients and demonstrates an increase in voltage, T-wave inversions, and pathologic Q waves. ECG abnormalities correlate poorly with the severity of hypertrophic cardiomyopathy.[155] Transthoracic echocardiography is indispensable for making the diagnosis, determining prognosis, and guiding management decisions.[154] Diagnostic criteria include a septal thickness greater than 15 mm and an increased septal-to-posterior wall thickness ratio (1.3). Systolic anterior motion of the mitral valve has a specificity of 98% for hypertrophic cardiomyopathy. Left ventricular outflow tract obstruction is apparent during Doppler interrogation; the continuous wave tracing has a classic "dagger-shaped" contour (Figure 42-8). In addition, echocardiography allows identification of various morphologic variants and assessment of the extent of hypertrophy. A wall thickness of 30 mm or greater is associated with a high risk for sudden cardiac death.[242] Patients with a gradient of 50 mm Hg or greater are at highest risk for complications.[154]

Fortuitously, the increase in blood volume allows most patients with hypertrophic cardiomyopathy to tolerate pregnancy well.[156,243,244] Both asymptomatic and symptomatic women with hypertrophic cardiomyopathy should continue taking a beta-adrenergic receptor antagonist throughout pregnancy and the peripartum period.[154]

Patients with hypertrophic cardiomyopathy are at increased risk for developing atrial fibrillation. Treatment of atrial fibrillation rests on rate and rhythm control as well as systemic anticoagulation to prevent thromboembolic stroke. Rate control can alleviate symptoms; beta-adrenergic receptor antagonists and nondihydropyridine calcium entry–blocking agents (e.g., verapamil, diltiazem) provide best results. Digoxin is less effective in controlling rate and may be harmful in patients with hypertrophic cardiomyopathy in the absence of atrial fibrillation.[154] Amiodarone can be successfully used for rate control in patients with hypertrophic cardiomyopathy. Rhythm control can be attempted pharmacologically with amiodarone and sotalol. In patients with a rapid ventricular response and significant hemodynamic compromise, electric cardioversion should be performed.

Obstetric and Anesthetic Management. Traditionally, general anesthesia has been considered the anesthetic technique of choice for parturients with hypertrophic cardiomyopathy.[245-249] It avoids a precipitous decrease in preload, and the negative inotropic effect of inhalation anesthetic agents may help reduce the degree of dynamic obstruction (see Table 42-2). No prospective controlled trials have compared general anesthesia with neuraxial anesthesia in parturients with hypertrophic cardiomyopathy; numerous case reports have described

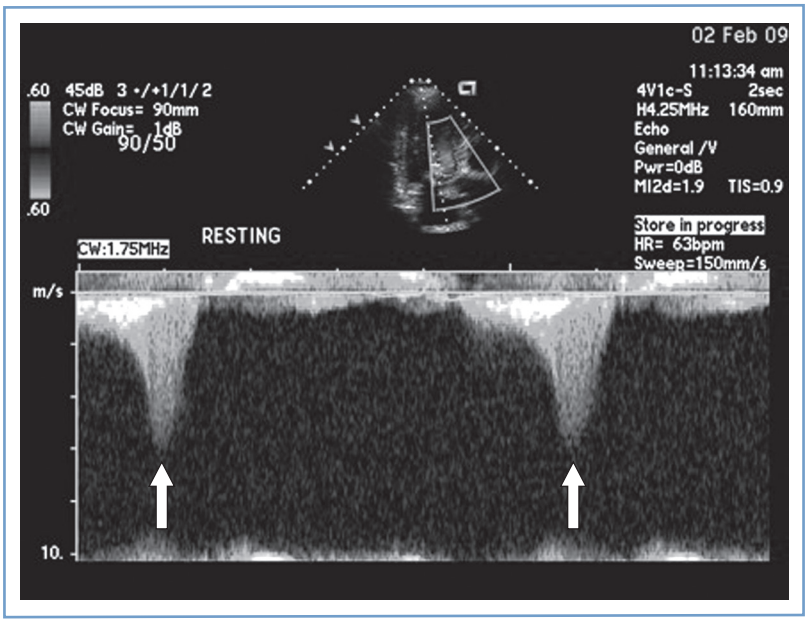

FIGURE 42-8 ■ Dynamic left ventricular outflow obstruction in hypertrophic cardiomyopathy. Continuous wave Doppler tracing in left ventricular outflow tract displays typical late-peaking ("dagger-shaped") contour of dynamic outflow obstruction (*arrows*). (Courtesy Dr. Mayank Kansal, University of Illinois at Chicago, Chicago, IL.)

successful use of neuraxial anesthesia in these patients.[250-257] Given that hypertrophic cardiomyopathy is a heterogeneous condition, and given the high likelihood of selection and publication bias in these case reports, it is difficult to make generalized recommendations for these patients. In deciding whether to administer general or neuraxial anesthesia, it is important to recognize the degree of left ventricular outflow tract obstruction. For cesarean delivery, it appears reasonable to recommend general anesthesia for patients with a gradient of 50 mm Hg or greater or for those with symptoms of heart failure during pregnancy. In asymptomatic parturients with a lower gradient, slowly titrated neuraxial analgesia/anesthesia appears safe.

Because a decrease in preload is expected to increase the degree of left ventricular outflow tract obstruction, central venous pressure monitoring seems reasonable. Similarly, invasive arterial blood pressure monitoring may be helpful. Transthoracic echocardiography facilitates assessment of intravascular volume. Beta-adrenergic receptor antagonists decrease myocardial contractility and decrease the severity of left ventricular outflow tract obstruction. Phenylephrine is the drug of choice for the treatment of hypotension. Inotropic agents (e.g., dopamine, dobutamine) may be harmful in these patients.[154] Rapid administration of intravenous oxytocin has been associated with hypotension; slow administration is therefore recommended.

Stress-Induced Cardiomyopathy

Stress-induced cardiomyopathy, also known as *takotsubo cardiomyopathy*, *broken heart syndrome*, or *apical ballooning syndrome*, is a transient cardiomyopathy with typical left ventricular systolic dysfunction of the apical and midcavity segments.[258] The basal ventricular segments are frequently hyperkinetic and may cause left ventricular outflow tract obstruction. Affected patients typically do not have underlying coronary artery disease. Stress-induced cardiomyopathy occurs predominantly in postmenopausal women in the seventh and eight decades of life and is frequently associated with emotional and physical stressors. It has also been described during pregnancy in the setting of emotional and physical triggers, postpartum depression, and administration of pharmacologic triggers such as ergot alkaloids. It has been reported in the absence of apparent triggers[259] during otherwise uncomplicated spinal anesthesia for cesarean delivery.[260,261]

Clinically, patients have chest pain, dyspnea, and symptoms of left ventricular systolic dysfunction and heart failure. ECG abnormalities are frequently observed in left precordial leads and may mimic STEMI due to plaque rupture. Coronary angiography is required to rule out STEMI; ventriculography or echocardiography allows recognition and characterization of wall motion abnormalities. The most critical differential diagnoses are STEMI and peripartum cardiomyopathy. When treating patients who develop shock, it is critically important to determine the degree of left ventricular outflow tract obstruction. Shock without left ventricular outflow tract obstruction can be treated in standard fashion with an inotropic agent. Patients with left ventricular outflow tract obstruction require optimization of intravascular volume and administration of a beta-adrenergic receptor antagonist; use of an intra-aortic balloon pump may be necessary to relieve the obstruction.

Dilated and Other Cardiomyopathies

In women with **idiopathic** or **anthracycline-induced cardiomyopathy,** pregnancy is associated with a high risk for adverse maternal, fetal, and neonatal outcomes.

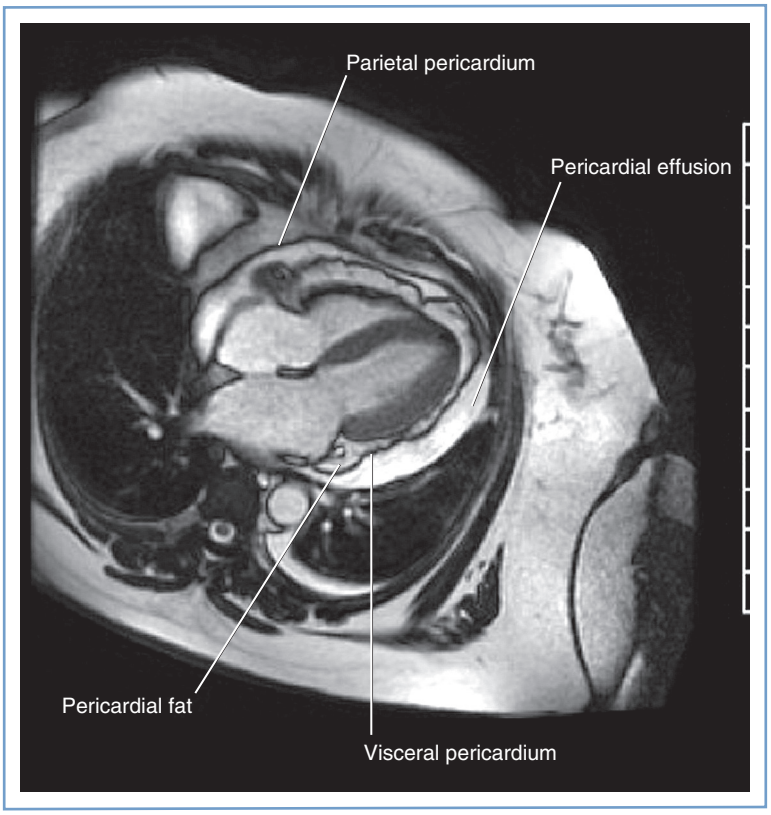

FIGURE 42-9 ■ Cardiac magnetic resonance image of pericardial effusion. (Courtesy Dr. Afshin Farzaneh-Far, University of Illinois at Chicago, Chicago, IL.)

Pregnancy appears to unfavorably affect the short-term course of these cardiomyopathies. The NYHA functional status and ejection fraction may predict outcomes in this population.[262] Other causes of cardiomyopathy during pregnancy include **cocaine abuse** and **hemochromatosis**; the latter results in an infiltrative cardiomyopathy.

Rapid atrial or ventricular rates due to arrhythmia can cause **tachycardia-induced cardiomyopathy**. This cardiomyopathy is a potentially reversible condition that has been described in pregnancy[263] and successfully treated with radiofrequency ablation.[264,265] Differentiation from other forms of cardiomyopathy may be difficult, but it is important from a prognostic standpoint.

Medical Management of Heart Failure

Principles of heart failure management for pregnant patients are similar to those for nonpregnant patients with two notable exceptions: angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blocking agents and aldosterone antagonists (spironolactone, eplerenone) should *not* be used in pregnant women. A beta-adrenergic receptor antagonist should be administered, and hydralazine can be substituted for ACE inhibitors/angiotensin receptor blocking agents. Digoxin use is safe in pregnancy. Loop diuretics and sodium restriction are indicated to prevent or treat volume overload. In patients with decompensated heart failure, treatment with intravenous nitroglycerin and dopamine or dobutamine is indicated.

Ventricular Assist Devices

Anecdotal reports have described ventricular assist device use during pregnancy. A successful completion of pregnancy with cesarean delivery in a patient with a ventricular assist device has been reported.[266] In another patient with myocardial infarction and subsequent severe left ventricular dysfunction, a ventricular assist device was placed, although pregnancy was not recognized at the time of placement; fetal death subsequently ensued.[267] The preconception presence of a ventricular assist device remains a contraindication to pregnancy.

PERICARDIAL DISEASE

Pericardial Effusion

Asymptomatic pericardial effusions are frequently found in otherwise healthy pregnant women (Figure 42-9). A pericardial effusion may be seen in 15% to 20% of pregnancies in the first and second trimester; this rate increases to approximately 40% in the third trimester. The effusion is seen more often in nulliparous women than in parous women.[268] These effusions are transudative and disappear within 2 months after delivery. Treatment is rarely required. Physical signs of tamponade or pulsus paradoxus are rarely seen. Similarly, electrical alternans is not seen on the ECG.

Acute Pericarditis

Pericarditis remains a clinical diagnosis confirmed by ECG and echocardiography. Patients typically have precordial pain that improves with sitting and learning forward. A pericardial friction rub may be appreciated on physical examination; this finding is frequently evanescent, and repeat examinations may be required. ECG findings consist of diffuse concave ST-segment elevations. Diffuse PR interval depression is frequently seen except in lead aVR, which demonstrates near-pathognomonic PR-interval elevation. Echocardiography may demonstrate various degrees of pericardial effusion. Importantly, the presence of a pericardial effusion is not synonymous with pericarditis because pericarditis remains a clinical diagnosis.

The etiology of acute pericarditis during pregnancy is most likely similar to that in the general population. A viral etiology is most common. Less common causes include tuberculosis, connective tissue disease (e.g., systemic lupus erythematosus), and neoplasm.

Treatment of pericarditis in the general population includes nonsteroidal anti-inflammatory drugs, glucocorticoids, colchicine, and, rarely, immunosuppressant drugs. During pregnancy, the maternal and fetal risks and benefits of these agents should be weighed carefully.

Cardiac Tamponade

Therapeutic and diagnostic pericardiocentesis or a surgical pericardial window can be safely performed during pregnancy. However, echocardiographic rather than fluoroscopic guidance is preferred because it avoids fetal radiation exposure.

Constrictive Pericarditis

Constrictive pericarditis is a condition in which a noncompliant pericardium prevents filling of the right- and left-sided heart chambers; specific hemodynamic features include equalization and elevation of both left and right ventricular diastolic pressures, preserved systolic function, and a "dip and plateau" pattern of the ventricular pressure tracing. Potential causes of constrictive pericarditis during pregnancy include previous irradiation, recurrent pericarditis due to rheumatoid arthritis, tuberculosis, and neoplasm. Patients may be asymptomatic before pregnancy; the physiologic changes of pregnancy may exacerbate the condition.

Anesthetic Management

Constrictive physiology and cardiac tamponade share some common pathophysiologic features that are important for the conduct of anesthesia (see Table 42-2). Impaired filling of the right side of the heart results from either a noncompliant pericardium (constrictive physiology) or pericardial fluid (tamponade physiology). Cardiac output is reduced by any intervention that reduces preload (e.g., aortocaval compression, sympathectomy with neuraxial anesthesia, positive-pressure ventilation with general anesthesia). Therefore, maintenance of preload is critically important; this goal can be achieved with central venous pressure monitoring, slowly titrated neuraxial anesthesia, and avoidance of positive-pressure ventilation. Invasive blood pressure monitoring is recommended.

CARDIOPULMONARY RESUSCITATION DURING PREGNANCY

Cardiac arrest during pregnancy is rare; it occurs in 1 in 20,000 to 30,000 pregnancies. Overall survival rates are poorer than expected compared with other clinical arrest scenarios.[269,270] The reversible causes of cardiac arrest during pregnancy are similar to those in nonpregnant patients. Additional causes specific to pregnancy include amniotic fluid embolism, eclampsia, placental abruption, and uterine atony (see Box 55-5).

Standard Basic Life Support (BLS) and Advanced Cardiac Life Support (ACLS) principles apply to these patients. However, anatomic and physiologic changes of pregnancy require several specific modifications to the resuscitation protocol (Box 42-11; see also Box 55-5).[269] The hands performing chest compressions should be placed slightly higher on the sternum because the abdominal contents and the diaphragm are displaced cephalad during the third trimester of pregnancy. Intravenous access should be obtained above the diaphragm. In pregnant patients, aortocaval compression reduces the cardiac output that results from chest compressions. Although it is typically advised to tilt the patient 15 to 30 degrees to facilitate left uterine displacement and optimize venous return and cardiac output, such a maneuver may impede the effectiveness of chest compressions. Therefore, current guidelines advocate manual left uterine displacement rather than the usual whole-body tilt (see Figure 55-2). If this technique is not successful, a firm wedge

BOX 42-11 Modifications of Cardiopulmonary Resuscitation in Pregnancy

- Left uterine displacement (15 to 30 degrees)
- Airway
  - Consider airway edema associated with pregnancy
- Breathing
  - Be aware of the impact of decreased functional residual capacity in pregnancy
- Circulation
  - Perform chest compressions higher on the sternum than in nonpregnant patients
- Defibrillation
  - May use automated external defibrillator (AED)
  - Apply same energies as in nonpregnant patients
  - Remove all fetal monitoring probes and leads
- Drugs
  - Drugs (and doses) are the same as those used in nonpregnant patients

Modified from Vanden Hoek TL, Morrison LJ, Shuster M, et al. Part 12: Cardiac arrest in special situations: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Circulation 2010; 122:S829-61.

may be placed under a resuscitation board to tilt the patient approximately 30 degrees. In the field, the responder may use his or her knees to tilt the patient.

If spontaneous circulation does not return within 4 minutes of cardiac arrest, hysterotomy or cesarean delivery should be performed, with the goal of achieving delivery within 5 minutes of cardiac arrest. The primary purpose of cesarean delivery is to improve the chance of maternal survival, but timely delivery also improves the chances of infant survival.

Defibrillation should be performed based on current ACLS protocols. Transthoracic impedance is not changed during pregnancy, and the standard recommended electric energies should be used. Both cardioversion and defibrillation are considered safe at all stages of pregnancy. External and internal fetal monitoring probes and leads should be removed before defibrillation or cardioversion.

An intra-aortic balloon pump, a percutaneous left ventricular assist device, cardiopulmonary bypass, and extracorporeal membrane oxygenation have been successfully used in pregnant women with cardiac arrest; favorable outcomes have been reported. Therapeutic hypothermia has also been used after cardiac arrest during pregnancy, with successful delivery and favorable neonatal outcome.

PREGNANCY AFTER HEART TRANSPLANTATION

The first successful pregnancy in a heart transplant recipient was described in 1988. Subsequently, several reports have documented the feasibility and relative safety of pregnancy and delivery in female heart transplant recipients.[271,272] Successful patient management requires an interdisciplinary team approach.

The transplanted heart is denervated and the increase in cardiac output with pregnancy primarily results from an increase in stroke volume rather than heart rate. Because the risk for acute rejection is not increased in pregnant patients with a heart transplant, the immunosuppressant medications should be maintained at the lowest possible dose. The risk for infection is greater in patients receiving immunosuppression therapy. The AHA considers the presence of valvulopathy in heart transplant recipients a high-risk lesion for the development of bacterial endocarditis. Thus, given the unfavorable outcomes in heart transplant recipients who develop endocarditis, it appears reasonable to recommend antibiotic endocarditis prophylaxis at the time of membrane rupture for these parturients undergoing labor and vaginal delivery (see Box 42-7).[127]

Cardiac transplant vasculopathy is a disease specific to transplanted hearts; it consists of concentric and longitudinal intimal hyperplasia in the coronary arteries. In contrast, native coronary atherosclerosis manifests as focal, noncircumferential lesions. After malignancy, cardiac transplant vasculopathy constitutes the second most common cause of death 1 year after heart transplantation. Therefore, monitoring for ischemia appears prudent in these patients, especially because they may not present with classic anginal symptoms owing to denervation of the transplanted heart.

Baseline echocardiography allows assessment of ejection fraction and the presence of transplant valvulopathy. Most parturients with a heart transplant with a normal ejection fraction and normal right-sided pressures tolerate labor and delivery well; both neuraxial and general anesthesia are acceptable. Peripartum immunosuppression therapy should be managed by a multidisciplinary team.

CARDIOPULMONARY BYPASS DURING PREGNANCY

In the current era, maternal mortality associated with elective cardiopulmonary bypass during pregnancy is comparable to that for nonpregnant women.[273] Fetal mortality remains high (16% to 33%),[274-276] although some series report excellent fetal outcomes.[277] The optimal timing of cardiopulmonary bypass appears to be the second trimester of pregnancy. Procedures performed immediately after delivery and on an emergency basis appear to confer added risk for maternal mortality. The degree of hypothermia is associated with poor fetal outcome. There is no evidence that anesthesia *per se* contributes to adverse maternal or fetal outcomes in this setting.[273] The need for intraoperative FHR monitoring is universally accepted. Measures to lower fetal mortality include normothermic cardiopulmonary bypass with flow rates in excess of 2.4 L/min/m^2 while maintaining mean arterial blood pressure above 70 to 75 mm Hg. Left uterine displacement and maintenance of hematocrit greater than 28% are recommended.

KEY POINTS

- Heart disease is the primary medical cause of nonobstetric maternal mortality.
- Congenital heart disease is the cause of 60% to 80% of cases of cardiac disorders in pregnant women in developed countries such as the United States.
- The management of most forms of congenital heart disease, including Eisenmenger syndrome, rarely requires pulmonary artery catheterization.
- Intrathecal administration of a lipophilic opioid is an excellent choice of intrapartum analgesia for women who may not tolerate decreased systemic vascular resistance and decreased venous return.
- Cardiac lesions do not represent an absolute contraindication to the use of neuraxial anesthesia, assuming that the induction of anesthesia proceeds slowly and the potentially adverse hemodynamic changes are corrected promptly. Single-shot spinal anesthesia can

produce circulatory collapse in parturients with severe aortic stenosis, primary pulmonary hypertension, and Eisenmenger syndrome.

- The treatment of most arrhythmias during pregnancy is similar to that for nonpregnant women.
- When cardiopulmonary resuscitation is required during pregnancy, the standard advanced cardiac life support protocols should be used. Left uterine displacement should be employed to prevent aortocaval compression and a reduction in preload. Choice of drugs (and doses) as well as indications for defibrillation are the same as those for nonpregnant adult women. After 20 weeks' gestation, early hysterotomy and uterine evacuation may be necessary to facilitate resuscitation of the mother. Rescuers should be prepared to proceed with cesarean delivery if spontaneous circulation does not return within 4 minutes of cardiac arrest.
- Infective endocarditis prophylaxis is not recommended for vaginal or cesarean delivery except in patients with cardiac conditions at highest risk for endocarditis.

CHAPTER 49

Neurologic and Neuromuscular Disease

Angela M. Bader, MD, MPH

CHAPTER OUTLINE

The choice of anesthetic technique for pregnant women with neurologic disease requires knowledge of the pathophysiology of the disorder and an understanding of controversies involved in the diagnosis and management of the disease. If a patient's neurologic condition deteriorates postpartum, the cause may be unclear and the anesthetic technique may be blamed unfairly. There are limited published data on specific neurologic and neuromuscular disorders in pregnant women. However, few of these disorders contraindicate the use of neuraxial anesthesia. In most cases, the obstetrician should obtain early antepartum consultation from an anesthesiologist. Early

consultation allows accurate antepartum documentation of the extent and pattern of the neurologic deficit as well as discussion and formulation of the anesthetic plan with the patient, her obstetrician, and a neurologist or neurosurgeon.

Because patients with a wide variety of neurologic disorders will present for preoperative evaluation, the following thought process will assist the clinician with completing a proper evaluation and formulating an anesthetic plan.

What is the basic pathophysiology of the particular neurologic disorder? Neurologic disorders may be stable, progressive, or relapsing/recurrent. It is important to understand the common disease patterns. The potential for progression of the disease after delivery will depend on the pattern of progression and underlying pathophysiology and on the effect of pregnancy on disease progression.

What is the patient's history and current findings after neurologic examination? A history should include the onset date and current course of the disorder. Symptoms related to neurologic issues should be documented (e.g., seizure type and frequency, deficits after cerebrovascular events, cognitive deficits). A basic physical examination should be conducted to document existing deficit patterns, including cognitive dysfunction (e.g., ability to understand and cooperate), deficits involving vision, hearing, speech, and swallowing; respiratory symptoms; and weakness and sensory deficits in the head and neck, trunk, and extremities. Motor and sensory deficits are classified as mild, moderate, or severe, with a description of the affected area. Special attention should be directed to limitations in ambulatory ability (e.g., bed-bound, wheelchair, walking with assistance) or positioning.

What are the current treatments and what testing results are available? Documentation of medical and nonmedical therapies is essential. For some disorders (e.g., myasthenia gravis), documentation of the timing of treatment is also critical. In most cases, specific laboratory testing will not influence management and outcome. However, pulmonary function testing should be considered in patients with neurologic disorders that result in significant respiratory compromise; the findings may assist the anesthesiologist in making decisions about anesthetic management.

What is the impact of the neurologic disorder on other organ systems (e.g., cardiac, respiratory, airway)? The patient's neurologic disease may affect organ systems that are relevant to the anesthetic plan. For example, central core disease is associated with a risk for malignant hyperthermia. In addition, progressive neurologic disorders may significantly compromise the patient's respiratory status, thereby increasing the risks associated with neuraxial and general anesthesia.

What are the potential impacts, risks, or benefits of particular anesthetic options based on the disease's pathophysiology, symptoms, and treatment? Can treatment be initiated antepartum or before delivery that will improve outcome? For most rare neurologic disorders there is limited evidence on which to base decisions about anesthetic management. In these cases, the anesthesiologist should consider the disease's basic pathophysiology and its possible direct and indirect interactions with specific anesthetic techniques. Encouraging the obstetrician to send these patients for early antepartum consultation will enable the anesthesiologist to obtain formal input from a neurologist or other consultant if necessary. A multidisciplinary discussion that includes the patient may be necessary to weigh the risks and benefits of specific obstetric and anesthesia plans.

In all cases, accurate documentation of the responses to the previous questions will greatly assist the team providing analgesic or anesthetic care for these patients. Some of the more common neurologic conditions are addressed in this chapter, and the existing literature is surveyed relative to the peripartum management of these patients. This knowledge allows the anesthesiologist an opportunity to formulate a safe and rational anesthetic plan as well as enable an appropriate discussion with the patient regarding the risks and benefits of particular anesthetic options.

MULTIPLE SCLEROSIS

Multiple sclerosis is a major cause of neurologic disability in young adults. The prevalence of the disorder varies with the population. Recent data suggest that the prevalence of the disease is increasing, especially in females, and may be as high as 300 per 100,000 in some parts of North America.[1] Both environmental and genetic factors appear to play a role in the incidence and prevalence of disease.

The disease is characterized by variable neurologic disabilities with two general patterns of presentation: (1) **exacerbating remitting**, which accounts for 85% of cases, in which attacks appear abruptly and resolve over several months, and (2) **chronic progressive**, in which continued deterioration occurs over time.[2] The relapse rate varies significantly among patients, averaging approximately 0.4 attacks per year; this rate reflects the large proportion of patients with relapsing/remitting disease. The deficits tend to become more progressive and debilitating over time. Environmental factors (e.g., stress, infection, increased body temperature) may provoke a relapse. Most relapses reproduce previously experienced neurologic deficits, which can manifest as pyramidal, cerebellar, or brainstem symptoms.

The etiology remains unclear. There is a clinically significant heritable component, and alleles in the HLA locus have been identified as risk factors for multiple sclerosis.[3] Pathologic findings include inflammation and loss of myelin in the central nervous system (CNS). It is possible that the disease results from a yet undetermined combination of genetic predisposition and exposure to specific environmental factors.

The more common symptoms include motor weakness, impaired vision, ataxia, bladder and bowel dysfunction, and emotional lability. Cerebrospinal fluid (CSF) immunoglobulin and lymphocyte concentrations are increased, and magnetic resonance imaging (MRI) studies demonstrate white matter plaques. Lesions may be documented by the demonstration of prolonged evoked potentials in areas of involvement.

There is no cure. Immunosuppressive therapies may hasten recovery from a relapse, but no evidence suggests

that these agents influence the progressive course of the disease. Administration of interferon-beta may significantly reduce the relapse rate and retard disability; however, an increased risk for fetal loss and low birth weight (LBW) has been observed with the use of this therapy during the first trimester of pregnancy.[4] In contrast, administration of intravenous immunoglobulin may reduce the risk for relapse and has no known adverse effects on pregnancy outcome.[5] Acute relapses during pregnancy can be treated with intravenous corticosteroids, although their use may be associated with maternal glucose intolerance and neonatal adrenal suppression.[6]

Interaction with Pregnancy

Evidence regarding the effect of multiple sclerosis on pregnancy is conflicting. In one cohort study that compared 198 affected women with 1584 healthy women, the number of maternal complications was not higher in women with multiple sclerosis.[7] However, infants delivered of women with multiple sclerosis appear to be at greater risk for meconium aspiration, even though the presence of moderate to heavy meconium is not significantly increased.[7] This finding may reflect an intrauterine environment in patients with multiple sclerosis that is more susceptible to acute hypoxic events.[7] A subsequent cohort study of 649 pregnancies in women with multiple sclerosis concluded that infants of these women were more likely to be small for gestational age; this outcome was also attributed to a suboptimal intrauterine environment.[8] Moreover, this study found that mothers with multiple sclerosis were more likely to undergo induction of labor and operative delivery, possibly as a result of neuromuscular weakness and spasticity.

In a 2011 meta-analysis of reports of pregnant women with multiple sclerosis, the relapse rate was lower during pregnancy than before or after pregnancy.[9] It is unclear whether the prevalence of cesarean deliveries, spontaneous abortions, preterm births, and LBW neonates is higher in women with multiple sclerosis than in healthy women, although the rates did not reach levels that would warrant great concern.

Data from prospective studies suggest that the rate of relapse increases during the first 3 months postpartum in comparison with the year before pregnancy.[10] Relapses during this period were more likely in women who had higher relapse rates in the year before pregnancy or during pregnancy. Stress, exhaustion, infection, the loss of antenatal immunosuppression, and the postpartum decline in concentrations of reproductive hormones may account for the higher postpartum relapse rate. Treatment with immunologically active agents (e.g., interferon-beta) may result in a decreased postpartum relapse rate, but data are limited.[10]

Pregnancy does not negatively affect the long-term outcome of multiple sclerosis. Rather, at least one study has suggested that parturition may have a slightly favorable effect on long-term disease activity.[11] Data are conflicting as to whether exclusive breast-feeding is associated with a lower risk for relapse than partial or no breast-feeding.[12,13]

Anesthetic Management

The anesthesiologist should assess the patient's level of compromise, document the pattern of deficits, and give special attention to respiratory involvement. Historically, the optimal route of anesthesia in patients with multiple sclerosis has been controversial. Most anesthesia providers have considered general anesthesia to be safe, although published data are limited.[14,15] Many anesthesia providers have been reluctant to administer neuraxial anesthesia because the effect of local anesthetic drugs on the course of the disease is unclear. Some anesthesiologists have expressed concern that neuraxial anesthesia may expose demyelinated areas of the spinal cord to potentially neurotoxic effects of local anesthetic agents. Several animal studies have investigated the histologic effects of local anesthetic agents on the normal spinal cord. In one study, subarachnoid injection of small doses of a local anesthetic agent produced no histologic changes in the spinal cord or meninges.[16] Injection of very large doses caused reversible inflammatory and degenerative changes, but all changes resolved within 14 days of injection.

Diagnostic lumbar puncture is not associated with a higher rate of relapse.[17] Two small reports have implicated spinal anesthesia in the exacerbation of multiple sclerosis.[15,18] Bamford et al.[15] described one case of relapse after the administration of spinal anesthesia in 9 patients, and Stenuit and Marchand[18] identified two cases of relapse after the administration of spinal anesthesia in 19 patients. The relationship of these relapses to spinal anesthesia or other postoperative conditions (e.g., stress, infection, hyperpyrexia) known to exacerbate multiple sclerosis is unclear.

There are few published data on the use of epidural anesthesia in patients with multiple sclerosis. Warren et al.[19] reported minor exacerbations after the administration of epidural anesthesia for two separate vaginal deliveries in one patient. Crawford et al.[20] reported one postoperative relapse in 50 nonobstetric and 7 obstetric patients who received epidural analgesia. Confavreux et al.[21] reported a study of 269 pregnancies in 254 women with multiple sclerosis, of whom 42 received epidural analgesia. They noted that epidural analgesia did not have an adverse effect on the rate of relapse or on the progression of disability in these patients. Bader et al.[22] retrospectively evaluated 32 pregnancies in women with multiple sclerosis; they observed that women who received epidural anesthesia for vaginal delivery did not have a higher incidence of relapse than those who received only local infiltration anesthesia. In a prospective study of 227 women who had multiple sclerosis for at least 1 year before conception, of whom 42 received epidural analgesia during labor, no adverse effect of epidural analgesia on the rate of relapse or the progression of disability was identified.[10]

Bader et al.[22] observed that all of the women who experienced a relapse after epidural anesthesia had received a concentration of bupivacaine greater than 0.25%. The concentration of local anesthetic in the CSF progressively increases during prolonged administration of epidural anesthesia, and the authors suggested that the higher concentration may overwhelm the protective effect of

dilution within the CSF. An alternative explanation is that women who require a higher concentration of neuraxial local anesthetic may have more stressful labor. However, these observations suggest that anesthesia providers should use a dilute solution of local anesthetic for epidural analgesia during labor, when possible.

The addition of an opioid reduces the total dose of local anesthetic required for epidural analgesia during labor. Berger and Ontell[23] reported the administration of intrathecal morphine, which was added to low-dose tetracaine for surgical anesthesia and postoperative analgesia, and observed no exacerbation of multiple sclerosis at 1 and 6 months after surgery. Leigh et al.[24] described the successful use of intrathecal diamorphine for postoperative analgesia in a patient with multiple sclerosis who underwent a laparotomy.

The administration of neuraxial anesthesia for cesarean delivery is controversial. Because the operation is of limited duration, multiple doses of local anesthetic are typically not needed, so a progressive increase in CSF concentration of local anesthetic over time is less likely. In light of the significant benefits of neuraxial techniques for intraoperative anesthesia and postoperative analgesia, either spinal or epidural anesthesia is the principal anesthetic technique used for cesarean delivery in patients with multiple sclerosis in many institutions, including my own.

In summary, published data do not contraindicate the use of neuraxial anesthetic techniques for labor analgesia or operative anesthesia. The patient should be aware that there is a higher incidence of relapse during the postpartum period, even without the use of neuraxial analgesia or anesthesia. In addition, when anesthetic techniques are used, the type of anesthesia selected does not appear to influence the relapse rate. Neither pregnancy nor anesthesia appears to have a negative influence on the long-term course of the disease. The willingness of anesthesiologists to use neuraxial techniques in pregnant patients with multiple sclerosis is reflected in a survey of obstetric anesthesiologists published in 2006.[25] The majority (91%) of respondents had seen fewer than 10 cases of multiple sclerosis in the past 10 years; 79% and 98% of anesthesiologists indicated they would perform a neuraxial anesthetic technique for labor and elective cesarean delivery, respectively.

HEADACHE DURING PREGNANCY

Headaches are among the most frequently observed neurologic symptoms during pregnancy (Table 49-1). Tension headaches, migraine headaches, and headaches associated with hypertension in pregnancy, including preeclampsia, are commonly observed during pregnancy. A pregnant patient with a history of chronic headaches who reports new or different symptoms should be closely evaluated to exclude serious etiologies such as preeclampsia, tumor, or intracranial vascular malformation. Symptoms of concern include sudden onset, intense severity, altered mental status, meningeal signs, fever, vomiting, and any localizing or lateralizing abnormality.

Tension Headache

Tension or muscle contraction headaches are the most common type of headache observed during pregnancy.[26] The symptoms typically consist of dull, persistent pain that extends over the entire head. The onset is usually gradual, but the symptoms may persist for long periods. Although the etiology is unknown, this type of headache is believed to be associated with stress rather than hormonal changes. These headaches are more common in women, are frequently associated with anxiety, and may be a symptom of postpartum depression.[27]

Treatment

In the nonpregnant patient, treatment of tension headaches may involve acetaminophen, aspirin, opioids, tricyclic antidepressants, and benzodiazepines. In the pregnant

TABLE 49-1 **Headache during Pregnancy**

Etiology	Symptoms	Pattern	Treatment
Tension headache	Dull, widespread headache	Increased incidence during peripartum period	Analgesics Tricyclic antidepressants
Migraine headache	Frontotemporal throbbing Prodrome of scotomata	Improvement in 79% of patients during pregnancy	Ergotamine contraindicated during pregnancy Promethazine Beta-adrenergic receptor antagonist for prophylaxis
Preeclampsia	Generalized headache Occasional scotomata and/or blurred vision	Occurrence during pregnancy and occasionally postpartum	Blood pressure control Delivery
Meningeal irritation (subarachnoid hemorrhage, meningitis)	Generalized headache	Increased risk for subarachnoid hemorrhage during pregnancy	Based on etiology
Brain tumor	Variable	No increase in incidence during pregnancy, possible increased growth rate	Based on etiology
Idiopathic intracranial hypertension	Generalized headache Visual symptoms	Increased incidence and worsened symptoms during pregnancy	Typically remits within 1 to 3 months or after childbirth

patient, acetaminophen should be used as a first-line analgesic. Caffeine may be contained in combination analgesic products (e.g., Fioricet, Fiorinal). The American College of Obstetricians and Gynecologists (ACOG) has stated that, at the current time, there is no clear evidence that caffeine exposure increases the risk for fetal growth restriction (also known as intrauterine growth restriction).[28] Because a final conclusion regarding risk of high caffeine intake and miscarriage cannot be made, the ACOG recommends moderate caffeine intake (< 200 mg/d) during pregnancy. Limited data suggest that butalbital is not associated with congenital anomalies.[29] Ergot alkaloids (e.g., ergotamine) are contraindicated during pregnancy; these agents may cause marked increases in uterine tone, which may compromise placental perfusion and fetal oxygenation.[29] Use of nonsteroidal anti-inflammatory drugs (NSAIDs) should be limited during the third trimester because of concerns about their association with premature closure of the fetal ductus arteriosus and prolongation of pregnancy. Although a 2013 review did not find evidence that first-trimester exposure to benzodiazepines is associated with an increased risk for congenital malformations,[30] these drugs are not usually used to treat headache during pregnancy. Opioids and tricyclic antidepressants have a long record of safe use during pregnancy; one study suggested that tricyclic antidepressants do not have detrimental effects on the neurodevelopment of children exposed *in utero*.[31]

Obstetric and Anesthetic Management

Pregnancy is not likely to reduce the frequency or severity of tension headaches because they are not hormonally mediated. Obstetric and anesthetic management are rarely affected by the presence of tension headaches, although a history of chronic tension headaches has been associated with an increased risk for placental abruption (adjusted odds ratio, 1.60).[32]

Migraine Headache

Migraine headaches are classically described as unilateral, throbbing headaches sometimes accompanied by nausea and vomiting. The duration varies from hours to days. Visual disturbances (e.g., scotomata) typically precede the onset of these headaches, and focal neurologic symptoms (e.g., aphasia, hemiplegia) may also occur. Most investigators favor neurovascular vasospasm, followed by cerebral vasodilation, as a cause of these headaches; a primary vascular disorder or a disturbance in the noradrenergic nervous system also may be involved. Patients appear to be more susceptible to symptoms when serotonin levels are low.

The 1-year period prevalence of migraine headache in the United States is 3.9% for men and 5.1% for women.[33] Prevalence is higher in middle life, between the ages of 30 and 59 years. Hormonal influences have a strong association with these headaches; estrogen withdrawal is associated with an exacerbation of symptoms.[34] After delivery, the reduction in hormonal concentrations coincides with an increase in migraine symptoms.[35] In a prospective study of 208 Japanese women,[36] 85% of women had headache regression during pregnancy; no patient had worsening of headache symptoms during pregnancy. More than 50% of women experienced recurrence of migraine headache in the first postpartum month; breastfeeding was protective against the recurrence of headache.

Treatment

In nonpregnant patients, therapy often involves ergotamine tartrate, typically in combination with caffeine (e.g., Cafergot, Migergot). However, ergot alkaloids are contraindicated during pregnancy because of associated uterotonic effects and possible (but unproven) teratogenic effects.[29,35,37] In general, acetaminophen is the first-line treatment during pregnancy. Combination therapy with agents containing caffeine and/or butalbital can be used with caution; the caffeine component should be limited to a dose less than 200 mg/day (see earlier discussion). Use of NSAIDs should be limited during the third trimester because of concerns about their association with premature closure of the ductus arteriosus, oligohydramnios, and prolongation of pregnancy. Beta-adrenergic receptor antagonists (e.g., propranolol) may be used for prophylaxis; however, owing to their ability to cross the placenta, these agents should be used only when a patient's symptoms are severe. Occasionally, calcium entry–blocking agents are used. The use of sumatriptan or other selective serotonin agonists is controversial. A higher incidence of congenital anomalies has been observed after administration of high doses of sumatriptan in animals[37]; however, in a review of human studies, no evidence of any specific adverse effect of sumatriptan on pregnancy outcome was found.[38]

Obstetric and Anesthetic Management

Women with a history of migraines have a higher risk for developing gestational hypertension or preeclampsia (adjusted odds ratio, 2.85).[37,39] In addition, patients with a lifetime history of migraine have been reported to have a twofold increased risk for placental abruption.

Cerebral ischemia has been reported after the administration of terbutaline in pregnant patients with migraine. Rosene et al.[40] recommended that physicians avoid the administration of terbutaline in pregnant women with a history of vascular headache.

There are no published data on the relationship between intrapartum anesthesia and postpartum migraine headaches.

SPINAL CORD INJURY

Worldwide, there are large geographic differences in the incidence, prevalence, and lethality of spinal cord injuries.[41] In the United States, traumatic spinal cord injuries occur with an incidence of 23.7 to 77.0 per million population per year; the prevalence per million inhabitants is 473 to 1800.[41] Improved handling and stabilization of victims at the site of an accident and the availability of

extensive rehabilitation services have resulted in a higher number of women who present for obstetric care after spinal cord injury than in the past.

Patient disability and residual function depend on the anatomic location of the injury.[42] Cord injuries below S2 involve mainly bladder, bowel, and sexual functions. Affected patients have relaxed perineal muscles, and women with such injuries experience pain during labor. Women with a lesion above T10 do not experience labor pain. Patients with a lesion above T6 have varying levels of respiratory compromise and are at risk for autonomic hyperreflexia (see later discussion).

Spinal shock, defined as transient sensorimotor dysfunction resolving in less than 24 hours, may develop in about half of spinal cord–injured patients.[43] Neurogenic shock consists of hemodynamic and sensorimotor abnormalities and is characterized by flaccid paralysis with loss of tendon and autonomic reflexes for weeks to months.[43] Patients with neurogenic shock lose vasomotor tone, temperature regulation, sweating, and piloerection in the parts of the body below the lesion. Pulmonary edema, hemodynamic instability, and circulatory collapse can develop in the absence of brainstem regulation of vasomotor tone. Patients are at risk for aspiration, infection, and other pulmonary complications. Paraplegic patients may have a compensatory tachycardia, whereas quadriplegic patients may have bradycardia due to unopposed vagal tone.

After a variable period, the patient progresses to a chronic stage in which reflex activity is regained. In most cases, this return of reflex activity occurs within 1 to 6 weeks after the injury; rarely, return of reflex activity may take several months. This stage is characterized by disuse atrophy, flexor spasms, and an exaggeration of reflexes. The **mass motor reflex** results from the absence of central inhibitory mechanisms. A stimulus that normally would cause the contraction of a few muscle units leads to the widespread spasm of entire muscle groups. The mass motor reflex can occur with any level of spinal cord injury. It may occur with autonomic hyperreflexia in a patient with a lesion above T6.[44]

Approximately 85% of patients with chronic spinal cord injuries at or above T6 experience the syndrome of **autonomic hyperreflexia.**[43] This is a life-threatening complication that results from the absence of central inhibition on the sympathetic neurons in the cord below the injury. Noxious stimuli, bladder or bowel distention, and uterine contractions result in afferent transmission by means of the dorsal spinal root (Figure 49-1).[45] These afferent neurons synapse with sympathetic neurons, and the impulse is propagated both cephalad and caudad in the sympathetic chain, without central inhibition. The propagation results in extreme sympathetic hyperactivity and severe systemic hypertension secondary to vasoconstriction below the level of the lesion. In response, the reflex arcs involving the baroreceptors of the aortic and carotid bodies lead to bradycardia and vasodilation above the level of the lesion. In patients with lesions of T6 and above, these compensatory mechanisms are insufficient to compensate for the severe hypertension. Intracranial hemorrhage, arrhythmias, and myocardial infarction occur in some cases. A variety of agents have been used

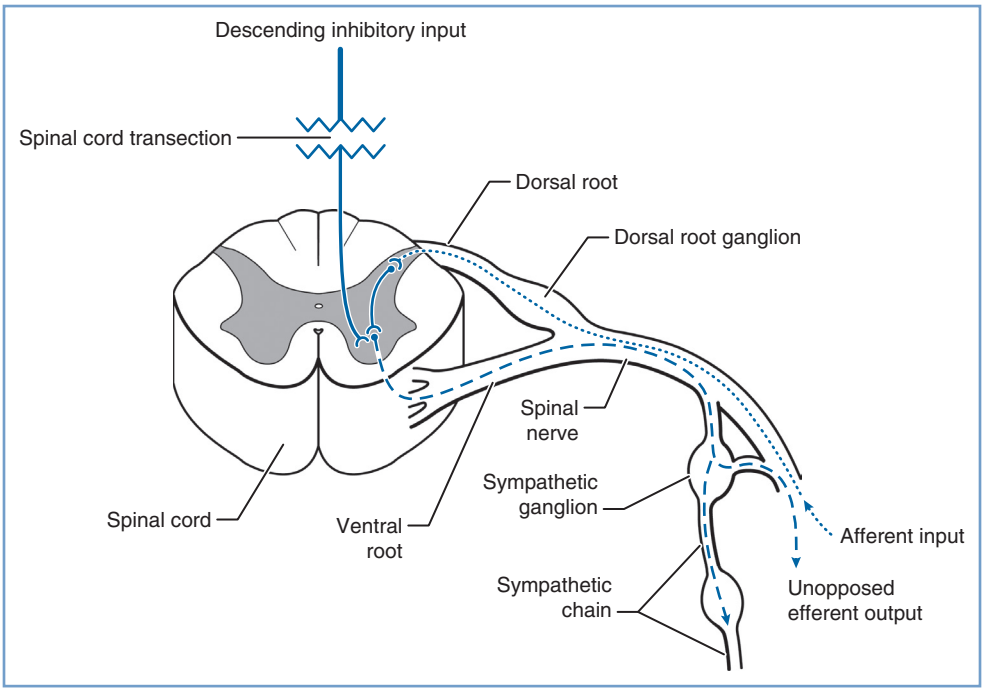

FIGURE 49-1 ■ Noxious stimuli enter the dorsal horn of the spinal cord through the dorsal spinal root (*dotted line*). These afferent neurons synapse either directly or by means of interneurons (*solid line*) with sympathetic neurons in the intermediolateral columns of the lateral horns, which then project through the anterior roots to the paraspinal sympathetic chain (*dashed line*). The impulse is propagated peripherally at that spinal level and also travels both cephalad and caudad in the sympathetic chain, exiting at multiple thoracic and lumbar levels (*dashed line*) and resulting in sympathetic hyperactivity. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

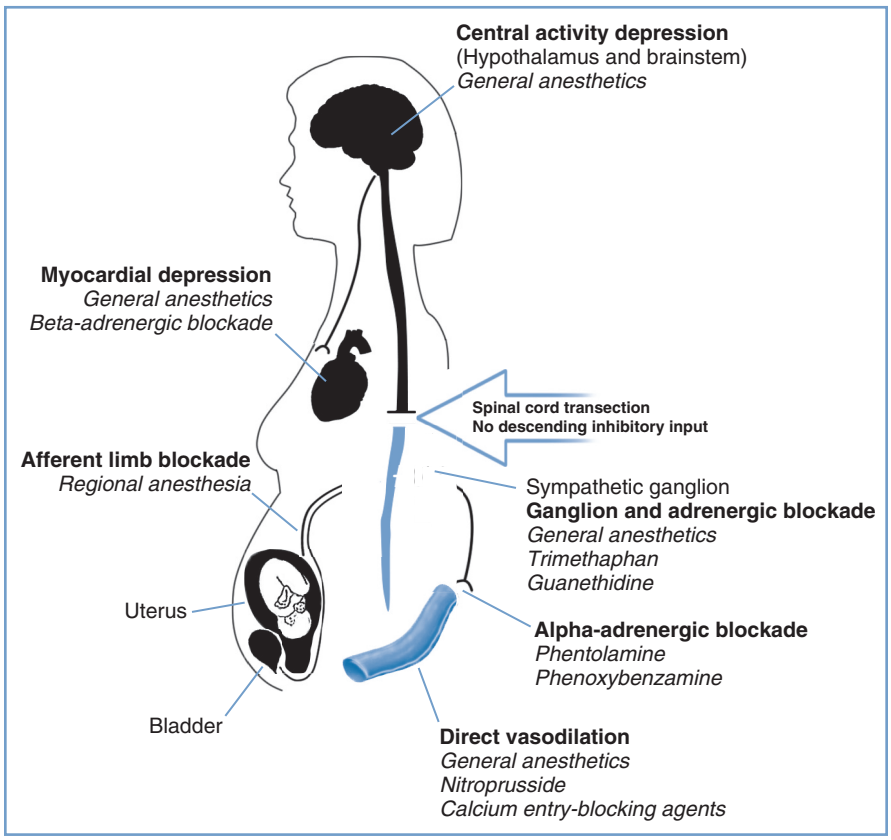

FIGURE 49-2 ■ Sites of action for agents used in the control of hypertension associated with autonomic hyperreflexia. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

for control of the hypertension of autonomic hyperreflexia (Figure 49-2).

Obstetric Management

Pregnancy may aggravate many of the medical complications of spinal cord injury (Box 49-1).[45] The loss of both functional residual capacity and expiratory reserve volume during pregnancy may increase the likelihood of respiratory compromise associated with spinal cord injury. Pregnancy increases the risks for thromboembolic phenomena and urinary tract infection. Loss of sympathetic tone below the level of the lesion renders pregnant patients with spinal cord injury particularly prone to orthostatic hypotension, which may result in a decrease in uteroplacental perfusion. Uterine contractions can stimulate autonomic hyperreflexia, and the resultant vasoconstriction can result in fetal hypoxia and bradycardia. In pregnant women, autonomic hyperreflexia occurs most commonly during labor.

Women with a lesion above T11 may have a higher risk for preterm labor.[42] Because these women do not experience labor pain, obstetric management includes weekly cervical examinations during the third trimester. Vaginal delivery is preferred. The use of assisted vaginal delivery may be necessary because of the parturient's inability to push.[42] In a study of 52 pregnancies in spinal cord–injured women, 9 of 12 patients with lesions above T5 had symptoms of autonomic hyperreflexia. The cesarean delivery rate was 47% for women with lesions above T5 and 26% for women with lesions at T5 or below.[46]

BOX 49-1 Medical Complications of Spinal Cord Injury Aggravated by Pregnancy

Pulmonary
- Decreased respiratory reserve
- Atelectasis and pneumonia
- Impaired cough

Hematologic
- Anemia
- Deep vein thrombosis
- Thromboembolic phenomena

Urogenital
- Chronic urinary tract infections
- Urinary tract calculi
- Proteinuria
- Renal insufficiency

Dermatologic
- Decubitus ulcers

Cardiovascular
- Hypertension
- Autonomic hyperreflexia

From Crosby E, St. Jean B, Reid D, Elliot RD. Obstetric anaesthesia and analgesia in chronic spinal cord-injured women. Can J Anaesth 1992; 39:487-94.

Preterm delivery occurred in 19% of patients. Autonomic hyperreflexia may affect uteroplacental blood flow, necessitating careful monitoring of the fetal heart rate (FHR).

Anesthetic Management

Women with spinal cord lesions at or above T6 are at risk for autonomic hyperreflexia. This syndrome can be distinguished from other causes of intrapartum hypertension by the occurrence of cyclic hypertension (i.e., blood pressure increases during contractions and decreases between contractions). The ACOG[47] recommends continuous hemodynamic monitoring during labor for all patients at risk for autonomic hyperreflexia.

Administration of neuraxial anesthesia is the most common method for prevention or treatment of autonomic hyperreflexia during labor and delivery. Spinal anesthesia has effectively controlled blood pressure in paraplegic patients undergoing general surgical procedures.[48] Although some anesthesiologists contend that distortion of the vertebral column in paraplegic patients makes it more difficult to predict and control the level of spinal anesthesia, published data do not lend support to this argument.[48] If spinal anesthesia is chosen, insertion of an intrathecal catheter and use of a continuous technique may be appropriate; this approach may allow careful titration of the resulting neuroblockade.

Most obstetric anesthesiologists prefer the use of epidural analgesia for the prevention or treatment of autonomic hyperreflexia during labor and delivery. Consideration also should be given to providing epidural analgesia after vaginal delivery to minimize the possibility of autonomic hyperreflexia, which has been reported to occur in response to pain as late as 5 days after delivery.[49]

Case reports have described the successful epidural administration of 0.25% or 0.5% bupivacaine or the administration of combined spinal-epidural (CSE) anesthesia for the mitigation of autonomic hyperreflexia.[50-52] Baraka[53] reported the successful use of epidural meperidine, an opioid with local anesthetic qualities, in avoiding the signs of autonomic hyperreflexia. Abouleish et al.[54] observed that epidural fentanyl alone did not effectively treat the hypertension of autonomic hyperreflexia, but the addition of 0.25% bupivacaine led to a decrease in blood pressure to baseline levels. Maehama et al.[55] described the successful use of magnesium sulfate for management of autonomic hyperreflexia during labor.

Patients with spinal cord injury often have a low baseline blood pressure and some hemodynamic instability. Placement of an intra-arterial catheter before induction of anesthesia allows the continuous assessment of blood pressure.

Positioning for neuraxial block may be difficult; the anesthesiologist should consider performing the block with the patient in a lateral position because the sitting position may cause hypotension from venous pooling in the lower body. Therapeutic doses of a local anesthetic agent should be administered cautiously with the understanding that the cephalad level of the sensory block can be fully assessed only if it is higher than the level of the spinal cord lesion. As a result, the typical epidural test dose may not identify unintentional subarachnoid injection in a patient with spinal cord injury. Neuraxial blockade can be partially assessed by evaluating segmental reflexes below the level of the lesion. For example, the anesthesiologist can lightly stroke each side of the abdomen above and below the umbilicus, looking for contraction of the abdominal muscles and deviation of the umbilicus toward the stimulus. Reflexes are absent below the level of the block. In some patients with spastic paresis at baseline, the level of anesthesia may be confirmed by the conversion of spastic paresis to flaccid paresis.[50] A decline in blood pressure may also herald the onset of neuraxial blockade. Using a nerve stimulator connected to a saline-filled, wire-reinforced epidural catheter was found to be a reliable and relatively simple method of confirming catheter placement in the epidural space.[56]

Alternative means of treating autonomic hyperreflexia should be available if neuraxial anesthesia is not successful. Antihypertensive medications such as magnesium sulfate or arteriolar vasodilators may be effective, recognizing that hypotension can result in decreased uterine blood flow.[46] Careful titration of nitroprusside, noting the potential for fetal/neonatal cyanide intoxication, or beta-adrenergic receptor blockade, may also be useful. The anesthesiologist should recognize that increased vagal activity during autonomic hyperreflexia can result in electrocardiographic changes including first- and second-degree atrioventricular block and sinus arrest.[57]

If cesarean delivery is necessary, epidural or spinal anesthesia can be administered. Spinal anesthesia is generally associated with a more rapid onset and a more unpredictable level of neuroblockade and can lead to significant hypotension.[58] The effect of neuraxial blockade on respiratory function may be less severe with epidural anesthesia than with spinal anesthesia.

Severe respiratory insufficiency or technical difficulties with neuraxial anesthesia may necessitate the use of general anesthesia.[59] If general anesthesia is required, a depolarizing muscle relaxant such as succinylcholine should not be given during the period of denervation injury. By a conservative definition, this period begins 24 hours after the injury and lasts for 1 year. The use of succinylcholine during this period of denervation injury may cause severe hyperkalemia[60]; therefore, a nondepolarizing muscle relaxant should be used to facilitate laryngoscopy and tracheal intubation.

MYASTHENIA GRAVIS

Myasthenia gravis is an autoimmune disorder characterized by episodes of muscle weakness that are made worse by activity. Its prevalence is 50 to 125 cases per million. Women are twice as likely to have the disease as men, and the onset is earlier (second or third decade in women versus the sixth or seventh decade in men).[61] Myasthenia gravis has been classified according to severity as follows[61]:

I. Ocular myasthenia
II. Mild generalized myasthenia; may include ocular, oropharyngeal, and respiratory involvement
III. Moderate generalized disease

IV. Severe generalized weakness
V. Defined by requirement for tracheal intubation, with or without mechanical ventilation

Myasthenia gravis results from an abnormality in autoimmune regulation, which leads to the production of antibodies against the nicotinic acetylcholine receptor on the neuromuscular end plate of skeletal muscle. The result is receptor destruction as well as antibody-induced blockade of the remaining acetylcholine receptors.[62] Smooth muscle and cardiac muscle are not affected. Thymic hyperplasia is common, and thymic tumors occur in approximately 10% of patients. There is an association between myasthenia gravis and other autoimmune disorders, such as rheumatoid arthritis and polymyositis. In general, an early age at onset and an extended duration of purely ocular myasthenia are good prognostic signs.

Medical Management

Treatment involves a thymectomy, administration of anticholinesterase medications and/or immunosuppressive agents, and plasmapheresis. A thymectomy improves the disease course in approximately 96% of patients; 46% of these patients undergo complete remission, and an additional 50% are asymptomatic or experience improvement with therapy.[63] In addition, a thymectomy appears to exert a favorable influence on the outcome of pregnancy.[64] One study noted decreased maternal and perinatal morbidity as well as less frequent clinical exacerbations in patients who had undergone thymectomy.[64]

Anticholinesterase drugs, which inhibit the breakdown of acetylcholine, are the mainstay of therapy. Decreased muscle weakness within minutes of administering an intravenous dose of edrophonium (10 mg) confirms the diagnosis of myasthenia gravis. Physostigmine crosses the blood-brain barrier and is not used for long-term therapy. Neostigmine and pyridostigmine are quaternary ammonium compounds that do not cross the blood-brain barrier. These drugs may be administered orally or intravenously. In general, pyridostigmine is preferred because it has less severe muscarinic side effects.[65]

Corticosteroids and azathioprine have been used with some success. Plasmapheresis can be especially helpful for patients in crisis. One study noted that preoperative plasmapheresis resulted in less need for mechanical ventilation and less time in the intensive care unit postoperatively.[66]

Myasthenia gravis can manifest in two types of crises. A **cholinergic crisis** results from an excess of the muscarinic effects of anticholinesterase medications combined with a poor response to anticholinesterase therapy. Symptoms include muscle weakness, respiratory difficulty or failure, increased sweating, salivation, bronchial secretions, and miosis. In contrast, a **myasthenic crisis** results from a worsening of the disease; its symptoms include more severe muscle weakness, including the respiratory muscles. These two crises can be distinguished by the administration of edrophonium. The symptoms do not improve if the crisis is cholinergic. In contrast, improvement indicates a myasthenic crisis and the need for a higher dose of anticholinesterase medication.

Many drugs can cause a worsening of myasthenic symptoms. These patients are extremely sensitive to drugs that potentiate muscle weakness.[67] These agents include neuromuscular blocking agents, quinidine, propranolol, aminoglycoside antibiotics, and tocolytic agents such as magnesium sulfate[68,69] and terbutaline. One case report noted worsened symptoms after the maternal administration of betamethasone.[70]

Obstetric Management

The course of myasthenia gravis during pregnancy varies. In general, approximately 29% of cases improve, 41% worsen, and 30% show no change.[71] Approximately 30% of patients experience a relapse postpartum. The highest chance of exacerbations occurs in the first trimester and in the acute postpartum period.[72]

Myasthenia gravis increases the rates of pregnancy wastage, preterm labor, and maternal mortality and morbidity.[72,73] In 1991 Plauché[71] estimated that maternal mortality is approximately 40 per 1000 live births and perinatal mortality is approximately 68 per 1000 births. Maternal mortality risk is inversely proportional to the duration of myasthenia gravis, with the highest risk occurring in the first year; consequently, myasthenic women are sometimes counseled to delay childbirth for the first few years after diagnosis.[73]

The maternal physiologic changes of pregnancy, including alterations in drug absorption, increases in blood volume, and changes in renal clearance, may require adjustments in the doses of anticholinesterase drugs. However, in the presence of a myasthenic crisis, aggressive intravenous therapy is essential, even during labor. Anticholinesterase agents are quaternary ammonium compounds that undergo minimal placental transfer but have known uterotonic effects[73]; thus, uterine activity should be monitored during the administration of these drugs. Each patient should be monitored carefully for progressive respiratory compromise secondary to diaphragmatic elevation during pregnancy. Vital capacity can be measured to monitor fatigue during labor. The treatment of the myasthenic patient with preeclampsia or preterm labor is problematic because the use of magnesium sulfate for maternal seizure prophylaxis or fetal neuroprotection may be associated with a significant increase in maternal and fetal muscle weakness.[72]

The uterus consists of smooth muscle; therefore, myasthenia gravis should not affect the first stage of labor. However, the second stage of labor often requires the use of striated muscle and consequently an assisted (e.g., vacuum or forceps) vaginal delivery may be required.

Maternal antibodies to the acetylcholine receptor are transferred across the placenta. Neonatal myasthenia gravis occurs in approximately 16% of infants of mothers with myasthenia gravis.[64,71] Physiologic variations in the levels of alpha-fetoprotein, which can block the binding of the antibody to the acetylcholine receptor, can alter the clinical course of myasthenia during pregnancy.[74] The rapid decrease in alpha-fetoprotein concentrations in the neonate after birth may be responsible for transient symptoms of myasthenia (e.g., feeding problems, hypotonia, respiratory difficulty) within the first 4 days of

life.[72] The symptoms abate as the antibodies are metabolized, with resolution typically occurring within 2 to 4 weeks; however, anticholinesterase therapy may be required during the interim.

Anesthetic Management

Myasthenia gravis patients should undergo early antepartum consultation with an anesthesiologist. This evaluation should assess the extent of bulbar and respiratory involvement and overall baseline muscle strength. Pulmonary function testing should be performed in patients with evidence of respiratory compromise. In a study of surgical patients, the presence of bulbar symptoms, a preoperative serum level of antiacetylcholine receptor antibody greater than 100 nmol/L, and intraoperative blood loss greater than 1000 mL were risk factors for having a postoperative myasthenic crisis.[75]

Patients with respiratory compromise may be more susceptible to opioid-induced respiratory depression, and consideration should be given to minimizing or avoiding opioids when possible. Neuraxial techniques are the preferred method for labor analgesia in patients with myasthenia gravis, given their association with low pain scores and high maternal satisfaction, even without the addition of opioids.[76] The use of anticholinesterase drugs may prolong the half-life of ester local anesthetic agents.

Neuraxial anesthetic techniques are preferred for cesarean delivery unless the patient has significant bulbar involvement or respiratory compromise. The use of bilevel positive airway pressure for ventilatory support in patients with moderate respiratory compromise may improve the safety of neuraxial anesthesia.[77]

In the patient with severe bulbar involvement or respiratory compromise, it may be prudent to secure the airway before surgery. Sodium thiopental, ketamine, and propofol have been used successfully for the induction of general anesthesia in patients with myasthenia gravis.[73,77,78] Depolarizing muscle relaxants (e.g., succinylcholine) have an unpredictable effect in these patients, with affected and unaffected muscles being more sensitive and resistant to these agents, respectively.[63] However, the commonly administered dose of succinylcholine (1 to 1.5 mg/kg), which is three to five times the effective dose in 95% of normal patients, will most likely provide adequate relaxation even for resistant muscles. Anticholinesterase agents and plasmapheresis cause decreases in the activity of plasma cholinesterase and may cause delays in succinylcholine hydrolysis.

Myasthenic patients are extremely sensitive to nondepolarizing muscle relaxants. If a nondepolarizing muscle relaxant must be given, the anesthesia provider should administer a small amount of an agent with a short half-life (e.g., rocuronium, atracurium, vecuronium).[63] Mivacurium is metabolized via plasma pseudocholinesterase, which may be inhibited by pyridostigmine. In general, greater disease severity corresponds with enhanced sensitivity to nondepolarizing muscle relaxants, necessitating the use of clinical judgment and neuromuscular monitoring to determine the amount and timing of drug doses. Myasthenia may prevent a full-strength contraction with nerve stimulation; therefore, a control train-of-four stimulus test should be performed before paralysis for later comparison. For nondepolarizing agents, approximately 50% of the standard dose may be adequate, and a prolonged recovery should be anticipated. Small doses of neostigmine may be given cautiously for the reversal of neuromuscular blockade.

After delivery, fluid shifts and decreased maternal alpha-fetoprotein concentrations may necessitate an adjustment of anticholinesterase drug doses. Some patients who receive general anesthesia require postoperative ventilation. The following factors are predictive of an increased risk for postoperative ventilation: (1) female gender, (2) $FEF_{25\%-75\%}$ (forced expiratory flow during the middle half of the forced vital capacity) less than 3.3 L/sec and less than 85% of that predicted, (3) FVC (forced vital capacity) less than 2.6 L/sec and less than 78% of that predicted, and (4) $MEF_{50\%}$ (maximal expiratory flow at 50% of expired vital capacity) less than 3.9 L/sec and less than 80% of that predicted.[79]

EPILEPSY

Epilepsy is a condition characterized by recurrent seizure activity in the absence of metabolic disorders or acute brain disease. The classification scheme for epileptic seizures is evolving; however, most seizures are grouped into the two major types: partial and generalized.[80,81] In partial seizures, the excess neuronal discharge is thought to originate in one region of the cerebral cortex; in generalized seizures, the discharge occurs bilaterally and involves the entire cortex.

Medical Management

A variety of antiepileptic agents are used for seizure therapy, depending on the type of seizure and clinical response (Table 49-2). A variety of adverse effects have been reported with these agents, including early-onset events (e.g., somnolence, dizziness, hypersensitivity, rash, gastrointestinal symptoms) and late-onset events (e.g., depression, leukopenia, aplastic anemia, thrombocytopenia, megaloblastic anemia, hyponatremia).[81]

Prognosis for medical control of seizures is good for patients with generalized seizure disorders; as many as 2% to 40% of newly diagnosed epilepsy patients become seizure-free without or with minimal antiepileptic drug therapy.[82] Two of three newly treated epilepsy patients will eventually enter long-term remission (5 years or more without a seizure).[82] However, about one third of patients will have an intermittent pattern (early remission with late recurrence or late remission). Finally, the standard mortality ratio for patients with epilepsy (observed number of deaths in the study compared with the general population) is consistently increased in the first several years after the diagnosis of epilepsy.

Interaction with Pregnancy

Three to five births per thousand occur in women with epilepsy.[83] A 2009 systematic review by the American Academy of Neurology and American Epilepsy Society

TABLE 49-2 Epilepsy Drugs

Antiepilepsy Drug	Enzyme Inducer*	Enzyme Inhibitor†	Target Dose (mg/d)	Target Plasma Concentration (mg/L)‡
Carbamazepine	Yes	No	600-1200 bid or tid	3-12
Clobazam	No	No	10-20 bid	–
Felbamate	No	No	2400-3600 bid or tid	20-45
Gabapentin	No	No	900-2400 bid or tid	–
Lamotrigine	Yes	Yes	100-400 qd or bid	2-15
Levetiracetam	No	No	1000-3000 bid	–
Oxcarbazepine	Yes	No	800-1800 bid or tid	7.5-20 (MHD)
Phenobarbital	Yes	No	50-200 qd or bid	10-40
Phenytoin	Yes	No	200-300 bid or tid	5-25
Pregabalin§	No	No	150-600 bid or tid	–
Primidone	Yes	No	500-750 tid	10-40 (PHB)
Tiagabine			36-60 tid	–
Topiramate	Yes¶	No	100-400 bid	–
Valproate	No	Yes	600-1500 bid (slow release) or tid	40-120
Vigabatrin§	No	No	500-3000 bid	–
Zonisamide§	No	No	300	–

MHD, monohydroxy derivative; *PHD,* phenobarbital.
*Enzyme inducer of the CYP cytochrome P450 system.
†Enzyme inhibitor of the CYP cytochrome P450 and uridine diphosphate glucuronyl transferase systems.
‡Dash (–) indicates not relevant.
§Dose should be reduced in patients with renal dysfunction.
¶For doses > 200 mg/d.
From Elger CE, Schmidt D. Modern management of epilepsy: a practical approach. Epilepsy Behav 2008; 12:501-39.

concluded that there is insufficient evidence to determine whether seizure frequency changes during pregnancy.[84] Women who are free of seizures for at least 9 months to 1 year before pregnancy have a probability of 84% to 92% of remaining seizure-free during pregnancy.[84]

Optimizing antiseizure therapy before pregnancy is critical. Because of the teratogenic aspects of many antiepileptic agents, some physicians consider withdrawal of these drugs after 2 years without seizures and recommend waiting at least 6 additional months after withdrawal before attempting to conceive. Substituting new antiepileptic agents after conception is not recommended.

A variety of causes have been proposed for the increase in seizure frequency observed in some pregnant women (Table 49-3). Higher estrogen concentrations in pregnancy lower the seizure threshold.[85] Greater sodium and water retention, alkalosis secondary to hyperventilation, sleep deprivation, and increased stress and anxiety also have been suggested as mechanisms.[86] In addition, anticonvulsant drug levels can decrease during pregnancy, often despite the administration of a larger dose[87]; this may be partially explained by the decreased plasma protein binding and greater drug clearance observed during pregnancy.[88] The American Academy of Neurology and American Epilepsy Society concluded that monitoring of lamotrigine, carbamazepine, and phenytoin levels should be considered during pregnancy. Monitoring of levetiracetam and oxcarbazepine (and its active metabolite, monohydroxy derivative) may be considered, and monitoring of other antiepileptic agents should not be discouraged despite limited data regarding their pharmacokinetic behavior during pregnancy.[89]

TABLE 49-3 Possible Causes of Increased Seizure Frequency during Pregnancy

Mechanism	Examples
Hormonal	Changes in levels of estrogen (proconvulsant) and progesterone (anticonvulsant)
Metabolic	Increased water and sodium retention
Psychological	Stress, sleep deprivation
Pharmacokinetics	Increase in liver metabolism, renal clearance, or volume of distribution
Physiologic	Decreased gastrointestinal absorption

Maternal seizures can have devastating consequences. Hypoxia and acidosis that occur during a generalized seizure can result in fetal compromise or intrauterine fetal death. During the past three decades, the overall risk for obstetric complications in epileptic women has declined. Although some studies have suggested an increased risk for hypertension in pregnancy (including preeclampsia), bleeding, and preterm birth, a systematic review concluded that evidence is inconclusive.[84] However, women with epilepsy may have a moderately increased risk for cesarean delivery.[84]

Fetuses and neonates of women with epilepsy are approximately twice as likely to have adverse pregnancy

outcomes, including intrauterine fetal death, cesarean delivery, 1-minute Apgar score less than 7, neonatal and perinatal death, LBW, and abnormal development.[90] Antiepilepsy drugs taken in the first trimester of pregnancy are associated with an increased risk for major *congenital malformations*.[83,90,91] Data are insufficient to judge whether *in utero* exposure to antiepileptic agents in general increases the risk for *cognitive impairment* in the offspring of women with epilepsy, although there is some evidence that the risk may be increased for specific drugs.[83,91] Specifically, *in utero* exposure to valproate has been associated with maladaptive childhood behavior and autism.[91]

The risk for congenital malformations in women with epilepsy receiving antiepileptic drug monotherapy is 4% to 6%[90,91] Malformations have been associated with all currently used therapeutic modalities; those most often observed are cleft lip and palate and cardiac, neural tube, and urogenital defects (hypospadias).[91]

Certain drugs have been associated with a higher relative risk for congenital defects than others. Data from prospective studies indicate that valproate in particular is associated with significantly higher rates of major malformations.[83,91] Animal studies suggest that newer agents (e.g., lamotrigine, gabapentin, felbamate, topiramate, tiagabine, levetiracetam, pregabalin) have less teratogenic effect in animals, but adequate human studies have not been performed.[91] Lamotrigine may be less teratogenic in humans than other antiepileptic agents, although neonates with orofacial clefts have been reported in association with its use.[92] Collaborative international registries are collecting more information regarding the dose-dependent effects of antiepileptic agents during pregnancy, particularly information regarding the newer drugs.[93] Several studies suggest that maternal folic acid supplementation before conception may decrease the risk for major congenital abnormalities in the offspring of women with epilepsy on antiepileptic therapy.[89]

Tomson and Battino[91] reviewed data from the International Registry of Antiepileptic Drugs and Pregnancy (EURAP) and made the following suggestions: (1) before conception select the most appropriate agent for the woman's type of epilepsy, (2) select the drug with the lowest teratogenic potential, (3) aim for monotherapy with the lowest effective dose, (4) whenever possible avoid valproate, and (5) if possible avoid valproate at doses of 700 mg/d and higher.

Neonates of mothers undergoing long-term antiepileptic therapy may be at risk for deficiencies in vitamin K–dependent clotting factors or other coagulation defects, despite the absence of clinically evident maternal coagulation abnormalities.[89] Enzyme-inducing antiepileptic agents (e.g., phenytoin, phenobarbital, carbamazepine) can cross the placenta and may increase the rate of oxidative degradation of vitamin K in the fetus. Affected infants are at risk for neonatal hemorrhage and respond to vitamin K (1 mg) given intramuscularly at birth. The administration of prenatal vitamin K to epileptic women with long-term exposure to these particular antiepileptic agents has not been conclusively shown to reduce the risk for neonatal hemorrhage.[89]

Anesthetic Management

There are significant interactions between antiepileptic drugs and anesthetic agents.[94] Carbamazepine, phenytoin, phenobarbital, and primidone are potent inducers of the cytochrome P450 enzymes in hepatic metabolism (see Table 49-2), which may result in decreased plasma concentrations of many medications, including beta-adrenergic receptor antagonists and calcium entry–blocking agents.[81]

Serum levels of antiepileptic drugs should be checked if therapeutic levels are known (see Table 49-2). Drug doses should not be missed during the peripartum period. If the patient experiences a seizure during labor, airway protection and support of ventilation are essential. Small doses of a benzodiazepine, propofol, or sodium thiopental arrest most seizures. Fetal bradycardia may necessitate immediate delivery.

Oral antiepileptic therapies should be continued whenever possible throughout the peripartum period. Unfortunately many of the agents are not available in parenteral forms. If oral agents cannot be taken, conversion to a parenteral agent such as phenytoin may be required. In general, antiepileptic agents have sedating properties and some are known to induce liver enzymes; this feature could potentially lead to more rapid breakdown of anesthetic agents that are metabolized by the liver.

The presence of epilepsy is not a contraindication to the administration of neuraxial analgesia or anesthesia. In a retrospective review of 100 epileptic obstetric patients, 19 received general anesthesia, 48 received spinal anesthesia, 21 received epidural or caudal anesthesia, and 12 received pudendal nerve block.[95] Of the 5 women who had a postpartum seizure, 4 had received spinal anesthesia and 1 had received general anesthesia with enflurane. No seizures occurred in patients who received epidural or caudal anesthesia. Although antiepileptic drugs have been associated with adverse effects on the coagulation system, Manohar et al.[96] observed no abnormal clotting parameters or platelet counts preoperatively in a series of patients with epilepsy undergoing surgery.

If general anesthesia is necessary, it seems prudent to avoid drugs such as ketamine and meperidine, which may lower the seizure threshold.[86,97] Sevoflurane has stronger epileptogenic properties than isoflurane, but co-administration of nitrous oxide and hyperventilation both counteract this effect.[98] Low doses of propofol also have been shown to cause activation of the electrocorticogram in epileptic patients, but at higher doses burst suppression was induced.[99] The highest incidence of seizure activity with induction of anesthesia is believed to occur with etomidate, followed by thiopental, methohexital, and propofol. Ketamine may also facilitate seizures at low dosages, but at high doses each of these induction agents acts as an anticonvulsant.[94] Induction of general anesthesia can be performed with propofol or sodium thiopental and succinylcholine, and anesthesia may be maintained with a mixture of oxygen, nitrous oxide, and isoflurane. One study noted that some patients who receive phenytoin are resistant to vecuronium but not to atracurium.[100]

MYOTONIA AND MYOTONIC DYSTROPHY

Myotonia is the general term used to describe a prolonged contraction of certain muscles after stimulation, which is followed by a delay in relaxation. **Myotonic dystrophies** are a genetically and phenotypically heterogeneous group of neuromuscular disorders caused by expansion defects in nucleotide sequences, principally on chromosome 19.[101] Based on clinical ascertainment, the estimated prevalence of myotonic dystrophy is about 1 in 8000; however, prevalence estimates vary widely.[101] As the most common form of myotonic disorders, myotonic dystrophies manifest in two distinct forms with different nucleotide sequences, DM1 and DM2. Both DM1 and DM2 are multisystem disorders characterized by skeletal muscle weakness and myotonia, cardiac conduction abnormalities, cataracts, hypogammaglobulinemia, and insulin resistance. DM1, also known as Steinert's disease, is generally more severe and exists in congenital, juvenile, and adult forms, whereas only an adult form has been identified for DM2.[101]

Myotonias can involve specific muscles, typically the hand, facial, masseter, and pretibial muscles, which become dystrophic or wasted. The disorder is slowly progressive with continual deterioration and gradual involvement of pharyngeal and laryngeal muscles, proximal limb muscles, and the diaphragm. Uterine smooth muscle is affected, and cardiac conduction abnormalities are often present. Patients typically succumb to either pulmonary or cardiac failure.

Congenital myotonic dystrophy is a severe form of myotonic dystrophy (DM1) that manifests early in infancy with hypotonia and feeding difficulties.[102] Myotonia becomes apparent during the first few years of life. In most cases the mother has myotonic dystrophy.

Myotonia congenita is a milder familial disorder characterized by myotonia of the skeletal muscles; multisystem involvement does not occur.[103] Unlike myotonic dystrophy, cardiac abnormalities are not present and smooth muscles are not affected. In some cases, muscle hypertrophy rather than wasting occurs. This disorder can be compatible with long life. It is distinguished from DM1 and DM2 by characteristic clinical features and an absence of significant histopathology in the muscle biopsy specimen. Myotonia congenita is characterized by dysfunction of the chloride channel.

Central core disease is a rare disorder in which muscle biopsies demonstrate the absence of oxidative enzyme activity in the longitudinal axis of the muscle fiber (i.e., the "central core"). Affected individuals have proximal muscle weakness and often scoliosis. This disease is caused by mutations in the skeletal muscle ryanodine receptor gene (*RYR1*) at chromosome 19q13.1, which has been associated with malignant hyperthermia.[104] Many patients with central core disease test positive for the malignant hyperthermia susceptibility trait on the caffeine-halothane contracture test (*in vitro* contracture test) (see Chapter 47); these patients should be considered at risk for malignant hyperthermia when exposed to triggering agents (i.e., succinylcholine, volatile halogenated agents).[104] Some patients with multiminicore and nemaline rod myopathy may also be at risk for malignant hyperthermia.[105]

Drugs such as quinine and mexiletine are most commonly used to relieve myotonic symptoms.[101-103] Corticosteroids, phenytoin, and tocainide also have been prescribed.

Obstetric Management

In patients with myotonic dystrophy, symptoms of weakness and myotonia usually remain unchanged during pregnancy; however, in a minority of women, symptoms worsen during pregnancy but generally resolve after delivery.[106] Antepartum evaluation should include pulmonary function testing, to assess the severity of restrictive lung disease due to muscle wasting, and an electrocardiogram, which may reveal conduction abnormalities.

There may be a higher risk for preterm labor in patients with myotonic dystrophy. Other complications of pregnancy include polyhydramnios (secondary to reduced fetal swallowing) and an increased risk for placenta previa.[107] Magnesium sulfate has been reported to cause respiratory compromise.[108] Poor uterine contractions may result in prolonged labor, uterine atony, and an increased risk for postpartum hemorrhage.[109,110] Muscle weakness may result in a prolonged second stage of labor and a higher incidence of operative delivery.[107] The neonate also may have respiratory distress if affected by congenital myotonic dystrophy.

There are reports of patients with myotonia congenita who experience temporary worsening of symptoms during pregnancy.[111] Obstetric problems have not been described, most likely because this disease involves skeletal muscle only; uterine smooth muscle is not affected in these patients.

Anesthetic Management

Patients with myotonic disorders may be especially sensitive to the respiratory depressant effects of opioid analgesic and general anesthetic agents.[112] Sedative-hypnotic agents should be used with caution; in some cases, opioids or sedatives may precipitate apnea. Thus, neuraxial anesthesia is preferred for labor and vaginal or cesarean delivery. Both spinal and epidural anesthesia have been used successfully in patients with myotonic dystrophy.[113-115] Although the clinical characteristics of myotonic dystrophy DM2 are generally more benign than DM1, anesthesiologists should be aware that both may be associated with dysphagia, cardiomyopathy, and cardiac conduction abnormalities.[116]

The prolonged contractions witnessed in patients with myotonia are due to an intrinsic muscle disorder that is not relieved by spinal or epidural anesthesia; however, infiltration with a local anesthetic agent may partially release contractions. Cold external temperatures and shivering are known triggers of myotonia, so the patient should be kept warm. Some anesthesiologists recommend the cautious administration of intrathecal or epidural opioids for their anti-shivering effect.[113] Patients

with myotonic dystrophy have a high incidence of pulmonary complications after general anesthesia.[117]

If general anesthesia is required, it is prudent to limit the use of opioids and carefully titrate muscle relaxants to mitigate the risk for postoperative pulmonary complications.[118] Depolarizing agents such as succinylcholine should be avoided because fasciculations may trigger myotonia,[119] thereby making ventilation and tracheal intubation difficult. By contrast, patients with myotonic dystrophy appear to have a normal response to nondepolarizing muscle relaxants. Regardless, careful neuromuscular monitoring is essential, particularly in those with significant baseline muscle weakness. Patients receiving quinine may require a smaller dose of a nondepolarizing muscle relaxant. In a review of dystrophic myotonias and their possible association with malignant hyperthermia, Parness et al.[120] concluded that susceptibility to malignant hyperthermia in this group of patients is similar to that of the general population. Patients with central core disease should be assumed to be susceptible to malignant hyperthermia.[104]

MUSCULAR DYSTROPHY

Muscular dystrophy is a group of disorders characterized by a progressive degeneration of skeletal muscle with intact innervation.[121] Research on the subsarcolemmal muscle fiber protein dystrophin has led to a reclassification of these disorders. Analysis of dystrophin quality and quantity can be used diagnostically before and during pregnancy and can identify carriers in some cases.

Duchenne and **Becker muscular dystrophies** are transmitted as X-linked recessive disorders and occur almost exclusively in males. The most common muscular dystrophies affecting females are fascioscapulohumeral dystrophy and limb-girdle dystrophies. **Fascioscapulohumeral dystrophy** is an autosomal dominant, slowly progressive disorder that primarily involves the muscles of the shoulders and face.[121] Over time the pelvic and pretibial muscles may be affected. Tachycardia and arrhythmias have been infrequently reported. **Limb-girdle dystrophies** involve slow degeneration of the shoulder and pelvic muscles.[121] The inheritance pattern and severity of these diseases are variable. Cardiac conduction disorders and cardiomyopathies occur in some affected patients.

Obstetric Management

The classification of the muscular dystrophies is defined by DNA and dystrophin analysis. The presentations of these dystrophinopathies are variable, and the overall management is guided by the presence and severity of symptoms. If significant weakness is present, pulmonary function testing should be obtained to assess the extent of restrictive disease. An antepartum electrocardiogram and echocardiogram should also be considered. Pregnant women with muscular dystrophies may have an increased incidence of operative delivery; the presence of severe pelvic wasting may necessitate an instrumental vaginal or cesarean delivery.[122,123] In a series of pregnant women with fascioscapulohumeral dystrophy, increased rates of LBW infants and operative deliveries were observed; the disorder worsened in 24% of these pregnancies and generally did not resolve after delivery.[122] A larger study of the course of pregnancy in women with hereditary neuromuscular disorders reported a high rate (27%) of abnormal fetal presentation in women with limb-girdle muscular dystrophy, especially in chair-bound patients.[106] About half of patients with limb-girdle muscular dystrophy reported a deterioration of symptoms during and after pregnancy.

Anesthetic Management

Limb-girdle muscular dystrophy is associated with various cardiac abnormalities, including cardiomyopathies and conduction abnormalities. Reduced lung function and respiratory compromise can be exacerbated by the physiologic changes of pregnancy; one report of a parturient with limb-girdle muscular dystrophy noted the requirement of noninvasive positive-pressure ventilation during the third trimester of pregnancy for progression of severe restrictive pulmonary disease.[124] Neuraxial techniques are preferred for labor analgesia and cesarean delivery anesthesia. Severe disease may result in both airway abnormalities and spinal deformities, which may complicate the administration of either general or neuraxial anesthesia. Severe kyphoscoliosis during pregnancy can prevent adaptive hyperventilation and gradually result in respiratory insufficiency.[125]

Whereas most females are asymptomatic carriers of the abnormal gene for muscular dystrophies, approximately 2.5% of female carriers have symptoms of the disease—although usually in milder forms than those witnessed in men.[126] There are reported cases of muscular dystrophy associated with "malignant hyperthermia." In a systematic review, Gurnaney et al.[127] summarized reported cases of patients with muscular dystrophy who developed hyperthermia, tachycardia, rhabdomyolysis, and hyperkalemia after exposure to succinylcholine and/or volatile anesthetic agents. However, none of these patients had other classic signs of malignant hyperthermia or evidence of hypermetabolism. The mechanism for this response is not well understood but may be related to the ability of these agents to exacerbate instability and permeability of dystrophin-deficient muscle membranes.[127] Although the authors concluded that muscular dystrophy patients are unlikely to be at increased risk for malignant hyperthermia, they recommended that volatile anesthetic agents be used cautiously because of the risk for severe rhabdomyolysis. Succinylcholine may lead to hyperkalemia because of up-regulation of extrajunctional acetylcholine receptors or as a result of rhabdomyolysis. Thus, succinylcholine should not be administered to patients with known muscular dystrophy. In general, these patients have a normal response to nondepolarizing muscle relaxants, but careful neuromuscular monitoring is needed, especially in patients with severe muscle wasting.

THE PHAKOMATOSES (NEUROCUTANEOUS SYNDROMES)

The phakomatoses are congenital disorders that manifest as CNS and cutaneous abnormalities. Structures of ectodermal origin such as skin, nervous system, and eyes are commonly affected.[128] The diseases are classified into three main groups: neurofibromatoses, tuberous sclerosis, and angiomatoses with CNS abnormalities (Box 49-2). The most common phakomatoses are neurofibromatosis types 1 and 2, tuberous sclerosis, Sturge-Weber disease, and von Hippel-Lindau disease. Abnormalities of the brain and spinal cord can have significant implications for anesthetic management.

Neurofibromatosis

Neurofibromatosis occurs as a result of excessive proliferation of neural crest elements such as Schwann cells, melanocytes, and fibroblasts. Clinical manifestations include hyperpigmented lesions (*café-au-lait* spots) accompanied by a variety of cutaneous and subcutaneous tumors. This disorder is now believed to exist in two distinct forms with gene abnormalities on two different chromosomes. Neurofibromatosis type 1, the "classic" form, has an incidence of approximately 1 in 3000. The severity and progression of the disease are variable, with the neurologic symptoms depending on the location of the tumors. Intracranial tumors and paraspinal neurofibromas are a cause of concern and may require surgical excision. The risk for pheochromocytoma is greater in these patients.[129] Neurofibromatosis type 2 is a less common, more recently discovered, form of the disease with fewer cutaneous lesions. Acoustic neuromas as well as other cranial or spinal neurofibromas, meningiomas, and gliomas may be present.

BOX 49-2 The Congenital Neuroectodermoses

True Phakomatoses

- Tuberous sclerosis
- Neurofibromatosis
  - Type 1 (classical)
  - Type 2 (acoustic)
  - Familial schwannomatosis

Cutaneous Angiomatosis with Abnormalities of the Central Nervous System

- Sturge-Weber syndrome (meningofacial or encephalofacial angiomatosis with cerebral calcification)
- Dermatomal hemangiomas and spinal vascular malformations
- Epidural nervus (linear sebaceous nevus) syndrome
- Osler-Rendu-Weber disease (hereditary hemorrhagic telangiectasia)
- von Hippel-Lindau disease
- Ataxia-telangiectasia (Louis-Bar disease)
- Fabry disease

Modified from Ropper AH, Samuels MA. Adams and Victor's Principles of Neurology. 9th edition. New York, McGraw Hill, 2009: online version Chapter 38.

Obstetric Management

Pregnancy may exacerbate the disease by increasing tumor growth.[130] Regression occurs after delivery in some women. Although early, small studies suggested an increased risk for obstetric complications in women with type 1 neurofibromatosis, a review of 247 pregnancies did not confirm a higher rate of preeclampsia, preterm delivery, fetal growth restriction, spontaneous abortion, or perinatal mortality compared with healthy women.[130] The high cesarean delivery rate (36%) was associated with pregnancy-related complications of the disease, including the compression of the birth canal by pelvic neurofibromas.[130] The presence of intracranial masses may be problematic during labor and vaginal delivery, particularly with the increased intracranial pressure (ICP) that occurs with the Valsalva maneuver during the second stage of labor.

Anesthetic Management

An anesthesiologist should thoroughly assess the patient's current symptoms and known lesions, particularly if they involve neck and laryngeal tumors; these tumors are common, particularly in patients with neurofibromatosis type 1.[131]

Neuraxial anesthetic techniques can be used for labor analgesia and operative anesthesia in most patients with the disorder. However, severe kyphoscoliosis owing to the presence of paraspinal tumors may complicate the administration of neuraxial anesthesia. The presence of asymptomatic paraspinal and intracranial tumors has prompted some anesthesiologists to suggest that neuraxial anesthesia should be administered only after careful clinical and radiographic evaluations.[132]

The use of muscle relaxants in these patients is controversial, because both increased and decreased sensitivity to succinylcholine has been reported; increased sensitivity to nondepolarizing agents has been reported as well.[133-135] However, a number of investigators observed only minimal alterations in dose response to both depolarizing and nondepolarizing muscle relaxants in these patients and have recommended no alterations in the dose of drug.[133]

Tuberous Sclerosis

Tuberous sclerosis is a phakomatosis characterized by epilepsy, mental retardation, and adenoma sebaceum.[136] The brain shows abnormal growth of glial cells in hamartomas called tubers. Hamartomatous tumors can occur in multiple organs, including the heart, kidneys, liver, and lungs. The inheritance pattern is autosomal dominant with a variable expression, and the disease is slowly progressive.

Obstetric and Anesthetic Management

There are few reports of pregnancy in women with tuberous sclerosis. The obstetrician and anesthesiologist should know the locations of lesions in an individual patient. Hemorrhage into the tumors, renal failure,

and hypertension may complicate pregnancy.[137] Renal involvement appears to represent an important prognostic factor during pregnancy, and spontaneous rupture of a renal angiomyolipoma has been reported.[138] Published reports have included several patients who required cesarean delivery.[137,138] Factors that could potentially impact anesthetic management of these patients include the presence of cardiac and renal tumors (angiomyolipomas), spinal and intracranial tubers, epilepsy, pharyngeal tumors, and pulmonary involvement.[139] Cardiac rhabdomyosarcomas have been reported to occur in over 60% of children with this disorder. These tumors generally regress with age, but arrhythmias and cardiac failure from ventricular obstruction may occur. In the presence of known elevated ICP from cerebral lesions, some anesthesiologists believe that neuraxial anesthesia is contraindicated. Imaging should be considered before administration of neuraxial blockade if intracranial or spinal lesions are suspected. In addition, the airway should be assessed closely for the presence of oral tubers, which have been described in approximately 15% of these patients.

Cutaneous Angiomatosis with Central Nervous System Abnormalities

One group of phakomatoses consists of disorders in which a cutaneous vascular anomaly is accompanied by CNS abnormalities (see Box 49-2).[140] There are few reports of pregnancy in patients with these disorders. Patients may have neurologic problems related to hemangiomas of the CNS. Cesarean delivery with epidural anesthesia has been reported in a patient with spinal hemangiomas.[141] The presence of widespread varicosities in these disorders may result in a chronically low ventricular preload; if a significant increase in preload occurs during the peripartum period, cardiac overload and peripartum cardiomyopathy may occur.[142]

ACUTE IDIOPATHIC POLYNEURITIS (GUILLAIN-BARRÉ SYNDROME)

Acute idiopathic polyneuritis, also known as Guillain-Barré syndrome, is an inflammatory demyelinating illness with a reported incidence of approximately 1 case per 100,000 persons per year.[143] In 60% of patients, a viral illness precedes neurologic symptoms by 1 to 3 weeks. Cases also have occurred after the administration of antirabies and influenza vaccines.

Patients with this disorder initially have weakness in the limbs, followed by the trunk, neck, and facial muscles. Loss of reflexes, total motor paralysis, and respiratory failure can occur. Sensory loss typically is not detectable. Symptoms peak at 2 to 3 weeks. The majority of patients recover completely; approximately 10% of patients have severe residual disability, and in 3% the syndrome is fatal.[143]

Slowing of nerve conduction occurs. Pathologic changes include lymphoid cellular infiltration and areas of demyelination that most likely result from a cell-mediated immunologic reaction against peripheral nerves. Autonomic nervous system involvement and dysfunction may occur.

Treatment is largely supportive and may include mechanical ventilatory support. Plasmapheresis reduces the duration of illness when instituted during the evolution phase and has been used safely during pregnancy.[143,144]

Obstetric Management

The incidence of this syndrome appears to be lower in pregnant women than in nonpregnant women. Using data from several nationwide registries, Jiang et al.[145] found that the age-adjusted relative risk of Guillain-Barré syndrome appears to be decreased during pregnancy but increases in the first 3 postpartum months. In severe cases, the risk for preterm labor is increased and neurologic deterioration may occur after delivery.[146] Termination of pregnancy does not appear to improve the course of the disease, but induction of labor may be indicated if autonomic dysfunction occurs. Instrumental vaginal delivery may be necessary.[146]

Anesthetic Management

Anesthetic management depends on patient status at the time of delivery; epidural, spinal, and CSE techniques have been described in patients with Guillain-Barré syndrome.[147-149] However, some anesthesiologists have expressed concern regarding the use of neuraxial techniques in these patients, citing the theoretical potential for neurologic changes as a result of anesthetic toxicity or immunologic modulation. Steiner et al.[150] implicated epidural anesthesia as a trigger of Guillain-Barré syndrome in four patients; Wiertlewski et al.[148] reported the immediate worsening of neurologic status after delivery in a pregnant patient with Guillain-Barré syndrome who had received epidural anesthesia. These reports did not establish a causal relationship between the disease and neuraxial anesthesia techniques, nor did they properly acknowledge the increased frequency of Guillain-Barré syndrome in the postpartum period.

If general anesthesia is necessary in a patient with Guillain-Barré syndrome, succinylcholine most likely should be avoided because of the risk for hyperkalemia in patients with acute muscle wasting. Careful titration of nondepolarizing muscle relaxants is also necessary.

The parturient with a history of remote Guillain-Barré syndrome may have persistent diminished respiratory reserve, even in the absence of obvious residual disability.[151] Pulmonary evaluation should be considered before the administration of anesthesia. Approximately 5% of patients experience a relapse, with a small number of cases progressing to a chronic disorder.

POLIOMYELITIS

Poliomyelitis is a disease caused by a picornavirus that is transmitted by the fecal-oral route. Most cases are asymptomatic or are accompanied by mild systemic symptoms. More severe symptoms and nervous system involvement

occur in approximately 1% of patients.[152] Motor neurons in the cerebral cortex, brainstem, and spinal cord are affected. Asymmetric flaccid paralysis develops over several days. Bulbar paralysis is more common in young adults. The CSF findings are consistent with viral meningitis. Recovery occurs 3 to 4 months after onset, most likely from motor axon terminal sprouting that reinnervates the previously denervated muscle fibers; however, residual deficits often persist.

A slowly progressive syndrome called **postpoliomyelitis muscular atrophy** may develop as many as 40 years after the acute illness. Klingman et al.[153] speculated that the increased functional demands on the surviving neurons or the motor axon terminal sprouts eventually result in their death. Others believe that this syndrome results from a reactivation of the initial viral infection.[154]

Obstetric Management

Currently, polio is a cause for concern only in countries with ineffective vaccination programs. Although the poliovirus vaccine has been available since the 1950s, the last phase of poliomyelitis eradication has been difficult; as of 2011, transmission of the disease continues in countries such as such as Nigeria, India, Pakistan, and Afghanistan.[155] The oral form of the vaccination does not appear to have harmful effects on fetal development and can be used if vaccination is required during pregnancy.[156] In the past, a history of poliomyelitis was believed to affect labor and delivery only if residual deficits resulted in pelvic asymmetry or an inability to push effectively[157]; however, more recent data suggest a higher incidence of preeclampsia, maternal renal dysfunction, LBW infants, perinatal death, and cesarean delivery in poliomyelitis survivors.[158] Some of these adverse outcomes may be related to chronic pulmonary issues or mechanical obstruction during labor.

Anesthetic Management

A complete preanesthetic evaluation should be performed for the presence of respiratory impairment, sleep apnea, swallowing difficulties, and other neurologic and motor deficits in all parturients with a history of poliomyelitis.[152] Some anesthesiologists have feared that administration of neuraxial anesthesia in patients with a history of poliomyelitis might cause reactivation of the virus or postpoliomyelitis and muscular atrophy. However, there is no evidence that neuraxial analgesia or anesthesia worsens symptoms in these patients. Crawford et al.[147] reported the successful use of epidural analgesia with no adverse complications in patients with a history of poliomyelitis. Rezende et al.[159] reported a series of 123 patients with a history of poliomyelitis undergoing 162 surgical procedures and observed postoperatively for 22 months; neuraxial blockade was used in 64% of cases, with no patients exhibiting worsening of neurologic symptoms. Anesthetic considerations in these patients should include assessment for pulmonary restrictive disease as well as anatomic issues that may make neuraxial techniques difficult.[160,161] A study from India reported that about one third of pregnancies complicated by kyphoscoliosis occurred in patients with a history of poliomyelitis in infancy.[161] Radiographic imaging has been successfully used to guide spinal needle placement in these patients.

Suneel et al.[162] reported a patient with a history of poliomyelitis who developed muscle weakness after general anesthesia that responded to additional neostigmine, suggesting that these patients may have a low threshold for the effects of neuromuscular blocking agents. For the patient with poliomyelitis in whom general anesthesia is needed, some anesthesiologists have suggested the use of a decreased dose of a short-acting nondepolarizing muscle relaxant in lieu of succinylcholine, which may provoke severe acute hyperkalemia.[163]

BRAIN NEOPLASMS

Intracranial neoplasms vary in incidence, histology, clinical presentation, and prognosis (Table 49-4).[164] Brain neoplasms in pregnant women appear to occur with the same relative frequency as in nonpregnant women; however, the physiologic alterations that occur during pregnancy can have profound implications for symptomatology and management.

Gliomas are the most common intracranial neoplasms, accounting for approximately 39% of all primary intracranial tumors.[165] These tumors, which result from anaplasia of astrocytes, exhibit diversity in invasive potential and include glioblastoma multiforme, astrocytomas, ependymomas, and oligodendrocytomas. Glioblastoma multiforme is the most lethal, whereas oligodendrocytomas have a better prognosis.

Meningiomas account for approximately one third of all primary brain tumors.[165] These benign tumors originate from the dura mater or arachnoid. Surgery typically is curative.

TABLE 49-4 **Classification of Brain Tumors in Women**

Histologic Type	Percentage of all Diagnosed Tumors
Benign	
Meningioma	35
Schwannoma	7
Pituitary neoplasms	7
Malignant	
Gliomas:	
Low-grade astrocytoma	3
Glioblastoma multiforme (plus high-grade astrocytoma)	23
Other astrocytoma	8
Other	5
Lymphoma	2
Medulloblastoma	2
Other brain neoplasms	8

Modified from Swensen R, Kirsch W. Brain neoplasms in women: a review. Clin Obstet Gynecol 2002; 45:904-27.

Pituitary adenomas account for 7% of diagnosed primary brain neoplasms, but postmortem studies suggest a significantly higher incidence.[165] Only a small fraction of these tumors cause symptoms (e.g., visual field deficits). These tumors may secrete prolactin, growth hormone, or adrenocorticotropic hormone. Growth of pituitary tumors is physically limited by the sella turcica of the sphenoid bone and, in a cephalad orientation, the hypothalamus. Compression of the hypothalamus or pituitary may result in respective decreases in the production or release of vasopressin, leading to diabetes insipidus. Bromocriptine often provides effective medical therapy for prolactin-secreting adenomas. Irradiation and surgery also represent effective therapies, and the prognosis is generally good.

Schwannomas, also called **neurinomas,** account for 7% of all brain tumors.[165] These lesions originate in the Schwann cells surrounding the nerve. Clinical presentation depends on the location of the tumor. Acoustic neuromas result when the eighth cranial nerve is involved; these lesions are often seen in patients with neurofibromatosis. The treatment is surgical excision.

Metastatic carcinomas account for a significant number of brain neoplasms.[165] Common primary cancers include those of the lung, breast, and colon. Prognosis and therapy depend on the tumor of origin.

Brain tumors share several pathophysiologic features. Neurologic deficits can result from a mass effect or increased ICP, even if the tumor is benign. Brain edema, which may result from a combination of vasogenic and cytotoxic mechanisms, is a prominent feature of cerebral neoplasms.

The potential for herniation must be considered in any patient with a mass lesion. The brain is divided into three basic compartments. The falx cerebri separates the cerebrum into right and left halves, and the tentorium isolates the cerebellum. High pressure from a mass can cause shifts from one compartment to another with devastating effects.

Obstetric Management

The incidence of primary brain tumors first manifesting in pregnancy does not appear to be greater than that in aged-matched, nonpregnant women.[165] Approximately 9% of patients with **choriocarcinoma** have brain metastases at the time of diagnosis.[166] In one epidemiologic study, patients with primary brain tumors had a higher incidence of spontaneous abortion, possibly because of hormonal factors.[167] A 2012 study using a retrospective cohort from the National Inpatient Sample reported an increased rate of maternal mortality, cesarean delivery, and preterm labor in patients with malignant brain tumors, and an increased rate of preterm labor and cesarean delivery in patients with benign brain tumors.[168] Pregnancy complications were significantly more likely to occur in patients having a neurosurgical procedure during their admission.

Although pregnancy does not affect the incidence of brain tumors, some of these lesions appear to grow faster during pregnancy. Visual field defects from pituitary adenomas worsen as a result of tumor enlargement during pregnancy, and symptoms have been observed to improve during the postpartum period.[169] Edema and the increased blood volume may account for some of these symptoms. Pregnancy-induced hormonal changes also may play a role because estrogen and progesterone receptors are present in meningiomas and some gliomas.[170]

Diagnosis during pregnancy requires intracranial imaging. In general, MRI is preferred because it avoids the use of ionizing radiation. MRI may require the use of gadolinium-based contrast agents. Gadolinium has the advantage compared with other contrast agents of not containing iodine, and studies demonstrating adverse fetal effects are lacking in humans. However, gadolinium appears rapidly in the fetal bladder and amniotic fluid, from where it may be swallowed by the fetus and absorbed from the gastrointestinal tract. Its fetal half-life is unknown. The American College of Radiology has stated that the "decision to administer a gadolinium-based MR contrast agent to pregnant patients should be accompanied by a well-documented and thoughtful risk-benefit analysis."[171]

Management during pregnancy depends on the nature of the tumor. Surgery for benign tumors (e.g., meningiomas) with mild symptoms can often be delayed until after delivery. Women with more aggressive, malignant tumors or with tumors causing seizures or severe visual impairment may require urgent surgery during pregnancy to avoid acute neurologic deterioration. Delivery also may be recommended as soon as reasonable fetal survival can be expected, sometimes by cesarean delivery immediately before neurosurgery. For women with pregnancies far from fetal viability, radiation therapy or stereotactic radiosurgery can be considered. Cranial radiation therapy is generally administered as a first therapeutic procedure to reduce the size of the mass in cases of aggressive neoplasm. However, radiation therapy, and particularly systemic chemotherapy, can pose significant hazards to the fetus, especially when administered during the first trimester.[165] Some women may opt for surgery after an elective abortion.

In the normal parturient, CSF pressure may increase significantly with painful uterine contractions.[172] In patients with an intracranial mass lesion, this situation could result in an increased risk for herniation. The location and size of the tumor should be assessed in the individual patient so that an appropriate delivery plan can be developed with multidisciplinary input. In general, either a pain-free second stage (with instrumental vaginal delivery to avoid pushing) or cesarean delivery may be appropriate.[173]

Anesthetic Management

The optimal anesthetic technique for labor analgesia and cesarean delivery anesthesia in the patient with an intracranial tumor is controversial. Epidural analgesia prevents the increase in ICP that can result with pushing during the second stage of labor.[174] Several published reports have described the successful use of labor epidural analgesia in women with intracranial neoplasms[174,175]; in addition, the use of spinal anesthesia for an emergency cesarean delivery in a patient with a glioblastoma has

been described.[176] However, in pregnant women with increased ICP, an unintentional dural puncture associated with an attempted epidural catheter placement can result in a fatal brain herniation.[177] As a consequence, many anesthesiologists favor general anesthesia for cesarean delivery in the patient with a brain neoplasm[178]; however, potential disadvantages of general anesthesia include (1) the loss of verbal and motor responses that facilitate neurologic assessment and (2) the risks of increased ICP with tracheal intubation and extubation.

Wang and Paech[179] have reviewed specific elements in the anesthetic management of the pregnant patient undergoing neurosurgery, many of which are also relevant to the patient with an intracranial tumor undergoing cesarean delivery. The induction of general anesthesia may consist of the administration of an induction dose of propofol or sodium thiopental and either a depolarizing or a rapid-acting nondepolarizing neuromuscular blocking agent. Some anesthesiologists avoid succinylcholine because it may cause a transient increase in ICP, but others consider this effect to be clinically insignificant.[179] A combination of a volatile halogenated agent (sevoflurane or isoflurane), nitrous oxide, and an opioid is commonly used for maintenance of anesthesia. The FHR should be monitored during intracranial surgery when possible.

To preserve cerebral and uteroplacental perfusion, hemodynamic stability should be maintained through appropriate fluid administration, avoidance of aortocaval compression, the prophylactic or early use of vasopressor drugs, and intra-arterial blood pressure monitoring instituted before induction of anesthesia.[179] In general, blood pressure should be kept close to baseline measurements; in the setting of an emergency neurosurgical procedure in a patient with increased ICP, a drop in blood pressure may compromise cerebral perfusion. Fluid management for intracranial surgery should involve administration of isonatremic, isotonic, and glucose-free intravenous solutions to reduce the risk for cerebral edema and hyperglycemia.[179] Mannitol administered to a pregnant woman slowly accumulates in the fetus, leading to fetal hyperosmolality and the subsequent physiologic changes of reduced fetal lung fluid production, decreased fetal urine production, and increased fetal plasma sodium concentrations[180,181]; however, mannitol in doses of 0.25 to 0.5 mg/kg has been reported in individual cases and appears to be associated with good maternal and fetal outcomes.[179] Furosemide is an alternative diuretic that also should be administered cautiously.

There may be some conflict between maternal and fetal interests in the patient with increased ICP. Moderate mechanical hyperventilation may be used to reduce the increased ICP that occurs in nonpregnant patients with a brain tumor or brain injury. Minute ventilation increases during normal pregnancy, resulting in a maternal $Paco_2$ of 28 to 32 mm Hg; additional hyperventilation and hypocapnia may cause uterine artery vasoconstriction and a leftward shift in the maternal oxyhemoglobin dissociation curve (see Chapter 2). For pregnant women with an acute increase in ICP, Wang and Paech[179] have suggested a target $Paco_2$ range of 25 to 30 mm Hg; however, data are currently insufficient to support evidence-based recommendations specific to pregnant women undergoing intracranial surgery. In pregnant patients with increased ICP, we recommend maintenance of maternal $Paco_2$ in the middle or at the lower end of the normal range for pregnancy. Management should be individualized according to the clinical setting.

When the decision is made to perform a cesarean delivery and brain tumor resection sequentially during a single anesthetic, hypertension should be avoided to prevent deleterious effects from tumor expansion. To avoid this complication during induction, some authors have used a combination of a high dose of fentanyl, thiopental, or propofol with succinylcholine.

A recent report of a patient with an unresected astroglioma undergoing cesarean delivery describes the postoperative use of transversus abdominis plane block to provide analgesia and reduce opioid requirements, thus reducing the risk for postoperative respiratory depression and potential exacerbation of ICP.[182] In cases for which it is considered optimal to initially perform neurosurgery and then allow completion of the pregnancy, neuraxial techniques may be considered for delivery. The patient should be assessed to determine if ICP is elevated because this may preclude the use of a neuraxial technique. After neurosurgery, a reduction in ICP from a CSF leak may cause intracranial hypotension and may make confirmation of correct spinal needle placement by identification of CSF difficult.[179]

IDIOPATHIC INTRACRANIAL HYPERTENSION

Idiopathic intracranial hypertension, previously referred to as *pseudotumor cerebri* or *benign intracranial hypertension*, is defined as an increase in ICP with a normal CSF composition in the absence of hydrocephalus or a mass lesion.[183] The disorder most often occurs in obese women of childbearing age, suggesting that hormonal factors may play a role in the pathophysiology. The majority of patients have a headache, and in some cases visual symptoms occur. Over time the disorder generally improves, but there is a small risk for recurrence.

Traditional therapies have varied in efficacy; they include serial lumbar punctures and the administration of a carbonic anhydrase inhibitor and/or corticosteroid. Lumboperitoneal shunting may be required in severe cases with visual symptoms. Weight loss appears to improve the condition.

Interaction with Pregnancy

Symptoms of idiopathic intracranial hypertension worsen during pregnancy in 50% of cases and typically improve after delivery.[184] However, in the presence of severe maternal symptoms, the placement of an intracranial shunt can result in clinical improvement and normal perinatal outcomes.[185] Overall, this disorder does not seem to adversely affect maternal and perinatal outcomes.[186]

Anesthetic Management

Deliberate lumbar puncture represents a common form of treatment for idiopathic intracranial hypertension. Cerebellar tonsillar herniation does not occur because of the uniform, global increase in ICP. Paruchuri et al.[187] noted that there are only two published cases of cerebellar tonsillar herniation after diagnostic lumbar puncture in patients with this disorder. Both patients had severe headache, neck pain exacerbated by movement, and focal neurologic deficits. In the absence of these signs and symptoms, the anesthesia provider can provide neuraxial analgesia or anesthesia.[188]

Some anesthesiologists recommend the administration of general anesthesia for cesarean delivery in patients with *lumboperitoneal shunt*. They contend that local anesthetic agents that reach the subarachnoid space may escape into the peritoneum, making it difficult to achieve adequate anesthesia. Moreover, the performance of neuraxial anesthesia may result in trauma to the shunt catheter. Bédard et al.[189] reported the successful administration of epidural anesthesia in a preeclamptic patient with a lumboperitoneal shunt that had been placed for the treatment of idiopathic intracranial hypertension. Preoperative radiographic examination may help the anesthesia provider avoid needle placement near the catheter, although such imaging was not used in this published case. Provision of neuraxial anesthesia with an intrathecal catheter has been performed for both vaginal and cesarean delivery in parturients with idiopathic intracranial hypertension and a lumboperitoneal shunt; in one case, the intrathecal catheter provided both labor analgesia and temporary control of ICP.[190,191] Questions regarding the functional status of an *in situ* subarachnoid shunt or the possible (very rare) use of the shunt for the administration of spinal anesthesia should be discussed with neurologic or neurosurgical consultants.[192]

MATERNAL HYDROCEPHALUS WITH SHUNT

Hydrocephalus results from a variety of conditions. The most common are intracranial hemorrhage in preterm infants, fetal and neonatal infections, the Arnold-Chiari malformation, aqueductal stenosis, and the Dandy-Walker syndrome.[193] The Arnold-Chiari malformation consists of extension of a portion of cerebellar tissue into the cervical canal, with progressive hydrocephalus. The Dandy-Walker syndrome occurs with failure of development of the midline of the cerebellum, with resultant hydrocephalus of the fourth ventricle.

Ventriculoatrial or ventriculoperitoneal shunt catheters are placed for the treatment of many of these disorders. Because of advances in neonatal and neurosurgical care, hydrocephalic women with CSF shunt catheters are reaching childbearing age in increasing numbers.

Obstetric Management

Obstetric management depends on the presence of other medical and neurologic conditions. In general, although maternal shunt dependency carries a relatively high risk for complications for some patients, proper management can lead to normal pregnancy and delivery.[194] Neurologic complications may occur in as many as 76% of pregnant women with preexisting shunts, including severe headache, shunt obstruction, and increased ICP.[195] Most symptoms resolve postpartum.

Most pregnant women with intracranial shunt catheters can undergo labor and vaginal delivery; elective cesarean delivery is recommended only in the presence of severe neurologic symptoms or instability.

Anesthetic Management

Anesthetic management of the patient with hydrocephalus may depend on the location of the shunt. There has been concern that some of the local anesthetic agent entering the CSF may escape into the atrium or peritoneum, resulting in inadequate analgesia. However, both epidural and spinal anesthesia have been used in patients with lumboperitoneal, ventriculoatrial, and ventriculoperitoneal shunts (as discussed earlier).[189-191] The anesthetic technique chosen for an urgent sequential ventriculoperitoneal shunt revision and cesarean delivery must balance the needs of the maternal neurologic condition and the pregnancy.

Because of the risk for shunt infection, some physicians recommend preoperative use of a prophylactic antibiotic regimen similar to that used to prevent bacterial endocarditis.[196]

INTRACEREBRAL HEMORRHAGE

Cerebrovascular disease during pregnancy can result from three major mechanisms—hemorrhage, arterial infarction, and venous thrombosis. Intracerebral hemorrhage is most commonly associated with an arteriovenous malformation or aneurysm (Figure 49-3). Using data from the National Inpatient Sample (1995 to 2008), the

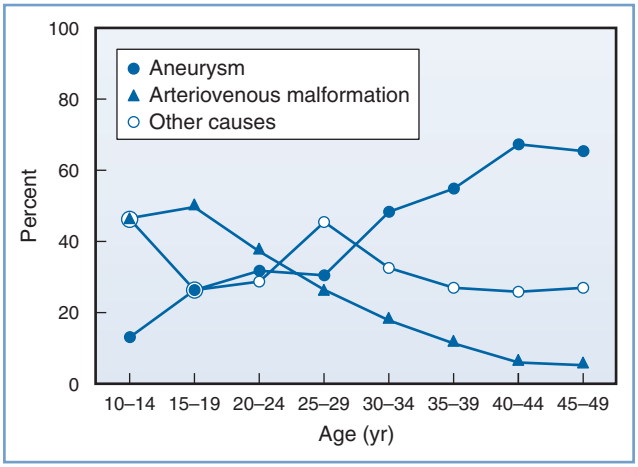

FIGURE 49-3 ■ Relative probability of major causes of subarachnoid hemorrhage for women stratified by age. (From Donaldson JO. Neurology of Pregnancy. 2nd edition. London, WB Saunders, 1989:139.)

prevalence of subarachnoid hemorrhage was 5.8 per 100,000 deliveries in women aged 15 to 44 years.[197] The ratio of hemorrhage from an arteriovenous malformation to that from an aneurysm was significantly higher in pregnant than in nonpregnant patients. The mortality rate was 10.6%; subarachnoid hemorrhage was associated with 4.1% of all pregnancy-related deaths.

Data are conflicting as to whether the aneurysm bleeding rate is higher during pregnancy.[198] Some authors have reported a progressive increase in the incidence of aneurysm bleeding throughout gestation and up to 6 weeks postpartum.[199] This interval corresponds with the period of physiologic increase in blood volume. In general, unruptured aneurysms diagnosed during pregnancy should be treated if they are symptomatic or enlarging.[200] The treatment of ruptured aneurysms during pregnancy should mimic treatment of aneurysms in nonpregnant patients.[200] The American Heart Association (AHA) guidelines for the management of aneurysmal subarachnoid hemorrhage include monitoring and controlling blood pressure (balancing the risk for stroke, rebleeding, and maintenance of cerebral perfusion pressure) and early surgical clipping or endovascular coiling.[201] Controversy exists as to whether endovascular coiling results in better outcomes than clipping. Although the AHA has suggested that "endovascular coiling can be beneficial," some experts argue that several factors may alter the risk-benefit ratio in pregnancy. These factors include (1) the need for exposure to ionizing radiation for coil placement, (2) the possible need for anticoagulation or use of antifibrinolytic agents, and (3) the increased rate of incomplete aneurysm occlusion associated with coiling compared with clipping.[196,202] Endovascular coiling has not been specifically studied in the pregnant population, although several cases of successful endovascular treatment of ruptured intracranial aneurysms in pregnant women have been reported.[200,203]

Bleeding from arteriovenous malformations has been reported to occur with equal or greater frequency with advancing gestational age.[196,199] The risk for hemorrhage from an arteriovenous malformation in pregnant women does not appear to differ from that in the general population, although the risk for bleeding appears greater during the second half of pregnancy and the first 6 postpartum weeks, corresponding to the period of high cardiac output.[196] The management of arteriovenous malformations in pregnancy does not differ from standard care of the nonpregnant patient. As with aneurysms, a multidisciplinary decision-making process allows planning based on the location of the lesion, the duration of pregnancy, and the relative risks of interventional and noninterventional methods of management. Management of arteriovascular malformations, including those that present during pregnancy, has increasingly shifted over the past decade from a surgical to an endovascular approach.

Obstetric Management

If the lesion has been treated surgically, the patient requires no special care during labor and delivery. For an untreated aneurysm or arteriovenous malformation, the hemodynamic stress occurring during labor and delivery should be minimized. Current data do not demonstrate a definite advantage of cesarean delivery over assisted vaginal delivery.[204] The decision about the method of delivery should be based on the individual patient and her pregnancy history. For labor and vaginal delivery, neuraxial analgesia and low outlet forceps or vacuum assistance may be used to shorten the second stage of labor and attenuate fluctuations in blood pressure.

Anesthetic Management

If the parturient has undergone surgical repair of either an aneurysm or arteriovenous malformation, anesthetic management need not differ from that for other obstetric patients. Hypertension should be avoided in the parturient with an untreated lesion. If vaginal delivery is planned, epidural or CSE analgesia should be considered. For cesarean delivery, either epidural or spinal anesthesia can be used. Some anesthesiologists contend that epidural anesthesia or sequential CSE anesthesia (e.g., initial use of a lower intrathecal drug dose, followed by block augmentation with epidural injection of local anesthetic) provides greater hemodynamic stability and is thus preferred for cesarean delivery. Interdisciplinary planning is important.[196,205]

In some cases, the neurosurgeon may ligate or excise the vascular lesion *during* pregnancy, *before* delivery. The anesthesiologist should consider the general principles of anesthetic management for pregnant women undergoing nonobstetric surgery (see Chapter 17) as well as the special considerations for pregnant women undergoing neurosurgery (as discussed earlier).[179] The risks for hypertension and intracranial bleeding, as well as the risk for aspiration should be considered during induction of anesthesia. It is critical to maintain stable blood pressure during induction of anesthesia, laryngoscopy, tracheal intubation, and extubation. The patient should receive adequate sedation before and after arrival in the operating room. Placement of an intra-arterial catheter is mandatory. The anesthesiologist may attenuate the hypertensive response to laryngoscopy and tracheal intubation by intravenous administration of esmolol, labetalol, lidocaine, nitroglycerin, nitroprusside, and/or an opioid (e.g., remifentanil). Succinylcholine can be used for tracheal intubation. Regardless of the choice of muscle relaxant, it is critical that laryngoscopy and tracheal intubation not be performed until the patient is anesthetized adequately.

The anesthesiologist may maintain anesthesia with nitrous oxide and modest doses of isoflurane and an opioid. Aggressive maternal hyperventilation may result in decreased uterine blood flow.[196] However, the anesthesiologist may use modest hyperventilation (e.g., $Paco_2$ of 28 to 30 mm Hg) as needed to reduce maternal ICP. The anesthesiologist should maintain left uterine displacement in patients beyond 20 weeks' gestation. Intraoperative FHR monitoring allows assessment of the fetal response to maternal general anesthesia and hyperventilation. At many institutions, including my own, intraoperative FHR monitoring is used beginning at 24 weeks' gestation, which corresponds to the onset of extrauterine neonatal viability. Typically, an obstetric nurse

monitors the FHR tracing during surgery and requests obstetric consultation if needed. An adverse change in the FHR tracing should prompt the anesthesiologist to ensure adequate maternal oxygenation, ventilation, and perfusion.

Use of deliberate hypotension may compromise uteroplacental perfusion, although its safe use has been reported during neurovascular intracranial surgery in pregnant women. There is no consensus regarding an acceptable or safe level of hypotension, or the ideal method for achieving hypotension, in these patients. The prolonged administration of large doses of nitroprusside may result in fetal cyanide toxicity, although short-term administration appears safe. Intraoperative FHR monitoring allows assessment of the fetal response to deliberate hypotension. Endovascular treatment with general anesthesia avoids the need for craniotomy and deliberate hypotension.

In some cases, the obstetrician and neurosurgeon may perform a combined procedure (e.g., a cesarean delivery followed by ligation or excision of the neurovascular lesion). Principles of anesthetic management are similar to those described earlier for intracranial neurovascular surgery during pregnancy.

Rarely, anesthesiologists may provide care for pregnant women who are receiving **extended somatic support** after brain death. Powner and Bernstein[206] reviewed 11 reports of 10 cases of brain death during pregnancy, in which somatic support was provided until successful delivery. Intracranial hemorrhage was the cause of maternal brain death in 6 of the 10 patients. The longest period of support was 107 days, from 15 to 32 weeks' gestation. All 10 infants survived. The authors concluded that preservation of uteroplacental blood flow is the most important priority during extended somatic support, but they acknowledged that this goal is difficult to achieve because of hemodynamic instability, the high prevalence of infection, and other adverse consequences (e.g., diabetes insipidus) associated with brain death.

CEREBRAL VEIN THROMBOSIS

Thrombosis of the cerebral veins and sinuses most often affects young adults and children; approximately 75% of the adult patients are women.[207] Thromboses commonly involve the cavernous sinus, lateral sinus, sagittal sinus, or cortical veins. Thrombosis of the cerebral veins causes venous obstruction with local effects, whereas thrombosis of the major sinuses causes intracranial hypertension. A prothrombotic risk factor or a direct cause can be identified in approximately 85% of patients. Pregnancy may be a precipitating factor for sinus thrombosis in a person with a genetically increased risk.[207]

Primary cerebral cortical vein thrombosis is the type of thrombosis most often seen in pregnancy. The estimated incidence of cerebral vein thrombosis during pregnancy is 12 cases per 100,000 deliveries in developed countries[208]; the incidence appears to be higher in some developing countries. Cerebral vein thrombosis occurs more frequently during the last trimester of pregnancy and in the second and third postpartum weeks.[208] Although the etiology is unclear, pregnancy may predispose patients to this condition because of at least two factors.[209] First, traumatic damage to the endothelial lining of vessels may occur during the second stage of labor. Second, pregnancy is a hypercoagulable state (see Chapters 2 and 39). Mechanical causes of sinus thrombosis may include head injury and lumbar puncture.[210] It has been postulated that low CSF pressure after a lumbar puncture causes the brain to shift downward, resulting in traction on the cortical veins and sinuses.

Patients with cerebral vein thrombosis may have headache, nausea and vomiting, and blurred vision. In more severe cases, lateralizing neurologic signs, lethargy, and seizures may occur. In severe cases, transtentorial herniation due to a focal mass effect can occur.

Care should be taken to differentiate cerebral vein thrombosis from post–dural puncture headache (PDPH).[209] In general, the headache associated with cerebral vein thrombosis is more diffuse in location. Earlier teaching suggested that the headache does not vary with position, but a 2007 review concluded that the nature of the headache may change over time and often manifests "as a positional headache that overlaps the usual timing…and treatment of PDPH in the parturient."[210]

Diagnosis can be confirmed by magnetic resonance (MR) venography. The American Heart Association/American Stroke Association published a set of management guidelines in 2011; the guidelines recommend full anticoagulation with unfractionated heparin (titrated to an activated partial thromboplastin time two times normal) or weight-adjusted low-molecular-weight heparin, continued for a minimum of 6 months' duration.[208]

Some patients with cerebral vein thrombosis may require anticonvulsant therapy. In some cases, residual neurologic deficits and seizures may persist.

Obstetric and Anesthetic Management

Cerebral vein thrombosis rarely occurs before delivery, although such an occurrence may prompt an urgent delivery if associated with maternal neurologic instability and fetal deterioration. Maternal anticoagulation contraindicates the administration of neuraxial anesthesia. The anesthesia provider should avoid systemic hypotension, which may reduce cerebral perfusion pressure and blood flow to injured areas already subjected to marginal perfusion. If the patient has an asymmetric cerebral hematoma, dural puncture may precipitate herniation of the brainstem. Thus, it seems preferable to administer general anesthesia for cesarean delivery, with special attention to the treatment of increased ICP. Cerebral venous thrombosis is a rare, but reported, complication after spinal and epidural anesthesia, presumably due to intracranial hypotension.[210]

MOTOR NEURON DISORDERS

Motor neuron diseases are a group of disorders characterized by progressive muscular weakness and atrophy.

These disorders may affect motor function alone or in conjunction with sensory deficits. There are few data on the course of these disorders in pregnant women. This discussion focuses on three of these disorders, amyotrophic lateral sclerosis and primary spinal muscular atrophy, which are pure motor neuron disorders, and peroneal muscular atrophy, which involves both motor and sensory degeneration. Currently there is no cure for any of these degenerative disorders.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis involves progressive degeneration of anterior horn cells with progressive atrophic weakness and hyperreflexia. Patients typically succumb to respiratory failure within 6 years of diagnosis.

This disease is seen more often in patients older than 50 years, but there are several reports of this disorder in pregnant women.[211,212] Physicians should assess and frequently monitor the patient's respiratory compromise throughout the peripartum period. Epidural analgesia and anesthesia have been used in these patients without evidence of worsened neurologic function postoperatively.[213,214] Patients with amyotrophic lateral sclerosis may be sensitive to the effects of nondepolarizing muscle relaxants.[215] The physiologic changes during late stages of pregnancy may worsen marginal respiratory status in these patients, and early cesarean delivery may be warranted.[216]

Spinal Muscular Atrophy

Like amyotrophic lateral sclerosis, primary spinal muscular atrophy involves degeneration of anterior horn cells. However, affected patients tend to be younger, and this disorder progresses more slowly. Some types are hereditary. Spinal muscular atrophy mainly involves the spinal cord, without involvement of the corticospinal tract. Marked kyphoscoliosis combined with truncal and limb weakness, especially involving the proximal musculature, can occur and result in significant ventilatory limitations.

Spinal muscular atrophy may be associated with an increased incidence of preterm labor.[217] One series noted that pregnancy was associated with an exacerbation of muscle weakness in 8 of 12 patients.[217] Epidural and spinal analgesia and anesthesia have been used successfully in patients with this disorder.[218,219] In children with this rare disorder, both general and regional anesthesia have been successfully used; special attention should be paid to postoperative respiratory function.[220]

Peroneal Muscular Atrophy

Peroneal muscular atrophy, also known as *Charcot-Marie-Tooth disease*, includes several inherited peripheral motor and sensory neuropathies; it is one of the most common inherited neuromuscular diseases.[221] It involves a progressive sensory and motor degeneration of peripheral nerves and roots. The peroneal nerve is affected early. The disorder progresses to involve all the nerves and muscles of the legs and finally the hands. Paresthesias are typically present. Restrictive pulmonary impairment, phrenic nerve dysfunction, diaphragmatic dysfunction, thoracic cage abnormalities, and sleep apnea have been described in association with peroneal muscular atrophy. Vocal cord dysfunction, possibly due to laryngeal nerve involvement, can also be present. Assessment of peripartum respiratory function is essential. Approximately 30% of patients with this disorder report deterioration in overall function during pregnancy, with approximately 20% indicating persistent postpartum deficits.[106]

A review of 108 deliveries found that women with this disorder have higher rates of abnormal fetal presentation, emergency operative delivery, and postpartum bleeding.[222] Both neuraxial and general anesthesia have been used for delivery.[223] Careful titration of muscle relaxants is essential if general anesthesia is employed.

ISOLATED MONONEUROPATHIES DURING PREGNANCY

Pregnancy is associated with an increased incidence of several specific mononeuropathies: Bell's palsy, carpal tunnel syndrome, and meralgia paresthetica.

Bell's Palsy

Bell's palsy is a syndrome of acute-onset paralysis of the facial nerve; it tends to present during the third trimester and the first few postpartum weeks. The incidence during pregnancy is approximately 3.3 times higher than that in nonpregnant women, which in turn is 2 to 4 times higher than that in men.[224] Some studies have suggested an association with preeclampsia, which may be based on increased interstitial edema.[225] Interestingly, Maloney[226] proposed that the smile of the famed portrait "The Mona Lisa" was the result of Leonardo da Vinci's anatomically precise rendering of a new mother affected by Bell's palsy during her pregnancy.

One study noted that pregnant patients whose symptoms progressed to complete facial paralysis within 10 days of onset were less likely to experience satisfactory recovery than a comparison group of nonpregnant patients.[227] Patients may benefit from a short course of prednisone.[228]

Dorsey and Camann[229] retrospectively reviewed 36 cases of Bell's palsy associated with pregnancy; 25 women experienced symptoms during the third trimester, and the remaining 11 had symptoms during the first week postpartum. Of the 36 women, 27 received spinal or epidural analgesia or anesthesia. There were no differences in incidence or progression of the Bell's palsy or maternal and fetal outcomes in relation to the type of anesthesia given; therefore, neuraxial analgesia or anesthesia does not appear to be contraindicated in patients with Bell's palsy.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is common during pregnancy; in a systematic review, the reported incidence ranged

from 0.8% to 70%.[230] The disorder results from compression of the median nerve in the flexor retinaculum at the wrist. Patients typically report paresthesias and weakness in the median nerve distribution, with symptoms worse in the morning on awakening from sleep. Symptoms have been reported to persist in approximately 50% and 30% of patients after 1 year and 3 years, respectively.[230] Patients may be treated with splinting of the wrists, although in severe cases, surgery may be required. In many cases, symptoms resolve spontaneously within the first 2 months postpartum and appear to correlate with losing the weight gained during pregnancy.[231]

Meralgia Paresthetica

Meralgia paresthetica involves sensory loss and paresthesias in the lateral thigh stemming from compression of the lateral femoral cutaneous nerve. Obesity and the exaggerated lordosis of pregnancy can stretch the nerve. Symptoms of meralgia paresthetica typically resolve within 3 months of delivery. This peripheral nerve palsy and other neurologic deficits are discussed more fully in Chapter 32.

KEY POINTS

- Symptoms of multiple sclerosis may worsen postpartum, regardless of the anesthetic technique used during delivery. However, the long-term prognosis of this disease is most likely unaffected by pregnancy.
- Multiple sclerosis does not contraindicate the use of neuraxial analgesia or anesthesia.
- Continuous epidural anesthesia is the method of choice for the prevention or treatment of autonomic hyperreflexia during labor and delivery in patients with spinal cord injury.
- Patients with myasthenia gravis require close surveillance during labor. Increasing muscle weakness may require an adjustment in the dosage of the anticholinesterase drug. Severe respiratory involvement may preclude the use of neuraxial anesthesia for cesarean delivery.
- The anesthesia provider should avoid succinylcholine in patients with myotonic dystrophy because fasciculations can trigger myotonia.
- Neuraxial analgesia or anesthesia does not appear to precipitate the onset of postpoliomyelitis muscular atrophy.
- Hemodynamic stability should be maintained in the parturient with an untreated intracranial aneurysm or arteriovenous malformation. Epidural anesthesia should be considered during labor and delivery.
- Bell's palsy, carpal tunnel syndrome, and meralgia paresthetica occur at higher rates during pregnancy. Symptoms typically resolve postpartum.

CHAPTER 43

Endocrine Disorders

Richard N. Wissler, MD, PhD

CHAPTER OUTLINE

DIABETES MELLITUS

Definition and Epidemiology

Diabetes mellitus (DM) is a common metabolic disorder with a prevalence of 6.8% to 8.2% in the general adult population in the United States.[1,2] DM results from either an absolute deficiency in insulin secretion (type 1) or a combination of resistance to insulin in target tissues and inadequate insulin secretion (type 2).[3] Although a combination of genetic and environmental factors contributes to both types, type 1 DM is primarily an autoimmune disorder. Type 2 DM occurs primarily in obese individuals and accounts for 90% to 95% of cases of DM in the United States.[3] Gestational DM refers to DM or glucose intolerance that is first diagnosed during pregnancy. Gestational DM occurs in approximately 7% of pregnancies in the United States, reflecting a doubling of its prevalence between 1990 and 2000.[4,5]

Pathophysiology

Insulin is a peptide hormone secreted by the beta cells of the islets of Langerhans in the pancreas. Insulin binds to specific cell-surface receptors in insulin-responsive target tissues (e.g., liver, skeletal muscle, fat). The intracellular effects of insulin are mediated by tyrosine kinase in the beta-subunit of the receptor through a cascade of distal protein kinase–mediated phosphorylations.[6,7] Normal hepatic glucose metabolism represents a balance between the effects of insulin and several "counterregulatory" hormones (e.g., glucagon, cortisol, epinephrine, growth hormone).[8] This control system for glucose homeostasis permits rapid adjustments in glucose metabolism in the fed and fasted states. Insulin is also an important anabolic regulator of lipid and amino acid metabolism (Figure 43-1). Insulin deficiency (absolute or relative) associated with DM results in abnormal metabolism of carbohydrates, lipids, and amino acids.

Acute and chronic complications occur in patients with DM (Box 43-1). The three major acute complications are diabetic ketoacidosis, hyperglycemic nonketotic state, and hypoglycemia. **Diabetic ketoacidosis (DKA)** occurs predominantly in patients with type 1 DM. DKA may develop with a new source of insulin resistance (e.g., infection, trauma, stress) and/or as a result of failure to administer usual insulin doses. DKA results from decreased uptake of glucose by insulin-responsive tissues and greater use of free fatty acids as a hepatic energy source. The lack of insulin favors lipolysis, beta-oxidation of free fatty acids in the liver, and hepatic formation of acetoacetate and beta-hydroxybutyrate from the excess acetyl-coenzyme A generated by fatty acid oxidation.[9] These biochemical events result in metabolic acidosis, hyperglycemia, and dehydration secondary to osmotic diuresis. Signs and symptoms of DKA include nausea, vomiting, weakness, tachypnea, hypotension, tachycardia, stupor, and acetone on the breath. The diagnosis of DKA depends on the laboratory findings of hyperglycemia, ketosis, and acidosis.[10]

Hyperglycemic nonketotic state (HNS) occurs predominantly in patients with type 2 DM. Laboratory findings in HNS are hyperglycemia (blood glucose level

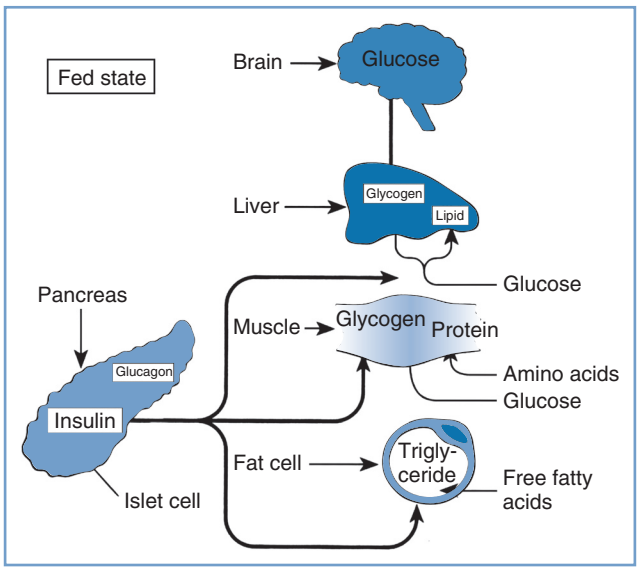

FIGURE 43-1 ■ Substrate use in the fed state, showing the role of insulin in the promotion of fuel storage. (From Kitabchi AE, Murphy MB. Diabetic ketoacidosis and hyperosmolar hyperglycemic nonketotic coma. Med Clin North Am 1988; 72:1545-63.)

BOX 43-1 Major Complications of Diabetes Mellitus

ACUTE

- Diabetic ketoacidosis
- Hyperglycemic nonketotic state
- Hypoglycemia

CHRONIC

Macrovascular (Atherosclerosis)

- Coronary
- Cerebrovascular
- Peripheral vascular

Microvascular

- Retinopathy
- Nephropathy

Neuropathy

- Autonomic
- Somatic

often > 600 mg/dL), hyperosmolarity (> 320 mOsm/kg), and moderate azotemia (serum blood urea nitrogen [BUN] often > 60 mg/dL), without ketonemia or significant acidosis.[10] The absence of significant ketosis in HNS may indicate an inhibition of lipolysis by hyperosmolarity or low levels of insulin. DKA and HNS are probably related conditions; inadequate insulin therapy and infection are the most common precipitating events for both.[10]

Hypoglycemia is a continuing health threat in diabetic patients, especially in patients receiving insulin therapy. Hypoglycemia results from an imbalance between insulin or oral hypoglycemic agents and available metabolic fuels. In hospitalized patients with DM, major risk factors for hypoglycemia include renal insufficiency and decreased caloric intake.[11] Symptomatic awareness of hypoglycemia and counterregulatory responses may be inadequate in some diabetic patients with autonomic neuropathy.[12] Problems with hypoglycemia awareness in patients receiving beta-adrenergic receptor antagonists can be minimized by using β_1-adrenergic receptor–selective antagonists.[13] Factitious hypoglycemia results from a deliberate, inappropriate self-administration of insulin or an oral hypoglycemic agent.[14]

In general, the prevalence of chronic complications increases with the duration of DM.[4,15] The Diabetes Control and Complications Trial, a randomized multicenter study of patients with type 1 DM, demonstrated a positive relationship between tight glucose control and a lower incidence or rate of progression of **retinopathy, nephropathy,** and **neuropathy**.[16] In a similar study of patients with type 2 DM—the U.K. Prospective Diabetes Study (UKPDS)—intensive glucose control lowered the incidence of microvascular complications but not of macrovascular complications or patient mortality.[17] In contrast, antihypertensive therapy reduced the incidence of macrovascular complications and mortality in patients with both type 2 DM and chronic hypertension.[17] DM may affect **cardiovascular function** as a result of coronary atherosclerosis, autonomic neuropathy, or development of a cardiomyopathy.[18]

BOX 43-2 Criteria for the Diagnosis of Diabetes Mellitus

1. Hemoglobin $A_{1c} \geq 6.5\%$. The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay.*
   OR
2. Fasting plasma glucose ≥ 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.*
   OR
3. Two-hour plasma glucose ≥ 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the World Health Organization using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.*
   OR
4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥ 200 mg/dL.

NGSP, National Glycohemoglobin Standardization Program; *DCCT*, Diabetes Control and Complications Trial.
*In the absence of unequivocal hyperglycemia, criteria 1 through 3 should be confirmed by repeat testing.
Modified from American Diabetes Association. Diagnosis and classification of diabetes mellitus. Diabetes Care 2012; 35(Suppl 1):S64-71.

Clinical Presentation and Diagnosis

Box 43-2 lists the current diagnostic criteria for DM in *nonpregnant* patients.[4]

Gestational DM is associated with (1) advanced maternal age, (2) obesity, (3) family history of type 2 DM,

BOX 43-3 Screening and Diagnostic Strategies for Gestational Diabetes Mellitus

1. Screen for undiagnosed type 2 diabetes at the first prenatal visit, using standard diagnostic criteria (see Box 43-2), in those who are overweight (BMI ≥ 25 kg/m^2) and who have one or more of the following risk factors:
   - Physical inactivity
   - First-degree relative with diabetes
   - High-risk race/ethnicity (e.g., African race, Latino, Native American, Asian race, Pacific Islander)
   - Women who delivered an infant weighing > 9 lb (4 kg) or who were diagnosed with gestational diabetes
   - Hypertension (blood pressure ≥ 140/90 mm Hg or receiving therapy for hypertension)
   - High-density lipoprotein (HDL) cholesterol level < 35 mg/dL (0.90 mmol/L) and/or a triglyceride level > 250 mg/dL (2.82 mmol/L)
   - Women with polycystic ovary syndrome
   - Hemoglobin A_{1c} ≥ 5.7%, impaired fasting glucose level, or impaired glucose tolerance on previous testing
   - Other clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)
   - History of cardiovascular disease
2. In pregnant women not previously known to have diabetes, screen for gestational diabetes at 24-28 weeks' gestation, as follows:
   - Perform a 75-g oral glucose tolerance test (OGTT), with three plasma glucose measurements (fasting and 1 and 2 hours)
   - The OGTT should be performed in the morning after an overnight fast of at least 8 hours.
   - The diagnosis of gestational diabetes is made when any of the following plasma glucose measurements are exceeded:
     Fasting: ≥ 92 mg/dL (5.1 mmol/L)
     1-hour: ≥ 180 mg/dL (10.0 mmol/L)
     2-hour: ≥ 153 mg/dL (8.5 mmol/L)

BMI, body mass index.

(4) prior history of gestational DM, (5) history of polycystic ovarian syndrome, (6) glycosuria, and/or (7) history of prior stillbirth, neonatal death, fetal malformation, or macrosomia. The clinical sensitivity of the medical history in detecting gestational DM is only 50%.[19] Box 43-3 lists the current recommendations of the American Diabetes Association (ADA) for screening and diagnosis of gestational DM.[4]

Several observational clinical studies, including the Hyperglycemia and Adverse Pregnancy Outcome Study,[20] have shown that adverse pregnancy outcomes are a continuous function of glucose intolerance in pregnancy. Based on these observations, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) has proposed new diagnostic criteria for gestational DM as described in Box 43-3.[21] In this system, gestational DM is diagnosed if even one of the three blood glucose samples is elevated in a 2-hour oral glucose tolerance test. The ADA has approved the more inclusive IADPSG diagnostic criteria[4]; the new criteria are estimated to increase the diagnosed incidence of gestational diabetes to 16% to 18% of pregnant women.[22] However, the American College of Obstetricians and Gynecologists (ACOG) has not accepted the new criteria of the IADPSG/ADA. The ACOG continues to recommend a two-step diagnostic process; screening all women at 24 to 28 weeks' gestation followed by a 100-g, 3-hour oral glucose tolerance test for those who screen positive. With this conservative approach, the incidence of gestational DM is approximately 7%.[23] The current controversy between the IADPSG/ADA and the ACOG diagnostic criteria for gestational diabetes is centered on whether treatment of an expanded patient population is cost-effective and will improve outcomes.[22-26]

Glycosylated hemoglobin measurements are used as time-integrated estimates of glycemic control but not as a diagnostic test for DM. The normal range for hemoglobin A_{1c} in nondiabetic pregnant women is 4.0% to 5.5%, compared with 4.8% to 6.5% in nondiabetic nonpregnant women.[27]

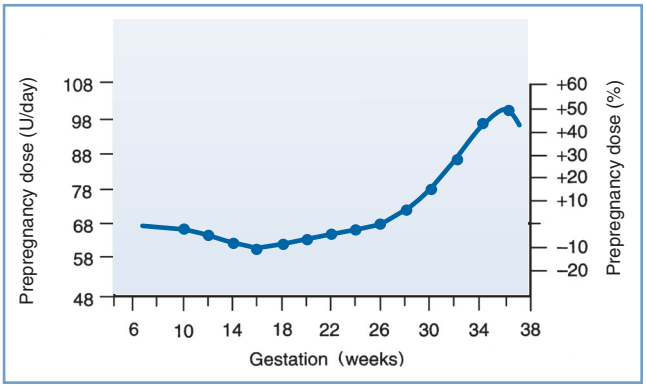

FIGURE 43-2 ■ **Insulin requirements in euglycemic women with type 1 diabetes mellitus during pregnancy.** (From Crombach G, Siebolds M, Mies R. Insulin use in pregnancy: clinical pharmacokinetic considerations. Clin Pharmacokinet 1993; 24:89-100.)

Interaction with Pregnancy

How Does Pregnancy Affect Diabetes Mellitus?

Pregnancy is characterized by progressive peripheral resistance to insulin at the receptor and postreceptor levels in the second and third trimesters (Figure 43-2).[28-30] The presumed mechanism involves an increase in counterregulatory hormones (e.g., placental lactogen, placental growth hormone, cortisol, progesterone) during pregnancy. The change in placental lactogen is a plausible mechanism, given that (1) a graph of serum lactogen levels during pregnancy is similar in shape to that of insulin requirements in pregnant women with type 1 DM and (2) placental lactogen has growth hormone–like activity. Also, maternal adipokines probably are important factors in insulin resistance of pregnancy[29]; they facilitate the provision of maternal fuels for the fetus.[30]

Gestational DM develops when a patient cannot mount a sufficient compensatory insulin response during pregnancy. In some patients, gestational DM can be viewed as a preclinical state of glucose intolerance that is not detectable before pregnancy. After delivery most patients return to normal glucose tolerance but remain at increased risk for DM (predominantly type 2) in later life.[31] The recurrence rate for gestational DM in a subsequent pregnancy is 35% to 70%.[32]

In patients with **pregestational DM,** insulin requirements progressively increase during pregnancy because of peripheral insulin resistance.[33] At term, the daily insulin requirement is approximately 1.0 insulin unit/kg, compared with 0.7 unit/kg before pregnancy.[33] Insulin requirements may be higher in pregnancies with multiple gestation.[34] During late pregnancy in normal healthy patients, basal and glucose-stimulated plasma insulin levels are twice the postpartum measurements.[30] These changes reflect pregnancy-related increases in pancreatic islet cell mass and glucose sensitivity, probably secondary to the net effect of competing progesterone and lactogenic hormone stimuli in the endocrine pancreas.[35,36] Near term, maternal overnight insulin requirements may decrease, presumably as a result of a "siphoning of maternal fuels" by the growing fetus during the overnight maternal fast.[37]

Endogenous plasma insulin concentrations during labor and delivery in nondiabetic parturients differ from exogenous insulin requirements in laboring diabetic women. In nondiabetic parturients, the plasma glucose concentration is only one of many factors that affect endogenous insulin secretion; glucose production and use are markedly higher during painful labor than postpartum.[38] Plasma insulin concentrations remain unchanged except for a brief increase during the third stage of labor and immediately postpartum.[38,39] This finding suggests that glucose use during labor is largely independent of insulin. The patterns of plasma insulin concentrations are similar in nondiabetic patients with and without analgesia (e.g., nitrous oxide, meperidine).[39]

In patients with type 1 DM, insulin requirements decrease with the onset of the first stage of labor.[40] These patients may require no additional insulin during the first stage of labor, although insulin requirements are modified by (1) the level of metabolic control before labor, (2) the residual effect of prior doses of subcutaneous insulin, and (3) the glucose infusion rate.[40,41] Insulin requirements increase during the second stage of labor via an unknown mechanism.[40,41] The use of epidural analgesia or oxytocin does not affect exogenous insulin requirements during the first and second stages of labor.[40] After delivery—either vaginal or cesarean—insulin requirements in women with type 1 DM decrease markedly for at least several days, although there is significant variability among individuals (Figure 43-3).[28,42] Presumably, the decreased insulin requirement results from loss of counterregulatory hormones produced by the placenta. Pituitary growth hormone responsiveness to hypoglycemia is blunted in late pregnancy and may contribute to impaired counterregulatory responses during the postpartum period.[43] Insulin requirements gradually return to prepregnancy levels within several weeks of delivery in women with type 1 DM.[37]

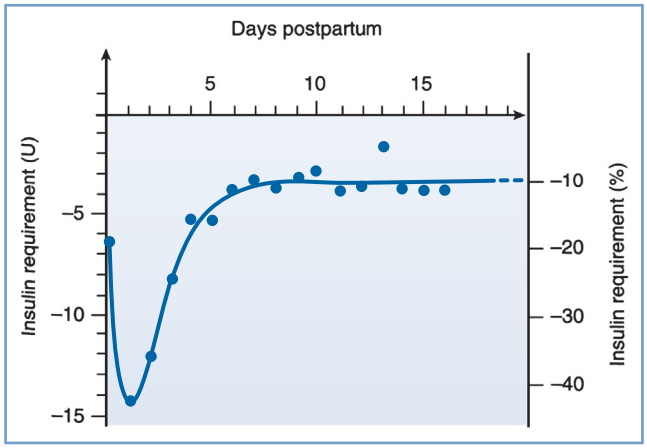

FIGURE 43-3 ■ Insulin requirements in the postpartum period. (From Crombach G, Siebolds M, Mies R. Insulin use in pregnancy: clinical pharmacokinetic considerations. Clin Pharmacokinet 1993; 24:89-100.)

Before the discovery of insulin in 1921, pregnancies were rare in diabetic patients. Insulin therapy improved the rate of survival in women with severe DM, allowing these women to reach childbearing age and become pregnant. Maternal outcomes improved, but fetal and neonatal morbidity and mortality remained high.[44]

In 1949, White[45] proposed a classification system for DM during pregnancy based on 439 consecutive cases. Physicians caring for pregnant diabetic patients should be familiar with the White system, which has endured with some modifications (Table 43-1). The system emphasizes the relationship among the duration of type 1 DM, vascular complications of type 1 DM, and poor fetal outcome.[46] In the 1950s, fetal survival rates were as follows: class A, 100%; class B, 67%; class C, 48%; class D, 32%, and class F, 3%.[46]

Diabetic Ketoacidosis. The incidence of DKA has decreased from 9% to between 1% and 2% of diabetic pregnancies,[47,48] probably as a result of improvements in medical care and patient education. Similarly, the incidence of perinatal and maternal mortality from DKA during pregnancy has decreased in the past several decades.[48,49] As is true for nonpregnant patients, DKA during pregnancy occurs predominantly in patients with type 1 DM. The higher risk for DKA during pregnancy reflects the metabolic adaptations of pregnancy, including peripheral insulin resistance.[28]

During pregnancy, DKA occurs most commonly during the second and third trimesters.[50] It is associated with (1) emesis, (2) infection, (3) poor compliance or noncompliance, (4) insulin pump failure, (5) use of beta-adrenergic receptor agonists, (6) use of corticosteroids, and (7) poor medical management.[48] The infection rate in pregnant women with pregestational type 1 DM is 3.2 times higher than that in nondiabetic pregnant women.[51] DKA may be the first clinical sign of type 1 DM during pregnancy.[52,53] Beta-adrenergic receptor agonists, which

TABLE 43-1 Modified White Classification of Diabetes Mellitus during Pregnancy

Class	Age at Onset of Diabetes (yr)		Duration of Diabetes (yr)	Vascular Disease	Insulin Required
Gestational Diabetes					
A_1	Any		Any	No	No
A_2	Any		Any	No	Yes

are used to treat preterm labor, and corticosteroids, which are used to accelerate fetal lung maturity, both have counterregulatory pharmacologic effects that oppose insulin action. Beta-adrenergic agonist tocolytic therapy, with or without concurrent corticosteroid therapy, and by any route of administration, can precipitate DKA during pregnancy.[54] Beta-adrenergic receptor stimulation worsens glucose intolerance by stimulating glucagon secretion[55]; beta-adrenergic receptor agonists may be well tolerated in pregnant women with DM if higher insulin requirements are anticipated and doses are adjusted in response to frequent blood glucose determinations.[53,54]

Nonreassuring fetal heart rate patterns during episodes of maternal DKA have been described.[56] After appropriate medical management of maternal DKA, preterm uterine contractions stopped and fetal heart rate patterns normalized. The mechanism of fetal compromise during DKA is unclear, but it may be related to changes in uterine blood flow. Blechner et al.[57] demonstrated that uterine artery blood flow is reduced by acute maternal metabolic acidosis. A single case report demonstrated reversible redistribution of fetal blood flow during an episode of maternal DKA on the basis of Doppler pulsatility indices of the umbilical and middle cerebral arteries.[58]

There are three case reports of HNS during pregnancy.[59-61] No conclusion can be drawn about HNS and pregnancy, except that HNS rarely occurs during pregnancy.

Hypoglycemia. Hypoglycemia is a significant health risk for pregnant women with pregestational type 1 DM, occurring in 33% to 71% of these patients.[62-65] This rate is 3 to 15 times higher than that in similar groups of nonpregnant patients with type 1 DM[62,63]; 80% to 84% of severe hypoglycemia episodes occur before 20 weeks' gestation.[64,65] In one study, patients with pregestational type 2 DM or gestational DM requiring insulin therapy experienced no episodes of severe hypoglycemia.[63] The risk for hypoglycemia during pregnancy in patients with type 1 DM increases with tight glucose control.[62,64] This pattern mirrors the clinical experience in nonpregnant women with type 1 DM, in which a threefold rise in the occurrence of severe hypoglycemia results from tight insulin control.[66] In both pregnant and nonpregnant patients with type 1 DM, counterregulatory hormone responses to hypoglycemia are impaired after intensive insulin therapy.[67,68] Two small series suggest that acute mild to moderate maternal hypoglycemia is not associated with acute alterations in fetal well-being in pregnant women with type 1 DM.[67,69]

Other Complications. The relationship between pregnancy and the development of macrovascular complications of DM is largely unknown. Patients with pregestational type 1 DM have higher systolic and diastolic blood pressures during pregnancy, and they are three times more likely than nondiabetic control subjects to have **gestational hypertension**.[70,71] In women with pregestational type 1 DM, the risk for preeclampsia is increased with increased severity of diabetes (White classification), and proteinuria early in pregnancy is associated with an increased risk for adverse outcomes.[72] **Myocardial infarction** is a rare complication.[73] The effect of gestational hypertension on the progression of **atherosclerotic disease** in diabetic patients is unclear.

Pregnancy may accelerate the development of **proliferative retinopathy,** a microvascular complication of DM. Hyperglycemia and hypertension are also associated with the progression of retinopathy.[74,75] The onset of strict glycemic control may transiently exacerbate diabetic retinopathy in both pregnant and nonpregnant patients with type 1 DM. The Diabetes Control and Complications Trial demonstrated that strict glycemic control is justified in nonpregnant patients.[16]

In contrast to diabetic retinopathy, pregnancy does not accelerate the progression of diabetic **nephropathy**.[76] It is unclear whether pregnancy accelerates the progression of **somatic** or **autonomic neuropathy** in diabetic women.

How Does Diabetes Mellitus Affect the Mother and Fetus?

Both pregestational and gestational DM are associated with higher rates of gestational hypertension, polyhydramnios, and cesarean delivery.[47,76-78] The incidence of cesarean delivery is higher in women with pregestational DM than in women with gestational DM.[47,76,78] Trial of labor after cesarean delivery (TOLAC) in patients with gestational DM is associated with rates of operative vaginal delivery and repeat cesarean delivery that are higher than those found in nondiabetic controls.[79] Pregestational DM—but not gestational DM—is associated with a twofold to threefold increase in the incidence of **preterm labor and delivery**.[76,80]

Box 43-4 lists the fetal complications of maternal DM during pregnancy. **Fetal macrosomia** is a well-recognized complication of maternal DM. Most studies suggest that both pregestational DM and gestational DM result in an increased incidence of fetal macrosomia.[81-83] Depending on the definition of macrosomia (4000 g versus 4500 g), pregestational DM results in fetal macrosomia in 9% to 25% of women—a fourfold to sixfold higher rate than in nondiabetic controls.

Macrosomia results in an increased risk for **shoulder dystocia** and **birth trauma** with vaginal delivery.[77,84,85] Moreover, when comparisons are made within birth weight categories above 4000 g, pregnancies in diabetic women have a higher risk for shoulder dystocia than nondiabetic women.[86] The use of intensive insulin therapy may reduce the risk for birth trauma in women with pregestational DM.[87] Several mechanisms have been suggested for the development of fetal macrosomia in diabetic pregnancy. Maternal hyperglycemia can result in fetal hyperglycemia, with reactive fetal hyperinsulinemia and an anabolic response in the fetus.[88] Shoulder dystocia may reflect the excessive growth of the fetal trunk (relative to the fetal head) in response to fetal hyperinsulinemia.[89]

Women with pregestational DM are at increased risk for **fetal anomalies** (see Box 43-4). The incidence of major anomalies, estimated to be 6% to 10%, is five times higher than in nondiabetic controls.[47,90-92] Overall, cardiovascular anomalies are most common, followed by anomalies of the central nervous system (CNS). The caudal regression syndrome is uncommon, but it is 200 times more likely in diabetic than in nondiabetic pregnancies.[90] The incidence of major congenital anomalies in infants of women with gestational DM is 3% to 8%, which is lower than in infants of women with pregestational DM.[76]

Metabolic factors that may be involved in the development of fetal structural malformations in diabetic pregnancies include hyperglycemia, hypoglycemia, arachidonic acid, polyol pathways, mitochondrial dysfunction, and apoptosis.[92] Most fetal structural malformations that occur during diabetic pregnancies are likely to have a multifactorial etiology. However, hyperglycemia during the period of critical organogenesis before the seventh week after conception is probably the single strongest etiologic factor in diabetic women and may be associated with embryonic oxidative stress.[92,93]

Studies have suggested that patient education and strict glycemic control during the preconception period may reduce the rate of major congenital anomalies from 10% to 1% in patients with pregestational DM.[94] The latter figure is similar to the baseline risk for major structural malformations in the general population. Strict glycemic control initiated during the preconception period also increases the incidence of maternal hypoglycemic episodes. These studies suggest that hypoglycemia is not a significant factor in the etiology of human malformations, because the rate of anomalies decreased 10-fold despite hypoglycemic episodes.[94] Similarly, strict glycemic control before conception also has been associated with a threefold decrease in the incidence of spontaneous abortion in women with pregestational DM.[95] Dicker et al.[96] observed normal induced ovulation, *in vitro* fertilization, and early embryonic development in a small series of infertile patients with pregestational DM who attended a preconception diabetes clinic. However, only 36% of women with known pregestational DM receive appropriate medical care before conception.

During the 1950s to 1970s, the **perinatal mortality rate** in women with pregestational DM was 15% to 18%.[47] Subsequent studies noted a decrease to 2%, a rate similar to that in nondiabetic controls.[76] In contrast, one study noted a rate of 8%, three times greater than in nondiabetic controls.[83] If the entire population is considered, the perinatal mortality rate likely remains higher in patients with pregestational DM than in nondiabetic controls. The rate in patients with gestational DM is

BOX 43-4 Fetal Complications of Maternal Diabetes Mellitus

During Pregnancy and the Puerperium

Chronic

- Macrosomia
  - Shoulder dystocia
  - Birth injury or trauma
- Structural malformations
  - Central nervous system: anencephaly, encephalocele, meningomyelocele, spina bifida, holoprosencephaly
  - Cardiac: transposition of great vessels, ventricular septal defect, situs inversus, single ventricle, hypoplastic left ventricle
  - Skeletal: caudal regression
  - Renal: agenesis, multicystic dysplasia
  - Gastrointestinal: anal or rectal atresia, small left colon
  - Pulmonary: hypoplasia

Acute

- Intrauterine or neonatal death
- Neonatal respiratory distress syndrome
- Neonatal hypoglycemia
- Neonatal hyperbilirubinemia

After Pregnancy

- Glucose intolerance
- Possible impairment of cognitive development

intermediate between the rate in women with pregestational diabetes and the rate in nondiabetic controls.[76,83]

Historically, **intrauterine fetal death** was responsible for approximately 40% of the perinatal deaths in women with DM; 68% of the stillbirths occurred between 36 and 40 weeks' gestation.[45,83] In contemporary reports, the ratio of intrauterine deaths to neonatal deaths in diabetic pregnancies has varied from 0 to 1.0. Fetal macrosomia is a risk factor for intrauterine fetal demise in both diabetic and nondiabetic pregnancies. Recurrent episodes of intrauterine hypoxia can occur in diabetic pregnancies that end in stillbirth; episodes of hypoxia may reflect reduced uteroplacental blood flow and changes in fetal carbohydrate metabolism. **Congenital anomalies** have now emerged as the leading cause of perinatal mortality in diabetic pregnancies.[92] This change likely reflects better obstetric care during pregnancy, despite the lack of adequate glycemic control before conception.

Two series that involved women who delivered between 1950 and 1979 demonstrated an incidence of **neonatal respiratory distress syndrome (RDS)** in diabetic pregnancies that was 6 to 23 times that in nondiabetic controls.[47,97] Respiratory distress is more common among newborns who are delivered preterm or who are surgically delivered without labor. Later studies of patients with both pregestational and gestational DM have not demonstrated a significant difference in the incidence of neonatal RDS between diabetic and nondiabetic pregnancies.[76,98,99]

The level of glycemic control during pregnancy affects the amniotic fluid phospholipid profile. In pregnancies of patients with poorly controlled diabetes, there may be a higher incidence of immature amniotic fluid fetal lung profiles at 34 to 38 weeks' gestation without an increase in the rate of clinical respiratory distress syndrome.[99,100] In reliably dated pregnancies of diabetic patients, fetal lung maturity testing has little clinical benefit.[101]

Neonatal hypoglycemia occurs in 5% to 12% of cases of pregestational and gestational DM.[76] This represents a 6-fold to 16-fold higher risk for neonatal hypoglycemia than in nondiabetic controls. Neonatal hypoglycemia likely results from sustained fetal hyperinsulinemia in response to chronic intrauterine hyperglycemia. Clinical studies have demonstrated higher fetal insulin levels and exaggerated fetal insulin responses to acute maternal hyperglycemia in diabetic pregnancies.[102,103] An acute increase in maternal glucose concentration, as might occur if a dextrose-containing solution was used for intravenous hydration during administration of neuraxial anesthesia, can lead to reactive neonatal hypoglycemia, even in nondiabetic women.[104]

There is a twofold to fivefold higher incidence of **neonatal hyperbilirubinemia** in women with pregestational and gestational DM than in nondiabetic controls.[76] Other associated factors include the severity of gestational DM and excess maternal weight gain during pregnancy.[105,106] Both the etiology and the clinical significance of neonatal hyperbilirubinemia are unknown, although one study noted the absence of long-term morbidity.[76]

Offspring of diabetic mothers are at increased risk for development of **DM,** likely from a combination of genetic and intrauterine environmental factors. Despite the well-known association of type 1 DM with human leukocyte antigen markers, studies of monozygotic human twins have suggested that genetic factors have a greater role in type 2 DM than in type 1 DM (100% versus 20% to 50% concordance, respectively).[105] In addition, fathers with type 1 DM are five times more likely than mothers with the same disease to have a child with type 1 DM. The intrauterine environment also affects the development of glucose intolerance in offspring.[31]

Some investigators have suggested that **cognitive development** may be impaired in the children of diabetic mothers,[107] but this issue remains controversial.

Obstetric Management

Glycemic Control

Early, strict glycemic control is the best way to prevent fetal structural malformations in women with pregestational DM.[92,94] Determination of hemoglobin A_{1c} concentrations may help the physician determine the adequacy of preconceptional glycemic control.

During pregnancy, the patient should frequently determine capillary blood glucose concentration using a reflectance meter.[108] Continuous glucose monitoring systems (e.g., transdermal, subcutaneous) are more recent approaches.[109] Glucose determinations guide adjustments in diet and insulin therapy. In general, insulin requirements increase progressively during the second and third trimesters. Both maternal and perinatal outcomes seem to improve when maternal glycemic control approaches that observed in normal pregnancies. Opinions vary about the optimum target glucose concentration in patients with pregestational DM, but a fasting blood glucose concentration of 60 to 95 mg/dL seems appropriate. Of course, strict glycemic control increases the risk for maternal hypoglycemia.

Therapeutic insulin is available in several forms. Initially, insulin was isolated as a natural product from domestic animals (e.g., cattle, pigs). In the past 20 years, synthetic human insulin has become commercially available and has largely replaced beef and pork insulin in human medicine, with an expected decrease in immune reactions among human recipients.[110]

The goal of insulin therapy is to provide plasma insulin concentrations that lead to tight glucose control without hypoglycemia. This goal is facilitated by the availability of several insulin preparations with different subcutaneous absorption rates (Table 43-2).[109] Regular insulin can be administered by the intravenous or subcutaneous route. Regular insulin administered intravenously has a half-life of approximately 4 minutes.[111] Other native insulins listed in Table 43-2 (i.e., neutral protamine Hagedorn [NPH], the zinc suspensions lente and ultralente) represent chemical complexes of regular insulin with protamine or zinc; subcutaneous administration of these insulins is associated with slower absorption and onset of action. Lente and ultralente insulins have been replaced clinically by insulin analogues and are of only historical interest. An alternative therapeutic strategy is to administer a rapid-acting insulin by the subcutaneous route

TABLE 43-2 **Pharmacokinetics of Subcutaneous Insulin Administration in Nonpregnant Humans**

Insulin Preparations	Onset (h)	Peak (h)	Duration (h)
Short-Acting Class			
Regular	0.5	2-4	5-7
Lispro*	0.25	0.5-1.5	6-8
Aspart*	0.25	1-3	3-5
Glulisine*	0.25	1	4
Intermediate Class			
NPH	1-2	6-12	18-24
Lente	1-3	6-12	18-24
Long-Acting Class			
Ultralente	4-6	8-20	> 36
Glargine*	1.1	5	24

NPH, neutral protamine Hagedorn.

using a continuous programmable pump.[112] It is unclear whether continuous subcutaneous pump–administered insulin is clinically superior to intermittent subcutaneous injections of currently available insulins.[113,114]

Human insulin therapy has fundamentally changed in recent years through the development of insulin analogues.[115,116] These molecules have specific chemical substitutions in portions of the human insulin protein not involved in receptor binding. Both short-acting and long-acting insulin analogues are in clinical use. **Lispro** and **aspart** are rapid acting, with a more physiologic onset and offset than regular insulin. **Glargine** is relatively insoluble at neutral pH in the subcutaneous compartment. In contrast to ultralente insulin, subcutaneous glargine has a sustained release without an initial peak of activity. Lispro, aspart, and glargine have all been used safely during human pregnancy.

Because insulin requirements decrease abruptly at delivery, it is important to verify the times, doses, insulin preparations, and routes of administration in the 24 hours before delivery to avoid maternal postpartum hypoglycemia.

Management of **DKA** is similar in pregnant and nonpregnant women. It involves (1) intravenous hydration, (2) intravenous insulin, (3) treatment of the underlying cause of DKA, (4) careful monitoring of blood glucose and electrolyte levels, and (5) restriction of bicarbonate therapy to cases of extreme acidosis.[9,10,48] In addition, left uterine displacement should be maintained and supplemental oxygen should be administered. Initial management of the critically ill pregnant woman should focus on the effective management of DKA. Fetal compromise is likely to resolve with appropriate medical management.[56,57]

Diet and exercise are the initial therapeutic approaches for glycemic control in women with gestational DM. Insulin therapy is initiated if the fasting glucose measurement exceeds a threshold of 80 to 105 mg/dL.[23,117] In the past, oral hypoglycemic agents were not used extensively in pregnancy, primarily because of concerns about potential teratogenicity and fetal hyperinsulinemia. In current practice, many women with gestational DM are treated with glyburide, glipizide, or metformin.[118,119] Concerns about the long-term health implications of gestational diabetes have resulted in national initiatives for postpartum metabolic surveillance.[120,121] The goal is to identify and treat postpartum type 2 DM, with an emphasis on lifestyle interventions.

Timing of Delivery

Timing of delivery is important in the management of diabetic pregnancies. White[46] noted, "Our problem must [be] … to prevent premature delivery of the infant of the diabetic mother prior to the period of its viability … and, secondly, the termination of the pregnancy at the point of viability and before the dreaded late intrauterine accident can occur." Typically a nonstress test is performed twice weekly in patients with pregestational DM, beginning at 32 weeks' gestation.[122,123] A nonreactive nonstress test should prompt the performance of a fetal biophysical profile (see Chapter 6). Risk factors for abnormal fetal testing in diabetic pregnancies include maternal nephropathy, hypertension, and poor glycemic control.[124] No consensus exists regarding antepartum testing in women with well-controlled gestational DM.[23] Patients with poorly controlled gestational DM should probably undergo antepartum fetal surveillance similar to that in patients with pregestational DM.[23,117]

In the presence of reassuring fetal testing, delivery can be delayed until after 38 weeks' gestation.[122] If fetal testing is abnormal and amniotic fluid analysis indicates fetal pulmonary maturity, the fetus should be delivered as soon as possible. If fetal testing is abnormal but amniotic fluid analysis suggests that the fetal lungs are immature, decisions about the timing of delivery are more difficult.

The decision regarding the method of delivery requires consideration of estimated fetal weight, fetal condition, cervical dilation and effacement, and previous obstetric history. The obstetrician may choose elective cesarean delivery in the diabetic parturient with evidence of fetal macrosomia to decrease the risk for shoulder dystocia.

Anesthetic Management

Few studies exist concerning the anesthetic management of pregnant women with DM. In general, neuraxial analgesia is the preferred technique for labor and cesarean delivery, but clinical decisions about these patients must be guided by logical extensions of studies of nonpregnant diabetic patients and nondiabetic pregnant patients.

Preanesthetic evaluation of the woman with DM should include a history and physical examination that focuses on the identification of the acute and chronic complications of DM (see Box 43-1). There are

no published data on the relationship between the complications of DM and responses to anesthetic agents or on anesthetic outcomes in pregnant patients. In a study of nonpregnant diabetic patients, preoperative evidence of **autonomic cardiovascular dysfunction** was predictive of the need for a vasopressor during general anesthesia.[125] Because of the potential for hypotension during neuraxial anesthesia, noninvasive testing of autonomic function may be useful in obstetric patients with pregestational DM. For example, in nonpregnant diabetic patients the corrected QT interval on an electrocardiogram correlates with the severity of autonomic neuropathy.[126] Patients with evidence of autonomic dysfunction may benefit from more frequent blood pressure determinations and more vigorous intravenous hydration before and during the administration of neuraxial anesthesia. **Gastroparesis** is a manifestation of autonomic neuropathy in diabetic patients.[127] In nonpregnant diabetic patients, autonomic neuropathy is associated with a decreased cough reflex threshold and a higher incidence of obstructive sleep apnea.[128,129]

Several studies have examined the maternal, fetal, and neonatal effects of **neuraxial anesthesia** for cesarean delivery for women with pregestational DM.[130-133] Datta and Brown[130] observed that spinal anesthesia was associated with a slightly but significantly lower umbilical cord blood pH measurement at delivery in patients with pregestational DM than in similar patients who received general anesthesia for cesarean delivery. Subsequently, these investigators noted an association between fetal acidosis and peripartum maternal hypotension in patients with pregestational DM who received epidural anesthesia for cesarean delivery.[131] In both studies, acute maternal hyperglycemia—secondary to intravenous hydration with 5% dextrose before administration of neuraxial anesthesia—was a potentially confounding factor.[130]

Neonatal acidosis is *not* likely to occur during **spinal** or **epidural anesthesia** for cesarean delivery in diabetic parturients, provided that (1) maternal glycemic control is satisfactory, (2) the patient receives aggressive preanesthetic volume expansion with a non–dextrose-containing balanced salt solution, and (3) hypotension is treated promptly and aggressively.[132,133]

Thalme and Engstrom[134] demonstrated normal umbilical arterial blood pH measurements after the administration of **general anesthesia** in a small series of patients with pregestational DM.

After administration of epidural anesthesia for cesarean delivery, Ramanathan et al.[133] observed an increased incidence of neonatal hypoglycemia in patients with pregestational DM compared with nondiabetic controls (35% versus 7%, respectively). In this study, maternal glycemic control was fair (mean fasting plasma glucose level was 127 mg/dL), a non–dextrose-containing solution was used for intravenous hydration, and intravenous insulin therapy was adjusted on the basis of frequent blood glucose determinations. This study illustrates the neonate's vulnerability to hypoglycemia after a diabetic pregnancy despite meticulous anesthesia care at the time of delivery.

A single case report describes a parturient who received combined spinal-epidural labor analgesia and subsequently became hypoglycemic. The authors hypothesize that the rapid decrease in catecholamine levels from the resultant analgesia led to hypoglycemia.[135]

Maternal insulin requirements decrease with the onset of labor, increase again during the second stage of labor, and decrease markedly during the early postpartum period.[40,41] Intravenous insulin therapy is the most flexible method of treatment during this period of rapid change. Absorption of subcutaneous insulin may be unpredictable and may increase the risk for maternal hypoglycemia, especially during the postpartum period.[41] Moreover, strict glycemic control in pregnant women with type 1 DM increases the risk for maternal hypoglycemia as a result of impaired counterregulatory hormone responses (as discussed earlier).

Intravenous glucose and insulin infusions during the peripartum period should be titrated to maintain a maternal blood glucose concentration of 70 to 90 mg/dL. During active labor, the glucose requirement is 2.5 mg/kg/min or more.[38] For cesarean delivery with patients using subcutaneous insulin pumps, a preoperative strategy should be formulated for perioperative insulin pump management. This plan should identify the individual(s), other than the patient, who are experienced and knowledgeable in adjusting her insulin pump if the patient is not able to adjust it herself during surgery. Some patients and obstetricians prefer discontinuing the subcutaneous insulin pump preoperatively in favor of an intravenous insulin infusion. The preanesthetic evaluation is an excellent opportunity to discuss with the patient the expected changes in insulin requirements at the time of delivery. The preprocedure and postprocedure "time-outs" are excellent opportunities to discuss the plan for perioperative pump management and other diabetic management concerns with all team members.

Many perioperative strategies have been proposed for metabolic control in nonpregnant patients with DM.[136-138] No convincing evidence suggests that one clinical strategy for perioperative diabetic control is superior in terms of patient outcome. Frequent blood glucose measurements (e.g., at 30- to 60-minute intervals), followed by appropriate adjustment of glucose and insulin infusions, represent the cornerstone of optimal perioperative care in patients with DM.

There are no published data on the effects of DM on the pharmacokinetics and pharmacodynamics of anesthetic agents in pregnant women. In nonpregnant women, DM is associated with (1) a delayed onset of muscle relaxation with tubocurarine and (2) prolonged blockade with vecuronium.[139,140]

The **diabetic stiff-joint syndrome** has been associated with difficult direct laryngoscopy and tracheal intubation in patients with DM.[141,142] This syndrome occurs in patients with long-standing DM type 1 and is associated with nonfamilial short stature, joint contractures, and tight skin.[143] Limited movement of the atlantooccipital joint may result in difficult direct laryngoscopy and tracheal intubation. During the preanesthesia evaluation of patients with DM, the anesthesia provider can screen for the stiff-joint syndrome by looking for the "prayer sign" (Figure 43-4). Management is controversial. Some authorities recommend preanesthesia

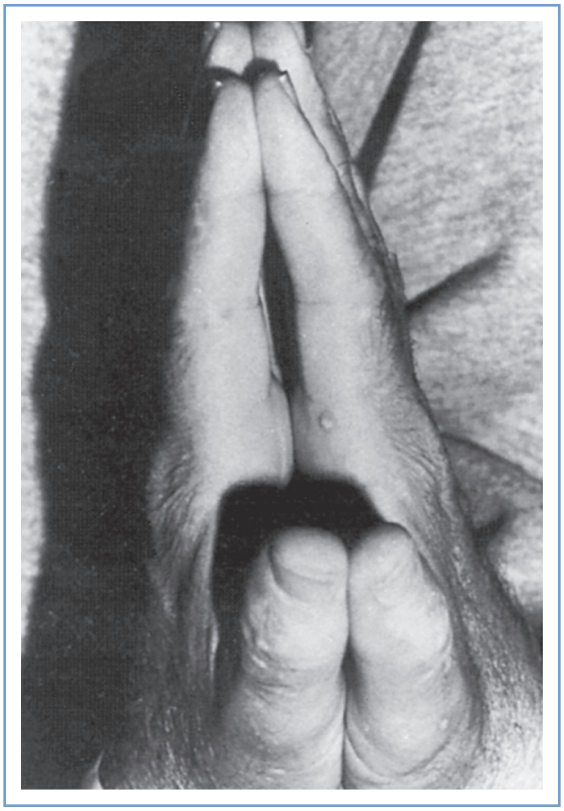

FIGURE 43-4 ■ Inability to approximate the palmar surfaces of the phalangeal joints despite maximal effort, secondary to diabetic stiff-joint syndrome. (From Hogan K, Rusy D, Springman SR. Difficult laryngoscopy and diabetes mellitus. Anesth Analg 1988; 67:1162-5.)

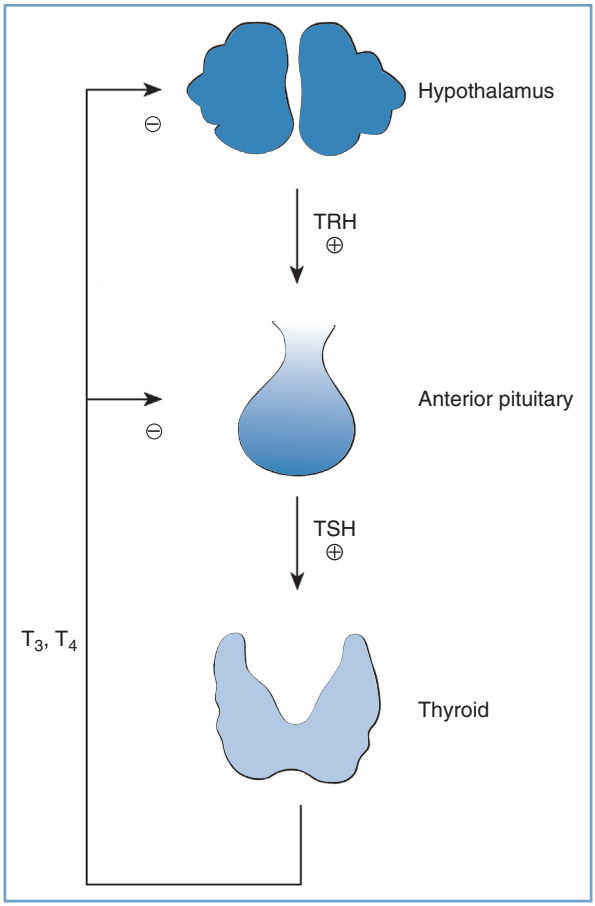

FIGURE 43-5 ■ Normal feedback control of thyroid hormone secretion. *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone; *T_3,* triiodothyronine; *T_4,* thyroxine. flexion-extension radiographic studies of the cervical spine followed by awake tracheal intubation.[142] Others have expressed doubt about the clinical significance of this syndrome and the reported frequency of airway management problems.[144,145] The term **diabetic scleredema** is synonymous with stiff-joint syndrome. There is one case report of a pregnant patient with pregestational DM and diabetic scleredema who experienced anterior spinal artery syndrome after the administration of epidural anesthesia for cesarean delivery.[146] The author suggested that spinal cord vascular compression resulted from a combination of (1) preexisting microvascular disease, (2) an epidural space that was stiff because of connective tissue disease, and (3) administration of a large volume (i.e., 35 mL) of the local anesthetic agent. In patients with a history and physical examination that suggest diabetic stiff-joint syndrome, the anesthesia provider should consider two potential problems: (1) difficult direct laryngoscopy and tracheal intubation and (2) a noncompliant epidural space.

Infection is an important cause of morbidity in pregnant women with pregestational DM.[49] There are no published data regarding the incidence of CNS infection after the administration of neuraxial anesthesia in pregnant diabetic patients except for one case of fungal meningitis due to contaminated spinal anesthesia equipment.[147] Strict aseptic technique always should be used during the administration of neuraxial anesthesia.

THYROID DISORDERS

Thyroid Hormone Physiology

The follicular cells of the thyroid gland sequester iodine and synthesize thyroglobulin, an iodinated precursor protein. Thyroglobulin is secreted into the lumen of the microscopic thyroid follicles before it undergoes reuptake, proteolysis, and transfer to lysosomes, where it undergoes degradation.[148] This process results in the systemic release of the thyroid hormones: thyroxine (T_4) and 3,5,3′-triiodothyronine (T_3). Reverse T_3 (3,3′,5′-triiodothyronine) is a structural variant with much less physiologic potency in most target organs.[149]

Thyroid hormone synthesis and release are controlled primarily by thyroid-stimulating hormone (TSH)—a trophic hormone from the pituitary—and the supply of iodine. The thyroid hormones normally participate in a negative feedback loop that regulates TSH secretion (Figure 43-5) and thyrotropin-releasing hormone production in the hypothalamus.[150]

Thyroid hormones are highly bound to protein in the blood. In euthyroid nonpregnant humans, the normal total serum concentrations of T_4 and T_3 are 50 to

150 nmol/L and 1.4 to 3.2 nmol/L, respectively.[151] The unbound or free fractions of T_4 and T_3 are 0.03% and 0.3% of total circulating T_4 and T_3, respectively.[152] Similar proportions of T_4 and T_3 are distributed among the three major plasma proteins that bind thyroid hormones, which are (1) thyroxine-binding globulin (70% to 80%), (2) thyroxine-binding prealbumin or transthyretin (10% to 20%), and (3) albumin (10% to 15%).[153,154] The serum concentration of unbound or free T_4 is typically the major determinant of thyroid hormone activity in target tissues. Thyroid hormones are temporarily inert while bound to plasma proteins. Changes in the concentrations of thyroxine-binding proteins can occur during various physiologic states (e.g., pregnancy) and disease processes. Thyroid hormone action does not change with fluctuations in the total concentration of T_4 as long as the concentration of free T_4 remains constant.

Thyroid hormone is an endocrine regulator in many target organs (e.g., liver, kidneys, skeletal and cardiac muscles, brain, pituitary, placenta).[155] The defined physiologic effects of thyroid hormones are mediated by regulation of specific gene products. These effects include (1) somatic and nervous system development, (2) calorigenesis, (3) augmented skeletal and cardiac muscle performance, (4) intermediary metabolism, and (5) feedback control.[156]

In target tissues, the molecular actions of T_4 begin with the enzymatic deiodination of T_4 to T_3. Iodothyronine deiodinase is widely distributed in the body and occurs in three molecular forms.[157] Only 20% of the daily T_3 production is secreted by the thyroid gland; the rest is formed by peripheral deiodination.[158] In the classic model of thyroid hormone action, T_3 enters the nuclei of target cells, binds to specific thyroid hormone receptors, and alters genomic transcription of specific proteins.[159] Research has now characterized other mechanisms of thyroid hormone action, including mitochondrial transcription and cytoplasmic or cell-surface nontranscriptional effects.[160,161] The thyroid hormone receptor belongs to a family of structurally related, intracellular ligand-binding proteins.[160] Variations in the number and types of thyroid hormone receptors, as well as receptor linkage to development- or tissue-specific genomic expressions, provide additional levels of physiologic control and vulnerability to disease processes.[157]

Antithyroid medications may affect single or multiple steps in thyroid hormone synthesis and release, as well as concentrations of plasma binding proteins, deiodinase activity, and peripheral uptake of thyroid hormones.[153,162,163]

Laboratory evaluation of thyroid function consists of two measurements. First, the serum concentration of free T_4 can be directly measured or indirectly calculated. Second, the serum concentration of TSH is measured to assess the negative feedback loop that controls the thyroid gland. The TSH concentration is judged as appropriate or inappropriate in the context of the serum concentration of free T_4.

During normal human pregnancy, the serum concentration of thyroxine-binding globulin (TBG) steadily increases until it reaches a plateau at 20 weeks' gestation, when it is 50% greater than the nonpregnant level.[151] The greater concentration of TBG results from a prolonged half-life—not higher synthesis—during pregnancy.[154] The normal pregnant woman is euthyroid because the serum concentrations of free T_4 and T_3 are in the normal or low-normal range for nonpregnant humans.[151] However, the increased concentration of TBG means that total serum concentrations of T_4 and T_3 during pregnancy are at or above the upper limit of normal for nonpregnant women.[151,164]

Human chorionic gonadotropin (hCG) is a placental protein that shares some structural features with TSH. The serum concentrations of TSH and hCG have an inverse relationship during normal human pregnancy,[151] reflecting the mild TSH-like activity that results from increased plasma concentrations of hCG during early pregnancy.[165,166]

Maternal iodine availability is decreased during pregnancy because of greater fetal uptake and increased maternal renal clearance.[167] In geographic areas with marginal iodine supplies, the lower availability may predispose the mother to goiter unless she receives dietary iodine supplementation.[151,168,169]

Hyperthyroidism

Definition and Epidemiology

Hyperthyroidism is defined as an abnormal increase in the serum concentration of unbound or free thyroid hormones. The prevalence of hyperthyroidism in the general population is 0.2% to 1.9%, with a female-to-male ratio of 10:1.[170,171] The etiology of hyperthyroidism is listed in Box 43-5. Graves' disease is responsible for 70% to 90% of cases; thyroiditis and the combined category of toxic adenoma and toxic multinodular goiter each account for approximately 5% of cases. There are multiple levels of interaction between the thyroid and reproductive endocrine systems in women, with specific implications for patients with hyperthyroidism and hypothyroidism.[172]

BOX 43-5 Etiology of Hyperthyroidism

Abnormal Thyroid Stimulation

- Graves' disease
- Gestational trophoblastic neoplasia
- Thyroid-stimulating hormone–secreting pituitary tumor

Intrinsic Thyroid Autonomy

- Toxic adenoma
- Toxic multinodular goiter

Inflammatory Disease

- Subacute thyroiditis

Extrinsic Hormone Source

- Ectopic thyroid tissue
- Thyroid hormone ingestion

Modified from Houston MS, Hay ID. Practical management of hyperthyroidism. Am Fam Physician 1990; 41:909-16.

Pathophysiology

Graves' disease is an autoimmune thyroid disease.[170,173] Its etiology is likely multifactorial and includes both **environmental** (e.g., stress, hormones) and **genetic** influences. Several autoantibodies against thyroid tissue have been described in patients with this disease. Autoantibodies directed against the TSH receptor in the thyroid gland may either augment or inhibit TSH action, depending on their binding specificities. These antibodies are called **thyroid receptor antibodies (TRAbs)**. The binding specificities of TRAbs in the blood of each patient with Graves' disease affect the net thyroid-stimulating activity. Autoantibodies against thyroid peroxidase, the sodium-iodine cotransporter, and thyroglobulin also have been described in patients with Graves' disease.

Among untreated patients with Graves' disease, approximately 20% undergo spontaneous remission.[173] However, the prognosis for individual patients cannot be predicted from results of clinical or laboratory examinations.

Clinical Presentation and Diagnosis

Hyperthyroidism presents as a physiologic state dominated by an increased metabolic rate. A hyperthyroid symptom scale has been developed on the basis of the following 10 clinical factors: nervousness, sweating, heat intolerance, hyperactivity, tremor, weakness, hyperdynamic precordium, diarrhea, appetite, and level of incapacitation.[174] This symptom scale has been useful to follow the clinical course of patients with Graves' disease. Exophthalmos or infiltrative ophthalmopathy is clinically apparent in most patients.[173-175] Other physical signs may occur at low frequency, including pretibial myxedema or dermopathy (1% to 2%) and nail changes or acropachy (< 1%). The infiltrative ophthalmopathy in Graves' disease is caused by enlargement of both the extraocular muscle bodies and intraorbital adipose tissue. The pathogenetic mechanism involves abnormal accumulation of hyaluronic acid and edema within these tissues; the orbital fibroblast appears to be the primary target cell of this autoimmune process.[175]

Hyperthyroidism stimulates the cardiovascular system in excess of the underlying increased metabolic rate, resulting in a hyperkinetic circulatory state.[163,176] Myocardial contractility, heart rate, stroke volume, and ventricular size all increase, and peripheral vascular resistance decreases in skin and muscle. Thyroid hormones can affect the ratio of alpha- and beta-adrenergic receptors in the heart.[176] Cardiomyopathy can be demonstrated during exercise in hyperthyroid patients, independent of beta-adrenergic receptors; it is reversible with normalization of thyroid function.[177]

The diagnosis of hyperthyroidism depends on increased serum concentrations of unbound or free T_4. The more common forms of hyperthyroidism (e.g., Graves' disease, toxic adenoma, toxic multinodular goiter) may be differentiated from the less common forms by a radioiodine uptake study.[171] The identification of TSH receptor autoantibodies may have some role in distinguishing Graves' disease from toxic adenoma or multinodular goiter.[173]

Interaction with Pregnancy

Normal human pregnancy is a euthyroid state, with normal serum concentrations of unbound or free T_4 despite increased serum concentrations of TBG and total T_4. During pregnancy, hyperthyroidism results from the same causes as in nonpregnant patients (see Box 43-5). Graves' disease is the leading cause of hyperthyroidism during pregnancy, with a prevalence of 0.2%, which is lower than in the general population.[178-180] The lower prevalence may reflect a beneficial effect of the immunotolerance of pregnancy on autoimmune disorders such as Graves' disease.[173] Human pregnancy is also associated with a change in the specificity of TSH receptor antibody activity from stimulatory to blocking activity.[181]

Gestational trophoblastic neoplasms are frequently associated with elevated serum hCG concentrations. High concentrations of hCG may possess significant thyroid-stimulating bioactivity because of the structural homology between hCG and TSH.[165,182] Transient hyperthyroidism during pregnancy has been reported in association with hyperemesis gravidarum; hyperthyroidism and hyperemesis gravidarum may be parallel disease processes in pregnancy, with elevated hCG as a shared mechanism.[183] Hyperthyroidism can, on rare occasions, result from two coincident disease processes (e.g., Graves' disease, struma ovarii) in both pregnant and nonpregnant women.[184]

Thyroid nodules occur in 4% to 7% of adults. Pregnancy is associated with increases in the number and size of thyroid nodules.[185] Pregnancy probably does not affect the development or progression of thyroid carcinoma, but this conclusion remains controversial.[186,187] Evaluation of a thyroid nodule that presents during pregnancy should include (1) measurement of serum TSH and free T_4 concentrations, (2) ultrasonographic examination to determine whether the lesion is cystic or solid, and (3) fine-needle aspiration or percutaneous needle biopsy. Malignant lesions, depending on the level of cellular differentiation, can be resected in the second trimester or observed until after delivery.[187] Radioactive iodine therapy should be delayed until the postpartum period.[186]

Medical and Surgical Management

Current therapies for Graves' disease in *nonpregnant* patients include radioactive iodine, antithyroid medications, and surgery.[170,171]

Radioactive iodine is administered orally as iodine-131 (^{131}I) in a dose range of 30 to 75 mCi.[188] All forms of iodine are sequestered by the thyroid gland, and ^{131}I exerts a therapeutic effect in Graves' disease primarily through local emission of beta radiation. In most patients with Graves' disease, hypothyroidism develops after a therapeutic dose of radioactive iodine, necessitating careful follow-up and long-term thyroid hormone replacement therapy. In nonpregnant patients, the long-term health risks of radioactive iodine therapy are minimal.[188] Radioactive iodine therapy is *contraindicated*

in pregnancy, because all forms of iodine readily cross the placenta to the fetus. Currently recommended treatment is to delay pregnancy for 4 to 6 months after radioactive iodine therapy, although ^{131}I has a half-life of only 8 days.[188]

Propylthiouracil and **methimazole** are the antithyroid medications used to treat Graves' disease.[163,189] These drugs interfere with the incorporation of iodine into thyroglobulin and with subsequent coupling reactions in the thyroid gland, and propylthiouracil inhibits iodothyronine deiodinase in peripheral tissues. Typical oral doses are 5 to 15 mg two times daily for methimazole and 100 to 150 mg three times daily for propylthiouracil. The long-term clinical strategy is to adjust the dose downward as tolerated. Some patients with Graves' disease experience remission after the administration of an antithyroid medication. Asymptomatic agranulocytosis, with an incidence of 0.03% to 0.5%, is a rare complication of antithyroid medications; onset typically occurs within 3 months of initiating therapy. Another rare complication of propylthiouracil, fulminant hepatic necrosis, prompted an FDA safety alert in 2009.[190] If treatment with antithyroid medications is unsatisfactory, *nonpregnant* patients may receive radioactive iodine.

Surgical therapy for Graves' disease is typically reserved for patients unable or unwilling to undergo treatment with radioactive iodine or antithyroid medications.[171,191] Controversy exists about the choice between subtotal and total thyroidectomy; the surgeon must weigh the risk for recurrent hyperthyroidism against that of permanent hypothyroidism requiring supplementation.[191] Perioperative complications of thyroid surgery include (1) unilateral or bilateral vocal cord paralysis secondary to laryngeal nerve injury, (2) wound hematoma, (3) pneumothorax, (4) hypoparathyroidism, and (5) thyroid storm.[191] Hypocalcemia secondary to acute hypoparathyroidism may manifest as laryngospasm during the postoperative period.[192]

Adjunctive therapies for hyperthyroidism include iodine, radiocontrast agents, lithium, and glucocorticoids.[163,170] Beta-adrenergic receptor antagonists also have been used to decrease cardiovascular responses to higher concentrations of thyroid hormones.

Thyroid Storm. Thyroid storm, also known as thyroid crisis, is a life-threatening exacerbation or decompensation of a preexisting hyperthyroid state.[193-196] It is a clinical diagnosis based on the following signs and symptoms: (1) fever, (2) mental and emotional disturbances, (3) tachycardia, (4) tachypnea, (5) diarrhea, (6) congestive heart failure, and (7) atrial fibrillation. Without treatment, thyroid storm may progress to coma, multiorgan system failure, and death. The mortality rate approached 100% in earlier series, but improved therapy has reduced the mortality rate to less than 20%.[195]

In most cases, thyroid storm is associated with a precipitating event in a patient with untreated or incompletely treated hyperthyroidism (Box 43-6). Historically, the precipitating events reflect the common serious medical illnesses of a given era[193,194-196]; cases of thyroid storm were categorized as "surgical" or "medical" depending on whether the exacerbation occurred during the perioperative period. With improved perioperative management, the incidence of *surgical* thyroid storm has decreased markedly, and this terminology is rarely used in contemporary medical practice.

BOX 43-6 Events Associated with Precipitation of Thyroid Storm

- Surgery
- Childbirth
- Trauma
- Iodinated contrast agents
- Treatment with iodine-131
- Emotional stress
- Pulmonary embolism
- Stroke
- Infection
- Diabetic ketoacidosis
- Hypoglycemia
- Congestive heart failure
- Bowel infarction

From Roth RN, McAuliffe MJ. Hyperthyroidism and thyroid storm. Emerg Med Clin North Am 1989; 7:873-83.

In the past, 2% to 7% of patients hospitalized for hyperthyroidism experienced thyroid storm.[193,194,196] The current incidence of thyroid storm in hyperthyroid patients is difficult to determine but appears to be much lower. Akamizu et al.[197] estimated that the incidence of thyroid storm in Japan was 0.2 per 100,000 hospitalized patients between 2004 and 2008.

The mechanism of the development of thyroid storm is unknown. On the basis of the clinical presentation and known precipitating events, one hypothesis is that it is caused by increases in thyroid hormone and catecholamine secretion. Limited data suggest that total serum concentrations of T_4 and T_3 do not increase during thyroid storm in hyperthyroid patients,[198] although one case report suggests otherwise.[199] Alternatively, the precipitating event in thyroid storm may augment thyroid hormone action by increasing the circulating free fraction of thyroid hormones. This hypothesis is supported by data that demonstrate higher serum concentrations of free T_4 during thyroid storm as well as by observations of changes in thyroid hormone binding during fever or systemic illness.[200]

Catecholamine secretion may also play a role in the development of thyroid storm. In hyperthyroid patients without thyroid storm, the endogenous secretion of epinephrine and norepinephrine is normal, as are the cardiovascular responses to exogenous epinephrine and isoproterenol.[201,202] These parameters have not been measured during episodes of thyroid storm, but symptoms respond well to medications that block the synthesis or receptor binding of beta-adrenergic receptor agonists.[194] The role of the sympathetic nervous system in thyroid storm is supported by historical observations that spinal anesthesia to the fourth thoracic dermatome level is therapeutic.[203] It is unclear whether thyroid storm can develop with baseline catecholamine secretions; a surge of catecholamines may be necessary to trigger this condition.

BOX 43-7 Treatment of Thyroid Storm

General Supportive Measures

- Cooling blanket and ice
- Chlorpromazine (25-50 mg IV) or meperidine (25-50 mg IV) to diminish shivering
- Intravenous hydration
- Glucose and electrolyte replacement
- Acetaminophen
- Oxygen
- Glucocorticoids: dexamethasone (2-4 mg IV q8h) or hydrocortisone (100 mg IV q8h)
- B-complex multivitamins

Reduction of Synthesis and Secretion of Thyroid Hormones

- Antithyroid medications: propylthiouracil (200-400 mg orally q6-8h) or methimazole (20-25 mg orally q6h)
- Iodine: sodium iodide (1 g IV or Lugol's solution 4-8 drops orally q6-8h) or supersaturated potassium iodide solution (5 drops orally q6h)
- Glucocorticoids

Reduction of Peripheral Conversion of Thyroxine (T_4) to 3,5,3′-Triiodothyronine (T_3)

- Propylthiouracil
- Glucocorticoids
- Radiographic contrast agents
- Propranolol

Decrease in the Metabolic Effects of Thyroid Hormones

- Beta-adrenergic receptor antagonists (propranolol, esmolol)

Other Therapeutic Maneuvers

- Plasma exchange

Diagnosis and Treatment of the Underlying Illness That Precipitated the Thyroid Storm

IV, intravenous.
Modified from Nayak B, Burman K. Thyrotoxicosis and thyroid storm. Endocrinol Metab Clin North Am 2006; 35:663-86.

Box 43-7 outlines the treatment of thyroid storm. Several points merit discussion. Glucocorticoid supplementation is listed as a general supportive measure because endogenous glucocorticoid production is impaired in patients with hyperthyroidism.[204] Glucocorticoids also inhibit both thyroid hormone production and the peripheral conversion of T_4 to T_3.[173] Propylthiouracil and methimazole reduce thyroid hormone production, but only propylthiouracil inhibits the peripheral conversion of T_4 to T_3 (as discussed earlier). In addition to the relief of many symptoms of hyperthyroidism, propranolol inhibits the peripheral conversion of T_4 to T_3. This latter property of propranolol is not related to its beta-adrenergic receptor blocking activity and is not shared by most other beta-adrenergic receptor antagonists.[205,206] Because of its dual action, propranolol is the beta-adrenergic receptor antagonist of choice in cases of thyroid storm. Esmolol also has been used successfully during the treatment of thyroid storm (see later discussion).[207,208]

Thyroid storm is an acute hypermetabolic state that may be difficult to distinguish clinically from malignant hyperthermia; rhabdomyolysis is one of the few features of the latter disorder that has not also been reported in thyroid storm.[209] Three cases of thyroid storm treated with dantrolene have been reported.[210-212] Two patients survived, but the third succumbed to multiorgan system failure that antedated the dantrolene therapy. In another case, a patient with known Graves' disease undergoing subtotal thyroidectomy had an intraoperative hypermetabolic crisis that was initially diagnosed and treated as thyroid storm. The correct diagnosis of malignant hyperthermia was made on the basis of subsequent blood gas analysis, and the patient was successfully treated with dantrolene.[213] Plasma exchange is another unusual but effective therapeutic option in cases of thyroid storm.[214]

In summary, treatment of thyroid storm consists of general supportive measures and the administration of glucocorticoids, propylthiouracil, sodium iodide, and propranolol. It is reasonable to delay iodine treatment until 1 hour after the administration of propylthiouracil to avoid increased iodine use by the thyroid gland.

Preoperative Preparation. The risk for thyroid storm during the perioperative period can be minimized by appropriate preparation of the hyperthyroid patient. Most cases of perioperative thyroid storm involve thyroid surgery. The preoperative therapeutic goals are to inhibit thyroid hormone synthesis and secretion in patients with preexisting hyperthyroidism and to decrease the vascularity of the thyroid gland. The four main therapies used in preoperative preparation are administration of (1) an antithyroid medication (primarily propylthiouracil), (2) a beta-adrenergic receptor antagonist, (3) a glucocorticoid, and (4) iodine.[163,191,215] Iodine inhibits thyroid hormone secretion more effectively in hyperthyroid patients than in euthyroid patients because the latter are capable of mounting a compensatory TSH response as serum T_4 levels decrease.[216]

In some patients, beta-adrenergic receptor blockade may be sufficient to prevent perioperative thyroid storm,[217] although thyroid storm has been reported after preoperative preparation with propranolol alone.[218] In some of these cases, patients probably did not receive effective beta-adrenergic receptor blockade. A 25% reduction in exercise-induced heart rate is a better indication of adequate beta-adrenergic receptor blockade than a change in the resting heart rate.[215] One advantage of beta-adrenergic receptor antagonists over antithyroid medications is the shorter time typically required for preoperative preparation: (i.e., 2 weeks versus 6 to 8 weeks, respectively).[217] Several investigators have recommended preoperative preparation with a beta-adrenergic receptor antagonist, with the addition of iodine beginning 10 days before surgery.[215,219] The use of beta-adrenergic receptor antagonists entails a risk for hypoglycemia in hyperthyroid patients, because they have reduced hepatic glucose reserves and nonspecific beta-adrenergic receptor blockade results in a pharmacologic blunting of counterregulatory sympathetic responses.[215]

No prospective randomized studies have compared the efficacy of various methods for preoperative preparation of hyperthyroid patients. A reasonable clinical approach would include the use of multiple therapeutic agents (e.g., a beta-adrenergic receptor antagonist, iodine, glucocorticoid), with the doses titrated to the clinical response of each patient. The clinical parameters may include exercise-induced heart rate, fine tremor, weight gain, and recovery of muscle strength.[163]

Elective surgery should not proceed without adequate preoperative preparation of hyperthyroid patients. In cases of emergency surgery, physicians should use the therapies discussed for the treatment of thyroid storm (as discussed earlier) (see Box 43-7).

Medical and Surgical Management during Pregnancy. All of the therapeutic options used in nonpregnant hyperthyroid patients should be efficacious in pregnant women. However, the potential effects on the fetus dictate modifications in the options for treatment of hyperthyroidism during pregnancy.

Radioactive iodine is *contraindicated* during pregnancy because iodine readily crosses the placenta to the fetus. Fetal effects of inadvertent maternal administration of ^{131}I vary with gestational age.[188] Before 10 weeks' gestation, the risk to the fetus is less well defined and likely approximates that of a low-level dose of radiation during early development[188]; after 10 weeks' gestation, however, the fetal thyroid gland can sequester iodine, and ^{131}I may destroy or significantly damage the gland.

The mainstays of therapy for hyperthyroidism during pregnancy are the antithyroid medications **propylthiouracil** and **methimazole,**[170,178,179,189] which cross the placenta much more easily than the maternal thyroid hormones—potentially inducing fetal hypothyroidism and goiter. Although these agents are similar in efficacy for treatment of hyperthyroidism during pregnancy,[179,189] propylthiouracil has been used more frequently than methimazole. Propylthiouracil is favored in the first trimester of pregnancy, owing to rare congenital anomalies reported with methimazole (e.g., scalp defects, choanal atresia, tracheoesophageal fistula).[187,220,221] After the first trimester, therapy can be switched to methimazole if there are concerns for hepatotoxicity with propylthiouracil.

Surgical therapy (e.g., subtotal thyroidectomy) is generally reserved for pregnant women in whom medical therapy has failed.[191] The pregnant woman should receive preoperative preparation with a beta-adrenergic receptor antagonist, a glucocorticoid, and iodine to minimize the risk for thyroid storm. Clinical data suggest that treating maternal Graves' disease with iodine does not result in fetal hypothyroidism,[222] implying that short-term preoperative maternal treatment with iodine should be safe for the fetus.

One national database study of pregnant women undergoing thyroid or parathyroid surgery demonstrated a threefold increase in general complications compared with age-matched nonpregnant controls.[223] In pregnant patients with Grave's disease, surgical thyroidectomy may lead to fetal hyperthyroidism through a combination of autoimmune and medication effects.[224]

During pregnancy, **thyroid storm** is a rare hypermetabolic event. Prior reports of a 2% to 4% incidence among pregnant patients are probably overestimates of the true incidence.[197] Most contemporary cases of thyroid storm during pregnancy occur in patients with undiagnosed or undertreated preexisting hyperthyroidism.[225-227] Precipitating events for thyroid storm during pregnancy include infection, thyroid cancer, normal labor, hemorrhage, cesarean delivery, and eclampsia.[225-228]

Treatment of thyroid storm is identical for both pregnant and nonpregnant patients (as discussed earlier) (see Box 43-7). Despite an association with fetal growth restriction (also known as intrauterine growth restriction) or preterm labor,[229] beta-adrenergic receptor antagonists are commonly prescribed during pregnancy. **Propranolol** is the most widely used beta-adrenergic receptor antagonist for treatment of thyroid storm.

Several case reports have described the use of the beta-adrenergic receptor antagonist **esmolol** for treatment of hyperthyroidism in both pregnant and nonpregnant patients,[207,208] although laboratory and clinical observations suggest that maternal administration of esmolol may result in fetal bradycardia and acidosis.[230,231] Esmolol may be considered when propranolol is contraindicated or the patient's hemodynamic status requires the use of a short-acting beta-adrenergic receptor antagonist. Esmolol is preferred for patients with a relative contraindication to nonspecific beta-adrenergic receptor blockade (e.g., asthma). Patients with significant cardiomyopathy from hyperthyroidism, who may be very sensitive to beta-adrenergic receptor blockade,[177,232,233] may benefit from esmolol because the dose can easily be titrated to the desired effect.[234] Hyperthyroid cardiomyopathy during pregnancy or the puerperium may require invasive monitoring and the use of multiple medications that require titration.[225,235,236] Esmolol's short half-life allows a rapid reversal of effect if needed. Untreated hyperthyroidism is associated with secondary pulmonary hypertension.[237]

In general, maternal and fetal interests are best served by optimal maternal therapy. When the physician opts for maternal therapy that could, in theory, adversely affect fetal well-being, the rationale should be documented in the medical record.

Obstetric Management

Poorly controlled hyperthyroidism during pregnancy increases the risks for severe preeclampsia in the mother and for low birth weight in the newborn.[238] Pregnant patients with treated hyperthyroidism have perinatal outcomes similar to those for euthyroid parturients.[239] The presence of hyperthyroidism does not affect the obstetric management of preeclampsia. In a retrospective study, Davis et al.[225] suggested that early diagnosis and treatment of hyperthyroidism during pregnancy is associated with better maternal and fetal outcomes.

The use of a nonselective beta-adrenergic receptor antagonist may precipitate or aggravate preterm labor. In women with Graves' disease, the placental transfer of antithyroid medications or thyroid-stimulating antibodies may result in the development of **fetal goiter**,[240] which can interfere with vaginal delivery or lead to airway

obstruction in the newborn. Fetal goiter can be diagnosed with ultrasonography; fetal hypothyroidism can be diagnosed with percutaneous umbilical cord blood sampling and can be treated with intra-amniotic injections of thyroxine.[241] In pregnant women with Graves' disease, maternal serum concentrations of TRAbs during the third trimester may predict neonatal thyroid function.[242]

Normal somatic and intellectual development have been reported in the children of hyperthyroid mothers treated with antithyroid medications[243]; such treatment does not contraindicate breast-feeding (see Chapter 14).[189]

Anesthetic Management

No prospective randomized studies have evaluated the efficacy or safety of various anesthetic techniques in patients with hyperthyroidism. The following features of hyperthyroidism may affect anesthetic management: (1) the hyperdynamic cardiovascular system and the possibility of cardiomyopathy, (2) partial airway obstruction secondary to an enlarged thyroid gland, (3) respiratory muscle weakness, and (4) electrolyte abnormalities.[163,244]

Halpern[245] described two patients with uncontrolled hyperthyroidism who required anesthesia for cesarean delivery and suggested that either neuraxial or general anesthesia can be safely administered in these parturients. On the basis of theoretical concerns, he suggested the omission of epinephrine from the epidural solution of local anesthetic agent and the use of an alpha-adrenergic receptor agonist (e.g., phenylephrine) for the treatment of hypotension. Earlier clinical studies in nonpregnant subjects with spontaneous hyperthyroidism, however, have shown normal hemodynamic responses to exogenous epinephrine, norepinephrine, phenylephrine, and clonidine.[246,247] It therefore appears safe to use epinephrine to minimize local anesthetic uptake and toxicity during the administration of epidural anesthesia in both euthyroid and hyperthyroid patients.

Hyperthyroid women should receive glucocorticoid supplementation because they have a relative deficiency of glucocorticoid reserves.[204] It seems prudent to avoid medications associated with tachycardia (e.g., ketamine, atropine).[163,245] Patients with Graves' disease may have exophthalmos and therefore may require additional care to prevent corneal abrasions during general anesthesia.[245] Some investigators have emphasized the efficacy of deep preoperative sedation in nonpregnant hyperthyroid patients.[163,203] The routine use of this technique in pregnant patients is not recommended because of the risks for maternal aspiration and neonatal depression.

Adequate preoperative preparation minimizes the risk for perioperative thyroid storm; when time permits, the goal is to make the patient euthyroid. In an emergency, the hyperthyroid patient can be prepared for surgery with oral propylthiouracil, an intravenous glucocorticoid, sodium iodide, and propranolol. The anesthesia provider should be prepared to treat perioperative thyroid storm (see Box 43-7).

Hypothyroidism

Definition and Epidemiology

Hypothyroidism is defined as an abnormal decrease in the serum concentration of unbound or free thyroid hormones. The prevalence of hypothyroidism in the general population is 0.1% to 2%, which is similar to that of hyperthyroidism.[248] Hypothyroidism is more common in women and the elderly. Screening tests for hypothyroidism in asymptomatic nonpregnant adults are not recommended by the American Academy of Family Physicians.[249] When clinically indicated, the preferred screening test is a sensitive assay for serum TSH.

Pathophysiology

The etiology of hypothyroidism can be divided into primary and secondary categories (Box 43-8); primary hypothyroidism is more common than secondary hypothyroidism. The clinical manifestations of hypothyroidism result from withdrawal of thyroid hormone from its many target organs and tissues.

BOX 43-8 Causes of Hypothyroidism

PRIMARY

Autoimmune

- Hashimoto's thyroiditis
- Atrophic hypothyroidism

Iatrogenic

- Radioiodine therapy for hyperthyroidism
- Subtotal thyroidectomy

Pharmacologic

- Iodine deficiency or excess
- Lithium
- Amiodarone
- Antithyroid drugs

Congenital

- Dyshormonogenesis
- Thyroid gland dysgenesis or agenesis

SECONDARY

Pituitary Dysfunction

- Irradiation
- Surgery
- Neoplasm
- Sheehan's syndrome
- Idiopathic

Hypothalamic Dysfunction

- Irradiation
- Granulomatous disease
- Neoplasm

From Gain LA. The diagnostic dilemmas of hyperthyroxinemia and hypothyroxinemia. Adv Intern Med 1988; 33:185-203.

Clinical Presentation and Diagnosis

The clinical presentation of hypothyroidism is dominated by constitutional signs and symptoms such as dry skin, decreased sweating, hoarseness, paresthesia, periorbital edema, and delayed reflexes.[250] A diagnosis of hypothyroidism may be suggested by detection of the following factors during the preanesthetic history and physical examination: (1) a history of neck irradiation or radioiodine therapy; (2) the use of lithium, iodine, amiodarone, antithyroid medications, or thyroid replacement medications; and (3) a history of thyroid surgery or the presence of a surgical scar overlying the site of the thyroid gland.

By definition, hypothyroidism is diagnosed by measuring a decreased serum concentration of unbound or free T_4. In the presence of an intact feedback loop, the serum concentration of TSH should be increased in patients with primary hypothyroidism. The serum TSH concentration is a more sensitive indicator of primary hypothyroidism than the serum T_4 concentration and is therefore the best initial laboratory test in a patient with suspected hypothyroidism.[248,249]

Interaction with Pregnancy

The prevalence of hypothyroidism during pregnancy is 0.3% to 0.5%.[251] This estimate is based on laboratory screening of all obstetric patients in a given geographic area. Pregnant women likely exhibit overt or symptomatic hypothyroidism at a much lower rate than nonpregnant women. Hypothyroid women have a lower fertility rate than euthyroid women; this difference reflects neuroendocrine and ovarian dysfunction.[172,252] The immunosuppressive effects of pregnancy may lead to a temporary improvement of Hashimoto's thyroiditis during pregnancy.

Medical Management

Hypothyroidism is treated by replacement therapy with oral thyroid hormones. The medication most commonly used in replacement therapy is **levothyroxine,**[253] which has a half-life of 7 days. Numerous studies have shown that the required replacement dose of thyroid hormone in hypothyroid women often increases during pregnancy.* Ideally, the increased dose of thyroid hormone replacement will begin as soon as pregnancy is recognized, and it will be titrated to serum TSH levels at 4-week intervals during the first half of pregnancy.[220,254,255]

Obstetric Management

Hypothyroidism is associated with an increased incidence of the following obstetric complications: anemia, preeclampsia, fetal growth restriction, gestational diabetes, preterm delivery, placental abruption, and postpartum hemorrhage.[178,251,256-258] However, several reports have emphasized successful pregnancy outcomes in some hypothyroid patients.[259,260] Early diagnosis and treatment of hypothyroidism appear to be associated with improved maternal and fetal well-being.

In most instances of maternal hypothyroidism, neonatal thyroid function is normal because fetal thyroid development is typically independent of maternal thyroid function. The fetus, however, depends on maternal thyroxine until the fetal thyroid system is fully functional at approximately 20 weeks' gestation. Therefore, maternal hypothyroidism in the first half of pregnancy may affect fetal brain development. In addition, fetal hypothyroidism during the second half of pregnancy may also affect normal maturation of the CNS.[261] With universal screening of neonates for hypothyroidism, these neonates should be readily identified. Published data suggest that cognitive development is relatively normal in hypothyroid infants who receive appropriate thyroid hormone replacement with an initial dose of 10 to 15 μg/kg/day.[262] Controversy continues on the issue of screening pregnant women for hypothyroidism with serum TSH levels. It is unclear whether screening should be universally applied to all pregnant women or restricted to a high-risk subgroup identified by medical history.[220,221,251,263-265] The current recommendations favor the second approach, but additional clinical studies are underway.[187,266,267]

Anesthetic Management

The clinical manifestations of hypothyroidism that may affect anesthetic management include the following[268-278]:

- Reversible myocardial dysfunction
- Coronary artery disease
- Reversible defects in hypoxic and hypercapnic ventilatory drives
- Obstructive sleep apnea
- Paresthesias
- Prolonged somatosensory-evoked potential central conduction time
- Abnormal peripheral nerve conduction
- Increased peripheral nociceptive thresholds
- Hyponatremia
- Decreased glucocorticoid reserves
- Anemia
- Abnormal coagulation factors and platelets

Hypothyroid patients may have an abnormal response to peripheral nerve stimulation that decreases the clinical use of a nerve stimulator during neuromuscular blockade.[279] Clinical studies of vasopressors in nonpregnant hypothyroid patients show normal responses to exogenous epinephrine and diminished responses to phenylephrine.[280,281]

Whether elective surgery should or should not be delayed in order to treat hypothyroidism adequately is controversial.[282] Patient safety issues may justify such a delay. For emergency procedures, anesthesia care should include glucocorticoid supplementation. **Myxedema** (hypothyroid) coma is likely the only circumstance in which acute intravenous thyroid hormone replacement is indicated.[195] In most hypothyroid patients, acute intravenous replacement therapy entails a significant risk for myocardial ischemia.[270]

No prospective randomized studies have compared the safety or efficacy of various anesthetic techniques in

*References 178, 180, 187, 220, 221, 248, 251.

pregnant or nonpregnant hypothyroid patients. Hypothyroidism is associated with qualitative platelet dysfunction and is a rare cause of acquired von Willebrand's disease.[278,283,284] The anesthesia provider should use findings from the history and physical examination as well as laboratory testing to verify the presence of normal coagulation before administering neuraxial anesthesia to the patient with severe untreated hypothyroidism. Although epidural hematoma represents a theoretical risk in such patients, there are no published reports of this complication in this patient population.

PHEOCHROMOCYTOMA

Definition and Epidemiology

Paragangliomas are a heterogeneous group of tumors that develop from neural crest–derived chromaffin cells.[285,286] Pheochromocytomas are paragangliomas that arise in the adrenal medulla (90%) or in the adjacent sympathetic nervous system tissues.[285,286] Extra-adrenal paragangliomas may develop from sympathetic or parasympathetic tissues and include such diverse neoplasms as glomus tumors, chemodectomas, carotid body tumors, and jugulotympanic tumors.[287] Pheochromocytomas occur bilaterally (e.g., in the medulla of both adrenal glands) in 5% to 10% of cases.[288] Approximately 10% of pheochromocytomas are malignant.[288,289] Histopathologic features are not reliable predictors of malignancy[290]; however, large tumor size, extra-adrenal location, and certain tumor susceptibility gene mutations (e.g., succinate dehydrogenase subunit B) are associated with malignant pheochromocytomas.[287]

Pheochromocytomas occur in 0.1% to 0.2% of hypertensive adults.[286] Men and women are affected relatively equally, and the peak incidence varies between the third and seventh decades of life.

Pheochromocytoma is one of the tumors found in two of the **multiple endocrine neoplasia (MEN)** syndromes, **MEN 2A** (e.g., medullary thyroid carcinoma, hyperparathyroidism, pheochromocytoma) and **MEN 2B** (e.g., medullary thyroid carcinoma, mucocutaneous neuromas, pheochromocytoma).[291] Other disease processes associated with pheochromocytoma include von Recklinghausen's disease, von Hippel–Lindau disease, Sturge-Weber syndrome, and tuberous sclerosis. At least 10 distinct genetic mutations have been identified in patients with paragangliomas; the estimated rate of the familial form of pheochromocytoma is 30%.[285,287] There is an evolving concept of combined genotype/biochemical phenotype classifications to predict the clinical behavior of pheochromocytomas in individual patients.[292]

Pathophysiology

The pathophysiology of pheochromocytoma is related almost entirely to the systemic effects of its endocrine secretory products, typically norepinephrine and epinephrine. Some pheochromocytomas may, however, secrete other catecholamines (e.g., dopamine, dihydroxyphenylalanine [DOPA]) or peptide hormones. In an individual patient, the clinical manifestations of pheochromocytoma represent the net systemic effects of the tumor's secretory products.

TABLE 43-3 Symptoms of Pheochromocytoma during Paroxysmal Attacks

Symptom	Patients Affected in Previous Series (%)		Patients Affected in Ross & Griffith Series (%)
	MEAN	RANGE	
Headache	59.9	43-80	57
Sweating	52.2	37-71	61
Palpitations	49.2	44-71	63
Pallor	42.9	42-44	43
Nausea	34.5	10-42	33
Tremor	33.5	30-38	13
Anxiety	28.9	15-72	30
Abdominal pain	25.8	5-62	14
Chest pain	25.0	19-50	0
Weakness	19.4	8-58	25
Dyspnea	17.0	15-39	23
Weight loss	16.5	14-23	7
Flushing	14.8	10-19	4
Visual disturbances	12.4	11-22	19

From Ross EJ, Griffith DN. The clinical presentation of phaeochromocytoma. Q J Med 1989; 71:485-96.

Clinical Presentation and Diagnosis

Patients with pheochromocytoma can have a variety of common or uncommon symptoms.[285-291] Patients typically have **paroxysmal symptoms** because of the episodic nature of hormone secretion by the tumor (Table 43-3). The most common symptoms are sweating, tachycardia, and headaches; one study suggested that the diagnosis of pheochromocytoma can be excluded with 99.9% certainty if a patient does not have these symptoms.[293] The attacks may remain the same or the symptoms may evolve over time.[289] Pallor is common and flushing is uncommon in patients with pheochromocytoma. Paroxysmal symptoms may be triggered by a wide variety of physical activities that patients learn to avoid.[289] Typically, these activities directly or indirectly increase the pressure around the tumor. As the tumor grows, the attacks may last longer and occur more frequently.[289]

The ability of pheochromocytomas to mimic other diseases has frustrated and confused several generations of physicians. In one series of patients with pheochromocytoma, 76% of the tumors were not diagnosed before autopsy.[289] Reports include numerous examples of pheochromocytomas that were initially confused with other medical or psychiatric disorders.[294-296] In addition to their systemic endocrine effects, pheochromocytomas can occasionally cause local abdominal symptoms.[297]

Hypertension is a common but not universal finding, occurring in 77% to 98% of patients with pheochromocytoma.[289] Although most patients have paroxysmal episodes of hypertension, half may also experience

sustained hypertension.[286] **Orthostatic hypotension** occurs in 70% of patients.[289,291] The presumed mechanisms for orthostatic hypotension are chronic vasoconstriction with intravascular volume depletion and impaired reflex responses secondary to receptor down-regulation or synaptic effects of circulating catecholamines.[289,291]

The current approach to the diagnosis of pheochromocytoma involves the following three steps: (1) biochemical testing for increased catecholamine secretion, (2) anatomic imaging, and (3) functional imaging.[285,286] Catecholamine secretion is evaluated by measuring norepinephrine and epinephrine or concentrations of their metabolites (normetanephrine, metanephrine, or vanillylmandelic acid) in plasma or urine samples. Although the relative merits of these laboratory tests have been debated for years, a consensus has emerged in favor of measuring the plasma concentration of free metanephrines as the initial laboratory test.[286,287,292,298-300]

Conversion of norepinephrine and epinephrine to the respective metanephrines by catecholamine-*O*-methyl transferase occurs to a large extent within the pheochromocytoma before secretion.[298] Several medical conditions may confound the diagnosis of pheochromocytoma by altering the plasma and urinary concentrations of catecholamine metabolites. These conditions include congestive heart failure, acute myocardial infarction, stroke, cocaine abuse, sleep apnea, and ethanol or clonidine withdrawal.[301] Medications that alter normal catecholamine secretion and metabolism include tricyclic antidepressants, acetaminophen, hydralazine, and beta-adrenergic receptor antagonists.[302] Chromogranin-A is a protein found with catecholamines inside secretory vesicles within pheochromocytoma and normal adrenal medullary cells. Originally, chromogranin-A was thought to be a packaging protein in secretory vesicles, but it is now recognized as a prohormone for several peptide hormones, including vasostatin.[303] The measurement of plasma concentrations of chromogranin-A is a confirmatory laboratory test for pheochromocytoma.[304,305]

For patients in whom initial laboratory findings are equivocal, a clonidine suppression test can be performed.[286,287] The basis of the test is that clonidine fails to suppress catecholamine secretion by pheochromocytoma cells.

After the laboratory diagnosis is confirmed, the pheochromocytoma is localized with anatomic and functional imaging.[306] The major anatomic imaging modalities are computed tomography (CT) and magnetic resonance imaging (MRI). Functional imaging relies on labeled compounds with a high affinity for pheochromocytoma cells. Meta-iodobenzylguanidine (MIBG) is an analogue of norepinephrine, and ^{123}I-MIBG is commonly used for scintigraphic localization. Positron emission tomography (PET) with either fluorine-18 (^{18}F)-fluoro-2-deoxy-D-glucose (^{18}F-FDG) or ^{18}F-fluoro-L-3,4-dihydroxyphenylalanine (^{18}F-DOPA) can be used to localize pheochromocytomas.[306]

Interaction with Pregnancy

Pheochromocytoma is rare during pregnancy, with an overall incidence estimated to be less than 0.2 per 10,000 pregnancies.[307] Although pregnancy may accelerate the growth of some tumors, no data suggest that it does so for pheochromocytoma.[308] Both sporadic and familial types of pheochromocytoma, as well as benign and malignant forms, may occur during pregnancy. Case reports have demonstrated specific tumor susceptibility gene mutations in pregnant patients who have familial cases of pheochromocytoma.[309-312]

Clinical signs and symptoms of pheochromocytoma are similar in pregnant and nonpregnant patients.[307,313] Noninvasive hemodynamic measurements demonstrated intense vasoconstriction and decreased cardiac output during episodes of hypertension in two pregnant patients with pheochromocytoma.[314,315] The clinical recognition of pheochromocytoma during pregnancy is especially difficult because of its rarity and its similarity to preeclampsia, a common obstetric disease.[316,317] The diagnosis of pheochromocytoma before labor and delivery may reduce maternal mortality from 35% to near zero.[307] Easterling et al.[315] demonstrated that either an inverse relationship between blood pressure and heart rate or an increasing hematocrit during treatment with a beta-adrenergic receptor antagonist in a patient with suspected preeclampsia suggests the presence of pheochromocytoma. Pheochromocytoma may also manifest in the early postpartum period after an unremarkable vaginal delivery.[318,319]

Plasma concentrations of epinephrine, norepinephrine, and dopamine in normal pregnant women do not differ significantly from those in nonpregnant controls.[320] These data suggest that the same threshold levels can be used to interpret most laboratory test results (except urinary norepinephrine and normetanephrine) for the diagnosis of pheochromocytoma in pregnant and nonpregnant patients. During pregnancy, ultrasonography or MRI is most commonly used for anatomic imaging of pheochromocytomas.[306] One case report described functional PET/CT imaging of a pheochromocytoma during pregnancy using ^{18}F-FDG.[321] However, this imaging was delayed until 21 weeks' gestation to minimize the fetal radiation effects.

Medical and Surgical Management

Definitive therapy for pheochromocytoma is surgical resection of the tumor.[286,322] The greatest challenge in perioperative management is to prevent or effectively treat wide swings in hemodynamic measurements. The patient is at risk for severe hypertension during induction of anesthesia and surgical manipulation of the tumor; severe hypotension frequently occurs after excision of the tumor because of an abrupt decline in circulating concentrations of catecholamines.

Preoperative Preparation

The preoperative preparation of a patient with pheochromocytoma relies on pharmacologic therapy to return the patient to a near-normal physiologic state. Patients with a norepinephrine-dominant pheochromocytoma have intense peripheral vasoconstriction and severe intravascular volume depletion. In these patients, preoperative

preparation includes alpha-adrenergic receptor blockade and intravascular volume repletion.[286,323,324] The most commonly used alpha-adrenergic receptor antagonist is **phenoxybenzamine**. The initial dose is 10 mg orally twice a day, titrated upward to 40 to 50 mg twice a day. **Doxazosin, prazosin,** and **phentolamine** are other alpha-adrenergic receptor antagonists that have been used successfully.[323-325] Beta-adrenergic receptor antagonists may be added to treat arrhythmias, but their use must be preceded by effective alpha-adrenergic receptor blockade to prevent a paradoxical hypertensive response.[323,324] Beta-adrenergic receptor blockade must be individualized because patients with pheochromocytoma are at risk for catecholamine-induced cardiomyopathy.[326]

The administration of **nicardipine**, a calcium entry–blocking agent, is an alternative approach in the preoperative preparation of these patients.[324,327] **Metyrosine** is another therapeutic option that interferes with catecholamine synthesis; it has been used as an adjunct to preoperative alpha-adrenergic receptor blockade at doses of 250 to 1000 mg orally twice a day.[323,328] Patients whose symptoms or early responses to alpha-adrenergic receptor blockade suggest an epinephrine-dominant pheochromocytoma may need beta-adrenergic receptor blockade as primary preoperative therapy.[329]

Alpha-adrenergic receptor blockade with phenoxybenzamine is the most commonly used technique for preoperative preparation of the patient with pheochromocytoma.[286,323] Administration of a long-acting alpha-adrenergic receptor antagonist (e.g., phenoxybenzamine) may be desirable before tumor excision but can contribute to hypotension after tumor removal.[330] Prospective randomized studies comparing different methods of patient preparation have not been performed. A retrospective review of patients with pheochromocytoma who were treated preoperatively with phenoxybenzamine, prazosin, or doxazosin suggests that all of these agents are effective and safe.[331] Regardless of the method chosen, the patient must be prepared adequately for surgery. Adequate preparation could be the major reason for the recent decline in operative mortality in patients with pheochromocytoma. Hull[329] stated, "Emergency surgery to remove a phaeochromocytoma from an unprepared patient should never be contemplated." Roizen and Fleisher [332] have established four widely accepted criteria for adequate preoperative alpha-adrenergic receptor blockade in patients with pheochromocytoma (Box 43-9). Most patients require 10 to 14 days of treatment to meet these criteria.[319] Individual reports of rapid preoperative patient preparation techniques for pheochromocytoma resection (e.g., intravenous urapidil plus magnesium) will need additional confirmation before they become mainstream clinical practices.[333]

BOX 43-9 Criteria for Adequate Preoperative Alpha-Adrenergic Blockade in Patients with Pheochromocytoma

1. No in-hospital blood pressure reading higher than 165/90 mm Hg should be evident for 48 hours before surgery. Arterial blood pressure can be measured every minute for 1 hour in a stressful environment (e.g., postanesthesia care unit). If no reading is greater than 165/90 mm Hg, this criterion is considered satisfied.
2. Orthostatic hypotension should be present, but blood pressure on standing should not be lower than 80/45 mm Hg.
3. The electrocardiogram should be free of ST-segment/T-wave changes that are not permanent.
4. No more than one premature ventricular contraction should occur every 5 minutes.

Modified from Roizen MF, Fleisher LA. Anesthetic implications of concurrent diseases. In Miller RD, editor. Anesthesia. 7th edition. New York, Churchill Livingstone, 2009:1067-149.

Intraoperative Management

Intraoperative management includes the treatment of episodic **hypertension** and **tachycardia** *before* excision and treatment of profound **hypotension** *after* excision. Many medications have been used successfully to manage intraoperative hypertension and tachycardia, including calcium entry–blocking agents, nitroprusside, nitroglycerin, esmolol, magnesium sulfate, dexmedetomidine, and adenosine.[324,327,334-339] Because of the episodic nature of catecholamine secretion and the change in cardiovascular status that occurs after tumor excision, the use of agents with a short duration of action may be advantageous. The successful use of various regimens implies that the intraoperative treatment of hypertension and tachycardia depends more on the vigilance and skill of the anesthesia provider than on the specific medication used.

Intraoperative monitoring of a patient with pheochromocytoma should include the use of standard monitors, an intra-arterial catheter, and a Foley catheter. Ongoing assessments of cardiac contractility and cardiac filling pressures and volumes facilitate the successful treatment of catecholamine-induced cardiomyopathy or postexcision hypotension. This information may be acquired via a pulmonary artery catheter or transesophageal echocardiography.[340] Laparoscopic resection of pheochromocytomas has almost completely replaced open surgical approaches, except for very large or malignant tumors.[341] Laparoscopic resection is associated with a shorter hospitalization and greater patient satisfaction.[342] In a small study, patients undergoing laparoscopic resection of a pheochromocytoma were randomized to receive one of two different intra-abdominal pressures during the carboperitoneum (either 8 to 10 or 15 mm Hg).[343] Patients with lower intra-abdominal pressure had less perioperative catecholamine release and fewer hemodynamic fluctuations than patients with higher intra-abdominal pressure. A retrospective review of 143 patients who underwent predominantly open resection of pheochromocytoma or paraganglioma at the Mayo Clinic from 1983 to 1996 showed a 25% incidence of sustained intraoperative hypertension but very few serious perioperative complications.[344]

Hypoglycemia may also be a serious problem after the resection of a pheochromocytoma.[345,346] Insulin secretion is inhibited by alpha-adrenergic receptor stimulation, and removal of the tumor may result in a rebound

of insulin release. Blood glucose concentration should be measured frequently after pheochromocytoma excision.

Medical therapy for pheochromocytoma is used only as a temporizing measure during pregnancy or in patients with inoperable or metastatic disease. Pheochromocytoma recurs in 6.5% of patients who have undergone complete surgical resection.[347]

Management during Pregnancy

When pheochromocytoma presents during pregnancy, surgical resection of the tumor is the preferred therapy.[307,314,348] A variety of clinical strategies have been associated with successful obstetric and surgical outcomes. They include (1) open or laparoscopic tumor resection at 16 to 23 weeks' gestation followed by vaginal or cesarean delivery at term,[349-352] (2) cesarean delivery with concurrent open tumor resection,[353] (3) cesarean delivery with open or laparoscopic tumor resection 2 to 8 weeks later,[313,354,355] and (4) vaginal delivery with laparoscopic tumor resection 6 weeks later.[349] A number of case reports describe successful laparoscopic resection of abdominal pheochromocytoma during pregnancy between 12 and 23 weeks' gestation with good maternal and fetal outcomes.[350,351,352] These reports include one robotic case and one set of twins. Before 24 weeks' gestation, surgery should proceed as soon as the patient is adequately prepared with adrenergic blockade.[322,356] After 24 weeks' gestation, the gravid uterus represents a mechanical obstruction to surgery for most abdominal pheochromocytomas. Women with pregnancy at this gestational age should receive adrenergic blockade for the remainder of the pregnancy, or until the tumor is removed.[322]

Phenoxybenzamine, the most widely used medication for preoperative preparation of the pregnant woman with pheochromocytoma, easily crosses the placenta.[356] A case series suggested that neonates should be monitored closely in an intensive care nursery after intrauterine exposure to phenoxybenzamine.[357] Other alpha-adrenergic receptor antagonists have been used successfully in pregnant patients with pheochromocytoma, including phentolamine, prazosin, and doxazosin.[307,348,358] Beta-adrenergic receptor blockade may be added if needed to control tachycardia or arrhythmias or to treat an epinephrine-dominant pheochromocytoma. Beta-adrenergic receptor antagonists that have been used successfully in pregnant patients with a pheochromocytoma include propranolol, atenolol, and metoprolol.[307,356,358] Clinical experience with metyrosine during pregnancy is very limited.[307] The current package insert lists metyrosine as a "pregnancy category C drug." Pending further assessment of safety during pregnancy, the use of metyrosine in pregnant women with pheochromocytoma should be restricted to those whose tumors are resistant to adrenergic blockade.

Medications that have been used successfully to control intraoperative hypertension and tachycardia in pregnant patients with pheochromocytoma include phentolamine, nitroprusside, nitroglycerin, magnesium sulfate, propranolol, remifentanil, esmolol, and hydralazine.[313,359,360] Esmolol, however, may not be an ideal medication during pregnancy (as discussed earlier).[228,229,230] The safety of maternal administration of nitroprusside has also been questioned because of possible fetal cyanide toxicity.[361] Adverse effects were noted in fetal lambs when high doses of nitroprusside were administered in pregnant ewes in which tachyphylaxis had developed.[361] Clinical case reports suggest that a low-dose maternal infusion of nitroprusside (approximately 1 μg/kg/min) should be safe during the peripartum period.[362,363] If maternal tachyphylaxis develops, nitroprusside should be discontinued and a different vasodilator used. Nitroprusside reduces uteroplacental vascular resistance in hypertensive sheep, and it antagonizes norepinephrine-induced uterine artery vasoconstriction in humans and guinea pigs.[364-366] These data suggest theoretical advantages for the perioperative use of nitroprusside in pregnant women with pheochromocytoma.

In summary, early diagnosis of pheochromocytoma during pregnancy and adequate adrenergic receptor blockade are essential to optimize maternal and fetal safety. Phenoxybenzamine is used for preoperative preparation of the pregnant patient. If beta-adrenergic receptor blockade is necessary, metoprolol can be used unless specifically contraindicated. During surgery, short-acting, titratable cardiovascular medications are preferred. Monitoring and therapy should be directed toward optimization of preload, afterload, and cardiac contractility for a patient with rapid changes in circulating concentrations of catecholamines. Attention to detail is likely more important than the choice of specific medications.

Obstetric Management

Pheochromocytoma during pregnancy is associated with an increased incidence of fetal death and fetal growth restriction.[307] The presumed mechanism is decreased uterine blood flow secondary to catecholamine secretion by the tumor; the metabolic activity of the placenta is an effective barrier to the transplacental passage of maternal catecholamines.[367] When pheochromocytoma is diagnosed and effective maternal alpha-adrenergic receptor blockade is instituted before delivery, the fetal death rate declines from 50% to near zero.[322]

Placental abruption has been reported in patients with pheochromocytoma.[368] From a hemodynamic standpoint, this process may be analogous to the occurrence of placental abruption in patients with acute cocaine intoxication.[369] Pheochromocytoma and preeclampsia may have overlapping clinical presentations; proteinuria, for example, occasionally occurs in patients with pheochromocytoma.[370]

To avoid the increased abdominal pressure on the tumor that can occur during active labor, cesarean delivery is preferred in patients with an unresected pheochromocytoma.[307,368]

Anesthetic Management

Preoperative preparation and intraoperative monitoring and management have already been discussed. A variety of general anesthetic agents as well as spinal and epidural anesthesia have been successfully used in nonpregnant

BOX 43-10 Perioperative Medications to Avoid in Patients with Pheochromocytoma

- Atracurium
- Droperidol
- Glucocorticoids
- Metoclopramide
- Morphine
- Pancuronium
- Pentazocine
- Succinylcholine
- Vancomycin

These medications may, either directly or indirectly, increase the release of catecholamines by the tumor.
Information from references 329 and 371.

patients with pheochromocytoma.[324,329] Box 43-10 lists perioperative medications that should be avoided to minimize hormone secretion by a pheochromocytoma. A case series of nonpregnant patients suggested that exogenous glucocorticoids can unpredictably trigger a pheochromocytoma crisis,[371] but this observation requires further confirmation. There are two published cases of nonpregnant patients with pheochromocytoma who were incorrectly diagnosed intraoperatively with malignant hyperthermia.[372,373] Manipulation of a pheochromocytoma during resection may result in a small increase in end-tidal carbon dioxide[374]; it is unlikely, however, that the modest magnitude of this effect would be confused with malignant hyperthermia.

In pregnant women with pheochromocytoma, analgesia during labor is not usually a concern because cesarean delivery is preferred. Cesarean delivery, with or without concurrent tumor resection, has been accomplished safely with **general anesthesia**,[313,353,358,360] **epidural anesthesia**,[354,359,375] and **combined epidural-general anesthesia**.[355] There are no prospective randomized studies of the anesthetic management of pregnant women with pheochromocytoma. It seems reasonable to avoid abrupt hemodynamic changes and to avoid the medications listed in Box 43-10. Either neuraxial or general anesthesia for cesarean delivery should be selected on the basis of factors other than the presence or absence of a pheochromocytoma. The care with which anesthesia is administered is probably more important than the specific technique selected.

KEY POINTS

- Pregnancy is characterized by a progressive increase in peripheral insulin resistance.
- Insulin requirements decrease during the first stage of labor, increase during the second stage, and decrease again after delivery.
- Maternal diabetes mellitus is associated with a higher incidence of polyhydramnios, preterm labor, preeclampsia, fetal macrosomia, neonatal hypoglycemia, and cesarean delivery.
- Fetal structural malformations are the leading cause of perinatal mortality in diabetic parturients; strict glycemic control before conception reduces the risk.
- Normal pregnancy is a euthyroid state because serum concentrations of unbound or free thyroid hormones are within the normal nonpregnant range.
- Thyroid storm is a rare but life-threatening disorder during pregnancy. It is best prevented by effective treatment of preexisting hyperthyroidism and adequate preparation of the patient for surgery.
- The required dose of thyroid hormone replacement medication increases during pregnancy; neonatal thyroid function is normal in most cases of maternal hypothyroidism.
- Maternal and fetal safety is enhanced by early diagnosis of pheochromocytoma and effective adrenergic receptor blockade before resection.
- At the time of pheochromocytoma resection, the anesthesiologist should anticipate the potential for (1) episodic hypertension and tachycardia during manipulation of the tumor and (2) severe hypotension after tumor resection.
- For women with an unresected pheochromocytoma, cesarean delivery is preferred.[375]
