CURRENT

Pediatric Diagnosis & Treatment

17th Edition

Edited by

William W. Hay, Jr., MD

*Professor, Department of Pediatrics
Section of Neonatology and the Division of Perinatal
Medicine and Research
University of Colorado School of Medicine and
The Children's Hospital, Denver*

Myron J. Levin, MD

*Professor, Departments of Pediatrics and Medicine
University of Colorado School of Medicine and
The Children's Hospital, Denver*

Judith M. Sondheimer, MD

*Professor, Department of Pediatrics, and Head, Section
of Pediatric Gastroenterology, Hepatology, and Nutrition
University of Colorado School of Medicine and
The Children's Hospital, Denver*

Robin R. Deterding, MD

*Associate Professor, Department of Pediatrics, Section of
Pediatric Pulmonary Medicine
University of Colorado School of Medicine and
The Children's Hospital, Denver*

and Associate Authors

*The Department of Pediatrics at the University of
Colorado School of Medicine is affiliated with
The Children's Hospital of Denver, Colorado.*

Contents

Authors	xi
Preface	xix
1. The Newborn Infant	1
<i>Elizabeth H. Thilo, MD, & Adam A. Rosenberg, MD</i>	
Evaluation of the Newborn Infant History 1	Infections in the Newborn Infant 49
Care of the Well Newborn Infant 8	Hematologic Disorders in the Newborn Infant 58
Common Problems in the Term Newborn Infant 11	Renal Disorders in the Newborn Infant 61
Neonatal Intensive Care 26	Neurologic Problems in the Newborn Infant 62
Cardiac Problems in the Newborn Infant 43	Metabolic Disorders in the Newborn Infant 64
Gastrointestinal & Abdominal Surgical Conditions in the Newborn Infant 46	
2. Child Development & Behavior	66
<i>Edward Goldson, MD, & Ann Reynolds, MD</i>	
Normal Development 66	Common Developmental Concerns 86
Behavioral & Developmental Variations 85	Developmental Disorders 93
Normality & Temperament 85	
3. Adolescence	102
<i>David W. Kaplan, MD, MPH, & Kathryn Love-Osborne, MD</i>	
Guidelines for Adolescent Preventive Services 104	Breast Disorders 125
Growth & Development 113	Gynecologic Disorders in Adolescence 128
Behavior & Psychological Health 115	
4. Substance Abuse	147
<i>Paritosh Kaul, MD, & Catherine Stevens-Simon, MD</i>	
Scope of the Problem 147	Predicting the Progression From Use to Abuse 155
Morbidity Associated with Substance Abuse 152	Management of Substance Abuse 156
Supplement Use and Abuse 154	Treatment & Referral 160
Response to the Problem 155	Prevention of Substance Abuse 164
5. Eating Disorders	165
<i>Eric J. Sigel, MD</i>	
Etiology 165	Complications 170
Incidence 166	Treatment 172
Predisposing Factors 166	Prognosis 175
Diagnosis 166	
6. Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics	176
<i>Jennifer Hagman, MD, & Donald W. Bechtold, MD</i>	
Psychosocial Aspects of Child Development & Family Life 176	Screening for Psychosocial Problems & Psychiatric Disorders Within the Context of Health Maintenance Visits 184
Challenges in Parenting Related to Child & Adolescent Development 179	Psychiatric Disorders of Childhood & Adolescence 188
The Chronically Ill Child 182	Overview of Pediatric Psychopharmacology 210

7. Child Abuse & Neglect 221
Andrew P. Sirotnak, MD, & Richard D. Krugman, MD
Forms of Child Maltreatment 221
Recognition of Abuse & Neglect 222
Management & Reporting of Child Abuse & Neglect 225
Prevention of Child Abuse & Neglect 225

8. Ambulatory & Community Pediatrics 227
Robert M. Brayden, MD, Matthew F. Daley, MD, & Jeffrey M. Brown, MD, MPH
Pediatric History 227
Pediatric Physical Examination 228
Health Supervision Visits 230
Other Types of General Pediatric Services 240
Common General Pediatric Issues 244

9. Immunization 248
Matthew F. Daley, MD, Ann-Christine Nyquist, MD, MSPH, & Eric A. F. Simoes, MD, DCH
The Composition of Immunizing Agents 249
Safety of Immunization 250
Vaccinations for Special Situations 276
Passive Prophylaxis 282
Legal Issues in Immunization 283

10. Normal Childhood Nutrition & Its Disorders 284
*Nancy F. Krebs, MD, MS, Laura E. Primak, RD, CNSD, CSP,
& K. Michael Hambidge, MD, BChir, ScD*
Nutritional Requirements 284
Infant Feeding 299
Pediatric Undernutrition 304

11. Emergencies & Injuries 317
F. Keith Battan, MD, & Marsha S. Anderson, MD
I. Emergencies & Injuries 317
Advanced Life Support for Infants & Children 317
Emergency Pediatric Drugs 323
Approach to the Seriously Ill Child 323
Approach to the Pediatric Trauma Patient 325
Head Injury 329
Burns 331
Hypothermia 334
Submersion Injuries 335
Bites: Animal & Human 336
II. Bioterrorism 337
Anthrax 337
Smallpox 340
Plague 343
Botulinum Toxin 344

12. Poisoning 346
Richard C. Dart, MD, PhD, & Barry H. Rumack, MD
Management of Specific Common Poisonings 350

13. Critical Care 372
*Todd C. Carpenter, MD, Emily L. Dobyms, MD, Stephanie N. Mateev, MD, Peter M. Mourani, MD,
Margaret A. Ferguson, MD, & Kurt R. Stenmark, MD*
Acute Respiratory Failure 372
Mechanical Ventilation 377
Acute Respiratory Distress Syndrome 380
Asthma (Life-Threatening) 384
Shock 386
Indications for Central Venous and Arterial Cannulation 393
Brain Injury/Cerebral Edema 397
Ethical Deliberation and End-of-Life Care in the PICU 401
Nutritional Support of the Critically Ill Child 402
Pain & Anxiety Control 406

14. Skin	411
<i>Joseph G. Morelli, MD, & William L. Weston, MD</i>	
General Principles of Diagnosis of Skin Disorders	411
General Principles of Treatment of Skin Disorders	411
Disorders of the Skin in Newborns	413
Common Skin Diseases in Infants, Children, & Adolescents	417
15. Eye	432
<i>Rebecca Sands, MD, Arlene Drack, MD, & Allan M. Eisenbaum, MD</i>	
Common Nonspecific Signs & Symptoms	432
Refractive Errors	433
Examination	434
Ocular Trauma	438
Injuries to the Eyelids	439
Disorders of the Ocular Structures	441
Disorders of the Nasolacrimal System	443
Diseases of the Conjunctiva	444
Disorders of the Iris	447
Glaucoma	448
Uveitis	448
Acquired Immunodeficiency Syndrome & the Eye	450
Disorders of the Cornea	450
Disorders of the Lens	451
Disorders of the Retina	452
Diseases of the Optic Nerve	454
Diseases of the Orbit	456
Nystagmus	457
Amblyopia & Strabismus	457
Unexplained Decreased Vision in Infants & Children	460
The Blind Child	460
Learning Disabilities & Dyslexia	460
Vision Screening	460
16. Oral Medicine & Dentistry	462
<i>William A. Mueller, DMD</i>	
Oral Examination of the Newborn & Infant	462
Eruption of the Teeth	464
Dental Caries & Periodontal Disease	466
Orofacial Trauma	468
Dental Emergencies	469
Antibiotics in Pediatric Dentistry	469
Special Patient Populations	469
Maternal-Fetal Relationship	470
Dental Referral	471
17. Ear, Nose, & Throat	472
<i>Candice E. Johnson, MD, PhD, Peggy Kelley, MD, & Norman R. Friedman, MD</i>	
I. The Ear	472
II. The Nose & Paranasal Sinuses	488
III. The Throat & Oral Cavity	494
18. Respiratory Tract & Mediastinum	506
<i>Gwendolyn S. Kerby, MD, Gary L. Larsen, MD, Frank J. Accurso, MD, Robin R. Deterding, MD, Vivek Balasubramaniam, MD, & Scott D. Sagel, MD</i>	
Respiratory Tract	506
Growth & Development	506
Diagnostic Aids	507
General Therapy of Pediatric Lung Diseases	510
Disorders of the Conducting Airways	511
Congenital Disorders of the Extrathoracic Airway	512
Acquired Disorders of the Extrathoracic Airway	513
Congenital Disorders of the Intrathoracic Airways	517
Acquired Disorders of the Intrathoracic Airways	518
Congenital Malformations of the Lung	528
Acquired Disorders Involving Alveoli	531
Diseases of the Pulmonary Circulation	544
Disorders of the Chest Wall	548
Disorders of the Pleura & Pleural Cavity	549
Disorders of the Control of Breathing	551
Mediastinum	555
19. Cardiovascular Diseases	558
<i>Anji T. Yetman, MD, Shelley D. Miyamoto, MD, & Henry M. Sondheimer, MD</i>	
Diagnostic Evaluation	558
Congenital Heart Disease	571
Acquired Heart Disease	599
Cardiac Transplantation	613
Disorders of Rate & Rhythm	615

20. Gastrointestinal Tract 625

Judith M. Sondheimer, MD

- Evaluation of the Child with Vomiting 625
- Gastroesophageal Reflux 625
- Achalasia of the Esophagus 626
- Caustic Burns of the Esophagus 627
- Hiatal Hernia 627
- Pyloric Stenosis 628
- Peptic Disease 628
- Congenital Diaphragmatic Hernia 629
- Congenital Duodenal Obstruction 630
- Congenital Intestinal Atresias & Stenoses 630
- Annular Pancreas 631
- Intestinal Malrotation With or Without Volvulus 631
- Meckel Diverticulum & Omphalomesenteric Duct Remnants 632
- Duplications of the Gastrointestinal Tract 632
- Congenital Aganglionic Megacolon (Hirschsprung Disease) 633
- Chylous Ascites 634
- Congenital Anorectal Anomalies 634
- Acute Abdomen 635
- Peritonitis 635
- Acute Appendicitis 636
- Intussusception 637
- Foreign Bodies in the Alimentary Tract 638
- Anal Fissure 638
- Inguinal Hernia 638
- Umbilical Hernia 639
- Tumors of the Gastrointestinal Tract 639
- Acute Infectious Diarrhea (Gastroenteritis) 641
- Chronic Diarrhea 642
- The Malabsorption Syndromes 643
- Constipation 650
- Gastrointestinal Bleeding 651
- Recurrent Abdominal Pain 654
- Inflammatory Bowel Disease 654

21. Liver & Pancreas 660

Ronald J. Sokol, MD, & Michael R. Narkewicz, MD

- Liver 660
 - Prolonged Neonatal Cholestatic Jaundice 660
 - Intrahepatic Cholestasis 660
 - Progressive Familial Intrahepatic Cholestasis (Byler Disease) 668
 - Extrahepatic Neonatal Cholestasis 668
 - Other Neonatal Hyperbilirubinemic Conditions (Noncholestatic Nonhemolytic) 670
 - Hepatitis A 673
 - Hepatitis B 675
 - Hepatitis C 677
 - Hepatitis D (Delta Agent) 678
 - Hepatitis E 678
 - Other Hepatitis Viruses 678
 - Fulminant Hepatic Failure (Acute Massive Hepatic Necrosis, Acute Liver Failure) 679
 - Autoimmune Hepatitis (Lupoid Hepatitis) 680
 - Steatohepatitis 682
 - α_1 -Antitrypsin Deficiency Liver Disease 682
 - Wilson Disease (Hepatolenticular Degeneration) 683
 - Reye Syndrome (Encephalopathy with Fatty Degeneration of the Viscera) 685
 - Cirrhosis 686
 - Portal Hypertension 688
 - Biliary Tract Disease 693
 - Pyogenic & Amebic Liver Abscess 695
 - Hepatoma 697
 - Liver Transplantation 698
- Pancreas 699
 - Acute Pancreatitis 699
 - Chronic Pancreatitis 700
 - Gastrointestinal & Hepatobiliary Manifestations of Cystic Fibrosis 701
 - Syndromes with Pancreatic Exocrine Insufficiency 701
 - Isolated Exocrine Pancreatic Enzyme Defect 705
 - Pancreatic Tumors 706

22. Kidney & Urinary Tract. 707

Gary M. Lum, MD

- Evaluation of the Kidney & Urinary Tract 707
- Congenital Anomalies of the Urinary Tract 711
- Hematuria & Glomerular Disease 712
- Diseases of the Renal Vessels 716
- Renal Failure 718
- Inherited or Developmental Defects of the Urinary Tract 725
- Urinary Tract Infections 729

23. Neurologic & Muscular Disorders 732

Paul G. Moe, MD, & Tim A. Benke, MD, PhD

- Neurologic Assessment & Neurodiagnostic Procedures 732
- Disorders Affecting the Nervous System in Infants & Children 739
- Infections & Inflammatory Disorders of the Central Nervous System 786
- Disorders of Childhood Affecting Muscles 794
- Miscellaneous Neuromuscular Disorders 805

24. Orthopedics	810
<i>Robert E. Eilert, MD</i>	
Disturbances of Prenatal Origin	810
Growth Disturbances of the Musculoskeletal System	814
Degenerative Problems (Arthritis, Bursitis, & Tenosynovitis)	817
Trauma	818
Infections of the Bones & Joints	821
Miscellaneous Diseases of Bone	827
25. Rehabilitation & Sports Medicine	829
<i>Pamela E. Wilson, MD, & Dennis J. Matthews, MD,</i>	
Basic Principles	829
Common Sports Medicine Issues and Injuries	834
26. Rheumatic Diseases	846
<i>J. Roger Hollister, MD</i>	
Juvenile Rheumatoid Arthritis (Juvenile Chronic Arthritis)	846
Spondyloarthropathy	848
Enteropathic Arthritis	849
Systemic Lupus Erythematosus	849
Dermatomyositis (Polymyositis)	851
Polyarteritis Nodosa	852
Scleroderma	852
Raynaud Phenomenon	852
Hypermobility Syndrome	853
27. Hematologic Disorders.	855
<i>Daniel R. Ambruso, MD, Taru Hays, MD, Peter A. Lane, MD, & Rachele Nuss, MD</i>	
Bone Marrow Failure	855
Anemias	858
Polycythemia & Methemoglobinemia	879
Disorders of Leukocytes	880
Bleeding Disorders	885
Thrombotic Disorders	898
Splenic Abnormalities	900
Transfusion Medicine	900
28. Neoplastic Disease	911
<i>Edythe A. Albano, MD, Mylène Bassal, MDCM, Christopher C. Porter, MD, Brian S. Greffe, MD, Nicholas K. Foreman, MD, & Linda C. Stork, MD</i>	
Major Pediatric Neoplastic Diseases	911
<i>Douglas K. Graham, MD, PhD, Roger H. Giller, MD, & Ralph R. Quinones, MD</i>	
Hematopoietic Stem Cell Transplantation	939
Late Effects of Pediatric Cancer Therapy	941
29. Immunodeficiency	944
<i>Anthony R. Hayward, MD, PhD</i>	
Nonspecific Factors in Resistance to Infection	944
Deficiencies of Specific Immunity	946
Combined Immunodeficiency Disorders	952
Other Disorders Associated with Immunodeficiency	954
Secondary Immunodeficiency	956
Investigation of Immunodeficiency	958
30. Endocrine Disorders.	961
<i>Philip S. Zeitler, MD, PhD, Sharon H. Travers, MD, Jennifer Barker, MD, Kristen Nadeau, MD, & Michael S. Kappy, MD, PhD</i>	
General Concepts	961
Disturbances of Growth	963
The Posterior Pituitary Gland	971
The Thyroid Gland	973
Disorders of Calcium Homeostasis	979
The Gonads (Ovaries & Testes)	987
Adrenal Cortex	995

31. Diabetes Mellitus	1006
<i>H. Peter Chase, MD, & George S. Eisenbarth, MD, PhD</i>	
General Considerations	1006
Etiology	1006
Prevention	1007
Diagnosis	1007
Treatment	1007
Laboratory Evaluations	1010
Acute Complications	1011
Chronic Complications	1013
32. Inborn Errors of Metabolism	1014
<i>Carol L. Greene, MD, Janet A. Thomas, MD, & Stephen I. Goodman, MD</i>	
Diagnosis	1014
Management of Metabolic Emergencies	1018
Newborn Screening	1018
Disorders of Carbohydrate Metabolism	1019
Primary Lactic Acidemias & Other Disorders of Energy Metabolism	1021
Disorders of Amino Acid Metabolism	1022
Organic Acidemias	1027
Disorders of Fatty Acid Oxidation & Carnitine	1030
Lysosomal Diseases	1033
Peroxisomal Diseases	1033
Carbohydrate-Deficient Glycoprotein Syndromes	1036
Smith—Lemli—Opitz Syndrome and Disorders of Cholesterol Synthesis	1036
Disorders of Neurotransmitter Metabolism	1037
33. Genetics & Dysmorphology	1039
<i>Ellen Roy Elias, MD, Anne Chun-Hui Tsai, MD, MSc, & David K. Manchester, MD</i>	
Principles of Genetics	1039
Foundations of Genetic Diagnosis	1039
Principles of Inherited Human Disorders	1048
Dysmorphology and Human Embryology	1056
Clinical Features of Common Genetic Disorders	1061
Chromosomal Disorders: Abnormal Number	1061
Sex Chromosomes	1062
Chromosomal Abnormalities: Structural	1063
Mendelian Disorders	1064
Nonmendelian Inheritance	1069
Multifactorial Inheritance	1071
Common Recognizable Disorders with Variable or Unknown Cause	1074
Perinatal Genetics	1076
Evaluation of the Developmentally Delayed Child	1078
34. Allergic Disorders	1080
<i>Mark Boguniewicz, MD</i>	
The Allergic Cascade	1080
Major Allergic Disorders Seen in Pediatric Practice	1080
Asthma	1080
Allergic Rhinconjunctivitis	1091
Atopic Dermatitis	1094
Urticaria & Angioedema	1098
Anaphylaxis	1100
Adverse Reactions to Drugs & Biologicals	1102
Food Allergy	1107
Insect Allergy	1108
35. Antimicrobial Therapy	1110
<i>John W. Ogle, MD</i>	
Principles of Antimicrobial Therapy	1110
Antimicrobial Susceptibility Testing	1111
Alteration of Dose & Measurement of Blood Levels	1113
The Use of New Antimicrobial Agents	1119
Prophylactic Antimicrobial Agents	1119
Initial Empiric Antimicrobial Choices for Selected Conditions	1121
Specific Antimicrobial Agents	1122
36. Infections: Viral & Rickettsial	1130
<i>Myron J. Levin, MD, & Adriana Weinberg, MD</i>	
I. Viral Infections	1130
Respiratory Infections	1130
Infections Due to Enteroviruses	1142
Infections Due to Herpesviruses	1146
Viral Infections Spread by Insect Vectors	1157
Other Major Viral Childhood Exanthems	1162
Infections Due to Other Viruses	1166
II. Rickettsial Infections	1170

37. Human Immunodeficiency Virus Infection	1174
<i>Elizabeth J. McFarland, MD</i>	
General Considerations	1174
Mode of Transmission	1174
Pathogenesis	1175
Clinical Findings	1176
Differential Diagnosis	1178
Prevention	1179
Treatment	1179
Prognosis	1184
Public Health Issues	1184
Conclusion	1185
38. Infections: Bacterial & Spirochetal	1186
<i>John W. Ogle, MD, & Marsha S. Anderson, MD</i>	
I. Bacterial Infections	1186
II. Spirochetal Infections	1241
39. Infections: Parasitic & Mycotic	1250
<i>Adriana Weinberg, MD, & Myron J. Levin, MD</i>	
I. Infections: Parasitic	1250
Protozoal Infections	1253
Metazoal Infections	1267
II. Infections: Mycotic	1275
40. Sexually Transmitted Infections	1290
<i>Ann-Christine Nyquist, MD, MSPH, Myron J. Levin, MD, & Eric J. Sigel, MD</i>	
The Most Common Antibiotic-Responsive Sexually Transmitted Infections	1292
The Spectrum of Sexually Transmitted Infections	1299
Evaluation of Sexually Transmitted Infections in Sexual Abuse and Assault	1309
41. Drug Therapy	1311
<i>Patricia Orma, PharmD, Jerrod Milton, RPh, BSc, & Douglas N. Fish, PharmD</i>	
Developing a Pediatric Drug Regimen	1311
Drug Interactions	1317
Preventing Medication Errors	1317
Sources of Pediatric Drug Information	1319
42. Fluid, Electrolyte, & Acid-Base Disorders & Therapy	1320
<i>Douglas M. Ford, MD</i>	
Regulation of Body Fluids, Electrolytes, & Tonicity	1320
Fluid & Electrolyte Management	1322
Acid—Base Balance	1322
Dehydration	1323
Hyponatremia	1325
Hypernatremia	1326
Potassium Disorders	1326
Acid-Base Disturbances	1327
Metabolic Acidosis	1327
Metabolic Alkalosis	1328
Respiratory Acidosis	1328
Respiratory Alkalosis	1328
43. Information Technology in Pediatrics	1330
<i>Carol S. Kamin, MS, EdD, & David W. Kaplan, MD, MPH</i>	
Continuing Medical Education	1330
Clinical Support	1333
Patient Education	1337
44. Chemistry & Hematology Reference Ranges	1339
<i>Iris M. Osberg, MT</i>	
Interpretation of Laboratory Values	1339
Laboratory Values	1340
Index	1353

Endocrine Disorders

Preface

The seventeenth edition of *Current Pediatric Diagnosis & Treatment* features practical, up-to-date, well-referenced information on the care of children from birth through infancy and adolescence. *CPDT* emphasizes the clinical aspects of pediatric care while also covering the important underlying principles. Its goal is to provide a guide to diagnosis, understanding, and treatment of the medical problems of all pediatric patients in an easy-to-use and readable format.

INTENDED AUDIENCE

Like all Lange medical books, *CPDT* provides a concise yet comprehensive source of current information. Students will find *CPDT* an authoritative introduction to pediatrics and an excellent source for reference and review. *CPDT* provides excellent coverage of The Council on Medical Student Education in Pediatrics (COMSEP) Curriculum used around the country in Pediatric clerkships. Residents in pediatrics (and other specialties) will appreciate the detailed descriptions of diseases and diagnostic and therapeutic procedures. Pediatricians, family practitioners, nurses and nurse practitioners, and other health-care providers who work with infants and children also will find *CPDT* a useful reference on management aspects of pediatric medicine.

COVERAGE

Forty-four chapters cover a wide range of topics, including neonatal medicine, child development and behavior, emergency and critical care medicine, and diagnosis and treatment of specific disorders according to major problems and organ systems. A wealth of tables and figures summarizes important information, such as acute and critical care procedures in the delivery room, the office, the emergency room, and the critical care unit; anti-infective agents; drug dosages; immunization schedules; differential diagnosis; and developmental screening tests. The final chapter is a handy guide to normal laboratory values.

NEW TO THIS EDITION

The seventeenth edition of *CPDT* has been revised comprehensively by the editors and contributing authors. New references as well as up-to-date and useful Web sites have been added, permitting the reader to consult original material and to go beyond the confines of the textbook. As editors and practicing pediatricians, we have tried to ensure that each chapter reflects the needs and realities of day-to-day practice.

New Editor: We are delighted to welcome Dr. Robin Deterding as a *CPDT* Editor. Robin brings a wealth of experience in pediatric education methods and in-depth experience in pulmonary medicine and patient diagnosis and management protocols.

Chapter Revisions: Eight chapters have been extensively revised, with new authors added in several cases, reflecting substantial new information in each of their areas of pediatric medicine. Especially important is new material added to the chapters on infectious diseases, including information on methicillin-resistant staphylococcus, SARS, human metapneumovirus, and West Nile virus infections. Chapters with major revisions include:

- 15. Eye
- 28. Neoplastic Disease
- 35. Antimicrobial Therapy
- 36. Infections: Viral & Rickettsial
- 37. Human Immunodeficiency Virus (HIV) Infections
- 38. Infections: Bacterial & Spirochetal
- 39. Infections: Parasitic & Mycotic
- 40. Sexually Transmitted Infections
- 43. Information Technology in Pediatric Practice

All other chapters are substantially revised and references have been updated. Seventeen new authors have contributed to these revisions.

Acknowledgment: The Editors would like to thank Dr. Anthony Hayward—who has assumed a position with the General Clinical Research Centers program at the National Institutes of Health—for his work as Editor of *CPDT*. Anthony served *CPDT* with outstanding scholarship and editorship for five editions (twelfth-sixteenth). We miss his attention to detail in the editorial work, but especially his friendship.

The Newborn Infant

Elizabeth H. Thilo, MD, & Adam A. Rosenberg, MD

The first 28 days of life are usually considered the newborn period. In practice, however, neonatal care may extend to many months for sick or very immature infants. Levels of newborn care are classified from level 1 (well newborns) to level 3 (critically ill newborns). Level 3 nurseries are often part of a perinatal center offering critical care to the mother and fetus as well as the newborn infant.

EVALUATION OF THE NEWBORN INFANT HISTORY

Taking the history in newborn medicine involves three key areas: (1) the medical history of the mother and father, including a relevant genetic history; (2) the history of the mother's previous pregnancies; and (3) the history of the current pregnancy, including antepartum and intrapartum events.

The mother's medical history should include any chronic medical conditions, medications taken during pregnancy, unusual dietary habits, smoking history, occupational exposures to chemicals or infections of potential risk to the fetus, and pertinent aspects of the social history that may suggest increased risks for parenting problems and child abuse. Family illnesses with genetic implications should be sought. The past pregnancy history should include maternal age, gravidity and parity, blood type, and pregnancy outcomes. The current obstetric history should include documentation and results of procedures such as ultrasound, amniocentesis, screening tests (eg, hepatitis B surface antigen [HBsAg], antibody screen, serum alpha fetoprotein [AFP], human immunodeficiency virus [HIV]), and antepartum tests of fetal well-being (eg, biophysical profiles nonstress tests, or Doppler assessment of fetal blood flow patterns). Information should be sought regarding pregnancy-related illnesses in the mother such as urinary tract infection, pregnancy-induced hypertension or preeclampsia, eclampsia, vaginal bleeding, and preterm labor. Peripartum events of importance include duration of ruptured membranes, maternal fever, fetal distress or meconium-stained amniotic fluid, type of delivery (vaginal or cesarean section), anesthesia and

analgesia used, reason for operative or forceps delivery, and condition of the infant at birth, including any resuscitation needed and Apgar scores.

ASSESSMENT OF GROWTH & GESTATIONAL AGE

It is important to know an infant's gestational age because its behavior and anticipated problems can be predicted on this basis. Accurate recall of the date of the last menstrual period is the best indicator of gestational age. Other obstetric observations, such as fundal height and early ultrasound examination, provide supporting information. A postnatal examination can also be used because fetal physical characteristics and neurologic development progress in predictable fashion. Table 1-1 lists the physical and neurologic criteria to be examined. The upper panel is the neuromuscular examination, assessing primarily muscle tone and strength. The lower panel catalogs a variety of physical characteristics. Adding the scores assigned to each characteristic yields a total score that corresponds to the gestational age.

Disappearance of the anterior vascular capsule of the lens is also helpful in determining gestational age. Until 27-28 weeks' gestation, the lens capsule is covered by vessels; by 34 weeks, this vascular plexus is completely atrophied. Foot length, measured carefully from the heel to the tip of the longest toe, also correlates with gestational age in appropriately grown infants. The foot measures 4.5 cm at 25 weeks' gestation and increases by 0.25 cm/week until term.

By convention, unless the physical examination indicates a gestational age more than 2 weeks different (in either direction) from the obstetric dates, the gestational age is as assigned by the dates. The birth weight and gestational age must be plotted on an appropriate standard to determine if the infant's weight is appropriate for gestational age (AGA), small for gestational age (SGA) or intrauterine growth restricted (IUGR), or large for gestational age (LGA) (Figure 1-1). Birth weight and gestational age distributions vary from one population to the next, depending on factors such as those listed in Table 1-2. Whenever possible, standards should be prepared from data derived from the local population, but when such information is not available,

^aSee text for a description of the clinical gestational age examination.

Reproduced, with permission, from Ballard JL et al: New Ballard Score, expanded to include extremely premature infants. J Pediatr 1991;119:417.

Figure 1-1. Intrauterine growth curves for weight, length, and head circumference for singleton births in Colorado. (Reproduced, with permission, from Lubchenco LO et al: Intrauterine growth in length and head circumference as estimated from live births at gestational ages from 26 to 42 weeks. *Pediatrics* 1966;37:403.)

any regional standard may be used. The birth weight-gestational age distribution of an infant is a screening tool that should be supplemented by clinical data confirming a tentative diagnosis of intrauterine growth restriction or excessive fetal growth. These data include not only the clinical features of the infant determined during the physical examination but also factors such as the size of the parents and the birth weight-gestational age distribution of infants previously born to the parents.

Table 1-3 lists causes of variations in neonatal size in relation to gestational age. An important distinction, particularly in SGA infants, is whether the growth dis-

order is symmetrical (weight, length, and occipitofrontal circumference [OFC] all $\leq 10\%$) or asymmetrical (only weight $\leq 10\%$). Asymmetrical growth retardation implies a problem late in the pregnancy, such as pregnancy-induced hypertension or placental insufficiency. Symmetrical growth restriction implies an event of early pregnancy: chromosomal abnormality, drug or alcohol use, congenital viral infections. In general, the outlook for normal growth and development is better in the asymmetrically growth-restricted infant whose intrauterine brain growth has been spared.

The fact that SGA infants have fewer problems (such as respiratory distress syndrome) than AGA infants of

Table 1–2. Factors affecting birth weight/gestational age distributions.

1. Socioeconomic factors that affect nutritional level and access to health care
2. Altitude
3. Environmental factors that affect birth weight (eg, smoking, alcohol, illicit drug use)
4. Race

the same birth weight but a lower gestational age has led to the common misconception that SGA infants have accelerated maturation. SGA infants, when compared with AGA infants of the same gestational age, actually have increased morbidity and mortality rates.

Knowledge of a baby’s birth weight in relation to gestational age is also helpful in anticipating neonatal problems. LGA babies are at risk for birth trauma, hypoglycemia, polycythemia, congenital anomalies, cardiomyopathy, hyperbilirubinemia, and hypocalcemia. SGA babies are at risk for fetal distress during labor and delivery, polycythemia, hypoglycemia, and hypocalcemia.

Chromosomal abnormalities
Intrauterine viral infection (eg, cytomegalovirus)

Thureen PJ et al: The small-for-gestational age infant. *Neoreviews* 2001;2:e139.

EXAMINATION AT BIRTH

The extent of the newborn physical examination depends on the condition of the infant and the environment in which the examination is being performed. In the delivery room, the examination consists largely of observation plus auscultation of the chest and inspection for congenital anomalies and birth trauma. Major congenital anomalies are present in 1.5% of live births and account for 20–25% of perinatal and neonatal deaths. Because the infant is recovering from the stress of birth, the examination should not be extensive. The Apgar score (Table 1–4) should be recorded at 1 and 5 minutes of age. In the case of severely depressed infants, a 10-minute score should also be recorded. Although the 1- and 5-minute Apgar scores have almost no predictive value for long-term outcome, serial scores do provide a useful shorthand description of the severity of perinatal depression and the quality of the resuscitative efforts needed.

The color of the skin is a useful indicator of cardiac output. Normally there is a high blood flow to the skin. Any stress that triggers a catecholamine response redirects cardiac output away from the skin to preserve oxygen delivery to more critical organs. Cyanosis and pal-

Table 1–4. Infant evaluation at birth—Apgar score.^a

	Score		
	0	1	2
Heart rate	Absent	Slow (< 100)	> 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active motion
Response to catheter in nostril ^b	No response	Grimace	Cough or sneeze

lor are thus two signs reflecting inadequate skin oxygenation and cardiac output.

The skeletal examination immediately after delivery serves two purposes: (1) to detect any obvious congenital anomalies and (2) to detect signs of birth trauma, particularly in LGA infants or those born after a protracted second stage of labor—in whom a fractured clavicle or humerus might be found.

The umbilical cord should be examined for the number of vessels. Normally, there are two arteries and one vein. In 1% of deliveries (5–6% of twin deliveries), the cord has only two vessels: an artery and a vein. The latter configuration may be considered a minor anomaly and, as with other minor anomalies, carries a slightly increased risk of associated defects. The placenta is usually examined by the physician delivering it. Small placentas are always associated with small infants. The placental examination emphasizes the identification of membranes and vessels—particularly in multiple gestations—as well as the presence and severity of placental infarcts or evidence of clot (placental abruption) on the maternal side.

GENERAL EXAMINATION IN THE NURSERY

It is important that the examiner have warm hands and a gentle approach. Start with observation, then auscultation of the chest, and then palpation of the abdomen. Examination of the eyes, ears, throat, and hips should be done last, since these maneuvers are most disturbing to the infant. The heart rate should range from 120 to 160 beats/min, and the respiratory rate from 30 to 60 breaths/min; blood pressure is affected by perinatal asphyxia and the need for mechanical ventilation more than by gestational age or birth weight. Systolic blood pressure on day 1 ranges from 50 to 70 mm Hg and increases steadily during the first week of life. **Note:** An irregularly irregular heart rate, usually caused by premature atrial contractions, is common. This irregularity should resolve in the first days of life and is not of pathologic significance.

The presence of minor anomalies (those occurring in < 4% of the population) should be noted. Approximately 15–20% of healthy newborns have one minor anomaly, with a 3% risk of having an associated major anomaly. Approximately 0.8% of newborns have two minor anomalies, and 0.5% have three or more, with a risk of 10% and 20%, respectively, of a major malformation. Common minor anomalies that require no further diagnostic evaluation if isolated in an otherwise normal infant include preauricular pits (although hearing should be assessed), a sacral dimple without other cutaneous abnormality that occurs within 2.5 cm of the anus, a single transverse palmar crease, and three or

fewer café-au-lait spots in a white infant or five or fewer in an African American infant.

Skin

Observe for bruising, petechiae (common over the presenting part), meconium staining, and jaundice. Peripheral cyanosis is commonly present when the extremities are cool or the infant is polycythemic. Generalized cyanosis merits immediate evaluation. Pallor may be caused by acute or chronic blood loss or by acidosis. In dark-skinned infants, pallor and cyanosis should be assessed in the oral region and nail beds. Plethora suggests polycythemia. Note vernix caseosa (a whitish, greasy material covering the body that decreases as term approaches) and lanugo (the fine hair covering the preterm infant's skin). Dry skin with cracking and peeling of the superficial layers is common in postterm infants. Edema may be generalized (hydrops) or localized (eg, on the dorsum of the feet in Turner syndrome). Check for birthmarks such as capillary hemangiomas (lower occiput, eyelids, forehead) and mongolian spot (bluish black pigmentation over the back and buttocks). Milia—small white keratogenous cysts—can be found scattered over the cheeks, forehead, nose, and nasolabial folds. Miliaria (blocked ducts of sweat glands) occurs in intertriginous areas and on the face or scalp. It can appear as small vesicles (crystallina), small erythematous papules (rubra), or pustules. Erythema toxicum is a benign rash characterized by fleeting erythematous papules and pustules filled with eosinophils. Pustular melanosis leaves pigmented macules when the pustules rupture. The pustules are noninfectious but contain neutrophils. Jaundice presenting in the first 24 hours is considered abnormal and should be evaluated (see section on Neonatal Jaundice).

Head

Check for cephalohematoma (a swelling over one or both parietal bones contained within suture lines) and caput succedaneum (edema over the presenting part that crosses suture lines). Subgaleal hemorrhages (beneath the scalp) are uncommon but can lead to extensive blood loss into this large potential space with resultant hypovolemic shock. Skull fractures may be linear or depressed and may be associated with cephalohematoma. Check the size and presence of the fontanelles. The anterior fontanelle varies from 1 to 4 cm in any direction, whereas the posterior fontanelle should be less than 1 cm. A third fontanelle is a bony defect along the sagittal suture in the parietal bones and may be a feature of certain syndromes, such as trisomy 21. Sutures should be freely mobile. Craniosynostosis is a prematurely fused suture.

Face

Odd facies may be associated with a specific syndrome. Bruising from birth trauma (especially with face presentation) and forceps marks should be identified. Face presentation may be associated with considerable soft tissue swelling around the nose and mouth, causing considerable distortion. Facial nerve palsy is observed when the infant cries; the unaffected side of the mouth moves normally, giving a distorted grimace.

Eyes

Subconjunctival hemorrhages are seen frequently as a result of the birth process. Less commonly, a corneal tear may occur, presenting as a clouded cornea. Ophthalmologic consultation is indicated in such cases. Extraocular movements should be assessed. Occasional uncoordinated eye movements are common, but persistent irregular movements are abnormal. The iris should be inspected for abnormalities such as Brushfield spots (trisomy 21) and colobomas. Examine for the red reflex of the retina. The red reflexes should be symmetrical. Dark spots, a blunted reflex on one side, lack of a reflex, and a white reflex are all indications for referral to an ophthalmologist. Leukokoria can be caused by glaucoma (cloudy cornea), cataract, or tumor (retinoblastoma). Infants at risk for chorioretinitis (congenital viral infection) should undergo a formal retinal examination with pupils dilated prior to nursery discharge or as an outpatient.

Nose

Examine the nose for size and shape. In utero compression can cause deformities. Because babies under age 1 month are obligate nose breathers, any nasal obstruction (eg, bilateral choanal atresia or stenosis) can cause respiratory distress. Unilateral choanal atresia can be diagnosed by occluding each naris. Patency is best checked by holding a cold metal surface (eg, a chilled laryngoscope blade) under the nose, and observing the fog from both nares on the metal. Purulent nasal discharge at birth suggests congenital syphilis.

Ears

Malformed or malpositioned (low-set or posteriorly rotated) ears are often associated with other congenital anomalies. The tympanic membranes should be visualized. Preauricular pits and tags are also common minor variants that can be associated with hearing loss.

Mouth

Epithelial (Epstein) pearls are retention cysts along the gum margins and at the junction of the hard and soft palates. Natal teeth may be present and sometimes need to be removed to avoid the risk of aspiration. Check the integrity and shape of the palate; rule out cleft lip and cleft palate. A small mandible and tongue with cleft soft palate is seen with Pierre-Robin syndrome and can result in respiratory difficulty as the tongue occludes the airway. Prone positioning can be very beneficial. A prominent tongue can be seen in trisomy 21 and Beckwith–Wiedemann syndrome. Excessive drooling suggests esophageal atresia.

Neck

Redundant skin or webbing is seen in Turner syndrome. Sinus tracts may be seen as remnants of branchial clefts. Check for masses: midline (thyroid), anterior to the sternocleidomastoid (branchial cleft cysts), within the sternocleidomastoid (hematoma, torticollis), and posterior to the sternocleidomastoid (cystic hygroma).

Chest & Lungs

Check for fractured clavicles (crepitus, bruising, and tenderness). Increased anteroposterior diameter (barrel chest) can be seen with aspiration syndromes. Check air entry bilaterally and the position of the mediastinum and heart tones. Decreased breath sounds with respiratory distress and a shift in the mediastinum suggests pneumothorax (tension) or a space-occupying lesion (eg, diaphragmatic hernia). With pneumomediastinum, the heart sounds are muffled. Expiratory grunting and decreased air entry are observed in hyaline membrane disease. Rales are not of clinical significance at this age.

Heart

Examination of the heart is described in detail in Chapter 19. **Note:** Murmurs are commonly present in the first hours and are most often benign. Severe congenital heart disease in the newborn infant may be present with no murmur at all. The two most common presentations of heart disease in the newborn infant are cyanosis and congestive heart failure with abnormalities of pulses. In hypoplastic left heart and critical aortic stenosis, pulses are diminished at all sites. In aortic coarctation and interrupted aortic arch, pulses are diminished in the lower extremities.

Abdomen

Check for softness, distention, and bowel sounds. If polyhydramnios was present or excessive oral secretions are noted, pass a soft catheter into the stomach to rule out esophageal atresia. Palpate for kidneys—most abdominal masses in the newborn infant are associated with kidney disorders (eg, multicystic or dysplastic, hydronephrosis). When the abdomen is relaxed, normal-sized kidneys may be felt but are not prominent. A markedly scaphoid abdomen plus respiratory distress suggests diaphragmatic hernia. Absence of abdominal musculature (prune belly syndrome) may occur in association with renal abnormalities. Check the size of the liver and the spleen. These organs are superficial and discernible by light palpation in the newborn infant. The outline of a distended bladder may be seen and palpated above the pubic symphysis.

Genitalia & Anus

Male and female genitals show characteristics according to gestational age (see Table 1–1). In the female during the first few days, a whitish vaginal discharge with or without blood is normal. Check the patency and location of the anus.

Skeleton

Check for obvious anomalies, for example, the absence of a bone, clubfoot, fusion or webbing of digits, and extra digits. Examine for hip dislocation by attempting to dislocate the femur posteriorly and then abducting the legs to relocate the femur. Look for extremity fractures and for palsies (especially brachial plexus injuries). Rule out myelomeningoceles and other spinal deformities (eg, scoliosis). Arthrogryposis (multiple joint contractures) results from chronic limitation of movement in utero, which may result from lack of amniotic fluid or from a congenital neuromuscular disease.

Neurologic Examination

Normal newborns are endowed with a set of reflexes that facilitate survival (eg, rooting and sucking reflexes), as well as sensory abilities (eg, hearing and smell) that allow them to recognize their mother within a few weeks of birth. Although the retina is well developed at birth, visual acuity is poor (20/400) because of a relatively immobile lens. Acuity improves rapidly over the first 6 months, with fixation and tracking becoming well developed by 2 months.

In examining the newborn, observe resting tone (normal-term newborns should exhibit flexion of the upper and lower extremities) and spontaneous movements. Look for symmetry of movements. Extension of

extremities should result in spontaneous recoil to the flexed position. Assess the character of the cry; a high-pitched cry may be indicative of disease of the central nervous system (CNS) (eg, hemorrhage). Hypotonia and a weak cry are indicative of systemic disease or a congenital neuromuscular disorder. Check for newborn reflexes:

1. Sucking reflex in response to a nipple or the examiner's finger in the mouth. This reflex is observed by 14 weeks' gestation.
2. Rooting reflex: Head turns to the side of a facial stimulus. This reflex develops by 28 weeks' gestation.
3. Traction response: The infant is pulled by the arms to a sitting position. Initially, the head lags, then with active flexion comes to the midline briefly before falling forward.
4. Palmar grasp with placement of the examiner's finger in the palm. This reflex develops by 28 weeks' gestation and disappears by age 4 months.
5. Deep tendon reflexes: Several beats of ankle clonus and an upgoing Babinski reflex may be normal.
6. Placing: Rub the dorsum of one foot on the underside of a surface. The infant will flex the knee and bring the foot up.
7. Moro (startle) reflex: Hold the infant and support the head. Allow the head to drop 1–2 cm suddenly. The arms will abduct at the shoulder and extend at the elbow. Adduction with flexion will follow. The hands show a prominent spreading or extension of the fingers. This reflex develops by 28 weeks' gestation (incomplete) and disappears by age 3 months.
8. Tonic neck reflex: Forcibly turn the infant's head to one side, and the arm and leg on that side extend while the opposite arm and leg flex ("fencing position"). This reflex disappears by age 8 months.

CARE OF THE WELL NEWBORN INFANT

The primary responsibility of the level 1 nursery is care of the well infant. This includes promoting mother–infant bonding, establishing feeding, and teaching the techniques of newborn care. Surveillance of the infant is a key function of the staff; they must be alert for the signs and symptoms of illness, including temperature instability, change in activity, refusal to feed, pallor, cyanosis, early or excessive jaundice, tachypnea and respiratory distress, delayed (beyond 24 hours) passage of first stool or voiding of urine, and bilious vomiting. Several preventive measures are undertaken routinely in the normal newborn nursery.

Eye prophylaxis to prevent gonococcal ophthalmia is routinely administered within 1 hour after birth with either erythromycin ointment or silver nitrate 1% drops. Because of the severe chemical conjunctivitis caused by silver nitrate, erythromycin is preferred.

Vitamin K, 1 mg, is given intramuscularly or subcutaneously within 4 hours after birth to prevent hemorrhagic disease of the newborn. The area to be injected must be cleansed thoroughly before injection to prevent infection.

All infants should be vaccinated against hepatitis B, but the first dose can wait until 1–2 months of age if the mother is HBsAg-negative. Hepatitis B vaccine and hepatitis B immune globulin (HBIG) are administered if the mother is known to be HBsAg-positive. If maternal HBsAg status is unknown at birth, the vaccine should be given. The mother's blood should be tested and HBIG given at less than 7 days of age if the test is positive.

Cord blood is collected on all infants at birth and used for blood typing and Coombs' testing if the mother is type O or Rh-negative. Cord blood is useful also for other tests, such as toxicology screens.

Rapid glucose testing should be performed in infants at risk for hypoglycemia (eg, infants of diabetic mothers [IDMs], preterm, SGA, LGA, or stressed infants). Values less than 45 mg/dL should be confirmed by laboratory blood glucose testing and treated. Hematocrit should be measured at age 3–6 hours in infants at risk for or those who have symptoms of polycythemia or anemia.

The state-sponsored newborn genetic screen (for inborn errors of metabolism such as phenylketonuria [PKU], galactosemia, sickle cell disease, hypothy-

roidism, and cystic fibrosis) is performed just prior to discharge, after 24–48 hours in hospital if possible. In many states, a repeat test is required at 8–14 days of age because the PKU test is often falsely negative when obtained before 48 hours of age. Not all state-mandated screens include the same panel of diseases; the most recent addition in some states is a screen for congenital adrenal hyperplasia. In infants with prolonged hospital stays, the test should be performed by 1 week of age. In addition to the state-mandated screen, some centers offer expanded newborn screening by tandem mass spectrometry that looks for a variety of other inborn errors such as fatty acid oxidation defects.

Infants should routinely be positioned supine or lying on the right side with the dependent arm forward to minimize the risk of sudden infant death syndrome (SIDS). Prone positioning is contraindicated unless specific problems, such as gastroesophageal reflux or respiratory distress, are present. Bed sharing with adults and prone positioning are both associated with increased risk of SIDS.

FEEDING THE WELL NEWBORN INFANT

Indications that the baby is ready for feeding include (1) alertness and vigor, (2) absence of abdominal distention, (3) good bowel sounds, and (4) normal hunger cry. All of these usually occur within 6 hours after birth, but fetal distress or traumatic delivery may prolong this period.

The healthy full-term infant should be allowed to feed every 2–5 hours on demand. The first feeding usually occurs by 3 hours of life, often as early as in the delivery room. Breast milk or formula (20 kcal/oz) can be given. For formula-fed babies, the volume generally increases from 0.5–1 oz per feeding initially to 1.5–2 oz per feeding on day 3. By day 3, the average full-term newborn takes in about 100 mL/kg/d of milk.

Although a wide range of infant formulas can satisfy the nutritional needs of most neonates, breast milk is the standard on which formulas are based (see also Chapter 10). The distribution of calories in human milk is 55% fat, 38% carbohydrate, and 7% protein, with a whey-to-casein ratio of 60:40, allowing for easy protein digestion. Despite the low concentrations of several vitamins and minerals, their bioavailability is high. All of the necessary nutrients, vitamins, minerals, and water are provided by human milk for the first 6 months of life except vitamin K (thus, 1 mg IM is administered at birth), vitamin D (200–300 IU/d if minimal sunlight exposure), fluoride (0.25 mg/d after 6 months if water supply not fluoridated), and vitamin B₁₂ (0.3–0.5 mg/d if the mother is a strict vegetarian and takes no B₁₂ supplement). Other advantages of breast milk include (1) the presence of immunologic,

antimicrobial, and antiinflammatory factors, including IgA, cellular, and protein or enzymatic components that decrease the incidence of upper respiratory and gastrointestinal (GI) infections in infancy; (2) the possibility that breast feeding may decrease the frequency and severity of childhood eczema and asthma; (3) promotion of mother–infant bonding; and (4) evidence that breast milk as a nutritional source improves neurodevelopmental outcomes.

Although approximately 65% of mothers in the United States initiate breast feeding, only 25% continue to breastfeed at 6 months. Hospital practices that facilitate the successful initiation of breast feeding include rooming-in, nursing on demand, and avoiding the use of pacifiers and supplemental formula (unless medically indicated). The nursery staff must be cognizant of problems associated with breast feeding and be able to provide help and support for mothers in the hospital. It is essential that an experienced professional observe and assist with at least one feeding to document good latch-on, important in preventing the common breast-feeding problems of sore nipples, unsatisfied babies, engorgement, poor milk supply, and excessive hyperbilirubinemia (“lack-of-breast-milk jaundice”).

Table 1–5 presents recommendations the nursing mother and health care provider can use to achieve successful breast feeding.

EARLY DISCHARGE OF THE NEWBORN INFANT

Discharge at 24–36 hours of age appears safe and appropriate for most infants if there are no contraindications (Table 1–6) and a follow-up visit at 48–72 hours after discharge is ensured. Most infants with severe cardiorespiratory disorders and infections are identified in the first 6 hours of life. The exception may be the infant treated with intrapartum antibiotic prophylaxis for maternal group B streptococcal (GBS) colonization or infection. The Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics (AAP) have recommended that these infants be observed in hospital for 48 hours because of the possibility of “partial treatment” with delayed onset of symptoms of infection. However, recent data show that exposure to antibiotics in labor does not appear to change the type or timing of symptoms related to GBS infection in full-term infants, and that hospital observation beyond 24 hours is unnecessary for the asymptomatic full-term infant who received intrapartum chemoprophylaxis. Other problems, such as jaundice and difficulties in breast feeding, typically occur after 48 hours and can usually be dealt with on an outpatient basis provided good follow-up has been arranged.

The AAP recommends a follow-up visit within 48–72 hours for any newborn discharged before 48 hours of age. Infants who are small or slightly premature—especially if breast feeding—are at particular risk for inadequate intake. Suggested guidelines for the follow-up interview and physical examination are presented in Table 1–7. The optimal timing of discharge must be determined in each case based on medical, social, and financial factors.

CIRCUMCISION

Circumcision is an elective procedure to be performed only in healthy, stable infants. The procedure probably has medical benefits, including prevention of phimosis, paraphimosis, balanoposthitis, and urinary tract infection. Later benefits include decreased incidence of cancer of the penis, cervical cancer (in partners of circumcised men), and sexually transmitted diseases (including HIV). Most parents decide on circumcision for non-medical reasons. The risks of the procedure include local infection, bleeding, removal of too much skin, and urethral injury. The combined incidence of these complications is less than 1%. Local anesthesia (dorsal penile nerve block or circumferential ring block with 1% lidocaine without epinephrine) or topical application of an anesthetic cream are safe and effective and should always be used. Techniques that allow visualization of the glans throughout the procedure (eg, Plas-

Table 1–5. Guidelines for successful breast feeding.

	First 8 Hours	8–24 Hours	Day 2	Day 3	Day 4	Day 5	Day 6 Onward
Milk supply	You may be able to express a few drops of milk.		Milk should come in between the second and fourth days.			Milk should be in. Breasts may be firm or leak milk.	Breasts should feel softer after feedings.
Baby's activity	Baby is usually wide-awake in the first hour of life. Put baby to breast within 30 min after birth.	Wake up your baby. Babies may not wake up on their own to feed.	Baby should be more cooperative and less sleepy.	Look for early feeding cues such as rooting, lip smacking, and hands to face.			Baby should appear satisfied after feedings.
Feeding routine	Baby may go into a deep sleep 2–4 h after birth.		Use chart to write down time of each feeding.			May go one longer interval (up to 5 h between feeds) in a 24-h period.	
01 Breast feeding	Baby will wake up and be alert and responsive for several more hours after initial deep sleep.	As long as the mother is comfortable, nurse at both breasts as long as baby is actively sucking.	Try to nurse both sides each feeding, aiming at 10 min per side. Expect some nipple tenderness.	Consider hand expressing or pumping a few drops of milk to soften the nipple if the breast is too firm for the baby to latch on.	Nurse a minimum of 10–30 min per side every feeding for the first few weeks of life.		Mother's nipple tenderness is improving or is gone.
					Once milk supply is well established, allow baby to finish the first breast before offering the second.		
Baby's urine output		Baby must have a minimum of one wet diaper in first 24 h.	Baby must have at least one wet diaper every 8–11 h.	You should see an increase in wet diapers (up to four to six) in 24 h.	Baby's urine should be light yellow.	Baby should have six to eight wet diapers per day of colorless or light yellow urine.	
Baby's stool		Baby should have a black-green (meconium) stool.	Baby may have a second very dark (meconium) stool.	Baby's stools should be in transition from black-green to yellow.		Baby should have three or four yellow, seedy stools a day.	The number of stools may decrease gradually after 4–6 wk of life.

Modified, with permission, from Gabrielski L: Lactation support services. The Children's Hospital, Denver, 1999.

Table 1–6. Criteria for early newborn discharge.**Contraindications to early newborn discharge**

1. Jaundice at ≤ 24 h
2. High risk for infection (eg, maternal chorioamnionitis); discharge allowed at 24 h with a normal transition
3. Known or suspected narcotic addiction or withdrawal
4. Physical defects requiring evaluation
5. Oral defects (clefts, micrognathia)

Relative contraindications to early newborn discharge (infants at high risk for feeding failure, excessive jaundice)

1. Prematurity or borderline prematurity (< 38 weeks' gestation)
2. Birth weight < 2700 g (6 lb)
3. Baby difficult to arouse for feeding; not demanding regularly in nursery
4. Medical or neurologic problems that interfere with feeding (Down syndrome, hypotonia, cardiac problems)
5. Twins or higher multiples
6. ABO blood group incompatibility or severe jaundice in previous child
7. Mother whose previous breast-fed infant gained weight poorly
8. Mother with breast surgery involving periareolar areas (if attempting to nurse)

tibell and Gomco clamp) are preferred to a blind technique (eg, Mogen clamp) because occasional amputation of the glans can occur with the latter technique. Circumcision is contraindicated in infants with genital abnormalities (eg, hypospadias). Coagulation screen should be performed prior to the procedure in infants with a confirmed family history of serious bleeding disorders.

HEARING SCREENING

Normal hearing is critical to normal language development. Significant bilateral hearing loss is present in 1–3 infants per 1000 in the well nursery and in 2–4 infants per 100 in the neonatal intensive care unit population. All infants should be screened for hearing loss by auditory brainstem evoked responses or evoked otoacoustic emissions as early as possible. Primary care providers and parents need to be advised of the possibility of hearing loss and offered ready referral in suspect cases.

COMMON PROBLEMS IN THE TERM NEWBORN INFANT**NEONATAL JAUNDICE****General Considerations**

Jaundice is a common neonatal problem. Sixty-five percent of newborns develop clinical jaundice with a bilirubin level above 5 mg/dL during the first week of

life. From an evolutionary standpoint, hyperbilirubinemia ought to confer some biologic advantage if it occurs so often. Bilirubin is a potent antioxidant and peroxyl scavenger that may help the newborn, who is deficient in most antioxidant substances such as vitamin E, catalase, and superoxide dismutase, to avoid oxygen toxicity in the days after birth. Hyperbilirubinemia can also be toxic, with high levels resulting in an encephalopathy known as kernicterus.

Metabolism of Bilirubin

Heme (iron protoporphyrin) is broken down by heme oxygenase to iron, which is conserved; carbon monoxide, which is exhaled; and biliverdin, which is then further metabolized to bilirubin by the enzyme bilirubin reductase. Each 1 g of hemoglobin breakdown results in the production of 34 mg of bilirubin (1 mg/dL = 17.2 mmol/L of bilirubin). Bilirubin is carried bound to albumin to the liver, where, in the presence of the enzyme uridyldiphosphoglucuronyl transferase (UDPGT; glucuronyl transferase), it is taken up by the hepatocyte and conjugated with two glucuronide molecules. The conjugated bilirubin is then excreted through the bile to the intestine. In the presence of normal gut flora, the conjugated bilirubin is metabolized further to stercobilins and excreted in the stool. In the absence of gut flora—and with slow intestinal motility, as in the first few days of life—the conjugated bilirubin remains in the intestinal lumen, where a mucosal enzyme (β -glucuronidase) can cleave off the glucuronide molecules, leaving unconjugated bilirubin to be reabsorbed (the enterohepatic circulation of bilirubin).

Bilirubin Toxicity

The exact mechanism by which bilirubin is toxic to cells is unknown. It is assumed that if the amount of lipid-soluble unconjugated bilirubin exceeds the available binding sites on albumin, “free” bilirubin will be available to enter neurons and damage them. The blood–brain barrier probably plays an important role in protecting an individual from brain damage, but its integrity is impossible to measure clinically. It is unknown whether a level of bilirubin exists above which brain damage always occurs even in a healthy individual.

The syndrome of bilirubin encephalopathy was well described in the era before exchange transfusion as treatment for Rh isoimmunization (see later discussion). The pathologic correlate is known as kernicterus, named for the yellow staining of the subthalamic nuclei (kerns) seen at autopsy. The early symptoms of bilirubin encephalopathy consist of lethargy, hypotonia, and poor sucking, progressing to hypertonia, opisthotonos,

and a high-pitched cry. Long-term sequelae include athetoid cerebral palsy, sensorineural deafness, limitation of upward gaze, and dental dysplasia—a syndrome that has been described as an intelligent mind trapped within an uncontrollable body wracked by painful spasms. Whether or not bilirubin causes more subtle neurologic abnormalities remains debatable.

Bilirubin encephalopathy is rare with current neonatal management, although upwards of 120 cases have been reported to an informal registry since 1990. A specific bilirubin level of 20 mg/dL [344 mmol/L] and above has been associated with an increased risk of kernicterus in the Rh-isoimmunized infant. For decades, the strategy of keeping bilirubin under 20 mg/dL with phototherapy and exchange transfusion if needed eliminated kernicterus in the United States. The reappearance of kernicterus over the past decade has been ascribed to early discharge of breast-feeding infants without appropriate follow-up or appreciation of the early signs of bilirubin encephalopathy. The risk of bilirubin encephalopathy is probably very small for full-term infants without hemolysis even at bilirubin levels of 25 mg/dL (430 mmol/L). Premature infants are probably at some increased risk because of associated illnesses that may affect the integrity of the blood–brain barrier as well as because of reduced albumin levels. For this reason, a lower level of bilirubin is generally assumed to represent the “exchange level” in these infants and is usually determined arbitrarily based on the infant’s birth weight and gestational age. One common approach is to use 1% of the birth weight in grams as the exchange level in milligrams per deciliter (mg/dL) (eg, 12 mg/dL for a 1200-g infant) down to a low of 10 mg/dL. Many other arbitrary approaches exist as well.

Causes of Unconjugated Hyperbilirubinemia

The causes of unconjugated hyperbilirubinemia can be grouped into two main categories: overproduction of bilirubin and decreased conjugation of bilirubin (Table 1–8).

A. INCREASED BILIRUBIN PRODUCTION

Increased production of bilirubin results from an increased rate of red blood cell destruction (hemolysis) due to the presence of maternal antibodies against fetal cells (Coombs’ test-positive), abnormal red cell membrane shape (ie, spherocytosis), or abnormal red cell enzymes (ie, glucose-6-phosphate dehydrogenase [G6PD] deficiency). Antibodies can be directed against the major blood group antigens (the type A or type B infant of a type O mother) or the minor antigens (the Rh system: D, E, C, d, e, c, Kell, Duffy, and so on).

Table 1–8. Causes of jaundice secondary to unconjugated hyperbilirubemia.

Overproduction of bilirubin

1. Increased rate of hemolysis (reticulocyte count elevated)
 - a. Patients with a positive Coombs test
 - Rh incompatibility
 - ABO blood group incompatibility
 - Other blood group sensitizations
 - b. Patients with a negative Coombs test
 - Abnormal red cell shapes
 - Spherocytosis
 - Elliptocytosis
 - Pyknocytosis
 - Stomatocytosis
 - Red cell enzyme abnormalities
 - Glucose-6-phosphate dehydrogenase deficiency
 - Pyruvate kinase deficiency
 - Hexokinase deficiency
 - Other metabolic defects
 - c. Patients with bacterial or viral sepsis
2. Nonhemolytic causes of increased bilirubin load (Unconjugated bilirubin elevated, reticulocyte count normal.)
 - a. Extravascular hemorrhage
 - Cephalohematoma
 - Extensive bruising
 - Central nervous system hemorrhage
 - b. Polycythemia
 - c. Exaggerated enterohepatic circulation of bilirubin
 - Gastrointestinal tract obstruction
 - Functional ileus

Decreased rate of conjugation

- (Unconjugated bilirubin elevated, reticulocyte count normal.)
- Physiologic jaundice
 - Crigler-Najjar syndrome
 - Type I glucuronyl transferase deficiency, autosomal-recessive
 - Type II glucuronyl transferase deficiency, autosomal-dominant
 - Gilbert syndrome
 - ?Hypothyroidism
-

1. Antibody-mediated hemolysis (Coombs' test-positive)—ABO blood group incompatibility is common, usually not severe, and can accompany any pregnancy in a type O mother. The severity is unpredictable because of variability in the amount of naturally occurring anti-A or anti-B IgG antibodies in the mother. Although 20% of pregnancies are the appropriate “set-ups” for ABO incompatibility (mother O, baby A or B), only about 33% of such infants are Coombs' test-positive and only about 20% of these develop excessive jaundice. In addition to hyperbilirubinemia in the first days of life, these infants may develop a significant ane-

mia over the first several weeks and on occasion may need to be transfused at a few weeks of age.

Rh isoimmunization is much less common and increases in severity with each immunized pregnancy because of an increased maternal IgG antibody production each time. Most Rh disease can be prevented by administering high-titer Rh₀ (D) immune globulin to an Rh-negative woman after any invasive procedure during pregnancy as well as after any miscarriage, abortion, or delivery of an Rh-positive infant. In severe cases, erythroblastosis fetalis (hydrops or generalized edema with heart failure related to severe anemia in the fetus) occurs, often resulting in fetal or neonatal death without appropriate antenatal intervention. In less severe cases, hemolysis is the main problem, with resultant hyperbilirubinemia and anemia. The cornerstone of antenatal management once isoimmunization has been diagnosed is transfusion of the fetus with Rh-negative cells, either directly into the umbilical vein via percutaneous cordocentesis or into the fetal abdominal cavity. Following delivery, phototherapy is usually started immediately, with exchange transfusion (see later discussion) as needed. A 500–750 mg/kg dose of intravenous immune globulin (IVIG) given to the infant as soon after delivery as the diagnosis is made has been shown to decrease the need for exchange transfusion. Ongoing hemolysis will still occur until all maternal antibody is gone; therefore, these infants need to be followed carefully over the first 2 months of life for development of anemia severe enough to require transfusion. The role of erythropoietin therapy in treating late anemia is under investigation.

2. Nonimmune hemolysis (Coombs' test-negative)—Hereditary spherocytosis is the most common red cell membrane defect, resulting in hemolysis because of decreased red cell deformability. These infants may have hyperbilirubinemia severe enough to require exchange transfusion. Mild to moderate splenomegaly may be present. Diagnosis is suspected by peripheral blood smear and confirmed by red cell osmotic fragility study. A family history of anemia, jaundice, and gallstones may be elicited.

G6PD deficiency is the most common red cell enzyme defect resulting in hemolysis and should be suspected in a male (it is X-linked) of African, Mediterranean, or Asian descent, particularly when the onset of jaundice is later than usual. The importance of this enzyme deficiency in cases of severe neonatal jaundice has likely been underestimated. In most cases, no triggering agent is found, although those infants who develop severe jaundice with G6PD deficiency also are found to have Gilbert syndrome.

3. Nonhemolytic increased bilirubin production—Enclosed hemorrhage, such as cephalohematoma, in-

tracranial hemorrhage, or extensive bruising in the skin, can lead to jaundice as the red blood cells are broken down and removed. Polycythemia leads to jaundice by increased red cell mass, with increased numbers of cells reaching senescence daily. Ileus, either paralytic or mechanical, related to a bowel obstruction, leads to hyperbilirubinemia secondary to increased enterohepatic circulation.

B. DECREASED RATE OF CONJUGATION

1. UDPGT deficiency [Crigler–Najjar syndrome type I (complete deficiency, autosomal recessive) and type II (partial deficiency, autosomal dominant)]—These syndromes result from a mutation in the exon or encoding region of the gene that codes for the enzyme UDPGT, resulting in complete absence or nearly complete absence of the enzyme. Both are rare and result in severe unconjugated hyperbilirubinemia, bilirubin encephalopathy, and death without therapy. In type II, the enzyme can be induced with phenobarbital, lowering bilirubin levels 30–80%. There is no cure, although phototherapy and hepatic transplantation prolong survival in type I.

2. Gilbert syndrome—This syndrome is a mild autosomal dominant disorder affecting 6% of the population and is characterized by decreased hepatic UDPGT levels, resulting from a genetic variant of polymorphism in the promoter region (a noncoding area that regulates the amount of structurally normal enzyme produced) of the UDPGT gene. Affected individuals have a greater propensity in the presence of other icterogenic factors such as G6PD deficiency, hereditary spherocytosis, or other factors that increase bilirubin production to develop significant hyperbilirubinemia. They may also be more likely to manifest prolonged jaundice.

C. HYPERBILIRUBINEMIA CAUSED BY UNKNOWN OR MULTIPLE FACTORS

1. Physiologic jaundice—The contributing factors to physiologic jaundice include UDPGT inactivity at birth, a relatively high red cell mass even in the non-polycythemic neonate, and an absence of intestinal flora, with initially slow intestinal motility leading to an active enterohepatic circulation of bilirubin. For jaundice to be physiologic rather than pathologic, the following criteria should be satisfied: (1) clinical jaundice appears after 24 hours of age; (2) total bilirubin rises by less than 5 mg/dL (86 mmol/L) per day; (3) peak bilirubin occurs at 3–5 days of age, with a total bilirubin of no more than 15 mg/dL (258 mmol/L); and (4) clinical jaundice is resolved by 1 week in the full-term infant and by 2 weeks in the preterm infant. Hyperbilirubinemia outside of these parameters—or jaun-

dice that requires treatment—is not physiologic and must be evaluated further (see later discussion).

2. High altitude—Infants at 3100 m (10,000 ft) have twice the frequency of bilirubin > 12 mg/dL (206 mmol/L) as infants at 1600 m (5200 ft) and four times that of infants at sea level: 39% versus 16% versus 8%, respectively. Possible mechanisms include increased bilirubin production secondary to increased hematocrit and decreased clearance caused by hypoxemia.

3. Racial differences—Asians are more likely than whites or blacks to have a bilirubin level > 12 mg/dL (206 mmol/L): 23% versus 10–13% versus 4%, respectively.

4. Prematurity—Premature infants frequently have poor enteral intake, delayed stooling, and increased enterohepatic circulation. Even at 37 weeks' gestation, they are four times more likely than at 40 weeks to have a bilirubin > 13 mg/dL (224 mmol/L).

5. Breast feeding and jaundice—Two syndromes of jaundice are associated with breast feeding: breast milk jaundice and breast feeding-associated jaundice (“lack-of-breast-milk jaundice”).

a. Breast milk jaundice—This uncommon syndrome of prolonged unconjugated hyperbilirubinemia is believed to be caused by a prolonged increased enterohepatic circulation of bilirubin in some breast-fed infants, perhaps related to increased free fatty acids in the milk. Homozygosity for the Gilbert syndrome 7/7 promoter genotype may also be involved. The presence of moderate unconjugated hyperbilirubinemia for 6–8 weeks in a thriving infant without evidence for hemolysis, hypothyroidism, or other disease strongly suggests this diagnosis.

b. Breast feeding-associated jaundice—This common entity is also known as “lack-of-breast-milk jaundice.” Breast-fed infants have a higher incidence (9%) of unconjugated serum bilirubin levels > 13 mg/dL (224 mmol/L) than formula-fed infants (2%) and are more likely to have bilirubin > 15 mg/dL (258 mmol/L) than formula-fed infants: 2% versus 0.3%. The pathogenesis appears to be decreased enteral intake and increased enterohepatic circulation. No increase in bilirubin production is seen, as measured by carbon monoxide exhalation. Although rarely severe enough to result in bilirubin encephalopathy, nearly 100% of the infants with kernicterus reported to the registry were breast-fed, and in 50% of them breast feeding was the only known risk factor. Jaundice should be considered a possible sign of failure to establish an adequate milk supply and should prompt specific inquiries into this possibility (Table 1–9). If intake is inadequate, the infant should receive supplementa-

Table 1–9. Signs of inadequate breast milk intake.

Weight loss of > 8–10% from birth
Fewer than six noticeably wet diapers per day
Fewer than four stools per day
Nursing fewer than eight times per 24 h for at least 10 min each feed

tion with formula if needed, and the mother should be instructed to nurse more frequently and to pump her breasts with an electric breast pump every 2 hours to enhance milk production. A consultation with a certified lactation specialist should be considered, because many physicians feel inadequately prepared to handle these situations. Because hospital discharge of normal newborns occurs before the milk supply is established, a follow-up visit 2–3 days after discharge is of obvious importance.

These two entities may sometimes overlap in the same infant, because prolonged jaundice is common in breast-fed infants (20–30%), and high bilirubin levels in many of these infants with high initial levels also persist longest.

D. PROLONGED HYPERBILIRUBINEMIA

Causes of prolonged unconjugated hyperbilirubinemia include hemolytic disease, breast milk jaundice, Crigler–Najjar or Gilbert syndrome, bowel obstruction, and congenital hypothyroidism. Galactosemia generally presents with hepatomegaly in an ill-appearing, often septic infant, and the hyperbilirubinemia is usually mixed.

Evaluation of Hyperbilirubinemia

Because most newborns are discharged at 24–36 hours of age prior to establishing a good milk supply or showing the extent of their jaundice, a predischarge bilirubin measurement, either transcutaneous or drawn with the newborn genetic screen, may help predict which infants are at risk for severe hyperbilirubinemia. Clinical jaundice appears at a bilirubin level of 5 mg/dL (86 mmol/L) and appears first on the head, progressing down the chest and abdomen as the level increases. By the time jaundice is noted on the distal extremities, the level is likely to be at least 15 mg/dL (258 mmol/L). When checking serum bilirubin levels, the level should be assessed based on the age in hours at which the sample was obtained. Infants with a total serum bilirubin level greater than the 95th percentile for age in hours have a 40% risk of developing subsequent significant hyperbilirubinemia (Figure 1–2). Infants who develop

clinical jaundice on the first day of life or who develop excessive jaundice require evaluation. The minimal evaluation consists of a feeding and elimination history, weight (and comparison with birth weight), examination for any source of excessive heme breakdown, and laboratory evaluation for blood type, Coombs' testing, complete blood count (CBC) with smear, and total bilirubin level. A G6PD test should be considered if the infant is a male of African, Asian, or Mediterranean racial background, particularly if the jaundice presents later than usual. A fractionated bilirubin level should be obtained if the infant appears acutely ill, if jaundice is prolonged, or if the infant has dark urine with light stools.

Because of large interlaboratory variability, serial bilirubin levels should be obtained from a single laboratory whenever possible to make interpretation of serial measurements more accurate.

Treatment of Hyperbilirubinemia

A. PROTOPORPHYRINS

Tin and zinc protoporphyrin or mesoporphyrin (Sn-PP, Zn-PP; Sn-MP, Zn-MP) are inhibitors of heme oxygenase, the enzyme that begins the catabolism of heme (iron protoporphyrin). Studies are underway involving a single injection of these substances shortly after birth to prevent the formation of bilirubin. Although early results are promising, these drugs are still experimental in the United States.

B. PHOTOTHERAPY

Phototherapy is used most commonly, because it is relatively noninvasive and safe. Light at a wavelength absorbed by bilirubin (blue or white spectrum) is used. The unconjugated bilirubin in the skin is converted by such light to a stereoisomer compound that is water-soluble and able to be excreted in the bile without conjugation. A minimum of 10–14 mW/cm² irradiance is required, and efficacy is dose-dependent. The dose can be raised by increasing the body surface area exposed to the light and by moving the lights closer to the baby. Fiberoptic blankets are effective, but are inadequate alone for full-term infants. The infant's eyes should be shielded from the light to prevent damage to retinal cells. A frequent side effect of phototherapy is diarrhea, which is managed by feeding a non-lactose-containing formula for the duration of the treatment.

Phototherapy is started when the bilirubin level is approximately 3–5 mg/dL (52–86 mmol/L) lower than the exchange level for that infant (eg, at levels of 15–18 mg/dL [258–310 mmol/L] for a full-term infant), depending also on the infant's age. Guidelines for the use of phototherapy in the full-term infant with and without ABO incompatibility are shown in Tables

Figure 1-2. Risk designation of full-term and near-term newborns based on their hour-specific bilirubin values. (Reproduced, with permission, from Bhutani VK et al: Predictive ability of a predischarge hour-specific serum bilirubin test for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics* 1999;103:6.)

1-10 and 1-11. Although phototherapy has been shown to decrease the likelihood of exchange transfusion, the long-term benefits of its use in infants with less severe jaundice are unknown.

C. EXCHANGE TRANSFUSION

Double-volume exchange transfusion (approximately 160–200 mL/kg body weight) remains necessary in some cases of hemolysis resulting from Rh isoimmunization, ABO incompatibility, or hereditary spherocytosis. In addition to decreasing the bilirubin level by approximately 50% acutely, the exchange also removes nearly 80% of the sensitized or abnormal red blood cells and offending antibody so that ongoing hemolysis will be decreased. The procedure is invasive and not without risk. The risk of mortality is 1–5% and is greatest in the smallest, most immature, and otherwise unstable infants, but sudden death during the proce-

Table 1-10. Guidelines for treatment of the full-term infant with ABO blood group incompatibility.

Phototherapy if-
Bilirubin ≥ 10 mg/dL at < 12 h
Bilirubin ≥ 14 mg/dL at 12–24 h
Bilirubin ≥ 15 mg/dL at > 24 h
Consider IVIG if hemoglobin is ≤ 13 g/dL and despite ≥ 4 h of phototherapy:
Bilirubin ≥ 12 mg/dL at < 12 h
Bilirubin ≥ 16 mg/dL at 12–24 h
Bilirubin ≥ 18 mg/dL at 24–72 h

IVIG = intravenous immune globulin.

Table 1–11. Guidelines for use of phototherapy in the full-term infant without hemolysis.

Bilirubin \geq 15 mg/dL, age < 2 d: Evaluation, phototherapy
Bilirubin \geq 18 mg/dL, age > 2–3 d: Evaluation, phototherapy
Bilirubin \geq 20 mg/dL: Evaluation, phototherapy; consider interruption of nursing and formula supplementation; have mother use electric breast pump during interruption of breast feeding
Bilirubin \geq 25 mg/dL: As above, plus consider exchange transfusion

cedure can occur in any infant. Risk of serious complications such as necrotizing enterocolitis (NEC), infection, electrolyte disturbances, or thrombocytopenia is 12%. Because of the rarity of the procedure and its inherent risk, it should be performed very cautiously, preferably at a referral center.

For the typical exchange transfusion, the umbilical vein is catheterized, and reconstituted whole blood with a hematocrit of approximately 50% is used in aliquots of 8–10 mL per pass. Albumin 1 g/kg can be given first to aid in binding and removal of bilirubin. Hypocalcemia occurs during the procedure because of binding to the citrate-phosphate-dextrose anticoagulant and needs to be corrected periodically. Hypoglycemia is common following the procedure and requires close monitoring. Thrombocytopenia occurs because of the removal of platelets. The entire procedure should take 1–2 hours and should be performed using aseptic technique.

HYPOGLYCEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Defined as blood glucose < 40–45 mg/dL.
- LGA, SGA, preterm, and stressed infants at risk.
- May be asymptomatic.
- Infants can present with lethargy, poor feeding, irritability, or seizures.

General Considerations

Blood glucose concentration in the fetus is approximately 15 mg/dL less than the maternal glucose concentration. Glucose concentration normally decreases in the immediate postnatal period, with concentrations below 40–45 mg/dL being considered indicative of hypoglycemia. By 3 hours, the glucose concentration in normal full-term babies stabilizes between 50 and 80 mg/dL. After the first few hours of life, concentrations below 40–45 mg/dL should be considered abnormal. The two most commonly encountered groups of full-term newborn infants at high risk for neonatal hypoglycemia are IDMs and IUGR infants.

Infants of Diabetic Mothers

The IDM has abundant glucose stores in the form of glycogen and fat but develops hypoglycemia because of hyperinsulinemia induced by maternal and fetal hyperglycemia. Other tissues also grow abnormally in utero, probably as a consequence of increased flow of nutrients from the maternal circulation. The result is a macrosomic infant who is at increased risk for trauma during delivery. Other problems related to the in utero metabolic environment include a cardiomyopathy (asymmetrical septal hypertrophy), which can present as a murmur with or without cardiac failure and respiratory distress, and, more rarely, microcolon, which presents as low intestinal obstruction. Infants whose mothers have diabetes at conception are also at increased risk for congenital anomalies probably related to first-trimester glucose control. Other neonatal problems include a hypercoagulable state and polycythemia, a combination that predisposes the infant to large venous thromboses (eg, renal vein thrombosis). Finally,

these infants are somewhat immature for their gestational age and are at increased risk for hyaline membrane disease, hypocalcemia, and hyperbilirubinemia.

Intrauterine Growth Restricted Infants

The IUGR infant has reduced glucose stores in the form of glycogen and body fat and therefore is prone to hypoglycemia despite relatively appropriate endocrine adjustments at birth. In addition to hypoglycemia, marked hyperglycemia and a transient diabetes mellitus-like syndrome may occasionally develop, particularly in the very premature SGA infant. These problems can usually be handled by adjusting glucose intake, though insulin is sometimes needed transiently.

Other Causes of Hypoglycemia

Hypoglycemia occurs with disorders associated with islet cell hyperplasia (Beckwith–Wiedemann syndrome [macroglossia, omphalocele, macrosomia], erythroblastosis fetalis, nesidioblastosis), inborn errors of metabolism [glycogen storage disease, galactosemia], and endocrine disorders [panhypopituitarism, other deficiencies of counterregulatory hormones]. It may also occur as a complication of birth asphyxia, hypoxia, or other stresses, including bacterial and viral sepsis. Premature infants are also at risk for hypoglycemia because of decreased glycogen stores.

Clinical Findings

The signs of hypoglycemia in the newborn infant are relatively nonspecific and may be subtle: lethargy, poor feeding, irritability, tremulousness, jitteriness, apnea, and seizures. The disorder is most severe and resistant to treatment if due to hyperinsulinemia. Cardiac failure may occur in severe cases, particularly in IDMs with cardiomyopathy. Infants with hyperinsulinemic states can experience the onset of hypoglycemia very early (within the first 30–60 minutes of life).

Blood glucose can be measured by heelstick using a bedside glucometer. All infants at risk should be screened, including IDMs, IUGR infants, premature infants, and any infant with symptoms that could be due to hypoglycemia. All low or borderline values should be confirmed by direct measurement of blood glucose concentration determined in the laboratory. It is important to continue surveillance of glucose concentration until the baby has been on full enteral feedings without intravenous (IV) supplementation for a 24-hour period. Relapse of hypoglycemia thereafter is unlikely.

Infants with hypoglycemia requiring IV glucose infusions for more than 5 days should be evaluated for

the less common causes of hypoglycemia. This work-up should include evaluation for inborn errors of metabolism, hyperinsulinemic states, and deficiencies of counterregulatory hormones.

Treatment

Therapy is based on provision of glucose either enterally or intravenously. Table 1–12 presents suggested treatment guidelines. In hyperinsulinemic states, boluses of glucose should be avoided and a higher glucose infusion rate used. After initial correction with a bolus of D₁₀W, 2 mL/kg, glucose infusion should be increased gradually as needed from a starting rate of 6 mg/kg/min. Finally, in both IDMs and IUGR infants, those with high hematocrits and hypoglycemia are most likely to show clinical signs of hypoglycemia. In such infants, both the hypoglycemia and the polycythemia should be treated—with IV glucose infusion and partial exchange transfusion, respectively.

Table 1–12. Hypoglycemia: suggested therapeutic regimens.

Screening Test ^a	Presence of Symptoms	Action
20–45 mg/dL	No symptoms of hypoglycemia	Draw blood glucose; ^b if the infant is alert and vigorous, feed; follow with frequent glucose monitoring. If the baby continues to have blood glucose < 40 mg/dL or is unable to feed, provide intravenous glucose at 6 mg/kg/min (D ₁₀ W at 3.6 mL/kg/h).
< 45 mg/dL	Symptoms of hypoglycemia present	Draw blood glucose; ^b provide bolus of D ₁₀ W (2 mL/kg) followed by an infusion of 6 mg/kg/min (3.6 mL/kg/h).
< 20 mg/dL	With or without symptoms of hypoglycemia	Draw blood glucose; ^b provide bolus of D ₁₀ W followed by an infusion of 6 mg/kg/min. If intravenous access cannot be obtained immediately, an umbilical vein line should be used.

^aRapid bedside determination.

^bLaboratory confirmation.

Prognosis

The prognosis of hypoglycemia is good if therapy is prompt. CNS sequelae are seen in infants with neonatal seizures resulting from hypoglycemia and are more likely in neonates with persistent hyperinsulinemic hypoglycemia.

RESPIRATORY DISTRESS IN THE TERM NEWBORN INFANT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Tachypnea, respiratory rate > 60 breaths/min.*
- *Retractions (intercostal, sternal).*
- *Expiratory grunting.*
- *Cyanosis on room air.*

General Considerations

Respiratory distress is among the most common symptom complexes seen in the newborn infant. It may result from both noncardiopulmonary and cardiopulmonary causes (Table 1–13). Chest radiography, arterial blood gases, and pulse oximetry are useful in assessing both the cause and the severity of the problem. It is important to consider the noncardiopulmonary causes listed in Table 1–13 because the natural tendency is to focus on the heart and lungs. Most of the noncardiopulmonary causes can be ruled out by the history, physical examination, and a few simple laboratory tests. The evaluation of cardiovascular disorders is discussed in a subsequent section.

The most common pulmonary causes of respiratory distress in the full-term infant are transient tachypnea,

aspiration syndromes, congenital pneumonia, and air leaks.

A. TRANSIENT TACHYPNEA (RETAINED FETAL LUNG FLUID)

Respiratory distress is typically present from birth, usually associated with a mild to moderate oxygen requirement (25–50% O₂). The infant may be full-term or near-term, nonasphyxiated, and born following a short

labor or cesarean section without labor. Chest radiograph shows perihilar streaking and fluid in interlobar fissures. Resolution usually occurs within 12–24 hours.

B. ASPIRATION SYNDROMES

The infant is typically full-term or near-term, frequently with some fetal distress prior to delivery or depression at delivery. Blood or meconium is usually present in the amniotic fluid, but occasionally the fluid is clear. Respiratory distress is present from birth, in many cases manifested by a barrel chest appearance and coarse breath sounds. An increasing O_2 need from pneumonitis may require intubation and ventilation. Chest radiograph shows coarse irregular infiltrates, hyperexpansion, and, in the worst cases, lobar consolidation. In some cases, secondary surfactant deficiency can ensue, with progression to a diffuse homogeneous infiltrate pattern.

When the amniotic fluid contains meconium or blood, suctioning of the infant's mouth and nose as the head is delivered and before delivery of the chest is recommended to prevent aspiration of these secretions with the onset of breathing. If the infant is not vigorous at birth, suctioning of the trachea under direct vision is recommended, especially before commencing resuscitation with positive-pressure ventilation. Although these procedures are recommended, they will not prevent all cases of meconium or blood aspiration. Aspiration often occurs in utero as the stressed infant gasps. Babies with aspirations are at risk of air leak (pneumothorax) because of uneven aeration with segmental overdistention and are at risk for persistent pulmonary hypertension (see section on Cardiac Problems). Standard treatment includes ventilatory support, antibiotics, and pressor support of systemic blood pressure.

C. CONGENITAL PNEUMONIA

Infants may be of any gestational age, with or without a maternal history of prolonged rupture of the membranes, chorioamnionitis, or maternal antibiotic administration. Onset of respiratory distress may be at birth or may be delayed for several hours. Chest radiograph may resemble that of retained lung fluid or hyaline membrane disease; rarely, there may be a lobar infiltrate.

The lungs are the most common site of infection in the neonate. Most commonly, infections ascend from the genital tract before or during labor, with the vaginal or rectal flora the most likely infectious agents (group B streptococci, *Escherichia coli*, *Klebsiella*). Shock, poor perfusion, absolute neutropenia ($< 2000/\text{mL}$), and an elevated C reactive protein provide corroborating evidence for pneumonia. Gram stain of tracheal aspirate may be helpful. Because no signs or laboratory findings can confirm the presence or absence of pneumonia with

certainty, all infants with respiratory distress should receive a blood culture and broad-spectrum antibiotic therapy (ampicillin 100 mg/kg in two divided doses and gentamicin 4 mg/kg q24h or 2.5 mg/kg q12h) until the diagnosis of a bacterial infection can be ruled out.

D. SPONTANEOUS PNEUMOTHORAX

Respiratory distress (primarily tachypnea) is present from birth, typically not severe, and requires mild to moderate supplemental O_2 . Breath sounds may be decreased on the affected side; heart tones may be shifted toward the opposite side and may be distant. Chest radiograph will show pneumothorax or pneumomediastinum.

This entity occurs in 1% of all deliveries. The risk is increased by manipulations such as positive-pressure ventilation in the delivery room. Treatment usually consists of supplemental O_2 and watchful waiting. Breathing 100% O_2 for a few hours may accelerate reabsorption of the extrapulmonary gas by creating a diffusion gradient for nitrogen across the surface of the lung (nitrogen washout technique). This is effective only if the infant was breathing room air or O_2 at low concentration at the time of the pneumothorax. Drainage by needle thoracentesis or tube thoracostomy is occasionally required. A small increased risk of renal abnormalities is associated with spontaneous pneumothorax; therefore, a careful physical examination of the kidneys and observation of urine output are indicated. If pulmonary hypoplasia with pneumothorax is suspected, renal ultrasound would also be indicated.

E. OTHER PULMONARY CAUSES

The other pulmonary causes of respiratory distress are fairly rare. Bilateral choanal atresia should be suspected if there is no air movement when the infant breathes through the nose. These infants present in the delivery room with good color and heart rate while crying but become cyanotic and bradycardiac when they quiet down and resume normal nasal breathing. Other causes of upper airway obstruction are usually characterized by some degree of stridor or poor air movement despite good respiratory effort. Pleural effusions can be suspected in hydropic infants (eg, those with erythroblastosis fetalis or nonimmune hydrops). Space-occupying lesions cause a shift of the mediastinum and asymmetrical breath sounds and would be apparent on chest radiograph.

Treatment

Whatever the cause, the cornerstone of treatment of neonatal respiratory distress is provision of adequate supplemental oxygen to maintain a PaO_2 of 60–70 mm

Hg and a saturation by pulse oximetry (SpO_2) of 92–96%. PaO_2 levels less than 50 mm Hg are associated with pulmonary vasoconstriction, which can exacerbate hypoxemia, whereas those greater than 100 mm Hg may increase the risk of oxygen toxicity without additional benefit. Oxygen should be warmed, humidified, and delivered through an air blender. Concentration should be measured with a calibrated oxygen analyzer. An umbilical or peripheral arterial line should be considered in any infant requiring more than 45% FiO_2 by 4–6 hours of life to allow frequent blood gas determinations. Noninvasive monitoring with a pulse oximeter should be used.

Other supportive treatment includes IV provision of glucose and water. Unless infection can be unequivocally ruled out, blood cultures should be obtained and broad-spectrum antibiotics started. Volume expansion (normal saline) can be given in infusions of 10 mL/kg over 30 minutes for low blood pressure, poor perfusion, and metabolic acidosis. Sodium bicarbonate (1–2 mEq/kg) is indicated for treatment of documented metabolic acidosis that has not responded to oxygen, ventilation, and volume. Specific work-up should be pursued as indicated by the history and physical findings. In most cases, a chest radiographic study, blood gas measurements, CBC, and blood glucose allow a diagnosis.

Intubation and ventilation should be undertaken for signs of respiratory failure ($PaO_2 < 60$ mm Hg in 60–80% FiO_2 , $PaCO_2 > 60$ mm Hg, or repeated apnea). Peak pressures should be adequate to produce chest wall expansion and audible breath sounds (usually 18–24 cm H_2O). Positive end-expiratory pressure (4–6 cm H_2O) should also be used. Ventilation rates of 20–50 breaths/min are usually required. The goal is to maintain a PaO_2 of 60–70 mm Hg and a $PaCO_2$ of 45–55 mm Hg.

Prognosis

Most of the respiratory conditions affecting the full-term infant are acute and resolve in the first several days. Meconium aspiration syndrome and congenital pneumonia are associated with significant long-term pulmonary morbidity (chronic lung disease) and mortality (approximately 10–20%). Mortality rates in these disorders have been reduced by use of high-frequency ventilation, inhaled nitric oxide to treat pulmonary hypertension, and extracorporeal membrane oxygenation (ECMO).

Ghidini A, Spong CY: Severe meconium aspiration syndrome is not caused by aspiration of meconium. *Am J Obstet Gynecol* 2001;185:931 [PMID: 11641681].

HEART MURMURS (SEE ALSO SECTION ON CARDIAC PROBLEMS)

Heart murmurs are common in the first days of life and do not usually signify structural heart problems. If a murmur is present at birth, however, it should be considered a valvular problem until proved otherwise because the common benign transitional murmurs (eg, patent ductus arteriosus) are not audible until minutes to hours after birth.

If an infant is pink, well-perfused, and in no respiratory distress and has palpable and symmetrical pulses (right brachial pulse no stronger than the femoral pulse), the murmur is most likely transitional. Transitional murmurs are soft (grade 1–3/6), heard at the left upper to midsternal border, and generally loudest during the first 24 hours. If the murmur persists beyond 24 hours, blood pressure in the right arm and a leg should be determined. If there is a difference of more than 15 mm Hg (arm > leg) or if the pulses in the lower extremities are difficult to appreciate, cardiology consultation should be arranged to evaluate for coarctation of the aorta. If there is no difference, the infant can be discharged home with follow-up in 2–3 days for auscultation and evaluation for signs of congestive failure. If signs of failure or cyanosis are present, the infant should be referred for evaluation without delay. If the murmur persists without these signs, the infant can be referred for elective evaluation at age 2–4 weeks. Some centers now recommend routine pulse oximetry screening in the nursery to identify infants with congenital heart disease, with a saturation < 95% at sea level triggering an echocardiogram. Further studies will need to be performed to document the accuracy, specificity, and cost-effectiveness of this technique.

BIRTH TRAUMA

Most birth trauma is associated with difficult delivery, particularly with a large infant, abnormal position, or fetal distress requiring rapid extraction. The most common injuries are soft tissue bruising, fractures (clavicle, humerus, or femur), and cervical plexus palsies, although skull fractures, intracranial hemorrhage (primarily subdural and subarachnoid), and cervical spinal cord injuries can also occur.

Fractures are often diagnosed by the obstetrician, who may feel and hear a snap during delivery. Clavicular fractures may cause decreased spontaneous move-

ment of the arm, with tenderness and crepitus over the area. Humeral or femoral fractures may cause tenderness and swelling over the shaft with a diaphyseal fracture, with limited spontaneous extremity motion in all cases. Epiphyseal fractures are harder to diagnose radiographically owing to the cartilaginous nature of the epiphysis. After 8–10 days, callus appears and is visible on radiographs. Treatment in all cases is gentle handling, with immobilization for 8–10 days: the humerus against the chest with elbow flexed; the femur with a posterior splint from below the knee to the buttock.

Brachial plexus injuries may result from traction as the head is pulled away from the shoulder during delivery. Injury to the C5–6 roots is most common and results in Erb–Duchenne paralysis. The arm is limp, adducted and internally rotated, extended and pronated at the elbow, and flexed at the wrist (so-called waiter’s tip posture). Grasp is present. If the lower nerve roots (C8–T1) are involved, the hand is flaccid (Klumpke palsy). Isolated involvement of these roots is rare. If the entire plexus is injured, the arm and hand are flaccid, with an associated sensory deficit.

Early treatment for brachial plexus injury is conservative, because function usually returns over several weeks. Referral should be made to a physical therapist so that the parents can be instructed on range-of-motion exercises and splinting and for further evaluation if needed. Return of function begins in the deltoid and biceps, with recovery by 3 months in most cases.

Spinal cord injury can occur at birth, especially in difficult breech extractions with hyperextension of the neck, or in midforceps rotations when the body fails to turn with the head. Infants are flaccid, quadriplegic, and without respiratory efforts at birth, although facial movements are preserved. The long-term outlook for such infants is grim.

Facial nerve palsy is sometimes associated with forceps use but more often results from chronic in utero

pressure of the baby’s head against the mother’s sacrum. The infant has asymmetrical mouth movements and eye closure with poor movement on the affected side. Most cases resolve spontaneously within a few days to 3 weeks.

Subgaleal hemorrhage into the large potential space under the scalp (Figure 1–3) is associated with difficult vaginal deliveries and repeated attempts at vacuum extraction. It can lead to hypovolemic shock and death from ongoing blood loss and severe coagulopathy triggered by both consumption of clotting factors and release of thromboplastin from accompanying brain injury. This is an emergency requiring rapid replacement of blood and clotting factors.

INFANTS OF MOTHERS WHO ABUSE DRUGS

The problem of newborn infants born to mothers who abuse drugs is increasing in all communities. The drugs most commonly abused are tobacco, alcohol, marijuana, and cocaine. Because these mothers may abuse many drugs and give an unreliable history of drug usage, it may be difficult to pinpoint which drug is causing the morbidity seen in a newborn infant. Early hospital discharge makes discovery of these infants based on physical findings and abnormal behavior much more difficult.

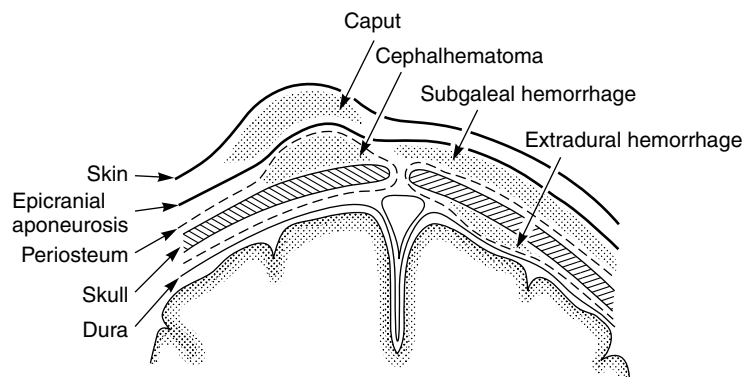

Figure 1–3. Sites of extracranial bleeding in the newborn. (Adapted and reproduced, with permission, from Pape KE, Wigglesworth JS: Haemorrhage Ischemia and the Perinatal Brain. JB Lippincott, 1979.)

1. Cocaine

Cocaine is currently the most commonly abused hard drug, identified in up to 20–40% of infants on urban delivery services by anonymous screening of urine or meconium; moreover, cocaine is often used in association with other drugs. The obstetric effects include maternal hypertension, decreased uterine blood flow, fetal hypoxemia, and uterine contractions. The rates of stillbirth, placental abruption, and preterm delivery are increased two- to fourfold over rates for nonusers, and IUGR is increased two- to fourfold over that for nonusers. In high-risk populations (no prenatal care, placental abruptions, and preterm labor), urine toxicology screens should be performed in mothers and infants. Analysis of meconium enhances diagnosis by indicating cumulative drug use prior to delivery.

As with other illegal drugs, cocaine may have long-term neurobehavioral effects, but multiple drug use and environmental factors preclude assigning specific effects to cocaine with certainty. The risk of SIDS is increased three to seven times over the risk in nonusers (0.5–1% of exposed infants), but may be lessened by supine infant positioning.

2. Opioids

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Irritability, hyperactivity, incessant hunger and salivation.
- Vomiting, diarrhea, excessive weight loss.
- Tremors, seizures.
- Nasal stuffiness, sneezing.
- Often IUGR.

Clinical Findings

The withdrawal signs in infants born to mothers who are addicted to heroin or who have been in maintenance methadone programs are similar. The clinical findings in infants born to methadone-maintained mothers may actually be more severe and prolonged than those seen with heroin. Clinical manifestations begin usually within 1–2 days. The clinical picture is typical enough to suggest a diagnosis even if a maternal history of drug abuse has not been obtained, although onset may not occur prior to discharge at 24 hours. Confirmation should be attempted with urine toxicol-

ogy, but results will be negative unless the last drug dose was within a few days before delivery. Meconium can also be tested for illicit drugs and is more likely to be positive because the substances accumulate throughout pregnancy.

Treatment

Careful observation of the infant is a requirement. If opioid abuse or withdrawal is suspected, the baby is not a candidate for early discharge. Supportive treatment includes swaddling the infant and providing a quiet, dimly lighted environment. In general, specific treatment should be avoided unless the infant has severe symptoms or excessive weight loss. No single drug has been uniformly effective, and the first choice varies among nurseries. The drugs that have been used include phenobarbital at an initial loading dose of 15–20 mg/kg IM, followed by a maintenance dose of 5 mg/kg/d in two divided doses, usually given orally. Opioids, diazepam, and clonidine have also been used, although the present authors prefer phenobarbital for irritability alone because of its safety and predictability. If diarrhea and weight loss are prominent findings, or if adequate control of symptoms has not been achieved, tincture of opium (25-fold dilution to 0.4 mg/mL morphine equivalent; 0.1 mL/kg qh4 to start) titrated to improve symptoms or methadone 0.05–0.1 mg/kg q6h will be more beneficial than phenobarbital alone. Treatment can be tapered over several days to a week. Both handling and procedures in the nursery should be kept to a minimum. It is also important to review maternal tests for syphilis, HIV, hepatitis B, and gonorrhea as all are common in women who use cocaine or opiates.

Prognosis

These infants demonstrate long-term neurobehavioral handicaps. However, it is difficult to distinguish the effects of in utero drug exposure from those of environmental influences during upbringing. Infants of opioid abusers have a four- to fivefold increased risk of SIDS.

3. Alcohol

The legal substances alcohol and tobacco have much greater effects on perinatal outcome than any illicit substances. Alcohol is the only recreational drug of abuse that is clearly teratogenic and is the most common preventable cause of mental retardation. The effects of alcohol on the fetus and the newborn are roughly proportionate to the degree of ethanol abuse, but there is no established safe dose. Fetal growth and development are adversely affected, and infants can experience with-

Table 1–14. Features observed in fetal alcohol syndrome in the newborn.

Craniofacial
Short palpebral fissures
Short, upturned nose
Flat midface
Thin vermilion of upper lip
Flattened philtrum
Growth
Prenatal and postnatal growth deficiency (SGA, failure to thrive)
Central nervous system
Microcephaly
Partial or complete agnesis of the corpus callosum
Optic nerve hypoplasia
Hypotonia, poor feeding

drawal similar to that associated with maternal opioid abuse. Features observed are listed in Table 1–14. Clinical features of fetal alcohol syndrome (FAS) are often not obvious in the newborn period.

Children with full-blown FAS demonstrate postnatal growth deficiency and mild to moderate mental retardation. Those with lesser effects are at increased risk for attention-deficit/hyperactivity disorder and subtle developmental delays.

4. Tobacco Smoking

Smoking has been shown to have a negative effect on the growth rate of the fetus. The more the mother smokes, the greater the degree of IUGR. There is a twofold increase in low birth weight even in light smokers (< 10 cigarettes/day). More recently, smoking during pregnancy has been associated with mild neurodevelopmental handicaps. The possible effects of multiple drug abuse apply to this category as well, and the potential interaction of multiple factors on fetal growth and development must be considered.

5. Toluene Embryopathy

Solvent abuse (paint, lacquer, or glue sniffing) is relatively common. The active organic solvent in these agents is toluene. Features attributable to in utero toluene exposure include prematurity, IUGR, microcephaly, craniofacial abnormalities similar to those associated with in utero alcohol exposure (see Table 1–14), nail hypoplasia, and renal anomalies. Long-term effects include postnatal growth deficiency and developmental delay.

6. Marijuana

Marijuana is the most frequently used illegal drug. It does not appear to be teratogenic, and although a mild abstinence-type syndrome has been described, infants exposed to marijuana in utero rarely require treatment. Some long-term neurodevelopmental problems, particularly disordered sleep patterns, have been noted.

7. Other Drugs

Drugs and their effects on the newborn should be considered in two categories. In the first are drugs to which the fetus is exposed because of the mother's exposure. In many cases these are drugs prescribed for therapy of maternal conditions. The human placenta is relatively permeable, particularly to lipophilic solutes. Whenever possible, maternal drug therapy should be postponed until after the first trimester. Drugs with potential fetal toxicity include antineoplastics, antithyroid agents, benzodiazepines, warfarin, lithium, angiotensin-converting enzyme inhibitors (eg, captopril, enalapril), and immunosuppressants.

In the second category are drugs the infant acquires from the mother during breast feeding. Most drugs taken by the mother at this time achieve some concentrations in breast milk, although they usually do not present a problem to the infant. If the drug is one that could have adverse effects on the baby, timing breast feeding to coincide with trough concentrations in the mother may be useful. The AAP (see second reference in the following list) has reviewed drugs contraindicated in the breast-feeding mother.

MULTIPLE BIRTHS

Twinning has historically occurred as a demographic variation in one of 80 pregnancies (1.25%). The incidence of twinning and higher-order multiple births in the United States has been increasing as a consequence of the increased use of in vitro fertilization and other assisted reproductive technologies. In 1999, twins occurred in 1/43 live births in the United States, with the multiple births accounting for 3% of all births.

A clear distinction should be made between dizygotic (fraternal) and monozygotic (identical) twins. Race, maternal parity, and maternal age affect the incidence only of dizygotic twinning. Drugs that induce ovulation, such as clomiphene citrate and gonadotropins, increase the incidence of dizygotic or polyzygotic twinning quite strikingly. Monozygotic twinning can be viewed as a birth defect; the incidence of malformations is also increased in identical twins and may affect only one of the twins. If a defect is found in one, the other should be examined carefully for lesser degrees of the same defect.

Examination of the placenta can help establish the type of twinning: Two amniotic membranes and two chorionic membranes are found in all cases of dizygotic twins and in one third of monozygotic twins; a single chorionic membrane always indicates monozygotic twins.

Complications of Multiple Births

A. INTRAUTERINE GROWTH RESTRICTION

There is some degree of IUGR in most multiple pregnancies after 34 weeks. If prenatal care is good, however, the growth restriction is rarely significant. There are two exceptions: The first is the monochorial twin pregnancy in which an arteriovenous shunt occurs from

one twin's circulation to that of the other (twin–twin transfusion syndrome). The infant on the venous side becomes plethoric and considerably larger than the smaller anemic twin. Morbidity and mortality rates are considerable in twin–twin transfusion syndrome. Discordance in size—birth weights that are significantly different—can also occur when separate placentas are present. One placenta develops poorly, presumably because of a poor implantation site. In this instance, no fetal exchange of blood takes place but the growth rates of the two infants are significantly different.

B. PRETERM DELIVERY

Gestation length tends to be inversely related to the number of fetuses. The prematurity rate is 5–10 times that of singletons, with 50% of twins and 90% of triplets born before 37 weeks. The prematurity rate tends to increase the mortality or morbidity rates occurring in twin pregnancies.

C. OBSTETRIC COMPLICATIONS

Polyhydramnios, pregnancy-induced hypertension, premature rupture of membranes, abnormal fetal presentations, and prolapsed umbilical cord occur more frequently in women with multiple fetuses. In general, most of the complications can be avoided or minimized by good obstetric management. Multiple pregnancy should always be identified prenatally with ultrasound examinations; doing so allows the obstetrician and pediatrician or neonatologist to plan management jointly. The neonatal complications are usually related to prematurity. Prolongation of pregnancy, therefore, leads to a significant reduction in neonatal morbidity.

Follow-up studies of twin pregnancies have yielded conflicting results. In general, the studies do not suggest that twinning has a significant effect on later development, especially if prematurity is excluded as a separate risk factor.

NEONATAL INTENSIVE CARE

PERINATAL RESUSCITATION

Perinatal resuscitation consists of the steps taken by the obstetrician to support the infant during labor and delivery as well as the traditional resuscitative steps taken by the pediatrician after delivery. Intrapartum support includes maintaining maternal blood pressure with volume expanders if needed, maternal oxygen therapy, positioning the mother to improve placental perfusion, readjusting oxytocin infusions or administering a tocolytic if appropriate, minimizing trauma to the infant (particularly important in infants of very low birth weight), suctioning the nasopharynx upon delivery of the head if meconium is present in the amniotic fluid, obtaining all necessary cord blood samples, and completing an examination of the placenta.

Steps taken by the pediatrician or neonatologist focus on temperature support, initiation and maintenance of effective ventilation, maintenance of perfusion and hydration, and glucose regulation.

A number of conditions associated with pregnancy, labor, and delivery place the infant at risk for birth asphyxia: (1) maternal diseases such as diabetes, pregnancy-induced hypertension, heart and renal disease, and collagen-vascular disease; (2) fetal conditions such as prematurity, multiple births, growth retardation, and fetal anomalies; and (3) labor and delivery conditions, including fetal distress with or without meconium in the amniotic fluid, and administration of anesthetics and opioid analgesics.

Physiology of Birth Asphyxia

Birth asphyxia can be the result of several mechanisms: (1) acute interruption of umbilical blood flow (eg, prolapsed cord with cord compression), (2) premature placental separation, (3) maternal hypotension or hypoxia, (4) chronic placental insufficiency, and (5) failure to execute newborn resuscitation properly.

The neonatal response to asphyxia follows a predictable pattern that has been demonstrated in a variety of species (Figure 1-4). The initial response to hypoxia is an increase in frequency of respiration and a rise in heart rate and blood pressure. Respirations then cease (primary apnea) as heart rate and blood pressure begin to fall. This initial period of apnea lasts 30–60 seconds. Gasping respirations (3–6/min) then begin, while heart rate and blood pressure gradually decline. Secondary or terminal apnea then ensues, with further decline in heart rate and blood pressure. The longer the duration of secondary apnea, the greater the risk for hypoxic

Figure 1-4. Schematic depiction of changes in rhesus monkeys during asphyxia and on resuscitation by positive-pressure ventilation. (Adapted and reproduced, with permission, from Dawes GS: *Fetal and Neonatal Physiology*. Year Book, 1968.)

organ injury. A cardinal feature of the defense against hypoxia is the underperfusion of certain tissue beds (eg, skin, muscle, kidneys, GI tract), which allows the perfusion of core organs (ie, heart, brain, adrenals) to be maintained.

The response to resuscitation also follows a predictable pattern. During the period of primary apnea, almost any physical stimulus causes the baby to initiate respirations. Infants in secondary apnea require positive-pressure ventilation. The first sign of recovery is an increase in heart rate, followed by an increase in blood pressure with improved perfusion. The time required for rhythmic, spontaneous respirations to occur is related to the duration of the secondary apnea. As a rough rule, for each 1 minute past the last gasp, 2 minutes of positive-pressure breathing is required before gasping begins, and 4 minutes is required to reach

rhythmic breathing. These times can vary depending on the degree and duration of intrauterine asphyxia. Not until some time later do spinal and corneal reflexes return. Muscle tone gradually improves over the course of several hours.

Delivery Room Management

When asphyxia is anticipated, a resuscitation team of at least two persons should be present: one to manage the airway and one to monitor the heartbeat and provide assistance. The necessary equipment and drugs are listed in Table 1–15.

Table 1–15. Equipment for neonatal resuscitation.

Clinical Needs	Equipment
Thermoregulation	Radiant heat source with platform, mattress covered with warm sterile blankets, servocontrol heating, temperature probe
Airway management	<p>Suction: Bulb suction, mechanical suction with sterile catheters (6F, 8F, 10F), meconium aspirator</p> <p>Ventilation: Manual infant resuscitation bag connected to manometer or with a pressure-release valve capable of delivering 100% oxygen, appropriate masks for term and preterm infants, oral airways, stethoscope</p> <p>Intubation: Neonatal laryngoscope with No. 0 and No. 1 blades; endotracheal tubes (2.5, 3.0, 3.5 mm outer diameter with stylet); extra bulbs and batteries for laryngoscope; scissors, adhesive tape, gloves, end tidal CO₂ detection device</p>
Gastric decompression	Nasogastric tube: 8F with 20-mL syringe
Administration of drugs and volume replacement	Sterile umbilical catheterization tray, umbilical catheters (3.5F and 5F), volume expanders, normal saline, drug box ^a with appropriate neonatal vials and dilutions, sterile syringes, needles, and alcohol sponges
Transport	Warmed transport isolette with oxygen source

^aEpinephrine 1:10,000; naloxone hydrochloride 1 mg/mL; sodium bicarbonate 4.2% (5 mEq/10 mL); 10% dextrose.

Modified, with permission, from Rosenberg AA: Neonatal adaptation. In: Gabbe SG et al (eds). *Obstetrics: Normal and Problem Pregnancies*. Churchill Livingstone, 1996.

A. STEPS IN THE RESUSCITATION (SEE FIGURE 1–5.)

1. Dry the infant well, and place him or her under the radiant heat source. Do not allow the infant to become hyperthermic.
2. Gently suction the mouth, then the nose.
3. Quickly assess the infant's condition. The best criteria are the infant's respiratory effort (apneic, gasping, regular) and heart rate (> 100 or < 100 beats/min). A depressed heart rate—indicative of hypoxic myocardial depression—is the single most reliable indicator of the need for resuscitation.
4. Infants who are breathing and have heart rates over 100 beats/min usually require no further intervention. Infants with heart rates less than 100 beats/min and apnea or irregular respiratory efforts should be stimulated vigorously. The baby's back should be rubbed with a towel while oxygen is provided near the baby's face.
5. If the baby fails to respond to tactile stimulation within a few seconds, begin bag and mask ventilation, using a soft mask that seals well around the mouth and nose. For the initial inflations, pressures of 30–40 cm H₂O may be necessary to overcome surface-active forces in the lungs. Adequacy of ventilation is assessed by observing expansion of the infant's chest accompanied by an improvement in heart rate, perfusion, and color. After the first few breaths, lower the peak pressure to 15–20 cm H₂O. The baby's chest movement should resemble that of an easy breath rather than a deep sigh. The rate of bagging should be 40–60 breaths/min.
6. Most neonates can be resuscitated effectively with a bag and mask. If the infant does not respond to bag and mask ventilation, try to reposition the head (slight extension), reapply the mask to achieve a good seal, consider suctioning the mouth and the oropharynx, and try ventilating with the mouth open. If the infant does not respond within 30 seconds, intubation is appropriate.

Failure to respond to intubation and ventilation can result from (1) mechanical difficulties (Table 1–16), (2) profound asphyxia with myocardial depression, and (3) inadequate circulating blood volume.

Quickly rule out the mechanical causes listed in Table 1–16. Check to ensure the endotracheal tube passes through the vocal cords. A CO₂ detector placed between the endotracheal tube and the bag can be very helpful as a rapid confirmation of tube position in the airway. Occlusion of the tube

Table 1–16. Mechanical causes of failed resuscitation.

Cause	Examples
Equipment failure	Malfunctioning bag, oxygen not connected or running
Endotracheal tube malposition	Esophagus, right main stem bronchus
Occluded endotracheal tube	
Insufficient inflation pressure to expand lungs	
Space-occupying lesions in the thorax	Pneumothorax, pleural effusions, diaphragmatic hernia
Pulmonary hypoplasia	Extreme prematurity, oligohydramnios

Reproduced, with permission, from Rosenberg AA: Neonatal adaptation. In: Gabbe SG et al (eds): *Obstetrics: Normal and Problem Pregnancies*. Churchill Livingstone, 1996.

should be suspected when there is resistance to bagging and no chest wall movement. Very few neonates (approximately 0.1%) require either cardiac massage or drugs during resuscitation. Almost all newborns respond to ventilation with 100% oxygen if done effectively.

- If mechanical causes are ruled out and the heart rate remains below 60 beats/min after intubation and positive-pressure ventilation for 30 seconds, cardiac compression should be initiated. Simultaneous delivery of chest compressions and positive-pressure ventilation is likely to decrease the efficiency of ventilation. Therefore, chest compressions should be interspersed with ventilation at a 3:1 ratio (90 compressions and 30 breaths/min).
- If drugs are needed (rarely), the drug and dose of choice is epinephrine 1:10,000 solution, 0.1–0.3 mL/kg given via the endotracheal tube or through an umbilical venous line. Sodium bicarbonate, 1–2 mEq/kg of the neonatal dilution (0.5 mEq/mL), can be used in prolonged resuscitation efforts in which the response to other measures is poor. If volume loss is suspected, 10 mL/kg of a volume expander (normal saline) should be administered through an umbilical vein line.

B. CONTINUED RESUSCITATIVE MEASURES

The appropriateness of continued resuscitative efforts should be reevaluated in an infant who fails to respond

to the previously described efforts. In current practice, resuscitative efforts are made even in apparent stillbirths (ie, infants whose Apgar score at 1 minute is 0–1). Modern resuscitative techniques have led to an increasing survival rate for these infants, with 60% of survivors showing normal development. It is clear from a number of studies that initial resuscitation of these infants should proceed; however, subsequent continued support must depend on response to resuscitation. All studies emphasize that if the Apgar score is not improving markedly over the first 10–15 minutes of life, the mortality rate and the incidence of severe developmental handicaps among survivors are high.

C. SPECIAL CONSIDERATIONS

1. Preterm infants-

a. Minimizing heat loss improves survival, so prewarmed towels should be available. The environmental temperature of the delivery suite should be raised to $> 25^{\circ}\text{C}$ (especially for infants weighing < 1500 g).

b. In the extremely low birth weight infant (< 1000 g), proceed quickly to intubation.

c. Volume expanders and sodium bicarbonate (if needed) should be infused more slowly to minimize rapid swings in blood pressure and serum osmolality.

2. **Narcotic depression**—In the case of opioid administration to the mother during labor, perform the resuscitation as described earlier. When the baby is stable with good heart rate, color, and perfusion but still has poor respiratory effort, a trial of naloxone (0.1 mg/kg IM, SQ, IV, or IT) is indicated. Naloxone should not be administered in place of positive-pressure ventilation. Naloxone should not be used in the infant of an opioid-addicted mother because it will precipitate withdrawal.

3. Meconium-stained amniotic fluid—

a. The obstetrician carefully suction the oropharynx and the nasopharynx after delivery of the head with a suction apparatus attached to wall suction.

b. The delivery is then completed, and the baby is given to the resuscitation team.

c. If the baby is active and breathing, requiring no resuscitation, and if obstetric suctioning has been performed, the airway need not be inspected—only further suctioning of the mouth and nasopharynx is required.

d. The airway of any depressed infant requiring ventilation must be checked and cleared (by passage of a tube below the vocal cords) before positive-pressure ventilation is instituted. Special adapters are available for use with regulated wall suction to allow suction to be applied directly to the endotracheal tube.

4. **Universal precautions**—In the delivery room, universal precautions should always be observed.

Treatment of the Asphyxiated Infant

Asphyxia is manifested by multiorgan dysfunction, seizures and hypoxic-ischemic encephalopathy, and metabolic acidemia. The infant who has experienced a significant episode of perinatal hypoxia and ischemia is at risk for dysfunction of multiple end organs (Table 1–17). The organ of greatest concern is the brain.

The clinical features of hypoxic-ischemic encephalopathy progress over time: birth to 12 hours, decreased level of consciousness, poor tone, decreased spontaneous movement, periodic breathing or apnea, and possible seizures; 12–24 hours, more seizures, apneic spells, jitteriness, and weakness; after 24 hours, decreased level of consciousness, further respiratory abnormalities (progressive apnea), onset of brainstem signs (oculomotor and pupillary disturbances), poor feeding, and hypotonia.

The severity of clinical signs and the length of time the signs persist correlate with the severity of the insult. Other evaluations helpful in assessing severity in the full-term infant include electroencephalogram (EEG), computed tomography (CT) scan, and evoked responses. Magnetic resonance imaging (MRI), particularly diffusion-weighted imaging, is becoming useful, especially in the early evaluation of the infant with perinatal asphyxia.

Markedly abnormal EEGs with voltage suppression and slowing evolving into a burst-suppression pattern are associated with severe clinical symptomatology. A CT scan early in the course may demonstrate diffuse hypodensity and loss of gray/white matter tissue differentiation, whereas later scans may demonstrate brain atrophy and focal ischemic lesions. Visual and so-

Table 1–17. Signs and symptoms caused by asphyxia.

Hypoxic-ischemic encephalopathy, seizures
Respiratory distress due to aspiration or secondary surfactant deficiency, pulmonary hemorrhage
Persistent pulmonary hypertension
Hypotension due to myocardial dysfunction
Transient tricuspid valve insufficiency
Anuria or oliguria due to acute tubular necrosis
Feeding intolerance; necrotizing enterocolitis
Elevated aminotransferases due to liver injury
Adrenal insufficiency due to hemorrhage
Disseminated intravascular coagulation
Hypocalcemia
Hypoglycemia
Persistent metabolic acidemia
Hyperkalemia

matosensory evoked potentials provide information about function. In most instances, it is not necessary to use all of these tests, but some are obtained to confirm an ominous prognosis. Management is directed at supportive care and treatment of specific abnormalities. Fluids should be restricted initially to 60–80 mL/kg/d; oxygenation should be maintained (with mechanical ventilation if necessary); blood pressure should be supported with judicious volume expansion (if hypovolemic) and pressors; and glucose should be in the normal range of 40–100 mg/dL. Hypocalcemia, coagulation abnormalities, and metabolic acidemia should be corrected and seizures treated with IV phenobarbital (20 mg/kg as loading dose, with total initial 24-hour dosing up to 40 mg/kg). Phenobarbital in large doses (40 mg/kg IV 1–6 hours after the event) given as a neuroprotective therapy is associated with improvement in neurologic outcome with minimal adverse effects on blood pressure, respirations, or blood gases. Other anticonvulsants should be reserved for refractory seizures. The role of hypothermia (in particular, selective head cooling), free oxygen radical scavengers, excitatory amino acid antagonists, and calcium channel blockers in minimizing cerebral injury after asphyxia is under active investigation.

Birth Asphyxia: Long-Term Outcome

Fetal heart rate tracings, cord pH, and 1-minute Apgar scores are imprecise predictors of long-term outcome. Apgar scores of 0–3 at 5 minutes in full-term infants result in an 18–35% risk of death in the first year of life and an 8% risk of cerebral palsy among survivors. The risks of mortality and morbidity increase with more prolonged depression of the Apgar score. The single best predictor of outcome is the severity of clinical hypoxic-ischemic encephalopathy (severe symptomatology including coma carries a 75% chance of death and a 100% rate of neurologic sequelae among survivors). The major sequela of hypoxic-ischemic encephalopathy is cerebral palsy with or without associated mental retardation and epilepsy. Other prognostic features include elevated nucleated red blood cell counts, prolonged seizures refractory to therapy, markedly abnormal EEGs, and CT or MRI scans with evidence of major ischemic injury. Other clinical features required to support perinatal hypoxia as the cause of cerebral palsy include the presence of fetal distress prior to birth, a low cord pH of < 7.00, evidence of other end organ dysfunction, and absence of a congenital brain malformation.

THE PRETERM INFANT

Premature infants account for the majority of high-risk newborns. The preterm infant faces a variety of physiologic handicaps:

1. The ability to suck, swallow, and breathe in a coordinated fashion is not achieved until 34–36 weeks' gestation. Therefore, enteral feedings must be provided by gavage. Furthermore, preterm infants frequently have gastroesophageal reflux and an immature gag reflex, which increases the risk of aspiration of feedings.
2. Decreased ability to maintain body temperature.
3. Pulmonary immaturity-surfactant deficiency, often with structural immaturity in infants of less than 26 weeks' gestation. Their condition is complicated by the combination of noncompliant lungs and an extremely compliant chest wall.
4. Immature control of respiration, leading to apnea and bradycardia.

5. Persistent patency of the ductus arteriosus, leading to further compromise of pulmonary gas exchange because of overperfusion of the lungs.
6. Immature cerebral vasculature, predisposing the infant to subependymal or intraventricular hemorrhage and periventricular leukomalacia.
7. Impaired substrate absorption by the GI tract, compromising nutritional management.
8. Immature renal function (including both filtration and tubular functions), complicating fluid and electrolyte management.
9. Increased susceptibility to infection.
10. Immaturity of metabolic processes, predisposing to hypoglycemia and hypocalcemia.

Delivery Room Care

See section on Perinatal Resuscitation.

Care in the Nursery

A. THERMOREGULATION

Maintaining a stable body temperature is a function of heat production and conservation balanced against heat loss. Heat production in response to cold stress can occur through voluntary muscle activity, involuntary

muscle activity (shivering), and thermogenesis not caused by shivering. Newborns produce heat mainly through the last of these three mechanisms. This metabolic heat production depends on the quantity of brown fat present, which is very limited in the preterm infant. Heat loss to the environment can occur through the following mechanisms: (1) radiation—transfer of heat from a warmer to a cooler object not in contact; (2) convection—transfer of heat to the surrounding gaseous environment, influenced by air movement and temperature; (3) conduction—transfer of heat to a cooler object in contact; and (4) evaporation—cooling secondary to water loss through the skin. Heat loss in the preterm newborn is accelerated because of a high ratio of surface area to body mass, reduced insulation of subcutaneous tissue, and water loss through the immature skin.

The thermal environment of the preterm neonate must be regulated carefully. The infant can be kept warm in an isolette, in which the air is heated and convective heat loss is minimized. Alternatively, the infant can be kept warm on an open bed with a radiant heat source. Although evaporative and convective heat losses are greater when the radiant warmer is used, this system allows easy access to a critically ill neonate. Ideally, the infant should be kept in a neutral thermal environment (Figure 1–6). The neutral thermal environment allows

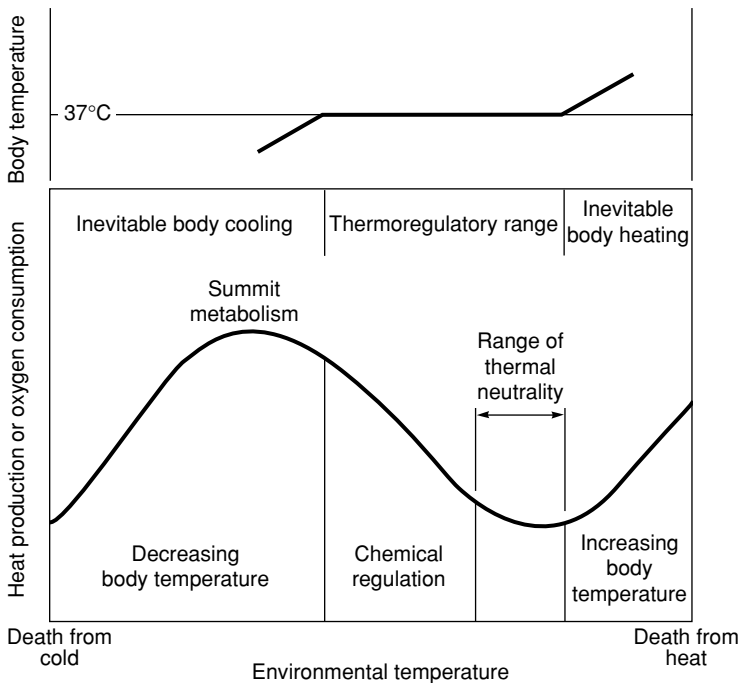

Figure 1–6. Effect of environmental temperature on oxygen consumption and body temperature. (Adapted and reproduced, with permission, from Klaus MH, Fanaroff AA, Martin RJ: The physical environment. In: Klaus MH, Fanaroff AA [editors]: *Care of the High-Risk Neonate*, 5th ed. WB Saunders, 2001.)

the infant to maintain a stable core body temperature with a minimum of metabolic heat production through oxygen consumption. The neutral thermal environment for a given infant depends on size, gestational age, and postnatal age. The neutral thermal environment (for either isolette or radiant warmer care) can be obtained by maintaining an abdominal skin temperature of 36.5°C. Generally, when infants reach 1700–1800 g, they can maintain temperature while bundled in an open crib.

B. MONITORING THE HIGH-RISK INFANT

Care of the high-risk preterm infant requires sophisticated monitoring techniques. At a minimum, equipment to monitor heart rate, respirations, and blood pressure should be available. Oxygen saturation can be assessed continuously using pulse oximetry. This determination can be correlated with arterial oxygen tension (PaO₂) as needed. Transcutaneous PO₂ and PCO₂ can also be used to assess oxygenation and ventilation. Finally, arterial blood gases, electrolytes, glucose, calcium, bilirubin, and other chemistries must be measured on small volumes of blood. Early in the care of a sick preterm infant, the most efficient way to sample blood for tests as well as to provide fluids and monitor blood pressure is through an umbilical arterial line. Once the infant is stable and the need for frequent blood samples is reduced (usually 4–7 days), the umbilical line should be removed. All indwelling lines are associated with morbidity from thrombosis or embolism, infection, and bleeding.

C. FLUID AND ELECTROLYTE THERAPY

Fluid requirements in preterm infants are a function of (1) insensible losses (skin and respiratory tract), (2) urine output, (3) stool output (< 5% of total), and (4) others, such as nasogastric losses. In most circumstances, the fluid requirement is determined largely by insensible losses plus urine losses. The major contribution to insensible water loss is evaporative skin loss. The rate of water loss is a function of gestational age (body weight), environment (losses are greater under a radiant warmer than in an isolette), and the use of phototherapy. Respiratory losses are minimal when infants are breathing humidified oxygen. The renal contribution to water requirement is influenced by the decreased ability of the preterm neonate to concentrate the urine and conserve water.

Electrolyte requirements are minimal for the first 24–48 hours until there is excretion in the urine. Basal requirements are as follows: sodium, 3 mEq/kg/d; potassium, 2 mEq/kg/d; chloride, 2–3 mEq/kg/d; and bicarbonate, 2–3 mEq/kg/d.

In the infant born before 30 weeks' gestation, sodium and bicarbonate losses in the urine are fre-

quently elevated, increasing the infant's requirement for these electrolytes.

Initial fluid management after birth is determined by the infant's size. Infants weighing more than 1500 g should start at 80–100 mL/kg/d of 10% dextrose in water (D₁₀W), whereas those weighing less should start at 100–120 mL/kg/d of either D₁₀W or 5% dextrose in water (D₅W) (infants < 800 g and < 26 weeks' gestation often become hyperglycemic on D₁₀W). The most critical issue in fluid management is monitoring. Measurements of body weight, urine output, fluid and electrolyte intake, serum and urine electrolytes, and glucose allow fairly precise determinations of the infant's water, glucose, and electrolyte needs. Parenteral nutrition should be started early and continued until an adequate enteral intake is achieved.

D. NUTRITIONAL SUPPORT

The average caloric requirement for the growing premature infant is 120 kcal/kg/d. Expected weight gain for the adequately nourished preterm infant is 10–30 g/d. Infants initially require IV glucose infusions to maintain blood glucose concentration in the range of 60–100 mg/dL. Infusions of 5–7 mg/kg/min (approximately 80–100 mL/kg/d of a D₁₀W solution) are usually needed. Nutritional support in the very low birth weight infant should be started as soon as possible after birth, with parenteral alimentation solutions given either peripherally or centrally via an umbilical vein line or percutaneous catheter (Table 1–18). Small-volume trophic feeds with breast milk or 20 kcal/oz of premature formula should be started by gavage at ≤ 10% of the infant's nutritional needs as soon as possible. After several days of trophic feeds the infant can be slowly advanced to full caloric needs over 5–7 days. Even extremely small feed volumes can enhance intestinal readiness to ultimately accept larger feeding volumes. Intermittent bolus feedings are preferred because these appear to stimulate the release of gut-related hormones and may accelerate maturation of the GI tract. A more rapid advancement schedule is used for infants weighing over 1500 g and the slowest schedule in the infant weighing less than 1000 g. **Note:** In the extremely low birth weight infant (< 1000 g) or the postsurgical neonate, continuous-drip feeds are sometimes better tolerated.

In general, long-term nutritional support for infants of very low birth weight consists either of breast milk supplemented to increase protein, caloric density, and mineral content or of infant formulas modified for preterm infants. In all of these formulas, protein concentrations (approximately 2 g/dL) and caloric concentrations (approximately 24 kcal/oz) are relatively high. In addition, premature formulas contain some of the fat as medium-chain triglycerides—which do not re-

Table 1–18. Use of parenteral alimentation solutions.

	Volume (mL/kg/d)	Carbohydrate (g/dL)	Protein (g/kg)	Lipid (g/kg)	Calories (kcal/kg)
Peripheral: Short-term (7–10 days)					
Starting solution	100–150	D ₁₀ W	2	1	46–64
Target solution	150	D _{12.5} W	3–3.5	3	102
Central: Long-term (>10 days)					
Starting solution	100–150	D ₁₀ W	2	1	46–64
Target solution	130	D ₂₀ W	3–3.5	3	123

Notes:

1. Protein calories should be no more than 10% of total calories.
2. Advance dextrose in central hyperalimentation as tolerated by 2.5% per day as long as blood glucose remains normal.
3. Advance lipids by 1.0 g/kg/d as long as triglycerides are normal. Use 20% concentration.
4. Total water should be 100–150 mL/kg/d, depending on the child's fluid tolerance.

Monitoring:

1. Blood glucose two or three times a day when changing dextrose concentration, then daily.
2. Electrolytes daily, then twice a week when the child is receiving a stable solution.
3. Every other week blood urea nitrogen and serum creatinine; total protein and serum albumin; serum calcium, phosphate, magnesium, direct bilirubin, and CBC with platelet counts.
4. Triglyceride level after 24 h at 2 g/kg/d and 24 h at 3 g/kg/d; then every other week.

quire bile for emulsification—as an energy source. Increased amounts of calcium and phosphorus are provided to enhance bone mineralization. In addition, as with formula for full-term infants, formulas for premature infants are now being enriched with long-chain polyunsaturated fatty acids in the hope of enhancing brain and retinal development. The infant should be advanced gradually to feedings of higher caloric density after a substantial volume (100–120 mL/kg/d) of either breast milk or formula (20 kcal/oz) is tolerated. Success of feedings is assessed by passage of feeds out of the stomach, abdominal examination free of distention, and normal stool pattern.

When the preterm infant approaches term, the nutritional source for the bottle-fed infant can be changed to a transitional formula (22 kcal/oz) until age 6–9 months. Iron supplementation (2–4 mg/kg/d) is recommended for premature infants, beginning at about age 2 months. This can be provided by iron-supplemented formulas. In some infants, iron supplementation may be indicated earlier. In particular, infants treated with erythropoietin (epoetin alfa) for prevention or treatment of anemia of prematurity require a higher dosage of 4–8 mg/kg/d.

1. Apnea in the Preterm Infant

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Respiratory pause of sufficient duration to result in cyanosis or bradycardia.
- Most common in infants born at < 34 weeks' gestation with onset at < 2 weeks of age.
- Methylxanthines (eg, caffeine) provide effective treatment for apnea of prematurity.

General Considerations

In preterm infants, recurrent apneic episodes are a common problem. Apnea is defined as a respiratory pause lasting more than 20 seconds—or any pause accompanied by cyanosis and bradycardia. Shorter respiratory pauses associated with cyanosis or bradycardia also qualify as significant apnea but must be differentiated from periodic breathing, which is common in full-term as well as preterm infants. Periodic breathing is defined as regularly recurring ventilatory cycles interrupted by short pauses not associated with bradycardia or color change. Although apnea in premature infants is often not associated with a predisposing factor, a variety of processes may precipitate apnea (Table 1–19). These

Table 1–19. Causes of apnea in the preterm infant.

Temperature instability—both cold and heat stress

Posthemorrhagic hydrocephalus
Seizures
Drugs (eg, morphine)
Apnea of prematurity

processes should at least be considered before a diagnosis of apnea of prematurity can be established.

Apnea of prematurity is the most frequent cause of apnea. Most apnea of prematurity is mixed apnea characterized by a centrally (brainstem) mediated respiratory pause preceded or followed by airway obstruction. Less common is pure central or pure obstructive apnea. Apnea of prematurity is the result of immaturity of both the central respiratory regulatory centers and protective mechanisms that aid in maintaining airway patency.

Clinical Findings

Onset, typically during the first 2 weeks of life, is gradual, with the frequency of spells increasing over time. Pathologic apnea can be suspected in an infant with a sudden onset of frequent or very severe apneic spells. Apnea presenting from birth or on the first day of life is unusual but can occur in the preterm infant who does not require mechanical ventilation for respiratory distress syndrome. In the full-term or near-term infant, this presentation can suggest neuromuscular abnormalities of an acute (asphyxia, birth trauma, or infection) or chronic (eg, congenital hypotonia, structural CNS lesion) nature.

The work-up depends on the clinical presentation. All infants—regardless of the severity and frequency of apnea—require a minimum screening evaluation, including a general assessment of well-being (eg, tolerance of feedings, stable temperature, normal physical examination), a check of the association of spells with feeding, measurement of PaO₂ or SaO₂, blood glucose, hematocrit, and a review of the drug history. Infants with severe apnea of sudden onset may require a more extensive evaluation, including a work-up for infection. Other specific tests are dictated by relevant signs, for example, evaluation for necrotizing enterocolitis in an infant with apnea and abdominal distention or feeding intolerance.

Treatment

The physician should first address any underlying cause. If the apnea is due simply to prematurity, treatment is dictated by the frequency and severity of apneic spells. Apneic spells frequent enough to interfere with other aspects of care (eg, feeding), or severe enough to necessitate bag and mask ventilation to relieve cyanosis and bradycardia, require treatment. First-line therapy is with methylxanthines. Caffeine citrate (20 mg/kg as loading dose and then 5–10 mg/kg/d) is the drug of choice because of once-daily dosing, wider therapeutic index, and fewer side effects than theophylline. Side effects of methylxanthines include tachycardia, feeding

intolerance, and (with overdosing) seizures. The dose used should be the smallest dose necessary to decrease the frequency of apnea and eliminate severe spells. Desired drug levels are usually in the range of 10–20 mg/mL for caffeine. Nasal CPAP (continuous positive airway pressure), by treating the obstructive component of apnea, can be effective treatment for some infants. Intubation and ventilation can eliminate symptomatic apneic spells but carry the risks associated with long-term endotracheal intubation.

Prognosis

In the majority of premature infants, apneic and bradycardiac spells cease by 34–37 weeks postconception. Spells that require intervention cease prior to self-resolved episodes. In infants born at less than 28 weeks' gestation, episodes may continue past term postconceptual age. Whether to provide home monitoring or outpatient methylxanthine therapy for such infants is controversial. Apneic and bradycardiac episodes in the nursery are not predictors of later SIDS. However, home monitoring in infants still experiencing self-resolving apnea and bradycardia at the time of hospital discharge may be indicated in some cases. The incidence of SIDS is slightly increased in preterm infants. Research in full-term infants has shown an increased incidence of SIDS in infants who sleep in the prone position. Whether this can be extrapolated to the preterm infant (in particular those with gastroesophageal reflux or persistent respiratory symptoms) is unclear. When possible, a supine sleeping position or one that is slightly to the right side seems prudent unless contraindicated by reflux or respiratory symptoms.

2. Hyaline Membrane Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Tachypnea, cyanosis, and expiratory grunting.
- Poor air movement despite increased work of breathing.
- Chest radiograph showing hypoexpansion and air bronchograms.

General Considerations

The most common cause of respiratory distress in the preterm infant is hyaline membrane disease. The incidence increases from 5% of infants born at

35–36 weeks' gestation to more than 50% of infants born at 26–28 weeks' gestation. This condition is caused by a deficiency of surfactant. Surfactant decreases surface tension in the alveolus during expiration, allowing the alveolus to remain partly expanded and in that way maintaining a functional residual capacity. The absence of surfactant results in poor lung compliance and atelectasis. The infant must expend a great deal of effort to expand the lungs with each breath, and respiratory failure ensues (Figure 1–7).

Clinical Findings

Infants with hyaline membrane disease demonstrate all the clinical signs of respiratory distress. On auscultation, air movement is diminished despite vigorous respiratory effort. Chest radiograph demonstrates diffuse bilateral atelectasis, causing a ground-glass appearance. Major airways are highlighted by the atelectatic air sacs, creating air bronchograms. In the unintubated child, doming of the diaphragm and underexpansion occur.

Treatment

Supplemental oxygen, use of nasal CPAP, early intubation for surfactant administration and ventilation, and placement of umbilical artery and vein lines are the initial interventions required. A ventilator that can deliver breaths synchronized with the infant's respiratory efforts (synchronized intermittent mandatory ventilation) should be used if available. High-frequency ventilators

Figure 1–7. Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. (Reproduced, with permission, from Jobe AH: The developmental biology of the lung. In: Fanaroff AA, Martin RJ [editors]: *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant*, 6th ed. Mosby, 1997.)

are also available for rescue of infants doing poorly on conventional ventilation or who have air leak problems.

Four exogenous surfactants (colfosceril palmitate [Exosurf Neonatal], beractant [Survanta], calf lung surfactant extract [Infasurf]), and poractant a (Curosurf) are approved in the United States by the Food and Drug Administration for use in infants with hyaline membrane disease. Surfactant replacement therapy, used both in the delivery room as prophylaxis and with established hyaline membrane disease as rescue, decreases the mortality rate in preterm infants and decreases air leak complications of the disease. During the acute course, ventilator settings and oxygen requirements are significantly less in surfactant-treated infants than in control subjects. The dose of the bovine-derived Survanta is 4 mL/kg, the calf-derived Infasurf is 3 mL/kg, and the porcine-derived Curosurf is 1.25–2.5 mL/kg, given intratracheally. When the first dose is given in the delivery room to prevent hyaline membrane disease the usual dosing schedule is a total of two or three doses given 6–12 hours apart as long as the infant remains ventilated on over 30–40% inspired oxygen concentration. Rescue surfactant is given as two to four doses 6–12 hours apart. The first dose is administered as soon as possible after birth, preferably before 2–4 hours of age. As the disease process evolves, proteins that inhibit surfactant function leak into the air spaces, making surfactant replacement less effective. The second dose should be administered to infants who continue to require ventilation and more than 30–40% inspired oxygen concentration. A prophylactic strategy offers some advantage in those infants born at 26 weeks' gestation or less. For infants over 26 weeks' gestation, early rescue therapy (as soon as a diagnosis of surfactant deficiency can be made) is the strategy of choice. In stable infants, a trial of nasal CPAP at 5–6 cm H₂O pressure can be attempted prior to intubation and surfactant administration. For those who do ultimately require intubation, extubation to nasal CPAP should be done as early as possible to minimize lung injury and evolution of chronic lung disease. Antenatal administration of corticosteroids to the mother is an important strategy used by obstetricians to accelerate lung maturation. Infants whose mothers were given corticosteroids more than 24 hours prior to preterm birth have less respiratory distress syndrome and a lower mortality rate. Antenatal corticosteroids and exogenous surfactant administration after birth appear to have a synergistic effect on outcome.

3. Chronic Lung Disease in the Premature Infant

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Oxygen requirement, respiratory symptoms, and abnormal chest radiograph at age 1 month.*
- *Incidence greatest in infants of the lowest gestational ages.*

General Considerations

Chronic lung disease in the premature infant, defined as respiratory symptoms, oxygen requirement, and chest radiograph abnormalities at age 1 month, occurs in about 20% of infants ventilated for surfactant deficiency. The incidence is higher at lower gestational ages. The development of chronic lung disease is a function of lung immaturity at birth and exposure to high oxygen concentrations and ventilator volutrauma. The use of surfactant replacement therapy or early nasal CPAP has, in general, diminished the severity of the chronic lung disease. The mortality rate from this complication is now very low, but significant morbidity still exists secondary to reactive airway symptoms, hospital readmissions during the first 2 years of life for intercurrent respiratory infection, and systemic hypertension.

Treatment

The mainstay of therapy for chronic lung disease has been dexamethasone, 0.3–0.5 mg/kg/d, used to decrease lung inflammation. Recently, however, more attention has been focused on the detrimental effects of dexamethasone therapy on long-term neurodevelopment. Attempts are being made to avoid this intervention unless the infant is on very high concentrations of supplemental oxygen and ventilator support with little response to other therapies such as diuretics (furosemide [Lasix] 1–2 mg/kg/d), inhaled β_2 -adrenergic bronchodilators, and inhaled corticosteroids. Inhaled steroids such as beclomethasone, fluticasone, or budesonide are unproven treatments, but may be helpful without the risk of systemic side effects. If it is necessary to use dexamethasone, a dose of 0.2 mg/kg/d for no more than 3 days is recommended. After hospital discharge, some of these infants will continue to require

oxygen at home. This can be monitored by pulse oximetry with a target SaO_2 of 94–96%.

4. Patent Ductus Arteriosus

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Hyperdynamic precordium.*
- *Widened pulse pressure.*
- *Hypotension.*
- *Presence of a systolic heart murmur in many cases.*

General Considerations

Clinically significant patent ductus arteriosus usually presents on days 3–7 as the respiratory distress from hyaline membrane disease is improving. Presentation can be on days 1 or 2, especially in infants born at less than 28 weeks' gestation and in those who have received surfactant replacement therapy. The signs include a hyperdynamic precordium, increased peripheral pulses, and a widened pulse pressure with or without a systolic heart murmur. Early presentations are sometimes manifested by systemic hypotension without a murmur or hyperdynamic circulation. These signs are often accompanied by an increase in respiratory support. The presence of significant patent ductus arteriosus can be confirmed by echocardiography. Before undertaking medical or surgical ligation, other structural heart disease should be ruled out.

Treatment

The ductus arteriosus is managed by medical or surgical ligation. A clinically significant ductus causing compromise in the infant can be closed (in about two thirds of cases) with indomethacin, 0.1–0.2 mg/kg IV q12–24h for three doses. If the ductus reopens or fails to close completely, a second course of drug may be used. If indomethacin fails to close the ductus or if a ductus reopens a second time, surgical ligation is called for. In some cases, a more prolonged course of indomethacin is being used to prevent recurrences. In addition, in the extremely low birth weight infant (< 1000 g) who is at very high risk of developing a symptomatic ductus, a prophylactic strategy starting indomethacin (0.1 mg/kg q24h for 3–5 days) on the first day of life can be used. The major side effect of indomethacin is transient oligo-

uria, which can be managed by fluid restriction until urine output improves. There may also be an increased incidence of necrotizing enterocolitis with more prolonged therapy. Transient decreases in intestinal and cerebral blood flow caused by indomethacin can be ameliorated by giving the drug as a slow infusion over 1–2 hours. The drug should not be used if the infant is hyperkalemic, if the creatinine is > 2 mg/dL, or if the platelet count is $< 50,000$ /mL.

5. Necrotizing Enterocolitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Feeding intolerance with gastric aspirates or vomiting.
- Bloody stools.
- Abdominal distention and tenderness.
- Pneumatosis intestinalis on abdominal radiograph.

General Considerations

Necrotizing enterocolitis is the most common acquired GI emergency in the newborn infant; it most often affects preterm infants, with an incidence of 10% in infants of birth weight < 1500 g. In full-term infants, it occurs in association with polycythemia, congenital heart disease, and birth asphyxia. The pathogenesis of the disease is multifactorial. Previous intestinal ischemia, bacterial or viral infection, and immunologic immaturity of the gut are thought to play a role in the genesis of the disorder. In up to 20% of affected infants, the only risk factor is prematurity.

Clinical Findings

The most common presenting sign is abdominal distention. Other signs include vomiting or increased gastric residuals, heme-positive stools, abdominal tender-

ness, temperature instability, increased apnea and bradycardia, decreased urine output, and poor perfusion. The CBC may show an increased white blood cell count with an increased band count or, as the disease progresses, absolute neutropenia. Thrombocytopenia is often observed along with stress-induced hyperglycemia and metabolic acidosis. Diagnosis is confirmed by the presence of pneumatosis intestinalis (air in the bowel wall) on radiograph. There is a spectrum of disease, and milder cases may exhibit only distention of bowel loops with bowel wall edema (thickened-appearing walls on radiograph).

Treatment

A. MEDICAL TREATMENT

Necrotizing enterocolitis is managed by decompression of the gut by nasogastric tube, maintenance of oxygenation, mechanical ventilation if necessary, and IV fluids (normal saline) to replace third-space GI losses. Enough fluid should be given to restore a good urine output. Other measures consist of broad-spectrum antibiotics (usually ampicillin, a third-generation cephalosporin, or an aminoglycoside and possibly additional anaerobic coverage), close monitoring of vital signs, serial physical examinations, and laboratory studies (blood gases, white blood cell count, platelet count, and radiographs).

B. SURGICAL TREATMENT

Indications for surgery are evidence of perforation (free air present on a left lateral decubitus or crosstable lateral film), a fixed dilated loop of bowel on serial radiographs, abdominal wall cellulitis, or progressive deterioration despite maximal medical support. All of these signs are indicative of necrotic bowel. In the operating room, necrotic bowel is removed and ostomies are created. Reanastomosis is performed after the disease is resolved and the infant is bigger (usually > 2 kg and after 4–6 weeks).

Course & Prognosis

Infants treated either medically or surgically should not be refed until the disease is resolved (normal abdominal examination, resolution of pneumatosis on radiograph), usually in 10–14 days. Nutritional support during this time should be provided by total parenteral nutrition.

Death occurs in 10% of cases. Surgery is needed in less than 25% of cases. Long-term prognosis is determined by the amount of intestine lost. Infants with short bowel require long-term support with IV nutrition and therefore have very long hospitalizations. Even for those infants, however, the outcome is favorable because of improved parenteral nutrition formulations.

Late strictures—about 3–6 weeks after initial diagnosis—occur in 8% of patients whether treated medically or surgically and generally require operative management.

6. Anemia in the Premature Infant

General Considerations

In the premature infant, the hemoglobin reaches its nadir at approximately 8–12 weeks and is 2–3 g/dL lower than that in the full-term infant. The lower nadir in premature infants appears to be the result of a decreased erythropoietin response to the low red cell mass. Symptoms of anemia include poor feeding, lethargy, increased heart rate, poor weight gain, and perhaps apnea.

Treatment

The decision to transfuse is based on the presence of clinical symptoms. Transfusion is not indicated in an asymptomatic infant simply because of an arbitrary hematocrit number. Most infants become symptomatic if the hematocrit drops below 20%. With risks of transfusion, alternative therapies have been explored. Epoetin alfa, 250 units/kg, given subcutaneously three times per week or added daily with iron dextran to parenteral nutrition, has been shown to increase hematocrit and reticulocyte count and to decrease the frequency and volume of transfused blood. This treatment should be reserved for the highest risk infants (those born at less than 28–30 weeks' gestation and below 1000–1200 g). For optimal effect, supplemental iron at a dosage of 4–8 mg/kg/d should be given. Other options include rescue epoetin alfa at 300 IU/kg/d for 7–10 days for hematocrits < 28% or a late transfusion from the same blood unit used for an infant's early transfusions.

Ohls RK: Human recombinant erythropoietin in the preterm and treatment of anemia of prematurity. *Paediatr Drugs* 2002;4:111 [PMID: 11888358].

7. Intraventricular Hemorrhage

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Large bleeds are accompanied by hypotension, metabolic acidosis, and altered neurologic status. Smaller bleeds can be asymptomatic.
- Routine cranial ultrasound scanning is essential for diagnosis in infants born at less than 32 weeks' gestation.

General Considerations

Periventricular-intraventricular hemorrhage occurs almost exclusively in premature infants. The incidence is 20–30% in infants born at less than 31 weeks' gestation and weighing less than 1500 g at birth. The highest incidence is observed in babies of the lowest gestational age (< 26 weeks). Bleeding most commonly occurs in the subependymal germinal matrix (a region of undifferentiated cells adjacent to or lining the lateral ventricles). Bleeding can extend into the ventricular cavity. The proposed pathogenesis of bleeding is presented in Figure 1–8. The critical event is ischemia with reperfusion injury to the capillaries in the germinal matrix that occurs in the immediate perinatal period. The actual amount of bleeding is also influenced by a variety of factors that affect the pressure gradient across the injured capillary wall. This pathogenetic scheme applies also to intraparenchymal bleeding (venous infarction in a region rendered ischemic) and to periventricular leukomalacia (ischemic white matter injury in a watershed region of arterial supply). Central nervous system complications in preterm infants are more frequent in infants exposed antenatally to intrauterine infection.

Clinical Findings

Up to 50% of hemorrhages occur at less than 24 hours of age, and virtually all occur by the fourth day. The clinical syndrome ranges from rapid deterioration (coma, hypoventilation, decerebrate posturing, fixed pupils, bulging anterior fontanelle, hypotension, acidosis, acute drop in hematocrit) to a more gradual deterioration with more subtle neurologic changes to absence of any specific physiologic or neurologic signs.

The diagnosis can be confirmed by real-time ultrasound scan. This can be performed whenever bleeding is clinically suspected. If symptoms are absent, routine

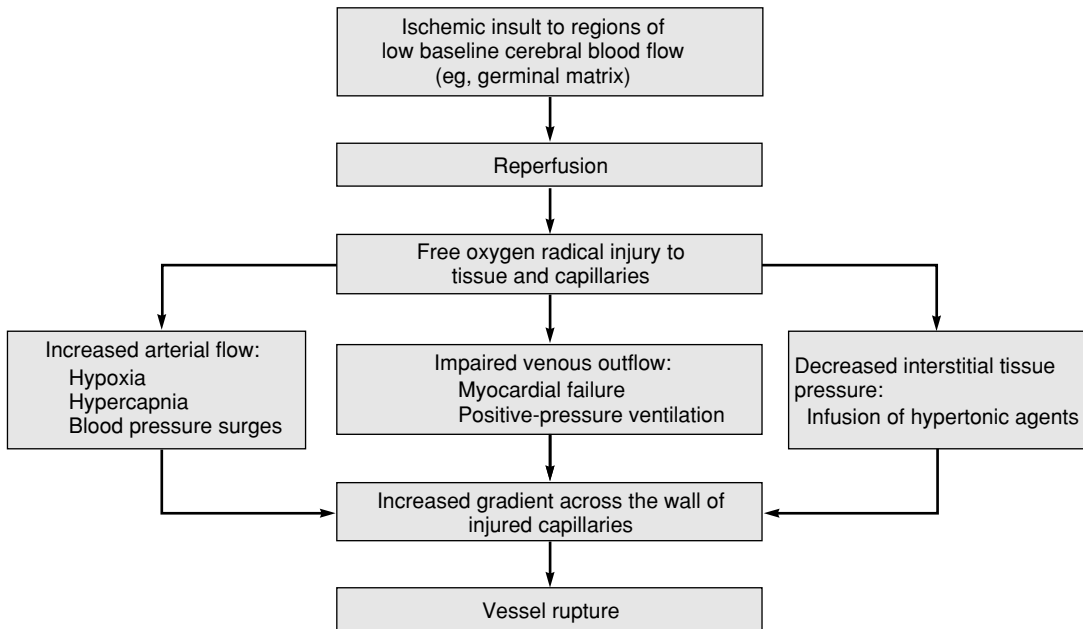

Figure 1–8. Pathogenesis of periventricular and intraventricular hemorrhage.

scanning should be done at 10–14 days in all infants born at < 29 weeks' gestation. Hemorrhages are graded as follows: grade I, germinal matrix hemorrhage only; grade II, intraventricular bleeding without ventricular enlargement; grade III, intraventricular bleeding with ventricular enlargement; and grade IV, any infant with intraparenchymal bleeding. The amount of bleeding is minor (grade I or II) in 75% of infants and major in the remainder.

Follow-up ultrasound examinations are based on the results of the initial scan. Infants with no bleeding or germinal matrix hemorrhage require only a single late scan at age 4–6 weeks to look for periventricular leukomalacia. Any infant with blood in the ventricular system is at risk for posthemorrhagic ventriculomegaly. This is usually the result of impaired absorption of cerebrospinal fluid (CSF), but it can also occur secondary to obstructive phenomena. An initial follow-up scan should be done 1–2 weeks after the initial scan. Infants with intraventricular bleeding and ventricular enlargement should be followed every 7–10 days until ventricular enlargement stabilizes or decreases. Infants without ventriculomegaly should have one additional scan at age 4–6 weeks. In addition, all infants born at 29–32 weeks' gestation should have at least a late scan (4–6 weeks) to look for ventriculomegaly and periventricular leukomalacia.

Treatment

During acute hemorrhage, supportive treatment (including restoration of volume and hematocrit, oxygenation, and ventilation) should be provided to avoid further cerebral ischemia. Progressive posthemorrhagic hydrocephalus (if it develops) is treated initially with a subgaleal shunt. When the infant is large enough, this can be converted to a ventriculoperitoneal shunt.

Although the incidence and severity of intracranial bleeding have decreased in premature infants, strategies to prevent this complication are still needed. Use of antenatal corticosteroids appears to be important in decreasing this complication, and phenobarbital may have a role in the mother who has not been prepared with steroids and is delivering at less than 28 weeks' gestation. The route of delivery may also play a role, with babies delivered by cesarean section showing a decreased rate of intracranial bleeds, but this issue remains controversial. Postnatal strategies appear less promising. Early indomethacin administration may have some benefit in minimizing bleeding, but does not affect long-term outcome.

Prognosis

No deaths occur as a result of grade I and grade II hemorrhages, whereas grade III and grade IV hemorrhages

carry a mortality rate of 10–20%. Posthemorrhagic ventricular enlargement is rarely seen with grade I hemorrhages but is seen in 54–87% of grade II–IV hemorrhages. Very few of these infants will require a ventriculoperitoneal shunt. Long-term neurologic sequelae are seen no more frequently in infants with grade I and grade II hemorrhages than in preterm infants without bleeding. In infants with grade III and grade IV hemorrhages, severe sequelae occur in 20–25% of cases, mild sequelae in 35% of cases, and no sequelae in 40% of cases. The presence of severe periventricular leukomalacia, large parenchymal bleeds, and progressive ventriculomegaly greatly increases the risk of neurologic sequelae.

8. Retinopathy of Prematurity

Retinopathy of prematurity occurs only in the incompletely vascularized retina of the premature infant. The incidence of any acute retinopathy in infants weighing < 1250 g is 66%, whereas only 6% have retinopathy severe enough to warrant intervention. The incidence is highest in babies of the lowest gestational age. The condition appears to be triggered by an initial injury to the developing retinal vessels. Hypoxia, shock, asphyxia, vitamin E deficiency, and light exposure have been associated with this initial injury. After the initial injury, normal vessel development may follow or abnormal vascularization may occur with ridge formation on the retina. The process can still regress at this point or may continue, with growth of fibrovascular tissue into the vitreous associated with inflammation, scarring, and retinal folds or detachment. The disease is graded by stages of abnormal vascular development and retinal de-

tachment (I–V), by the zone of the eye involved (1–3, with zone 1 the posterior region around the macula), and by the amount of the retina involved, in “clock hours” (eg, a detachment in the upper, outer quadrant of the left eye would be defined as affecting the left retina from 12 to 3 o’clock).

Initial eye examination should be performed at 4–6 weeks of age in infants with a birth weight < 1500 g or in those born at < 28 weeks’ gestation, as well as in infants weighing > 1500 g with an unstable clinical course. Follow-up is done at 2- to 4-week intervals until the retina is fully vascularized. Infants with zone 1 disease need to be followed at 1- to 2-week intervals. Infants with threshold disease (stage III, zone 1 or 2, in five or more continuous clock hours, with inflammatory changes of “plus” disease) are candidates for laser therapy. Although this treatment does not always prevent retinal detachment, it reduces the incidence of poor outcomes based on visual acuity and anatomic outcomes.

9. Discharge & Follow-Up of the Premature Infant

Hospital Discharge

Medical criteria for discharge of the premature infant include the ability to maintain temperature in an open crib, nipple all feeds and gaining weight, and the absence of apneic and bradycardiac spells requiring intervention. Infants going home on supplemental oxygen should not desaturate too badly (< 80%) in room air or should demonstrate the ability to arouse in response to hypoxia. Factors such as support for the mother at home and the stability of the family situation play a role in the timing of discharge. Home nursing visits and early physician follow-up can be used to hasten discharge.

Follow-Up

With advances in obstetric and maternal care, survival for infants born at < 28 weeks’ gestation or with birth weights as low as 1000 g is now better than 90%. Seventy to 80% survive at 26–27 weeks’ gestation and birth weights of 800–1000 g. Survival at gestational age

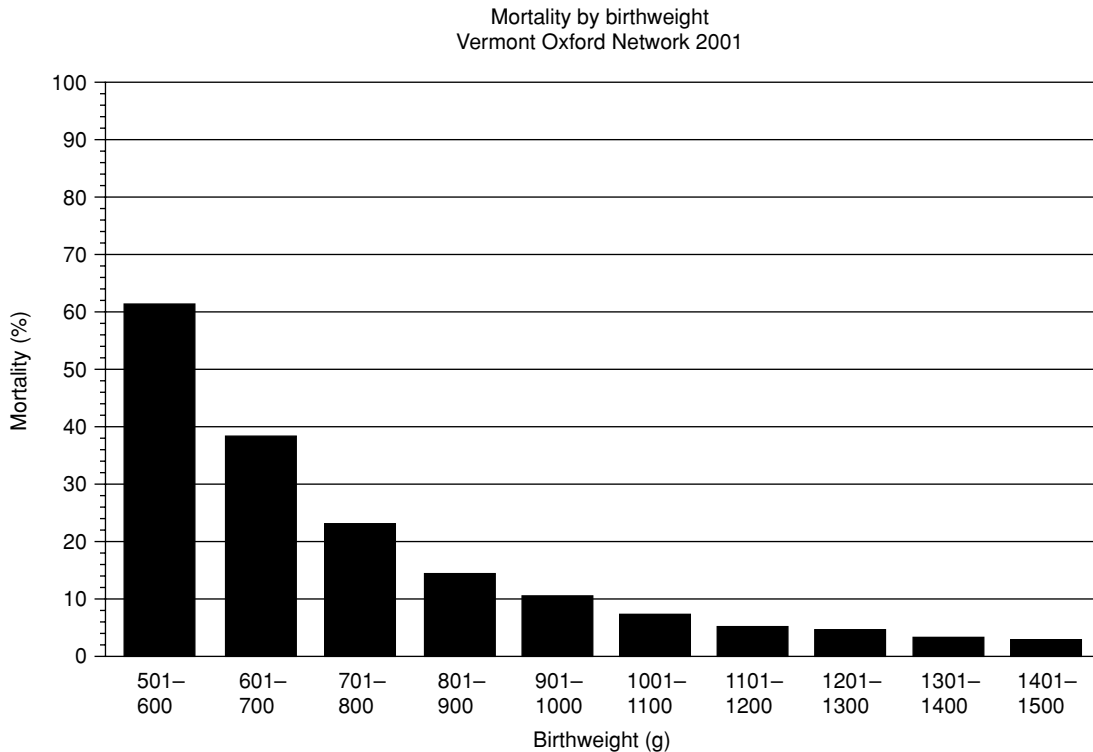

Figure 1–9. Mortality rates before discharge by 100-g birth weight subgroups in 2001. (Reproduced, with permission, from the Vermont Oxford Network, 2002.)

25 weeks and birth weight 700–800 g is 50–70%, with a considerable drop-off below this level (Figure 1–9).

These high rates of survival do come with a price in terms of morbidity. Major neurologic sequelae, including cerebral palsy, cognitive delay, and hydrocephalus, is reported in 10–25% of survivors with birth weights < 1500 g. The rate of these sequelae tends to be higher in infants with lower birth weights. In addition to a higher incidence of severe neurologic sequelae, infants with birth weights < 1000 g have an increased rate of lesser disabilities, including learning and behavioral problems. Risk factors for neurologic sequelae include seizures, grade III or IV intracranial hemorrhage, periventricular leukomalacia, severe IUGR, poor early head growth, need for mechanical ventilation, and low socioeconomic class. In addition, maternal fever and chorioamnionitis have been associated with an increased risk of cerebral palsy. Other morbidities in these infants include chronic lung disease and reactive airway disease, resulting in an increased risk from respiratory infections and hospital readmissions in the first 2 years, retinopathy of prematurity with associated loss of visual

acuity and strabismus, hearing loss, and growth failure. All of these issues require close multidisciplinary outpatient follow-up. Infants with residual lung disease are candidates for monthly palivizumab (Synagis) injections during their first winter after hospital discharge to prevent severe infection with respiratory syncytial virus. Routine immunizations should be done by chronologic age and not age-corrected for prematurity.

CARDIAC PROBLEMS IN THE NEWBORN INFANT

STRUCTURAL HEART DISEASE

1. Cyanotic Presentations

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Cyanosis, initially without associated respiratory distress.*
- *Failure to increase Pao₂ with supplemental oxygen.*
- *Chest radiograph with decreased lung markings suggests right heart obstruction, while increased lung markings suggest transposition or venous obstruction.*

General Considerations

The causes of cyanotic heart disease that occur in the newborn period are transposition of the great vessels (TOGV), total anomalous pulmonary venous return (TAPVR), truncus arteriosus (some types), tricuspid atresia, and pulmonary atresia or critical pulmonary stenosis.

Clinical Findings

Infants with these disorders present with early cyanosis. The hallmark of many of these lesions is cyanosis in an infant without associated respiratory distress. In most of these infants, tachypnea develops over time either because of increased pulmonary blood flow or secondary to metabolic acidemia from progressive hypoxemia. Diagnostic aids include comparing the blood gas or oxygen saturation in room air to that in 100% FiO₂. Failure of Pao₂ or SaO₂ to increase suggests cyanotic heart disease. **Note:** A PaO₂, if feasible, is the preferred measure. Saturation in the newborn may be misleadingly high due to the left-shifted oxyhemoglobin dissociation curve seen with fetal hemoglobin. Other useful aids are chest radiograph, electrocardiography, and echocardiography.

TOGV is the most common form of cyanotic heart disease presenting in the newborn period. Examination generally reveals a systolic murmur and single S₂. Chest radiograph shows a generous heart size and a narrow mediastinum with normal or increased lung markings.

There is little change in PaO₂ or SaO₂ with supplemental oxygen. Total anomalous pulmonary venous return, in which venous return is obstructed, presents early with severe cyanosis and tachypnea because the pulmonary venous return is obstructed, resulting in pulmonary edema. The chest radiograph typically shows a small to normal heart size with marked pulmonary edema. Infants with right heart obstruction (pulmonary and tricuspid atresia, critical pulmonary stenosis, and some forms of truncus arteriosus) have decreased lung markings on chest radiograph and, depending on the severity of hypoxia, may develop metabolic acidemia. Those forms with an underdeveloped right heart will have left-sided predominance on electrocardiography. Although tetralogy of Fallot is the most common form of cyanotic heart disease, the obstruction at the pulmonary valve is often not severe enough to result in cyanosis in the newborn. In all cases, diagnosis can be confirmed by echocardiography.

2. Acyanotic Presentations

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Most newborns who present with acyanotic heart disease have left-sided outflow obstruction.
- Differentially diminished pulses (coarctation) or decreased pulses throughout (aortic atresia).
- Metabolic acidemia.
- Chest radiograph showing large heart and pulmonary edema.

General Considerations

Newborn infants who present with serious acyanotic heart disease usually have congestive heart failure secondary to left-sided outflow tract obstruction. Infants with left-to-right shunt lesions (eg, ventricular septal defect) may have murmurs in the newborn period, but clinical symptoms do not occur until pulmonary vascular resistance drops enough to cause significant shunting and subsequent congestive heart failure (usually at 3–4 weeks of age).

Clinical Findings

Infants with left-sided outflow obstruction generally do well the first day or so until the ductus arteriosus—the source of all or some of the systemic flow—narrows.

Tachypnea, tachycardia, congestive heart failure, and metabolic acidosis develop. On examination, all of these infants have abnormalities of the pulses. In aortic atresia (hypoplastic left heart syndrome) and stenosis, pulses are all diminished, whereas in coarctation syndromes, differential pulses (diminished or absent in the lower extremities) are evident. Chest radiographic films in these infants show a large heart and pulmonary edema. Diagnosis is confirmed with echocardiography.

3. Treatment of Cyanotic & Acyanotic Lesions

Early stabilization includes supportive therapy as needed (eg, IV glucose, oxygen, ventilation for respiratory failure, pressor support). Specific therapy includes infusions of prostaglandin E₁, 0.025–0.1 µg/kg/min, to maintain ductal patency. In some cyanotic lesions (eg, pulmonary atresia, tricuspid atresia, critical pulmonary stenosis) in which lung blood flow is ductus-dependent, this improves pulmonary blood flow and PaO₂ by allowing shunting through the ductus to the pulmonary artery. In left-sided outflow tract obstruction, systemic blood flow is ductus-dependent; prostaglandins improve systemic perfusion and resolve the acidosis. Further specific management—including palliative surgical and cardiac catheterization procedures—is discussed in Chapter 19.

PERSISTENT PULMONARY HYPERTENSION IN THE NEWBORN INFANT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Onset of symptoms on day 1 of life.
- Hypoxia with poor response to high concentrations of inspired oxygen.
- Right-to-left shunts through the foramen ovale, ductus arteriosus, or both.
- Most often associated with parenchymal lung disease.

General Considerations

Persistent pulmonary hypertension (PPHN) results when the normal decrease in pulmonary vascular resistance after birth does not occur. Most infants so affected are full term or postterm, and many have experi-

enced perinatal asphyxia. Other clinical associations include hypothermia, meconium aspiration syndrome, hyaline membrane disease, polycythemia, neonatal sepsis, chronic intrauterine hypoxia, and pulmonary hypoplasia.

There are three causes of PPHN: (1) acute vasoconstriction resulting from perinatal hypoxia, (2) prenatal increase in pulmonary vascular smooth muscle development, and (3) decreased cross-sectional area of the pulmonary vascular bed because of inadequate vessel number. In the first, an acute perinatal event leads to hypoxia and failure of the pulmonary vascular resistance to drop. In the second, abnormal muscularization of the pulmonary resistance vessels results in persistent hypertension after birth. The third category includes infants with pulmonary hypoplasia (eg, diaphragmatic hernia).

Clinical Findings

Clinically, the syndrome is characterized by onset on the first day of life, usually from birth. Respiratory distress is prominent, and PaO_2 is usually poorly responsive to high concentrations of inspired oxygen. Many of the infants have associated myocardial depression with resulting systemic hypotension. Echocardiography reveals right-to-left shunting at the level of the ductus arteriosus or foramen ovale (or both). Chest radiograph usually shows lung infiltrates related to associated pulmonary pathology (eg, meconium aspiration, hyaline membrane disease). If the majority of right-to-left shunt is at the ductal level, pre- and postductal differences in PaO_2 and SaO_2 will be observed.

Treatment

Therapy for PPHN involves supportive therapy for other postasphyxia problems (eg, anticonvulsants for seizures, careful fluid and electrolyte management for renal failure). IV glucose should be provided to maintain normal blood sugar, and antibiotics should be administered for possible infection. Specific therapy is aimed at both increasing systemic arterial pressure and decreasing pulmonary arterial pressure to reverse the right-to-left shunting through fetal pathways. First-line therapy includes oxygen and ventilation (to reduce pulmonary vascular resistance) and crystalloid infusions (10 mL/kg, up to 30 mL/kg) to improve systemic pressure. Ideally, systolic pressure should be greater than 60 mm Hg. With compromised cardiac function, systemic pressors can be used as second-line therapy (eg, dopamine, 5–20 $\mu\text{g}/\text{kg}/\text{min}$; dobutamine, 5–20 $\mu\text{g}/\text{kg}/\text{min}$; or both). Metabolic acidemia should be corrected with sodium bicarbonate because acidemia exacerbates pulmonary vasoconstriction. In some cases, a

mild respiratory alkalosis may improve oxygenation. Pulmonary vasodilation can be enhanced using the inhaled gas nitric oxide, which is identical or very similar to endogenous endothelium-derived relaxing factor, at doses of 5–20 ppm. In addition, use of high-frequency oscillatory ventilation has proved effective in many of these infants, particularly those with severe associated lung disease.

Infants for whom conventional therapy is failing (poor oxygenation despite maximum support) may require extracorporeal membrane oxygenation (ECMO). The infants are placed on bypass, with blood exiting the baby from the right atrium and returning to the aortic arch after passing through a membrane oxygenator. The lungs are essentially at rest during the procedure, and with resolution of the pulmonary hypertension the infants are weaned from ECMO back to ventilator therapy. This therapy can save infants who might otherwise die but has major side effects that must be considered prior to its institution. Neurodevelopmental outcome among survivors of ECMO is similar to that of infants with PPHN managed without the procedure. Approximately 10–15% of survivors have significant neurologic sequelae, with cerebral palsy or cognitive delays. Other sequelae such as chronic lung disease, sensorineural hearing loss, and feeding problems have also been described in this population.

ARRHYTHMIAS

Irregularly irregular heart rates, commonly associated with premature atrial contractions and less commonly with premature ventricular contractions, are noted often in the first days of life in well newborns. These arrhythmias are benign and of no consequence. Clinically significant bradyarrhythmias are seen in association with congenital heart block. Heart block can be seen in an otherwise structurally normal heart (associated with maternal lupus) or with structural cardiac abnormalities. If fetal hydrops is absent, the bradyarrhythmia has been well tolerated. Indications for cardiac pacing include symptoms of inadequate cardiac output.

On electrocardiography, tachyarrhythmias can be either wide complex (eg, ventricular tachycardia) or narrow complex (eg, supraventricular tachycardia). Supraventricular tachycardia is the most common tachyarrhythmia in the neonate and may be a sign of structural heart disease, myocarditis, left atrial enlargement, and aberrant conduction pathways. Acute treatment is ice to the face and, if unsuccessful, adenosine given IV at a dose of 50–200 $\mu\text{g}/\text{kg}$. If there is no response, the dose can be increased up to 300 $\mu\text{g}/\text{kg}$. Long-term therapy is with digoxin or propranolol. Digoxin should not be used in cases with Wolff–Parkinson–White syndrome. Cardioversion is rarely needed for supraventricular

ular tachycardia but is needed acutely for hemodynamically unstable ventricular tachycardia.

GASTROINTESTINAL & ABDOMINAL SURGICAL CONDITIONS IN THE NEWBORN INFANT (SEE ALSO CHAPTER 20.)

ESOPHAGEAL ATRESIA & TRACHEOESOPHAGEAL FISTULA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polyhydramnios.
- Baby with excessive drooling and secretions, choking with attempted feeding.
- Unable to pass an orogastric tube to the stomach.

General Considerations

These associated conditions are characterized by a blind esophageal pouch and a fistulous connection between the proximal or distal esophagus (or both) and the airway. In 85% of affected infants, the fistula is between the distal esophagus and the airway. Polyhydramnios is common because of the high level of GI obstruction.

Clinical Findings

Infants present in the first hours of life with copious secretions, choking, cyanosis, and respiratory distress. Diagnosis can be confirmed with chest radiograph after careful placement of a nasogastric tube to the point at which resistance is met. On chest radiograph, the tube will be seen in the blind pouch. If a tracheoesophageal fistula is present to the distal esophagus, gas will be present in the bowel. In cases of esophageal atresia without tracheoesophageal fistula, there is no gas in the bowel.

Treatment

The tube in the proximal pouch should be placed on continuous suction to drain secretions and prevent aspiration. The head of the bed should be elevated to prevent reflux of gastric contents through the distal fistula into the lungs. IV glucose and fluids should be provided and oxygen administered as needed. Definitive treatment is by operation and depends on the distance between the segments of esophagus. If the distance is not too great, the fistula can be ligated and the ends of the esophagus anastomosed. In instances in which the ends of the esophagus cannot be brought together, the initial surgery entails fistula ligation and a gastrostomy for feeding. Echocardiography should be performed prior to surgery to rule out a right-sided aortic arch. In those cases, a left-sided thoracotomy would be preferred.

Prognosis

Prognosis is determined primarily by the presence or absence of associated anomalies. Vertebral, anal, cardiac, renal, and limb anomalies are the most likely anomalies to be observed (VACTERL association). Evaluation for associated anomalies should be done early.

INTESTINAL OBSTRUCTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Infants with high intestinal obstruction present soon after birth with emesis.
- Bilious emesis represents a malrotation with midgut volvulus until proved otherwise.
- Low intestinal obstruction is characterized by abdominal distention and late onset of emesis.

General Considerations

A history of polyhydramnios is common, and the fluid, if bile-stained, can easily be confused with thin meconium staining. The higher the obstruction in the intestine, the earlier the infant will present with vomiting and the less prominent the distention will be. The opposite is true for lower intestinal obstructions. Most obstructions are bowel atresias, believed to be caused by an ischemic event during development. Approximately 30% of cases of duodenal atresia are associated with Down syndrome. Meconium ileus is a distal small bowel obstruction caused by the exceptionally viscous meconium produced by fetuses with cystic fibrosis. Hirschsprung disease is caused by a failure of neuronal migration to the myenteric plexus of the distal bowel so that the distal bowel lacks ganglion cells, causing a lack of peristalsis in that region with a functional obstruction.

Malrotation with midgut volvulus is a surgical emergency that appears in the first days to weeks as bilious vomiting without distention or tenderness. If malrotation is not treated promptly, torsion of the intestine around the superior mesenteric artery will lead to necrosis of the entire small bowel. For this reason, bilious vomiting in the neonate always demands immediate attention and evaluation.

Clinical Findings

Diagnosis of intestinal obstructions depends on plain abdominal radiographs with either upper GI series

(high obstruction suspected) or contrast enema (lower obstruction apparent) to define the area of obstruction. Table 1–20 summarizes the findings expected.

All infants with meconium ileus are presumed to have cystic fibrosis. Infants with pancreatic Hirschsprung disease, colon pseudo-obstruction syndrome, or colonic dysgenesis or atresia may also present with meconium impacted in the distal ileum. Definitive diagnosis of cystic fibrosis is by the sweat chloride test (Na^+ and Cl^- concentration > 60 mEq/L) or by genetic testing. Approximately 10–20% of infants with cystic fibrosis present with meconium ileus. Infants with cystic fibrosis and meconium ileus generally have a normal immunoreactive trypsinogen test result on their newborn screen because of the associated severe exocrine pancreatic insufficiency in utero.

Any in utero perforation results in meconium peritonitis with residual intraabdominal calcifications. Many of these are completely healed at birth. If the infant has no signs of obstruction, no further immediate evaluation is needed. A sweat test to rule out cystic fibrosis should be done at a later date.

Low intestinal obstruction may present with delayed stooling (> 24 hours in term infants is abnormal) with mild distention. Radiograph findings of gaseous distention should prompt contrast enema to diagnose (and treat) meconium plug syndrome. If no plug is found, the diagnosis may be small left colon syndrome (occurring in IDMs) or Hirschsprung disease. Rectal biopsy will be required to make this diagnosis. Imperforate

Table 1–20. Intestinal obstruction.

Site of Obstruction	Clinical Findings	Plain Radiographs	Contrast Study
Duodenal atresia	Down syndrome (30%); early vomiting, sometimes bilious	“Double bubble” (dilated stomach and proximal duodenum, no air distal)	Not needed
Malrotation and volvulus	Bilious vomiting with onset anytime in the first few weeks	Dilated stomach and proximal duodenum; paucity of air distally (may be normal gas pattern)	UGI shows displaced duodenojejunal junction with “corkscrew” deformity of twisted bowel
Jejunioileal atresia, meconium ileus	Bilious gastric contents > 25 mL at birth; progressive distention and bilious vomiting	Multiple dilated loops of bowel; intraabdominal calcifications if in utero perforation occurred (meconium peritonitis)	Barium or osmotic contrast enema shows microcolon; contrast refluxed into distal ileum may demonstrate and relieve meconium obstruction (successful in about 50%)
Meconium plug syndrome; Hirschsprung’s disease	Distention, delayed stooling (> 24 h)	Diffuse bowel distention	Barium or osmotic contrast enema outlines and relieves plug; may show transition zone in Hirschsprung’s disease; delayed emptying (> 24 h) suggests Hirschsprung’s disease

UGI = upper gastrointestinal tract

anus should be apparent on physical examination, although a rectovaginal fistula with a mildly abnormal-appearing anus can occasionally be confused with normal.

Treatment

Nasogastric suction to decompress the bowel, IV glucose, fluid and electrolyte replacement, and respiratory support as necessary should be instituted. Antibiotics are usually indicated. The definitive treatment for most of these conditions (with the exception of meconium plug syndrome, small left colon syndrome, and some cases of meconium ileus) is surgery.

Prognosis

Up to 10% of infants with meconium plug syndrome are subsequently found to have cystic fibrosis or Hirschsprung disease. For this reason, some surgeons advocate performance of a sweat chloride test and rectal biopsy in all of these infants before discharge. The infant with meconium plug syndrome who is still symptomatic after contrast enema should have a rectal biopsy.

In cases of duodenal atresia associated with Down syndrome, the prognosis will depend on associated anomalies (eg, heart defects) and the severity of prestenotic duodenal dilation. Otherwise, these conditions usually carry an excellent prognosis after surgical repair.

ABDOMINAL WALL DEFECTS

1. Omphalocele

Omphalocele is a membrane-covered herniation of abdominal contents into the base of the umbilical cord. There is a high incidence of associated anomalies (cardiac, GI, chromosomal—eg, trisomy 13). The sac may contain liver and spleen as well as intestine.

Acute management of omphalocele involves covering the defect with a sterile dressing soaked with warm saline to prevent fluid loss, nasogastric decompression, IV fluids and glucose, and antibiotics. If the contents of the omphalocele will fit into the abdomen, a primary surgical closure is done. If not, a staged closure is performed, with gradual reduction of the omphalocele contents into the abdominal cavity and a secondary closure. Postoperatively, third-space fluid losses may be extensive; fluid and electrolyte therapy, therefore, must be monitored carefully.

2. Gastroschisis

In gastroschisis, the intestine extrudes through an abdominal wall defect lateral to the umbilical cord. There is no membrane or sac and no liver or spleen outside the abdomen. Gastroschisis is associated with no anomalies

except intestinal atresias in approximately 10%. The herniation is thought to be related to abnormal involution of the right umbilical vein, although the exact cause is unknown.

Therapy is as described for omphalocele.

DIAPHRAGMATIC HERNIA

This congenital malformation consists of herniation of abdominal organs into the hemithorax (usually left) through a posterolateral defect in the diaphragm. It presents in the delivery room as severe respiratory distress in an infant with poor breath sounds and scaphoid abdomen. The rapidity and severity of presentation—as well as ultimate survival—depend on the degree of pulmonary hypoplasia, which is a result of compression by the intrathoracic abdominal contents in utero. Affected infants are prone to development of pneumothorax.

Treatment includes intubation and ventilation as well as decompression of the GI tract with a nasogastric tube to intermittent suction. An IV infusion of glucose and fluid should be started. Chest radiograph confirms the diagnosis. Surgery to reduce the abdominal contents from the thorax and to close the diaphragmatic defect is performed after the infant is stabilized. The postoperative course is often complicated by severe pulmonary hypertension, requiring therapy with high-frequency ventilation, inhaled NO, or ECMO. The mortality rate for this condition is 25–40%, with survival dependent on the degree of pulmonary hypoplasia and presence of congenital heart disease.

GASTROINTESTINAL BLEEDING

Upper Gastrointestinal Bleeding

Upper GI bleeding is not uncommon in the newborn nursery. Old blood (“coffee-ground” material) may be either swallowed maternal blood or infant blood from a bleeding gastric irritation such as gastritis or stress ulcer. Bright red blood from the stomach is most likely acute bleeding, again due to gastritis. Treatment generally consists of gastric lavage (a sample can be sent for Apt testing to determine if it is mother’s or baby’s blood) and antacid medication. If the volume of bleeding is large, intensive monitoring, fluid and blood replacement, and endoscopy are indicated (see Chapter 20).

Lower Gastrointestinal Bleeding

Rectal bleeding is less common than upper GI bleeding in the newborn and is associated with infections (eg, *Salmonella* acquired from the mother perinatally), milk intolerance (blood streaks with diarrhea), or, in stressed infants, necrotizing enterocolitis. An abdominal radiograph should be obtained to rule out pneumatosis in-

testinalis (air in the wall of the bowel) or other abnormalities in gas pattern (eg, obstruction). If the radiograph is negative and the examination is benign, a protein hydrolysate or predigested formula (eg, Nutramigen or Pregestamil) should be tried or the mother instructed to avoid all dairy products in her diet if nursing. If the amount of rectal bleeding is large or persistent, endoscopy will be needed.

GASTROESOPHAGEAL REFLUX (See also Chapter 20.)

All people reflux occasionally, and physiologic regurgitant reflux is extremely common in infants. Reflux is pathologic and should be treated when it results in failure to thrive owing to excessive regurgitation, poor intake due to dysphagia and irritability, apnea or cyanotic episodes (acute life-threatening events), or chronic respiratory symptoms of wheezing and recurrent pneumonias. Diagnosis is clinical, with confirmation by barium swallow or pH probe study.

Initial steps in treatment include prone positioning and thickened feeds (rice cereal, 1 tbs/oz of formula) for those with frequent regurgitation and poor weight gain. Gastric acid suppressants such as ranitidine (2 mg/kg bid) or lansoprazole (1.5 mg/kg/d), along with a prokinetic agent such as metaclopramide (0.1 mg/kg tid–qid), can also be used. Because most infants improve by 12–15 months of age, surgery is reserved for the most severe cases, especially those with chronic neurologic or respiratory conditions that exacerbate reflux and those who have life-threatening events caused by reflux.

■ INFECTIONS IN THE NEWBORN INFANT

The fetus and the newborn infant are very susceptible to infections. There are three major routes of perinatal

infection: (1) blood-borne transplacental infection of the fetus (eg, cytomegalovirus [CMV], rubella, syphilis); (2) ascending infection with disruption of the barrier provided by the amniotic membranes (eg, bacterial infections after 12–18 hours of ruptured membranes); and (3) infection on passage through an infected birth canal or exposure to infected blood at delivery (eg, herpes simplex, hepatitis B, HIV, bacterial infections).

Susceptibility of the newborn infant to infection is related to immaturity of both the cellular and humoral immune systems at birth. This feature is particularly evident in the preterm neonate. Passive protection against some organisms is provided by transfer of IgG across the placenta during the third trimester of pregnancy. Preterm infants, especially those born at less than 30 weeks' gestation, do not have the benefit of the full amount of this passively acquired antibody.

BACTERIAL INFECTIONS

1. Bacterial Sepsis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Most infants with early-onset sepsis present at < 24 hours of age.
- Respiratory distress is the most common presenting symptom.
- Hypotension, acidemia, and neutropenia are associated clinical findings.
- The presentation of late-onset sepsis is more subtle.

General Considerations

The incidence of early-onset (< 5 days) neonatal bacterial infection is 4–5 per 1000 live births. If rupture of the membranes occurs more than 24 hours prior to delivery, the infection rate increases to 1 per 100 live births. If early rupture of membranes with chorioamnionitis occurs, the infection rate increases further to 1 per 10 live births. Irrespective of membrane rupture, infection rates are five times higher in preterm than in full-term infants.

Clinical Findings

Early-onset bacterial infections appear most commonly on day 1 of life, and the majority of cases appear at <

12 hours. Respiratory distress due to pneumonia is the most common presenting sign. Other features include unexplained low Apgar scores without fetal distress, poor perfusion, and hypotension. Late-onset bacterial infection (at > 5 days of age) presents in a more subtle manner, with poor feeding, lethargy, hypotonia, temperature instability, altered perfusion, new or increased oxygen requirement, and apnea. Late-onset bacterial sepsis is more often associated with meningitis or other localized infections.

Low total white counts, absolute neutropenia (< 1000/mL), and elevated ratios of immature to mature neutrophils are suggestive of neonatal bacterial infection. Thrombocytopenia is also a common feature. Other laboratory signs are hypoglycemia or hyperglycemia with no change in glucose administration, unexplained metabolic acidosis, and elevated C reactive protein. In early-onset bacterial infection, pneumonia is invariably present; chest radiograph films show infiltrates, but these infiltrates cannot be distinguished from those resulting from other causes of neonatal lung disease. Definitive diagnosis is made by positive cultures from blood, CSF, and the like.

Early-onset infection is most often caused by group B β -hemolytic streptococci (GBS) and gram-negative enteric pathogens (most commonly *Escherichia coli*). Other organisms to consider are *Haemophilus influenzae* and *Listeria monocytogenes*. Late-onset sepsis is caused by coagulase-negative staphylococci (most common in infants with indwelling central venous lines), *Staphylococcus aureus*, GBS, *Enterococcus*, *Pseudomonas*, and other gram-negative organisms.

Treatment

A high index of suspicion is important in the diagnosis and treatment of neonatal infection. Table 1–21 presents guidelines for the evaluation and treatment of full-term infants with risk factors or clinical signs of infection. Because the risk of infection is greater in the preterm infant and because respiratory disease is a common sign of infection, any preterm infant with respiratory disease requires blood cultures and broad-spectrum antibiotic therapy for 48–72 hours pending the results of cultures. An examination of CSF should be performed when infection is highly suspected on a clinical basis (eg, associated hypotension, persistent metabolic acidosis, neutropenia) or if the blood culture is positive. Antibiotic coverage should be directed initially toward suspected organisms. Early-onset sepsis is usually caused by GBS or gram-negative enteric organisms; broad-spectrum coverage, therefore, should include ampicillin plus an aminoglycoside or third-generation cephalosporin—for example, ampicillin, 100–150 mg/kg/d divided q12h, and gentamicin,

Table 1–21. Guidelines for evaluation of neonatal bacterial infection in the full-term infant.

Risk Factor	Clinical Signs of Infection	Evaluation and Treatment
Delivery 12–18 h after rupture of membranes	None	Observation
Delivery > 12–18 h after rupture of membranes, chorioamnionitis	None	Complete blood count (CBC), blood culture, broad-spectrum antibiotics for 48–72 h ^c
Delivery > 12–18 h after rupture of membranes, chorioamnionitis, maternal antibiotics ^a	None	CBC, blood culture, broad-spectrum antibiotics for 48–72 h ^c
With or without risk factors	Present	CBC, blood and CSF cultures, perhaps urine culture (see below); broad-spectrum antibiotics ^b

^aMinimum of 24 h of observation is indicated if no treatment is given.

^bIrrespective of age at presentation, any infant who appears infected by clinical criteria should undergo cerebrospinal fluid (CSF) examination. Urine culture is indicated in the evaluation of infants who were initially well but have developed symptoms after 2–3 d of age.

^cIf clinical signs are absent, close observation without treatment may be sufficient.

2.5 mg/kg/dose q12–24h (depending on gestational age), or cefotaxime, 100 mg/kg/d divided q12h. In infants > 34 weeks' gestation, gentamicin can also be given at a dose of 4 mg/kg q24h. Late-onset infections can also be caused by the same organisms, but coverage may need to be expanded to include staphylococci. In particular, the preterm infant with an indwelling line is at risk for infection with coagulase-negative staphylococci, for which vancomycin is the drug of choice in a dosage of 10–15 mg/kg q8–24h depending on gestational and postnatal ages. Initial broad-spectrum coverage should also include a third-generation cephalosporin (cefotaxime or ceftazidime 100 mg/kg/day divided q12h when *Pseudomonas aeruginosa* is strongly suspected). To prevent the development of vancomycin-resistant organisms, vancomycin should be stopped as soon as cultures and sensitivities indicate it is not needed for ongoing therapy. Other supportive therapy includes the administration of IVIG

(500–750 mg/kg) to infants with known overwhelming infection. The duration of treatment for proved sepsis is 10–14 days of IV antibiotics. In addition, recombinant human granulocyte colony-stimulating factor (rhG-CSF) is under investigation for treatment of neutropenia in the septic infant. In sick infants, the essentials of good supportive therapy should be provided: IV glucose and nutritional support, volume expansion, use of pressors as needed, and oxygen and ventilator support.

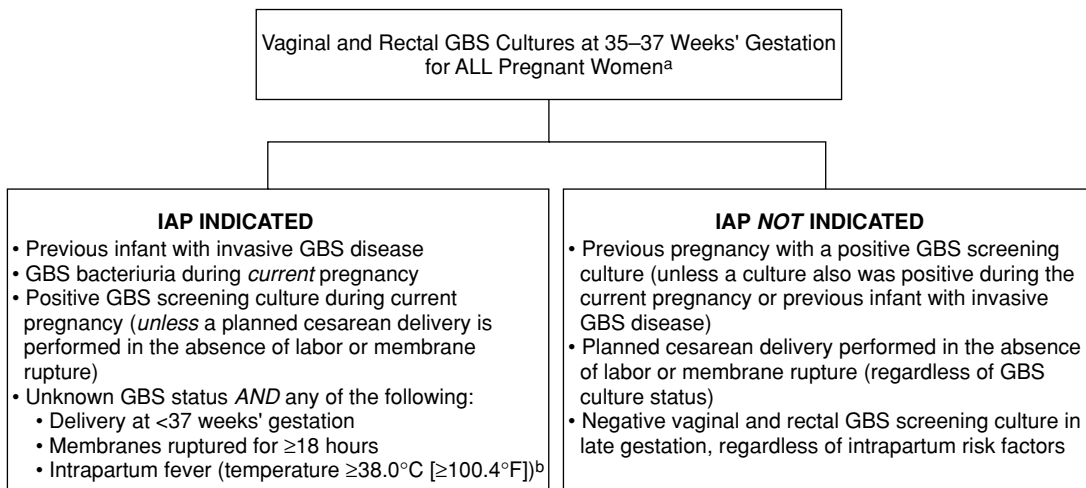

Prevention of neonatal GBS infection has been achieved with intrapartum administration of penicillin given > 4 hours prior to delivery. The current clinical guideline (Figure 1–10) is to perform a vaginal and rectal GBS culture at 35–37 weeks' gestation for all pregnant women. Prophylaxis with penicillin is given to GBS-positive women as well as those who have unknown GBS status at delivery with risk factors for infection. Figure 1–11 presents a suggested strategy for the infant born to a mother who received intrapartum prophylaxis for prevention of early-onset GBS or for suspected chorioamnionitis. Some authors also recommend selective neonatal prophylaxis with 50,000 U/kg of penicillin G given IM if adequate intrapartum treatment has not been given.

2. Meningitis

Any newborn with bacterial sepsis is also at risk for meningitis. The incidence is low in infants with early-onset sepsis but much higher in infants with late-onset infection. The work-up for any newborn with signs of infection should include a spinal tap. Diagnosis is suggested by a CSF protein > 150 mg/dL, glucose < 30 mg/dL, > 25 leukocytes/mL, and a positive Gram stain. The diagnosis is confirmed by culture. The most common organisms are GBS and gram-negative enteric bacteria. Although sepsis can be treated with antibiotics for 10–14 days, meningitis often requires 21 days. The mortality rate of neonatal meningitis is approximately 10%, with significant neurologic morbidity present in one third of the survivors.

3. Pneumonia

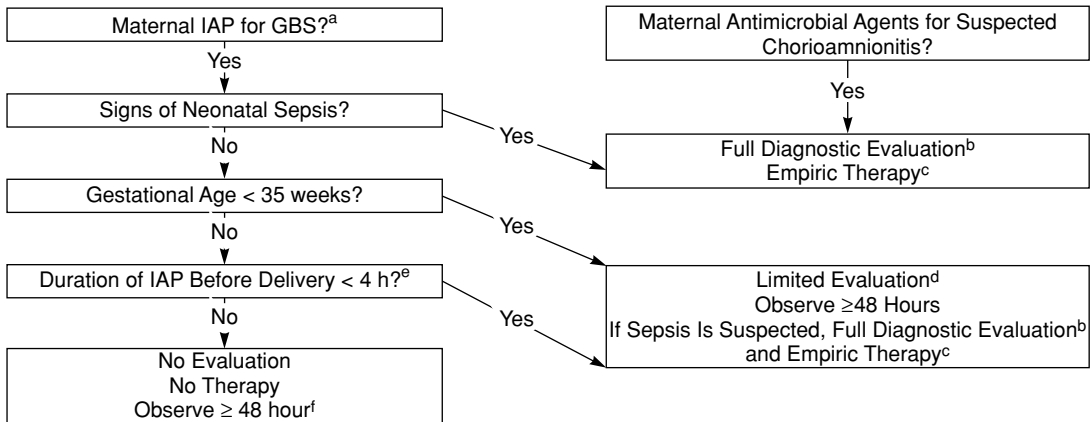

The respiratory system can be infected in utero or on passage through the birth canal. Early-onset neonatal infection is usually associated with pneumonia. Pneumonia should also be suspected in older neonates with a recent onset of tachypnea, retractions, and cyanosis. In infants already receiving respiratory support, an in-

^a Exceptions: women with GBS bacteriuria during the current pregnancy or women with a previous infant with invasive GBS disease.

^b If chorioamnionitis is suspected, broad-spectrum antimicrobial therapy that includes an agent known to be active against GBS should replace GBS IAP. GBS = group B streptococcus, IAP = intrapartum antimicrobial prophylaxis.

Figure 1–10. Indications for intrapartum antimicrobial prophylaxis to prevent early-onset GBS disease using a universal prenatal culture screening strategy at 35–37 weeks' gestation for all pregnant women. (Reproduced, with permission, from the American Academy of Pediatrics: *Red Book 2003 Report of the Committee on Infectious Disease*, 2003.)

^a If no maternal IAP for GBS was administered despite an indication being present, data are insufficient on which to recommend a single management strategy.

^b Includes complete blood cell (CBC) count with differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.

^c Duration of therapy varies depending on results of blood culture, cerebrospinal fluid findings (if obtained), and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 hours.

^d CBC including (WBC) count with differential and blood culture.

^e Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens.

^f A healthy-appearing infant who was ≥ 38 weeks' gestation at delivery and whose mother received ≥ 4 hours of IAP before delivery may be discharged home after 24 hours if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved.

Figure 1–11. Empiric management of a neonate born to a mother who received intrapartum antimicrobial prophylaxis (IAP) for prevention of early-onset GBS (group B streptococcal) disease or chorioamnionitis. (Reproduced, with permission, from the American Academy of Pediatrics: *Red Book 2003 Report of the Committee on Infectious Disease*, 2003.)

crease in the requirement for oxygen or ventilator support may indicate pneumonia. Not only common bacteria but also viruses (CMV, respiratory syncytial virus, adenovirus, influenza, herpes simplex, parainfluenza) and *Chlamydia* can cause the disease. In infants with preexisting respiratory disease, intercurrent pulmonary infections may contribute to the ultimate severity of chronic lung disease.

4. Urinary Tract Infection

Infection of the urine is uncommon in the first days of life. Urinary tract infection in the newborn can occur in association with genitourinary anomalies and is caused by gram-negative enteric pathogens, *Enterococcus*, or other organisms. Urine should be evaluated as part of the work-up for late-onset infection. Culture should be obtained either by suprapubic aspiration or bladder catheterization. Antibiotic IV therapy is continued for 7–10 days if the blood culture is negative and clinical signs resolve quickly. Evaluation for genitourinary

anomalies, starting with an ultrasound examination and a voiding cystourethrogram, should be done subsequently.

5. Otitis Media

Otitis media occurs in a significant number of long-term nursery occupants. It is particularly common in infants who have had prolonged endotracheal intubation or an indwelling nasogastric feeding tube. Evaluation for infection in such an infant is not complete without an ear examination. Gram-negative enteric pathogens are more commonly found infecting agents in nursery occupants than in outpatients.

6. Omphalitis

A normal umbilical cord stump will atrophy and separate at the skin level. A small amount of purulent material at the base of the cord is common but can be minimized by keeping the cord open to air and cleaning the

base with alcohol several times a day. The cord can become colonized with streptococci, staphylococci, or gram-negative organisms that can cause local infection. Infections are more common in cords manipulated for venous or arterial lines. Omphalitis is diagnosed when redness and edema develop in the soft tissues around the stump. Local and systemic cultures should be obtained. Treatment is with broad-spectrum IV antibiotics (usually nafcillin 50–75 mg/kg/d divided q8–12h and a third-generation cephalosporin). Complications are determined by the degree of infection of the cord vessels and include septic thrombophlebitis, hepatic abscess, necrotizing fasciitis, and portal vein thrombosis. Surgical consultation should be obtained because of the potential for necrotizing fasciitis.

FUNGAL SEPSIS

With the survival of smaller, sicker infants, infection with *Candida* species has become more common. Infants of low birth weight with central lines who have had repeated exposures to broad-spectrum antibiotics are at highest risk. For infants of birth weight < 1500 g, colonization rates of 27–64% have been demonstrated, with many of these infants developing cutaneous lesions although the GI tract appears to be the initial site

of colonization. A much smaller percentage (2–5%) develop systemic disease.

Clinical features of fungal sepsis can be indistinguishable from those of late-onset bacterial sepsis but may be more subtle. Thrombocytopenia may be the earliest and only sign. Deep organ involvement (renal, eye, endocarditis) is commonly associated with systemic candidiasis. Treatment is with amphotericin B (0.5–1.5 mg/kg/d). In severe infections, flucytosine (50–150 mg/kg/d) can be added for synergistic coverage. (See Chapter 39.) Prophylaxis with oral mycostatin at 0.5–1 mL PO qid or fluconazole at 3–6 mg/kg/d as a single dose diminishes intestinal colonization with yeast and decreases the frequency of systemic disease.

Malassezia furfur is also seen in infants with central lines receiving IV fat emulsion. To eradicate this organism, as well as *Candida* species, it is necessary to remove the indwelling line.

CONGENITAL VIRAL & PARASITIC INFECTIONS (SEE ALSO CHAPTERS 36 & 39.)

1. Cytomegalovirus Infection

CMV is the most common virus transmitted in utero. The incidence of congenital infection ranges from 0.2% to 2.2% of live births. Transmission of CMV can occur during either primary or reactivated infection in the mother. An important source of infection is children (especially those in a day care setting), who transmit the virus to parents and workers. The incidence of primary infection in pregnancy is 1–4%, with a 40% transplacental transmission rate to the fetus. Of these infants, 85–90% are asymptomatic at birth, whereas 10–15% have clinically apparent disease—hepatosplenomegaly, petechiae, small size for gestational age, microcephaly, direct hyperbilirubinemia, thrombocytopenia, intracranial calcifications, and chorioretinitis. The risk of neonatal disease is higher when the mother acquires the infection in the first half of pregnancy. The incidence of reactivated infection in pregnancy is less than 1%, with an incidence of clinically apparent disease of 0–1%. Diagnosis in the neonate should be confirmed by culture of the virus from urine. Rapid diagnosis is possible with antigen detection techniques and polymerase chain reaction (PCR) testing. Diagnosis can also be confirmed in utero from an am-

niocentesis specimen. Although experimental and not routinely recommended, ganciclovir therapy has been used in some severely ill neonates.

The mortality rate in patients with symptomatic congenital CMV may be as high as 20%. Sequelae such as hearing loss, mental retardation, delayed motor development, chorioretinitis and optic atrophy, seizures, language delays, and learning disability occur in 90% of symptomatic survivors. The incidence of complications is 5–15% in asymptomatic infants; the most frequent complication is hearing loss, which can be progressive.

Perinatal infection can also occur with acquisition of virus around the time of delivery. These infections are generally asymptomatic and without sequelae. Postnatal infection is usually asymptomatic but can cause hepatitis, pneumonitis, and neurologic illness in compromised seronegative premature infants. The virus can be acquired postnatally through transfusions or ingestion of CMV-infected breast milk. Transfusion risk can be minimized by using frozen, washed red blood cells or CMV antibody-negative donors.

2. Rubella

Congenital rubella infection occurs as a result of rubella infection in the mother during pregnancy. The frequency of infection and damage in the fetus is as high as 80% in mothers infected during the first trimester. Fetal infection rates decline in the second trimester before increasing again in the third trimester. Fetal damage generally does not occur in infections acquired after 18 weeks' gestation. Clinical features of congenital rubella include adenopathy, bone radiolucencies, encephalitis, cardiac defects (pulmonary arterial hypoplasia and patent ductus arteriosus), cataracts, retinopathy, growth retardation, hepatosplenomegaly, thrombocytopenia, and purpura. Affected infants can be asymptomatic at birth but develop clinical sequelae during the first year of life. The diagnosis should be suspected in cases of a characteristic clinical illness in the mother (rash, adenopathy, arthritis) confirmed by serologic testing. Diagnosis can be confirmed by an increase in serum rubella-specific IgM or culture of pharyngeal secretions in the baby. Congenital rubella is now rare because of widespread immunization.

3. Varicella

Congenital varicella infection is rare (< 5% after infection acquired during the first or second trimester) but may cause a constellation of findings, including limb hypoplasia, cutaneous scars, microcephaly, cortical atrophy, chorioretinitis, and cataracts. Perinatal exposure (5 days before to 2 days after delivery) can cause severe to fatal disseminated varicella in the infant. If maternal

varicella infection develops within this perinatal risk period, 1.25 mL of varicella immune globulin should be given to the newborn. If this has not been done, the illness can be treated with IV acyclovir (30 mg/kg/d divided q8h).

Hospitalized premature infants of at least 28 weeks' gestation whose mothers have no history of chickenpox—and all infants of less than 28 weeks' gestational age—should receive varicella immune globulin following any postnatal exposure. Susceptible women of child-bearing age should be immunized with varicella vaccine.

4. Toxoplasmosis

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*. Maternal infection occurs in 0.1–0.5% of pregnancies and is usually asymptomatic. When primary infection occurs during pregnancy, up to 40% of the fetuses become infected, of whom 15% have severe damage. The sources of transmission include exposure to cat feces and ingestion of raw or undercooked meat. Although the risk of transmission increases to 90% near term, fetal damage is most likely to occur when maternal infection occurs in the second to sixth month of gestation.

Clinical findings include growth retardation, chorioretinitis, seizures, jaundice, hydrocephalus, microcephaly, cerebral calcifications, hepatosplenomegaly, adenopathy, cataracts, maculopapular rash, thrombocytopenia, and pneumonia. The majority of affected infants are asymptomatic at birth but show evidence of damage (chorioretinitis, blindness, low IQ, hearing loss) at a later time. The serologic diagnosis is based on a positive IgA or IgM in the first 6 months of life or a persistent IgG beyond 12 months. Infants with suspected infection should have eye and auditory examinations and a CT scan of the brain. Organism isolation from placenta or cord blood and PCR tests are also available for diagnosis in the neonate and from amniocentesis specimens.

Spiramycin treatment of primary maternal infection is used to try to reduce transmission to the fetus. Neonatal treatment using pyrimethamine and sulfadiazine with folinic acid can improve long-term outcome. (See Chapter 39.)

PERINATALLY ACQUIRED VIRAL INFECTIONS

1. Herpes Simplex (See also Chapter 36.)

Herpes simplex virus (HSV) infection is most commonly acquired at the time of birth during transit through an infected birth canal. The mother may have either primary or reactivated secondary infection. Pri-

mary maternal infection, because of the high titer of organism and the absence of maternal antibodies, poses the greatest risk to the infant. The risk of neonatal infection with vaginal delivery in this setting is 33–50%. Seventy percent of mothers with primary herpes at the time of delivery are asymptomatic. The risk to an infant born to a mother with recurrent herpes simplex is much lower (< 0–5%). Time of presentation of localized (skin, eye, mouth) or disseminated disease (pneumonia, shock, hepatitis) in the infant is usually 5–14 days of age. CNS disease usually presents at 14–28 days with lethargy and seizures. In about 10% of cases, presentation can be as early as day 1 of life. Disease appearing this early suggests in utero infection. In about one third of patients, localized skin, eye, and mouth disease is the first indication of infection. In another third, disseminated or CNS disease precedes skin, eye, and mouth findings, whereas the remaining third have disseminated or CNS disease in the absence of skin, eye, and mouth disease. Preliminary diagnosis can be made by scraping the base of a vesicle and finding multinucleated giant cells. Viral culture from vesicles, usually positive in 24–72 hours, makes the definitive diagnosis. PCR technology can assist in diagnosis.

Acyclovir (60 mg/kg/d given q8h) is the drug of choice for neonatal herpes infection. Localized disease is treated for 14 days, and a 21-day course is used for disseminated or CNS disease. Treatment improves survival of neonates with CNS and disseminated disease and prevents the spread of localized disease. Prevention is possible by not allowing delivery through an infected birth canal (eg, by cesarean section within 6 hours after rupture of the membranes). However, antepartum cervical cultures are poor predictors of the presence of virus at the time of delivery. Furthermore, given the low incidence of infection in the newborn from secondary maternal infection, cesarean section is not indicated for asymptomatic mothers with a history of herpes. Cesarean sections are performed in mothers with active lesions (either primary or secondary) at the time of delivery. Infants born to mothers with a history of HSV infection but no active lesions can be observed closely after birth. Cultures should be obtained and acyclovir treatment initiated only for clinical signs consistent with herpes virus infection. Infants born to mothers with active lesions—irrespective of the route of delivery—should be cultured (eye, oropharynx, umbilicus, rectum) 24 hours after delivery. If the infant is colonized (positive cultures) or if symptoms consistent with herpes infection develop, treatment with acyclovir should be started. In cases of maternal primary infection at the time of vaginal delivery, the infant should be cultured and started on acyclovir pending the results of cultures. The major problem facing perinatologists is the high percentage of asymptomatic primary maternal

infection. In these cases, infection in the neonate is currently not preventable. Therefore, any infant who presents at the right age with symptoms consistent with neonatal herpes should be cultured and started on acyclovir pending the results of those cultures.

The prognosis is good for localized skin and mucosal disease that does not progress. The mortality rate for both disseminated and CNS herpes is high, with significant rates of morbidity among survivors despite treatment.

2. Hepatitis B & C (See also Chapter 21.)

Infants can be infected with hepatitis B at the time of birth. Clinical illness is rare in the neonatal period, but infants exposed in utero are at high risk of becoming chronic HBsAg carriers, developing chronic active hepatitis and, later, hepatocellular carcinoma. The presence of HBsAg should be determined in all pregnant women. If the result is positive, the infant should receive HBIG and hepatitis B vaccine as soon as possible after birth, followed by two subsequent vaccine doses at 1 and 6 months of age. If HBsAg has not been tested prior to birth in a mother at risk, the test should be run after delivery and hepatitis B vaccine given within 12 hours after birth. If the mother is subsequently found to be positive, HBIG should be given as soon as possible (preferably within 48 hours, but not later than 1 week after birth). Subsequent vaccine doses should be given at 1 and 6 months of age. In premature infants born to HBsAg-positive mothers, vaccine and HBIG should be given at birth, but a three-vaccine hepatitis B series should be given after a weight of 2000 g is attained.

Hepatitis C perinatal transmissions occur in about 5% of infants born to mothers who carry the virus. At the present time, no prevention strategies exist. Up to 12 months of age, the only reliable screen for hepatitis C infection is PCR. After that time, the presence of hepatitis C antibodies in the infant strongly suggests that infection has occurred.

3. Enteroviral Infection

Enteroviral infections occur with greatest frequency in the late summer and early fall. Infection is usually acquired in the perinatal period. There is often a history of maternal illness (fever, diarrhea, rash) in the week prior to delivery. The illness appears in the infant in the first 2 weeks of life and is most commonly characterized by fever, lethargy, irritability, diarrhea, and rash but is not severe. More severe forms occasionally occur, especially if infection occurs before 1 week of age, including meningoencephalitis and myocarditis, as well as a dis-

seminated illness with hepatitis, pneumonia, shock, and disseminated intravascular coagulation. Diagnosis can be confirmed by culture (rectum, CSF, blood) or by the more rapid PCR techniques.

No therapy has proved efficacy. The prognosis is good for all symptom complexes except severe disseminated disease, which carries a high mortality rate.

4. HIV Infection (See also Chapter 37.)

Human immunodeficiency virus (HIV) can be acquired in utero or at the time of delivery, or can be transmitted postpartum via breast milk. The majority of transmission occurs during the 2 weeks prior to delivery and during delivery. Transmission of virus occurs in 13–30% of births. Administration of zidovudine during pregnancy starting at 14–34 weeks' gestation, intrapartum, and for the first 6 weeks of life in the newborn at a dosage of 2 mg/kg PO qid decreases vertical transmission to 7%. Shorter courses of zidovudine are also associated with decreased disease transmission, as is cesarean delivery. The combination of zidovudine treatment and cesarean delivery can lower transmission to 2%. The addition of other anti-HIV therapy may further reduce the risk of ante- and intrapartum viral transmission. Current guidelines for use of antiretroviral drugs in pregnant HIV-infected women are similar to those for nonpregnant patients (eg, highly active retroviral combination therapy). The risk of transmission is increased in mothers with advanced disease, high viral loads, low CD4 counts, and p24 antigenemia. Prematurity, vaginal delivery, ruptured membranes over 4 hours, and chorioamnionitis also increase the transmission rate. Diagnosis is based on clinical, immunologic, and serologic findings. Newborns with congenitally acquired HIV are often free of symptoms. Jaundice, neonatal giant-cell hepatitis, and thrombocytopenia have been reported at birth. Failure to thrive, lymphadenopathy, hepatosplenomegaly, oral thrush, chronic diarrhea, bacterial infections with common organisms, and an increased incidence of upper and lower respiratory diseases, including lymphoid interstitial pneumonitis, may appear early in life or may be delayed for months to years.

Infants born to HIV-infected women should be tested by HIV DNA PCR at < 48 hours, at 1–2 months of age, and at 2–4 months old. In an infant who is age 4 months with no positive PCR, infection can be reasonably excluded. HIV-positive mothers should be counseled not to breast-feed their infants.

Protection of health care workers is an important issue. Testing should be performed in all pregnant women. Because such testing will fail to identify some infected patients, however, universal precautions should

be used. Gloves should be worn during all procedures involving blood and blood-contaminated fluids, intubation, and any invasive procedures using needles. When a splash exposure is possible (eg, in the delivery room), a mask and eye covers should be used.

OTHER INFECTIONS

1. Congenital Syphilis

The infant is usually infected in utero by transplacental passage of *Treponema pallidum*. Active primary and secondary maternal syphilis leads to fetal infection in nearly 100% of infants; latent disease in 40%; and late disease in 10%. Fetal infection is rare at under 18 weeks' gestation. Fetal infection can result in stillbirth or prematurity. Findings consistent with early congenital syphilis (presentation at under 2 years) include mucocutaneous lesions, lymphadenopathy, hepatosplenomegaly, bony changes, and hydrops. However, in the newborn period, infants are often asymptomatic, so that diagnosis is based on maternal and infant serologic testing and is only presumptive. Later manifestations (at over age 2 years) include Hutchinson teeth and mulberry molars, keratitis, chorioretinitis, glaucoma, hearing loss, saddle nose, saber shins, and mental retardation. An infant should be evaluated for congenital syphilis if it is born to a mother with positive nontreponemal tests confirmed by a positive treponemal test but without documented adequate treatment (parenteral penicillin G), including the expected fourfold decrease in nontreponemal antibody titer. Infants of mothers treated less than 1 month before delivery also require evaluation. Evaluation should include physical examination, a quantitative nontreponemal serologic test for syphilis, CSF examination for cell count, protein and VDRL, long bone radiographs, and antitreponemal IgM. A definitive diagnosis can be made on rare occasions when the organism is identified by dark-field microscopy or pathologic examination of the placenta. Guidelines for therapy are presented in Table 1–22. Infants should be treated for congenital syphilis if they have proven or probable disease, as evidenced by (1) physical or radiographic evidence, (2) quantitative nontreponemal antibody titers four times higher than the mother, (3) elevated CSF protein or cell count or positive VDRL, or (4) a positive antitreponemal IgM test. Asymptomatic infants should be treated if the mother did not receive adequate treatment for syphilis.

2. Tuberculosis (See also Chapter 38.)

Congenital tuberculosis (TB) is rare but may occur in the infant of a mother with hematogenously spread TB

Table 1–22. Recommended treatment of neonates (≤ 4 wk of age) with proven or possible congenital syphilis.

Clinical Status	Antimicrobial Therapy ^a
Proven or highly probable disease ^b	Aqueous crystalline penicillin G, 100,000–150,000 U/kg/d, administered as 50,000 U/kg per dose, IV, every 12 h during the first 7 d of life and every 8 h thereafter for a total of 10 d OR Penicillin G procaine, ^c 50,000 U/kg/d, IM, in a single dose for 10 d
Asymptomatic: normal CSF examination results, CBC and platelet count, and radiographic examination; and follow-up is certain with the following maternal treatment history: <ul style="list-style-type: none"> • (a) No penicillin treatment or inadequate or no documentation of penicillin treatment^d; (b) mother was treated with erythromycin or other nonpenicillin regimen; (c) mother received treatment ≤ 4 wk before delivery; (d) sequential serologic tests on the mother do not demonstrate a fourfold or greater decrease in a nontreponemal antibody titer • (a) Adequate therapy given >1 mo before delivery; (b) mother's nontreponemal titers decreased fourfold after appropriate therapy for early syphilis and remained stable and low for late syphilis; (c) mother has no evidence of reinfection or relapse 	Aqueous crystalline penicillin G, IV, for 10–14 d ^b OR Penicillin G procaine, ^c 50,000 U/kg/d, IM, in a single dose for 10 d OR Clinical, serologic follow-up, and penicillin G benzathine, ^e 50,000 U/kg, IM in a single dose Clinical, serologic follow-up, and penicillin G benzathine, 50,000 U/kg, IM in a single dose ^e

IV indicates intravenously; IM, intramuscularly; CSF, cerebrospinal fluid; and CBC, complete blood cell.

^aSee text for details.

^bIf more than 1 day of therapy is missed, the entire course should be restarted.

^cPenicillin G benzathine and penicillin G procaine are approved for IM administration *only*.

^dSee text for definition (includes infants in whom a serum quantitative nontreponemal serologic titer is the same or less than fourfold the maternal titer). If any part of the infant's evaluation is abnormal or not performed or if the CSF analysis is uninterpretable, the 10-day course of penicillin is required.

^eSome experts would not treat the infant but would provide close serologic follow-up.

Reprinted, with permission, from the American Academy of Pediatrics: Red Book 2003 Report on Infectious Diseases; 2003.

or by aspiration of infected amniotic fluid in cases of tuberculous endometritis. Women with pulmonary TB are not likely to infect the fetus until after delivery. Postnatal acquisition is the most common mechanism of neonatal infection. Management in these cases is based on the mother's evaluation.

1. Mother or other household contact with a positive skin test and negative chest radiograph, or mother with an abnormal chest radiograph but no evidence of tuberculous disease after clinical evaluation: Investigate family contacts. Treat the mother with isoniazid (INH).
2. Mother has an abnormal chest radiograph consistent with tuberculous disease: Mother and infant should be separated until the mother is evaluated for active TB. If active TB is found, maintain sep-

aration until the mother is receiving antituberculous therapy for 2 weeks. Investigate family contacts.

3. Mother with clinical or radiographic evidence of acute and possibly contagious TB: Evaluate the infant for congenital TB (skin test, chest radiograph, lumbar puncture, cultures) and HIV. Treat the mother and infant. If the infant is receiving INH and the mother has no risk for multidrug-resistant TB, separation is not necessary.

If congenital TB is suspected, multidrug therapy should be initiated.

3. Conjunctivitis

Neisseria gonorrhoeae may colonize an infant during passage through an infected birth canal. Gonococcal

ophthalmitis presents at 3–7 days with copious purulent conjunctivitis. The diagnosis can be suspected when gram-negative intracellular diplococci are seen on a Gram-stained smear and confirmed by culture. Treatment is with IV or IM ceftriaxone, 25–50 mg/kg (not to exceed 125 mg) given once. Prophylaxis at birth is with 1% silver nitrate or 0.5% erythromycin ointment. Infants born to mothers with known gonococcal disease should also receive a single dose of ceftriaxone.

Chlamydia trachomatis is another important cause of conjunctivitis, appearing at 5 days to several weeks of age with congestion, edema, and minimal discharge. The organism is acquired at birth after passage through an infected birth canal. Acquisition occurs in 50% of infants born to infected women, with a 25–50% risk of conjunctivitis. Prevalence in pregnancy is over 10% in some populations. Diagnosis is by isolation of the organism or by rapid antigen detection tests. Treatment is with oral erythromycin (30 mg/kg/d in divided doses q8–12h) for 14 days. Topical treatment alone will not eradicate nasopharyngeal carriage, leaving the infant at risk for the development of pneumonitis.

HEMATOLOGIC DISORDERS IN THE NEWBORN INFANT

BLEEDING DISORDERS

Neonatal coagulation is discussed in Chapter 27. Bleeding in the newborn infant may result from inherited clotting deficiencies (eg, factor VIII deficiency) or acquired disorders—hemorrhagic disease of the newborn, disseminated intravascular coagulation (DIC), liver failure, and thrombocytopenia.

1. Vitamin K Deficiency Bleeding of the Newborn

Vitamin K deficiency bleeding (VKDB) is caused by the deficiency of the vitamin K-dependent clotting factors (II, VII, IX, and X). Bleeding occurs in 0.25–1.7% of newborns who do not receive vitamin K prophylaxis after birth, generally in the first 5 days to 2 weeks but as late as 12 weeks in an otherwise well infant. Early VKDB (0–2 weeks) can be prevented by either parenteral or oral vitamin K administration, whereas late disease is most effectively prevented by administering parenteral vitamin K. Sites of ecchymoses and surface bleeding include the GI tract, umbilical cord, circumcision site, and nose, although devastating intracranial hemorrhage can occur. Bleeding from vitamin K deficiency is more likely to occur in exclusively breast-fed infants because of very low amounts of vitamin K in breast milk, with slower and more restricted intestinal colonization. Differential diagnosis includes disseminated intravascular coagulation (DIC) and hepatic failure, both occurring in ill infants (Table 1–23).

Table 1–23. Features of infants bleeding from vitamin K deficiency (VKDB), disseminated intravascular coagulation (DIC), or liver failure.

	VKDB	DIC	Liver Failure
Clinical	Well infant; no prophylactic vitamin K	Sick infant; hypoxia, sepsis, etc	Sick infant; hepatitis, inborn errors of metabolism, shock liver
Bleeding	GI tract, umbilical cord, circumcision, nose	Generalized	Generalized
Onset	2–3 d	Any time	Any time
Platelet count	Normal	Decreased	Normal or decreased
Prothrombin time (PT)	Prolonged	Prolonged	Prolonged
Partial thromboplastin time (PTT)	Prolonged	Prolonged	Prolonged
Fibrinogen	Normal	Decreased	Decreased
Factor V	Normal	Decreased	Decreased

GI = gastrointestinal.

Treatment consists of 1 mg of vitamin K SQ or IV. IM injections should be avoided in infants who are actively bleeding.

2. Thrombocytopenia

Infants with thrombocytopenia have generalized petechiae (not just on the presenting part) and platelet counts < 150,000/mL (usually < 50,000/mL, may be < 10,000/mL). Neonatal thrombocytopenia can be isolated or may occur in association with a deficiency of clotting factors. The differential diagnosis for thrombocytopenia with distinguishing clinical features is presented in Table 1–24. Treatment of neonatal thrombocytopenia is transfusion of platelets (10 mL/kg of platelets increases the platelet count by approximately 70,000/mL). Indications for transfusion in the full-term infant are clinical bleeding or a total platelet count < 10,000–20,000/mL. In the preterm infant at risk for intraventricular hemorrhage, transfusion is indicated for counts < 40,000–50,000/mL.

Table 1–24. Differential diagnosis of neonatal thrombocytopenia.

Disorder	Clinical Tips
Immune Passively acquired antibody; idiopathic thrombocytopenic purpura, systemic lupus erythematosus, drug-induced Isoimmune sensitization to HPA-1a antigen	Proper history, maternal thrombocytopenia No rise in platelet count from random donor platelet transfusion. Positive antiplatelet antibodies in baby's serum, sustained rise in platelets by transfusion of mother's platelets
Infections Bacterial infections Congenital viral infections	Sick infants with other signs consistent with infection
Syndromes Absent radii Fanconi's anemia	Congenital anomalies, associated pancytopenia
Disseminated intravascular coagulation (DIC)	Sick infants, abnormalities of clotting factors
Giant hemangioma	
Thrombosis	Hyperviscous infants, vascular catheters
High-risk with respiratory distress syndrome, pulmonary hypertension, etc	Isolated decrease in platelets is not uncommon in sick infants even in the absence of DIC (? localized trapping)

HPA = human platelet antigen.

Isoimmune thrombocytopenia (analogous to Rh isoimmunization, with a human platelet antigen (HPA)-1a-negative mother and HPA-1a-positive fetus) requires transfusion of maternal platelets, because 98% of the random population will also be HPA-1a-positive. The mother would be the most readily available known HPA-1a-negative donor. Treatment with steroids has been disappointing. Treatment with IVIG infusion, 1 g/kg/d for 2–3 days or until the platelet count has doubled or is over 50,000/mL, is recommended. Antenatal therapy of the mother with IVIG with or without steroids is also beneficial, since 20–30% of infants with isoimmune thrombocytopenia will experience intracranial hemorrhage, half of them before birth.

Infants born to mothers with idiopathic thrombocytopenic purpura are at low risk for serious hemorrhage

despite the thrombocytopenia, and treatment is usually unnecessary. If bleeding does occur, IVIG can be used.

ANEMIA

The newborn infant with anemia from acute blood loss presents with signs of hypovolemia (tachycardia, poor perfusion, hypotension), with an initially normal hematocrit that falls after volume replacement. Anemia from chronic blood loss is evidenced by pallor without signs of hypovolemia, with an initially low hematocrit and reticulocytosis.

Anemia can be caused by hemorrhage, hemolysis, or failure to produce red blood cells. Anemia occurring in the first 24–48 hours of life is the result of hemorrhage or hemolysis. Hemorrhage can occur in utero (fetoplacental, fetomaternal, or twin-to-twin), perinatally (cord rupture, placenta previa, incision through placenta at cesarean section), or internally (intracranial hemorrhage, cephalohematoma, ruptured liver or spleen). Hemolysis is caused by blood group incompatibilities, enzyme or membrane abnormalities, infection, and DIC and is accompanied by significant hyperbilirubinemia.

Initial evaluation should include a review of the perinatal history, assessment of the infant's volume status, and a complete physical examination. A Kleihauer-Betke test for fetal cells in the mother's circulation should be done. A CBC, blood smear, reticulocyte count, and direct and indirect Coombs' tests should be performed. This simple evaluation should suggest a diagnosis in most infants. It is important to remember that hemolysis related to blood group incompatibility can continue for weeks after birth. Serial hematocrits should be followed.

POLYCYTHEMIA

Polycythemia in the newborn is manifested by plethora, cyanosis, mild respiratory distress with tachypnea and oxygen need, hypoglycemia, poor feeding, emesis, and lethargy. The capillary hematocrit is > 68%, the venous hematocrit > 65%.

Elevated hematocrits occur in 2–5% of live births. Although 50% of polycythemic infants are AGA, the prevalence of polycythemia is greater in the SGA and LGA populations. Causes of increased hematocrit include (1) twin–twin transfusion, (2) maternal–fetal transfusion, (3) intrapartum transfusion from the placenta, and (4) chronic intrauterine hypoxia (SGA infants, LGA infants of diabetic mothers).

The consequence of polycythemia is hyperviscosity with decreased perfusion of the capillary beds. Clinical symptomatology can affect several organ systems (Table 1–25). Screening can be done by measuring a capillary (heelstick) hematocrit. If the value is greater than 68%,

Table 1–25. Organ-related symptoms of hyperviscosity.

Central nervous system	Irritability, jitteriness, seizures, lethargy
Cardiopulmonary	Respiratory distress, secondary to congestive heart failure, or persistent pulmonary hypertension
Gastrointestinal	Vomiting, heme-positive stools, distention, necrotizing enterocolitis
Renal	Decreased urinary output, renal vein thrombosis
Metabolic	Hypoglycemia
Hematologic	Hyperbilirubinemia, thrombocytopenia

a peripheral venous hematocrit should be measured. Values greater than 65% should be considered consistent with hyperviscosity.

Treatment is recommended for symptomatic infants. Treatment for asymptomatic infants based strictly on hematocrit is controversial. Definitive treatment is accomplished by an isovolemic partial exchange transfusion with normal saline, effectively decreasing the hematocrit. The amount to exchange (in milliliters) is calculated using the following formula:

$$\frac{PVH - DH}{PVH} \times \frac{BV}{kq} \times Wt$$

where PVH = peripheral venous hematocrit, DH = desired hematocrit, BV = blood volume, and Wt = weight.

Blood is withdrawn at a steady rate from an umbilical venous line while the replacement solution is infused at the same rate through a peripheral IV line over 15–30 minutes. The desired hematocrit value is 50–55%; the assumed blood volume is 80 mL/kg.

RENAL DISORDERS IN THE NEWBORN INFANT

Renal function depends on postconceptional age. The glomerular filtration rate (GFR) is 20 mL/min/1.73 m² in full-term neonates and 10–13 mL/min/1.73 m² in infants born at 28–30 weeks' gestation. The speed of maturation after birth also depends on postconceptional age. Creatinine can be used as a clinical marker of GFR. Values in the first month of life are shown in Table 1–26. Creatinine at birth reflects the maternal level and should decrease slowly over the first 3–4 weeks. An increasing serum creatinine is never normal. The ability to concentrate urine and retain sodium also depends on gestational age. Infants born at less than 28–30 weeks' gestation are compromised in this respect and if not observed carefully can become dehydrated and hyponatremic. Preterm infants also have an increased bicarbonate excretion and a low tubular maximum for glucose (approximately 120 mg/dL).

RENAL FAILURE

Renal failure is most commonly seen in the setting of birth asphyxia, hypovolemia, or shock from any cause. The normal rate of urine flow is 1–3 mL/kg/h. After a hypoxic or ischemic insult, acute tubular necrosis may ensue. Typically, 2–3 days of anuria or oliguria is associated with hematuria, proteinuria, and a rise in serum creatinine. The period of anuria or oliguria is followed by a period of polyuria and then gradual recovery. During the polyuric phase, excessive urine sodium and bicarbonate losses may be seen.

The initial step in management is restoration of the infant's volume status as needed. Thereafter, restriction of fluids to insensible water loss (40–60 mL/kg/d) with-

out added electrolytes, plus milliliter-for-milliliter urine replacement, should be instituted. Serum and urine electrolytes and body weights should be followed frequently. These measures should be continued through the polyuric phase. After urine output has been reestablished, urine replacement should be decreased to between 0.5 and 0.75 mL for each milliliter of urine output to see if the infant has regained normal function. If that is the case, the infant can be returned to maintenance fluids.

Finally, many of these infants experience fluid overload and should be allowed to lose enough water through urination to return to birth weight. Hyperkalemia, which may become life-threatening, may occur in this situation despite the lack of added IV potassium. If the serum potassium reaches 7–7.5 mEq/L, therapy should be started with glucose and insulin infusion, giving 1 unit of insulin for every 3 g of glucose administered, in addition to binding resins. Calcium chloride (20 mg/kg bolus) and correction of metabolic acidosis with bicarbonate are also helpful for arrhythmia resulting from hyperkalemia.

Peritoneal dialysis is occasionally needed for the management of neonatal acute renal failure.

URINARY TRACT ANOMALIES

Abdominal masses in the newborn are most frequently caused by renal enlargement. Most common is a multicystic or dysplastic kidney; congenital hydronephrosis is second in frequency. Chromosomal abnormalities and syndromes with multiple anomalies frequently include renal abnormalities. An ultrasound examination is the first step in diagnosis. In pregnancies associated with oligohydramnios, renal agenesis or obstruction secondary to posterior urethral valves should be considered. Only bilateral disease or disease in a solitary kidney is associated with oligohydramnios, significant morbidity, and death. Such infants will generally also have pulmonary hypoplasia and die from pulmonary rather than renal insufficiency.

Prenatal ultrasonography identifies infants with renal anomalies (most often hydronephrosis) prior to birth. Postnatal evaluation of these infants should include renal ultrasound and a voiding cystourethrogram at about 1–6 weeks of age, depending on the severity of the antenatal findings. Until genitourinary reflux is ruled out, these infants should receive antibiotic prophylaxis with low-dose penicillin or amoxicillin.

RENAL VEIN THROMBOSIS

Renal vein thrombosis occurs most often in IDMs and in the context of dehydration and polycythemia. Of particular concern is the IDM who is also poly-

Table 1–26. Normal values of serum creatinine (mg/dL).

Gestational Age at Birth (weeks)	Postnatal Age (days)	
	0–2	28
< 28	1.2	0.7
29–32	1.1	0.6
33–36	1.1	0.45
36–42	0.8	0.3

cythemic. If fetal distress is superimposed on these problems, prompt reduction in blood viscosity is indicated. Thrombosis usually begins in intrarenal venules and can extend into larger veins. Clinically, the kidney may be enlarged, and blood and protein may be in the urine. With bilateral renal vein thrombosis, anuria ensues. Diagnosis can be confirmed with an ultrasound examination that includes Doppler flow studies of the kidneys. Treatment involves correcting the predisposing condition and systemic heparinization for the thrombosis. Use of thrombolytics for this condition is controversial. Prognosis for a full recovery is uncertain. Some infants will go on to develop significant atrophy of the affected kidney and systemic hypertension.

■ NEUROLOGIC PROBLEMS IN THE NEWBORN INFANT

SEIZURES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Usual onset at 12–48 hours
- Most common seizure type is characterized by a constellation of findings
- Most common causes include hypoxic-ischemic encephalopathy, intracranial bleeds, and infection

Newborns rarely have well-organized tonic-clonic seizures because of their incomplete cortical organization and a preponderance of inhibitory synapses. The most common type of seizure is characterized by a constellation of findings, including horizontal deviation of the eyes with or without jerking; eyelid blinking or fluttering; sucking, smacking, drooling, and other oral-buccal movements; swimming, rowing, or paddling

movements; and apneic spells. Strictly tonic or multifocal clonic episodes are also seen.

Clinical Findings

The differential diagnosis of neonatal seizures is presented in Table 1–27. Most neonatal seizures occur between 12 and 48 hours of age. Later onset seizures suggest meningitis, benign familial seizures, or hypocalcemia. Information regarding antenatal drug use, the presence of birth asphyxia or trauma, and family history (regarding inherited disorders) should be obtained. Physical examination focuses on neurologic features, other signs of drug withdrawal, concurrent signs of infection, dysmorphic features, and intrauterine growth. Screening work-up should include blood glu-

Table 1–27. Differential diagnosis of neonatal seizures.

Diagnosis	Comment
Hypoxic-ischemic encephalopathy	Most common cause (60%), onset in first 24 hours
Intracranial hemorrhage	Up to 15% of cases, periventricular-intraventricular hemorrhage, subdural or subarachnoid bleeding, stroke
Infection	12% of cases
Hypoglycemia	Small for gestational age, infant of a diabetic mother (IDM)
Hypocalcemia, hypomagnesemia	Infant of low birth weight, IDM
Hyponatremia	Rare, seen with syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Disorders of amino and organic acid metabolism, hyperammonemia	Associated acidosis, altered level of consciousness
Pyridoxine dependency	Seizures refractory to routine therapy; cessation of seizures after administration of pyridoxine
Developmental defects	Other anomalies, chromosomal syndromes
Drug withdrawal	
No cause found	10% of cases
Benign familial neonatal seizures	

case, ionized calcium, and electrolytes in all cases. Further work-up depends on diagnoses suggested by the history and physical examination. If there is any suspicion of infection, a spinal tap should be done. Hemorrhages and structural disease of the CNS can be addressed with real-time ultrasound and CT scan. Infarctions are most easily seen on diffusion-weighted MRI scan. Metabolic work-up should be pursued when appropriate. EEG should be done; the presence of spike discharges must be noted and the background wave pattern evaluated. Not infrequently, correlation between EEG changes and clinical seizure activity is absent.

Treatment

Adequate ventilation and perfusion should be ensured. Hypoglycemia should be treated immediately with a 2 mL/kg infusion of D₁₀W followed by 6 mg/kg/min of D₁₀W (100 mL/kg/d). Other treatments such as calcium or magnesium infusion and antibiotics are indicated to treat hypocalcemia, hypomagnesemia, and suspected infection. Electrolyte abnormalities should be corrected. Phenobarbital, 20 mg/kg IV, should be administered to stop seizures. Supplemental doses of 5 mg/kg can be used if seizures persist, up to a total of 40 mg/kg. In most cases, phenobarbital controls seizures. If seizures continue, therapy with phenytoin, sodium valproate, or lorazepam may be indicated. For refractory seizures, a trial of pyridoxine is indicated.

Prognosis

Outcome is related to the underlying cause of the seizure. The outcomes for hypoxic-ischemic encephalopathy and intraventricular hemorrhage have been discussed earlier in this chapter. In these settings, seizures that are difficult to control carry a poor prognosis for normal development. Seizures resulting from hypoglycemia, infection of the CNS, some inborn errors of metabolism, and developmental defects also have a high rate of poor outcome. Seizures caused by hypocalcemia or isolated subarachnoid hemorrhage generally resolve without sequelae.

HYPOTONIA

One should be alert to the diagnosis of congenital hypotonia when a mother has polyhydramnios and a history of poor fetal movement. The newborn may present with poor respiratory effort and birth asphyxia. For a discussion of causes and evaluation, see Chapter 23.

INTRACRANIAL HEMORRHAGE¹

1. Subdural Hemorrhage

Subdural hemorrhage is related to birth trauma; the bleeding is caused by tears in the veins that bridge the subdural space. Prospective studies relating incidence to specific obstetric complications are not available.

The most common site of subdural bleeding is in ruptured superficial cerebral veins with blood over the cerebral convexities. These hemorrhages can be asymptomatic or may cause seizures, with onset on days 2–3 of life, vomiting, irritability, and lethargy. Associated findings include retinal hemorrhages and a full fontanelle. The diagnosis is confirmed by CT scan.

Specific treatment entailing needle drainage of the subdural space is rarely necessary. Most infants survive; 75% are normal on follow-up.

2. Primary Subarachnoid Hemorrhage

Primary subarachnoid hemorrhage is the most common type of neonatal intracranial hemorrhage. In the full-term infant, it can be related to trauma of delivery, whereas subarachnoid hemorrhage in the preterm infant is seen in association with germinal matrix hemorrhage. Clinically, these hemorrhages can be asymptomatic or can present with seizures and irritability on day 2 or, rarely, a massive hemorrhage with a rapid downhill course. The seizures associated with subarachnoid hemorrhage are very characteristic—usually brief, with a normal examination interictally. Diagnosis can be suspected on spinal tap and confirmed with CT scan. Long-term follow-up is uniformly good.

3. Neonatal Stroke

Focal cerebral ischemic injury can occur in the context of intraventricular hemorrhage in the premature infant and hypoxic ischemic encephalopathy. Neonatal stroke has also been described in the context of underlying disorders of thrombolysis and maternal drug use (cocaine). In some cases, the origin is unclear. The injury often occurs antenatally. The most common clinical presentation of an isolated cerebral infarct is with seizures, and diagnosis can be confirmed acutely with diffusion-weighted MRI scan. The most frequently described distribution is that of the middle cerebral artery.

Treatment is directed at controlling seizures. Long-term outcome is variable, ranging from normal to hemiplegias and cognitive deficits.

¹Intraventricular hemorrhage is discussed in the section on Care of the Premature Infant.

METABOLIC DISORDERS IN THE NEWBORN INFANT²

HYPERGLYCEMIA

Hyperglycemia may develop in preterm infants, particularly those of extremely low birth weight who are also SGA. Glucose concentrations may exceed 200–250 mg/dL, particularly in the first few days of life. This transient diabetes-like syndrome usually lasts approximately 1 week.

Management may include simply reducing glucose intake while continuing to supply IV amino acids to prevent protein catabolism with resultant gluconeogenesis. IV insulin infusions will be needed in infants who remain hyperglycemic despite glucose infusion rates of only 5–6 mg/kg/min or less.

HYPOCALCEMIA

Calcium concentration in the immediate newborn period decreases in all newborn infants. The concentration in fetal plasma is higher than that of the neonate or adult. Hypocalcemia is usually defined as a total serum concentration less than 7 mg/dL (equivalent to a calcium activity of 3.5 mEq/L), although the physiologically active fraction, ionized calcium, should be measured whenever possible. Ionized calcium is usually normal even when total calcium is as low as 6–7 mg/dL. An ionized calcium of greater than 0.9 mmol/L (1.8 mEq/L; 3.6 mg/dL) is not likely to be detrimental.

Clinical Findings

The clinical signs of hypocalcemia and hypocalcemic tetany include a high-pitched cry, jitteriness, tremulousness, and seizures.

Hypocalcemia tends to occur at two different times in the neonatal period. Early-onset hypocalcemia occurs in the first 2 days of life and has been associated with prematurity, maternal diabetes, asphyxia, and, rarely, maternal hypoparathyroidism. Late-onset hypocalcemia occurs at approximately 7–10 days and is observed in infants receiving modified cow's milk rather than infant formula (high phosphorus intake) or in infants with hypoparathyroidism (DiGeorge syndrome, 22q11 deletion). Mothers in Third-World countries often have vitamin D deficiency, which can also contribute to late-onset hypocalcemia.

TREATMENT

A. ORAL CALCIUM THERAPY

The oral administration of calcium salts, often along with vitamin D, is the preferred method of treatment for chronic forms of hypocalcemia resulting from hypoparathyroidism (see Chapter 30).

B. INTRAVENOUS CALCIUM THERAPY

IV calcium therapy is usually needed for infants with symptomatic hypocalcemia or an ionized calcium less than 0.9 mmol/L. A number of precautions must be observed when calcium gluconate is given intravenously. The infusion must be given slowly so that there is no sudden increase in calcium concentration of blood entering the right atrium, which could cause severe bradycardia and even cardiac arrest. Furthermore, the infusion must be observed carefully, because an IV infiltrate containing calcium can cause full-thickness skin necrosis requiring grafting. For these reasons, IV calcium therapy should be given judiciously and through a central venous line if possible. IV administration of 10% calcium gluconate is usually given as a bolus of 100–200 mg/kg (1–2 mL/kg) over approximately 10–20 minutes, followed by a continuous infusion (0.5–1 g/kg/d) over 1–2 days. Ten percent calcium chloride (20 mg/kg or 0.2 mL/kg per dose) may result in a larger increment in ionized calcium and greater improvement in mean arterial blood pressure in sick hypocalcemic infants and thus may have a role in the newborn. **Note:** Calcium salts cannot be added to IV solutions that contain sodium bicarbonate because they precipitate as calcium carbonate.

Prognosis

The prognosis is good for neonatal seizures entirely caused by hypocalcemia that is promptly treated.

²Hypoglycemia is discussed in the section on Common Problems in the Term Newborn Infant.

INBORN ERRORS OF METABOLISM

The individual inborn errors of metabolism are rare, but collectively have an incidence of 1/1000 live births. Expanded newborn genetic screening will undoubtedly aid in the diagnosis of these disorders. Nevertheless, many infants will present prior to these results being available. The diseases are considered in detail in Chapter 32. These diagnoses should be entertained when infants who were initially well present with sepsis-like syndromes, recurrent hypoglycemia, neurologic syndromes (seizures, altered levels of consciousness), or unexplained acidosis (suggestive of organic acidemias).

In the immediate neonatal period, urea cycle disorders present as an altered level of consciousness secondary to hyperammonemia. A clinical clue that supports this diagnosis is hyperventilation with primary respiratory alkalosis, along with a lower than expected blood urea nitrogen. The other major diagnostic category to consider consists of infants with severe acidemia secondary to organic acidemias.

Child Development & Behavior

2

Edward Goldson, MD, & Ann Reynolds, MD

Child development encompasses all aspects of pediatrics. It applies to somatic, psychological, and cognitive growth and to behavior. The developmental principle, that is, the concept of ongoing change and maturation, is integral to the daily practice of pediatrics. For example, we recognize that a 3-month-old infant is very different from a 3-year-old and from a 13-year-old adolescent, not only with respect to what the child can do but also in terms of the kind of illness he or she might have. This perspective is unique to pediatrics, separating it from other fields of medicine. Although the principles of child development have been the domain of the general pediatrician, the field of developmental and behavioral pediatrics has emerged as a subspecialty that addresses not only typical development but also the diagnosis and evaluation of atypical behavior and development.

This chapter does not attempt to cover the entire field of developmental and behavioral pediatrics. Instead, it focuses on three distinct areas. First, it discusses normal development but does not cover the newborn period or adolescence (see Chapters 1 and 3, respectively). Second, it addresses behavioral variations, emphasizing that these variations reflect the spectrum of normal development and not pathology. Third, it deals with developmental and behavioral disorders and their treatment.

I. NORMAL DEVELOPMENT

THE FIRST YEAR

Normal children follow a trajectory of increasing physical size (Figures 2-1 to 2-10) and increasing complexity of function (Figures 2-7, 2-8 and Tables 2-1, 2-2). Growth charts provide an overview of the normal growth trajectory of children, thus alerting the clinician to what is atypical. Table 2-3 provides the theoretical perspectives of human behavior, taking into consideration the work of Freud, Erikson, and Piaget.

The first 5 years of life are a period of extraordinary physical growth and increasing complexity of function. The child triples his or her birth weight within the first year and achieves two thirds of his or her brain size by

age 2½ to 3 years. The child progresses from a totally dependent infant at birth to a mobile, verbal person who is able to express his or her needs and desires by age 2-3 years. In the ensuing 2-3 years the child further develops the capacity to interact with peers and adults, achieves considerable verbal and physical prowess, and becomes ready to enter the academic world of learning and socialization.

It is critical for the clinician to identify disturbances in development during these early years because there may be windows of time or sensitive periods when appropriate interventions may be instituted to effectively treat developmental problems. Numerous screening tools are available to identify children with developmental disturbances; however, the clinician can use certain principles to identify problems without resorting to formal screening measures. From a motor perspective, children develop in a cephalocaudal direction. They can lift their heads with good control at 3 months, sit independently at 6 months, crawl at 9 months, walk at 1 year, and run by 18 months. The child learning to walk has a wide-based gait at first. Next, he or she walks with legs closer together, the arms move medially, a heel-toe gait develops, and the arms swing symmetrically by 18 to 24 months.

Clinicians often focus on gross motor development, but an appreciation of fine motor development and dexterity, particularly the grasp, can be instructive not only in monitoring normal development but also in identifying deviations in development. The grasp begins as a raking motion involving the ulnar aspect of the hand at age 3-4 months. The thumb is added to this motion at about age 5 months as the focus of the movement shifts to the radial side of the hand. The thumb opposes the fingers for picking up objects just before age 7 months, and the neat pincer grasp emerges at about age 9 months. Most young children have symmetrical movements. Asymmetries of movement noted in the first 2-3 years of life, be they facial asymmetries or gross motor asymmetries, should be investigated. This is particularly true if other developmental delays are present or if the child has a history of adverse experiences such as prematurity or intracranial hemorrhage. Children should not have a hand preference at 1 year of age and typically develop handedness between 18 and 30 months.

Language is a critical area to consider as well. Children usually have 5–10 comprehensible words by age 1 year; by age 2 years they are putting 2–3 words into phrases, 50% of which their caregivers can understand (see Tables 2-1 and 2-2 and Figure 2-11).

One may easily memorize the developmental milestones that characterize the trajectory of the typical child; however, these milestones become more mean-

ingful and clinically useful if placed in empirical and theoretical contexts. The work of Piaget and others is quite instructive and provides some insight into behavioral and affective development (see Table 2-3). Piaget described the first 2 years of life as the sensorimotor period, during which infants learn with increasing sophistication how to link sensory input from the environment with a motor response. Infants build on primitive

Table 2-1. Developmental charts.

<p style="text-align: center;">1–2 months</p> <p>Activities to be observed: Holds head erect and lifts head. Turns from side to back. Regards faces and follows objects through visual field. Drops toys. Becomes alert in response to voice.</p> <p>Activities related by parent: Recognizes parents. Engages in vocalizations. Smiles spontaneously.</p>	<p>Gives toys on request. Tries to build a tower of 2 cubes.</p> <p>Activities related by parent: Points to desired objects. Says 1 or 2 other words.</p>
<p style="text-align: center;">3–5 months</p> <p>Activities to be observed: Grasps cube—first ulnar then later thumb opposition. Reaches for and brings objects to mouth. Makes “raspberry” sound. Sits with support.</p> <p>Activities related by parent: Laughs. Anticipates food on sight. Turns from back to side.</p>	<p style="text-align: center;">18 months</p> <p>Activities to be observed: Builds tower of 3–4 cubes. Throws ball. Scribbles spontaneously. Seats self in chair. Dumps pellet from bottle.</p> <p>Activities related by parent: Walks up and down stairs with help. Says 4–20 words. Understands a 2-step command. Carries and hugs doll. Feeds self.</p>
<p style="text-align: center;">6–8 months</p> <p>Activities to be observed: Sits alone for a short period. Reaches with one hand. First scoops up a pellet then grasps it using thumb opposition. Imitates “bye-bye.” Passes object from hand to hand in midline. Babbles.</p> <p>Activities related by parent: Rolls from back to stomach. Is inhibited by the word <i>no</i>.</p>	<p style="text-align: center;">24 months</p> <p>Activities to be observed: Speaks short phrases, 2 words or more. Kicks ball on request. Builds tower of 6–7 cubes. Points to named objects or pictures. Jumps off floor with both feet. Stands on either foot alone. Uses pronouns.</p> <p>Activities related by parent: Verbalizes toilet needs. Pulls on simple garment. Turns pages of book singly. Plays with domestic mimicry.</p>
<p style="text-align: center;">9–11 months</p> <p>Activities to be observed: Stands alone. Imitates pat-a-cake and peek-a-boo. Uses thumb and index finger to pick up pellet.</p> <p>Activities related by parent: Walks by supporting self on furniture. Follows one-step verbal commands, eg, “Come here,” “Give it to me.”</p>	<p style="text-align: center;">30 months</p> <p>Activities to be observed: Walks backward. Begins to hop on one foot. Uses prepositions. Copies a crude circle. Points to objects described by use. Refers to self as I. Holds crayon in fist.</p> <p>Activities related by parent: Helps put things away. Carries on a conversation.</p>
<p style="text-align: center;">1 year</p> <p>Activities to be observed: Walks independently. Says “mama” and “dada” with meaning. Can use a neat pincer grasp to pick up a pellet. Releases cube into cup after demonstration.</p>	<p style="text-align: center;">3 years</p> <p>Activities to be observed: Holds crayon with fingers. Builds tower of 9–10 cubes.</p>

(continued)

Table 2-1. Developmental charts. (continued)

<p>Imitates 3-cube bridge. Copies circle. Gives first and last name.</p> <p>Activities related by parent: Rides tricycle using pedals. Dresses with supervision.</p>	<p>Knows right and left hand. Draws recognizable person with at least 8 details. Can describe favorite television program in some detail.</p> <p>Activities related by parent: Does simple chores at home (eg, taking out garbage, drying silverware). Goes to school unattended or meets school bus. Good motor ability but little awareness of dangers.</p>								
<p style="text-align: center;">3-4 years</p> <p>Activities to be observed: Climbs stairs with alternating feet. Begins to button and unbutton. "What do you like to do that's fun?" (Answers using plurals, personal pronouns, and verbs.) Responds to command to place toy <i>in, on, or under</i> table. Draws a circle when asked to draw a person. Knows own sex. ("Are you a boy or a girl?") Gives full name. Copies a circle already drawn. ("Can you make one like this?")</p> <p>Activities related by parent: Feeds self at mealtime. Takes off shoes and jacket.</p>	<p style="text-align: center;">6-7 years</p> <p>Activities to be observed: Copies a Δ. Defines words by use. ("What is an orange?" "To eat.") Knows if morning or afternoon. Draws a person with 12 details. Reads several one-syllable printed words. (My, dog, see, boy.) Uses pencil for printing name.</p>								
<p style="text-align: center;">4-5 years</p> <p>Activities to be observed: Runs and turns without losing balance. May stand on one leg for at least 10 seconds. Buttons clothes and laces shoes. (Does not tie.) Counts to 4 by rote. "Give me 2 sticks." (Able to do so from pile of 4 tongue depressors.) Draws a person. (Head, 2 appendages, and possibly 2 eyes. No torso yet.) Knows the days of the week. ("What day comes after Tuesday?") Gives appropriate answers to: "What must you do if you are sleepy? Hungry? Cold?" Copies + in imitation.</p> <p>Activities related by parent: Self-care at toilet. (May need help with wiping.) Plays outside for at least 30 minutes. Dresses self except for tying.</p>	<p style="text-align: center;">7-8 years</p> <p>Activities to be observed: Counts by 2s and 5s. Ties shoes. Copies a \diamond. Knows what day of the week it is. (Not date or year.) Reads paragraph #1 Durrell:</p> <p><i>Reading:</i> Muff is a little yellow kitten. She drinks milk. She sleeps on a chair. She does not like to get wet.</p> <p><i>Corresponding arithmetic:</i></p> <table style="margin-left: auto; margin-right: auto;"> <tbody> <tr> <td style="text-align: center;">7</td> <td style="text-align: center;">6</td> <td style="text-align: center;">6</td> <td style="text-align: center;">8</td> </tr> <tr> <td style="text-align: center;"><u>+4</u></td> <td style="text-align: center;"><u>+7</u></td> <td style="text-align: center;"><u>-4</u></td> <td style="text-align: center;"><u>-3</u></td> </tr> </tbody> </table> <p>No evidence of sound substitution in speech (eg, <i>fr</i> for <i>thr</i>). reflex patterns of behavior (termed schemata; sucking is an example) and constantly incorporate or assimilate new experiences. The schemata evolve over time as infants accommodate new experiences and as new levels of cognitive ability unfold in an orderly sequence. Enhancement of neural networks through dendritic branching occurs in spurts throughout the sensorimotor period. In the first year of life, the infant's percep-

tion of reality revolves around itself and what it can see or touch. The infant follows the trajectory of an object through the field of vision, but before age 6 months the object ceases to exist once it leaves the infant's field of vision. At age 9-12 months, the infant gradually develops the concept of object permanence, or the realization that objects exist even when not seen. The development of object permanence correlates with enhanced

Table 2-2. Normal speech and language development.

Age	Speech	Language	Articulation
1 month	Throaty sounds		Vowels: \ah\, \uh\, \ee\
2 months	Vowel sounds ("eh"), coos		
2½ months	Squeals		
3 months	Babbles, initial vowels		
4 months	Guttural sounds ("ah," "go")		Consonants, m, p, b
5 months			Vowels: \o\, \u\
7 months	Imitates speech sounds		
8 months			Syllables: da, ba, ka
10 months		"Dada" or "mama" nonspecifically	Approximates names: baba/bottle
12 months	Jargon begins (own language)	One word other than "mama" or "dada"	Understandable: 2-3 words
13 months		Three words	
16 months		Six words	Consonants: t, d, w, n, h
18-24 months		Two-word phrases	Understandable 2-word phrases
24-30 months		Three-word phrases	Understandable 3-word phrases
2 years	Vowels uttered correctly	Approximately 270 words; uses pronouns	Approximately 270 words; uses phrases
3 years	Some degree of hesitancy and uncertainty common	Approximately 900 words; intelligible 4-word phrases	Approximately 900 words; intelligible 4-word phrases
4 years		Approximately 1540 words; intelligible 5-word phrases or sentences	Approximately 1540 words; intelligible 5-word phrases
6 years		Approximately 2560 words; intelligible 6- or 7-word sentences	Approximately 2560 words; intelligible 6- or 7-word sentences
7-8 years	Adult proficiency		

Data on articulation from Berry MF: *Language Disorders of Children*. Appleton-Century-Crofts, 1969; and from Bzoch K, League R: *Receptive-Expressive Emergent Language Scale*. University Park Press, 1970.

frontal activity on the electroencephalogram. The concept attaches first to the image of the mother or primary caregiver because of his or her emotional importance and is a critical part of attachment behavior (discussed later). In the second year, children extend their ability to manipulate objects by using instruments, first by imitation and later by trial and error.

Freud described the first year of life as the oral stage because so many of the infant's needs are fulfilled by oral means. Nutrition is obtained through sucking on the breast or bottle, and self-soothing occurs through sucking on fingers or a pacifier. During this stage of symbiosis with the mother, the boundaries between mother and infant are blurred. The baby's needs are totally met by the mother, and the mother has been de-

scribed as manifesting "narcissistic possessiveness" of the infant. This is a very positive interaction in the bidirectional attachment process called bonding. The parents learn to be aware of and to interpret the infant's cues, which reflect its needs. A more sensitive emotional interaction process develops that can be seen in the mirroring of facial expressions by the primary caregiver and infant and in their mutual engagement in cycles of attention and inattention, which further develop into social play. A parent who is depressed or cannot respond to the baby's expressions and cues can have a profoundly adverse effect on the child's future development. Erikson's terms of basic trust versus mistrust are another way of describing the reciprocal interaction that characterizes this stage.

Table 2-3. Perspectives of human behavior.

Age	Theories of Development			Skill Areas		Psychopathology
	Freud	Erikson	Piaget	Language	Motor	
Birth to 18 months	Oral	Basic trust versus mistrust	Sensorimotor	Body actions; crying; naming; pointing	Reflex sitting, reaching, grasping, walking	Autism; anaclitic depression, colic; disorders of attachment; feeding, sleeping problems
18 months–3 years	Anal	Autonomy versus shame, doubt	Symbolic (preoperational)	Sentences; telegraph jargon	Climbing, running	Separation issues; negativism; fearfulness; constipation; shyness, withdrawal
3–6 years	Oedipal	Initiative versus guilt	Intuition (preoperational)	Connective words; can be readily understood	Increased coordination; tricycle; jumping	Enuresis; encopresis; anxiety; aggressive acting out; phobias; nightmares
6–11 years	Latency	Industry versus inferiority	Concrete operational	Subordinate sentences; reading and writing; language reasoning	Increased skills; sports, recreational cooperative games	School phobias; obsessive reactions; conversion reactions; depressive equivalents
12–17 years	Adolescence (genital)	Identity versus role confusion	Formal operational	Reason abstract; using language; abstract manipulation	Refinement of skills	Delinquency; promiscuity; schizophrenia; anorexia nervosa; suicide

Adapted and reproduced, with permission, from Dixon S: Setting the stage: Theories and concepts of child development. In Dixon S, Stein M (eds): *Encounters with Children*, 2nd ed. Year Book, 1992.

Turn-taking games, which occur between ages 3 and 6 months, are a pleasure for both the parents and the infant and are an extension of mirroring behavior. They also represent an early form of imitative behavior, which is important in later social and cognitive development. More sophisticated games, such as peek-a-boo, occur at approximately age 9 months. The infant's thrill at the reappearance of the face that vanished momentarily demonstrates the emerging understanding of object permanence.

Age 8–9 months is also a critical time in the attachment process because this is when separation anxiety and stranger anxiety become marked. The infant at this stage is able to appreciate discrepant events that do not match previously known schemata. These new events cause uncertainty and subsequently fear and anxiety. The infant must be able to retrieve previous schemata and incorporate new information over an extended time. These abilities are developed by age 8 months and give rise to the fears that subsequently develop: stranger anxiety and separation anxiety. In stranger anxiety, the infant analyzes the face of a stranger, detects the mismatch with previous schemata, and responds with fear or anxiety, leading to crying. In separation anxiety, the child perceives the difference between the primary care-

giver's presence and her absence by remembering the schema of her presence. Perceiving the inconsistency, the child first becomes uncertain and then anxious and fearful. This begins at age 8 months, reaches a peak at 15 months, and disappears by the end of 2 years in a relatively orderly progression as central nervous system (CNS) maturation facilitates the development of new skills. A parent can put the child's understanding of object permanence to good use by placing a picture of the mother near the child or by leaving an object (eg, her sweater) where the child can see it during her absence. A visual substitute for the mother's presence may comfort the child.

THE SECOND YEAR

Once the child can walk independently, it can move away from the parent and explore the environment. Although the child uses the mother as "home base," returning to her frequently for reassurance, he or she has now taken a major step toward independence. This is the beginning of mastery over the environment and an emerging sense of self. The "terrible twos" and the frequent self-asserting use of "no" are the child's attempt to develop a better idea of what is or might be under its

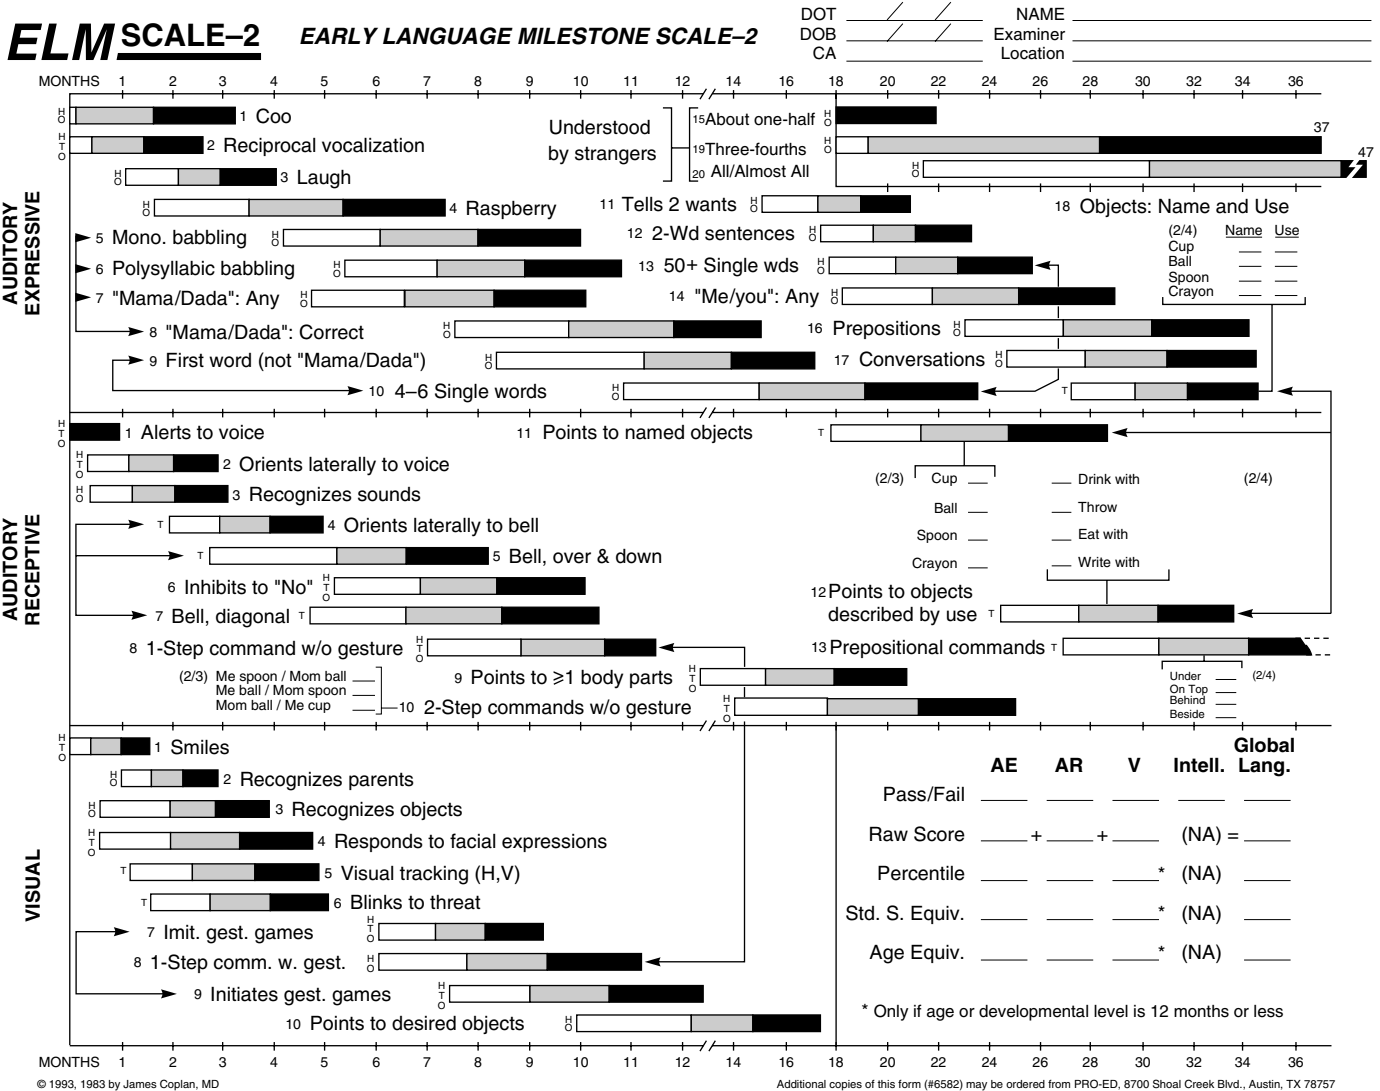

Figure 2-11. Early Language Milestone Scale-2. (Reproduced, with permission, from Coplan J: *Early Language Milestone Scale*. Pro Ed, 1993.)

control. The child is starting to assert his or her autonomy. Ego development during this time should be fostered but with appropriate limits.

As children develop a sense of self, they begin to understand the feelings of others and develop empathy. They hug another child who is in perceived distress or become concerned when one is hurt. They begin to understand how another child feels when he or she is harmed, and this realization helps them to inhibit their own aggressive behavior. Children also begin to understand right and wrong and parental expectations. They recognize that they have done something “bad” and may signify that awareness by saying “uh-oh” or with other expressions of distress. They also take pleasure in their accomplishments and become more aware of their bodies.

An area of child behavior that has often been overlooked is play. Play is the child’s work and a significant means of learning. Play is a very complex process whose purpose can include the practice and rehearsal of roles, skills, and relationships; a means of revisiting the past; a means of actively mastering a range of experiences; and a way to integrate the child’s life experiences. It involves emotional development (affect regulation, gender identification and roles), cognitive development (nonverbal and verbal function, executive functioning and creativity), and social/motor development (motor coordination, frustration tolerance, and social interactions such as turn taking). Of interest is the fact that play has a developmental progression. The typical 6- to 12-month-old engages in the game of peek-a-boo, which is a form of social interaction. During the next year or so, although children engage in increasingly complex social interactions and imitation, their play is primarily solitary. However, they do begin to engage in symbolic play such as by drinking from a toy cup and then by giving the doll a drink from a toy cup. By the second to third year children begin to engage in parallel play (engaging in behaviors that are imitative). This form of play gradually evolves into more interactive or collaborative play by the fourth year and is also more thematic in nature. There are of course wide variations in the development of play, reflecting cultural, educational, and socioeconomic variables. Nevertheless, the development of play does follow a sequence that can be assessed and can be very informative in the evaluation of the child.

Brain maturation sets the stage for toilet training. After age 18 months, toddlers have the sensory capacity for awareness of a full rectum or bladder and are physically able to control bowel and urinary tract sphincters. They also take great pleasure in their accomplishments, particularly in appropriate elimination, if it is reinforced positively. Children must be given some control over when elimination occurs. If parents impose severe restrictions, the achievement of this developmental

milestone can become a battle between parent and child. Freud termed this period the anal stage because the developmental issue of bowel control is the major task requiring mastery. It encompasses a more generalized theme of socialized behavior and overall body cleanliness, which is usually taught or imposed on the child at this age.

LANGUAGE DEVELOPMENT: AGES 1–4 YEARS

Communication is important from birth (see Table 2–2 and Figure 2–11), particularly the nonverbal, reciprocal interactions between infant and caregiver. By age 2 months, these interactions begin to include vocalizations such as cooing and reciprocal vocal play between parent and child. Babbling begins by age 6–10 months, and the repetition of sounds such as “da-da-da-da” is facilitated by the child’s increasing oral muscular control. Babbling reaches a peak at age 12 months. The child then moves into a stage of having needs met by using individual words to represent objects or actions. It is common at this age for children to express wants and needs by pointing to objects or using other gestures. The acquisition of expressive vocabulary varies greatly between 12 and 24 months of age. As a group, males and children who are bilingual tend to develop expressive language more slowly during that time. It is important to note, however, that for each individual, milestones should still fall within the expected range. Gender and exposure to two languages should never be used as an excuse for failing to refer a child who has significant delay for further evaluation. It is also important to note that most children are not truly bilingual. Most children have one primary language, and any other languages are secondary.

Receptive language usually develops more rapidly than expressive language. Word comprehension increases at age 9 months, and by age 13 months the child’s receptive vocabulary may be as large as 20–100 words. After age 18 months, expressive and receptive vocabularies increase dramatically, and by the end of the second year a quantum leap in language development permits a major advance in cognitive development. The child begins to put together words and phrases and begins to use language to represent a new world, the symbolic world. At this time, children begin to put verbs into their phrases and focus much of their language on describing their new abilities, for example, “I go out.” They incorporate prepositions into speech and ask “why?” and “what?” questions more frequently. They also begin to appreciate time factors and to understand and use this concept in their speech (see Table 2–1).

The Early Language Milestone (ELM) Scale (see Figure 2–11) is a simple tool for assessing early lan-

guage development in the pediatric office setting. It is scored in the same way as the Denver II (Figure 2–12) but tests receptive and expressive language areas in greater depth.

Piaget characterized the 2- to 6-year-old stage as pre-operational. This stage begins when language has facilitated the creation of mental images in the symbolic sense. The child begins to manipulate the symbolic world; sorts out reality from fantasy imperfectly; and may be terrified of dreams, wishes, and foolish threats. Most of the child's perception of the world is egocentric or interpreted in reference to his or her needs or influence. Cause–effect relationships are confused with temporal ones or interpreted egocentrically. For example, children may focus their understanding of divorce on themselves (“My father left because I was bad” or “My mother left because she didn't love me”). Illness and the need for medical care are also commonly misinterpreted at this age. The child may make a mental connection between a sibling's illness and a recent argument, a negative comment, or a wish for the sibling to be ill. The child may experience significant guilt unless the parents are aware of these misperceptions and take time to deal with them.

At this age, children also endow inanimate objects with human feelings. They also assume that humans cause or create all natural events. For instance, when asked why the sun sets, they may say, “The sun goes to his house” or “It is pushed down by someone else.” Magical thinking blossoms between ages 3 and 5 years as symbolic thinking incorporates more elaborate fantasy. Fantasy facilitates development of role playing, sexual identity, and emotional growth. Children test new experiences in fantasy, both in their imagination and in play. In their play, children often create magical stories and novel situations that reflect issues with which they are dealing, such as aggression, relationships, fears, and control. Children often invent imaginary friends at this time, and nightmares or fears of monsters are common. At this stage, other children become important in facilitating play, such as in a preschool group. Play gradually becomes more cooperative; shared fantasy leads to game playing. Freud described the oedipal phase between ages 3 and 6 years, when there is strong attachment to the parent of the opposite sex. The child's fantasies may focus on play-acting the adult role with that parent, although by age 6 years oedipal issues are usually resolved and attachment is redirected to the parent of the same sex.

EARLY SCHOOL YEARS: AGES 5–7 YEARS

Attendance at kindergarten at age 5 years marks an acceleration in the separation–individuation theme initi-

ated in the preschool years. The child is ready to relate to peers in a more interactive manner. The brain has reached 90% of its adult weight. Sensorimotor coordination abilities are maturing and facilitating pencil-and-paper tasks and sports, both part of the school experience. Cognitive abilities are still at the preoperational stage, and children focus on one variable in a problem at a time. However, most children have mastered conservation of length by age 5½ years, conservation of mass and weight by 6½ years, and conservation of volume by 8 years.

By first grade, there is more pressure on the child to master academic tasks—recognizing numbers, letters, and words and learning to write. Piaget described the stage of concrete operations beginning after age 6 years, when the child is able to perform mental operations concerning concrete objects that involve manipulation of more than one variable. The child is able to order, number, and classify because these activities are related to concrete objects in the environment and because these activities are stressed in early schooling. Magical thinking diminishes greatly at this time, and the reality of cause–effect relationships is better understood. Fantasy and imagination are still strong and are reflected in themes of play.

MIDDLE CHILDHOOD: AGES 7–11 YEARS

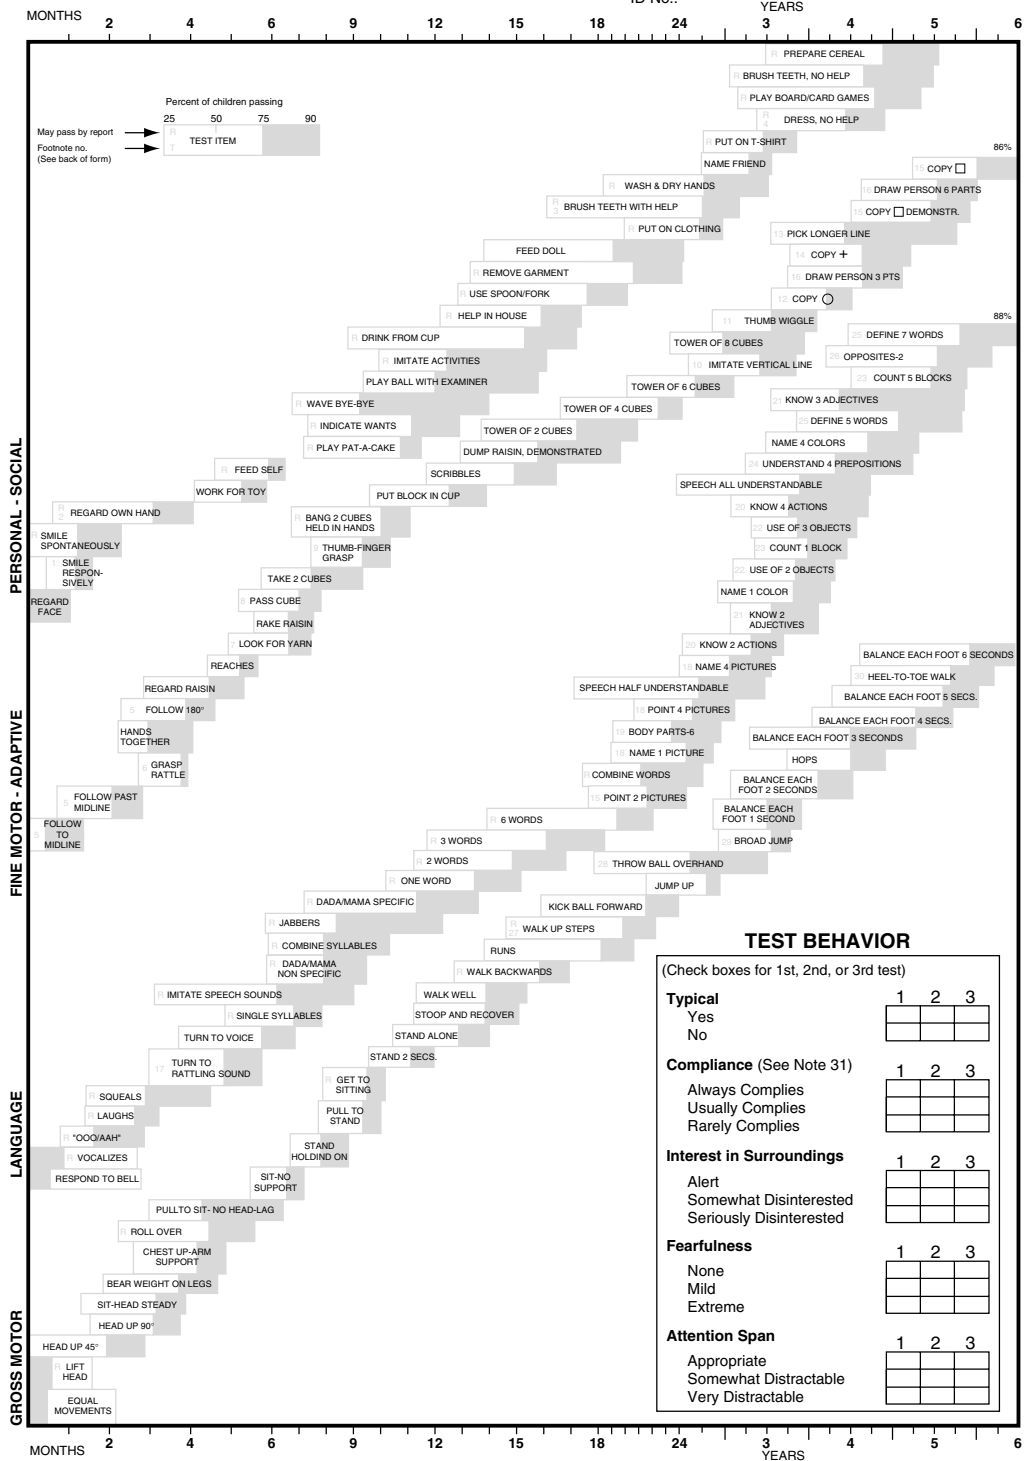

Freud characterized ages 7–11 years as the latency years, during which children are not bothered by significant aggressive or sexual drives but instead devote most of their energies to school and peer group interactions. In reality, throughout this period there is a gradual increase in sex drive, manifested by increasingly aggressive play and interactions with the opposite sex. Fantasy still has an active role in dealing with sexuality before adolescence, and fantasies often focus on movie and music stars. Organized sports, clubs, and other activities are other modalities that permit preadolescent children to display socially acceptable forms of aggression and sexual interest.

For the 7-year-old child, the major developmental tasks are achievement in school and acceptance by peers. Academic expectations intensify and require the child to concentrate on, attend to, and process increasingly complex auditory and visual information. Children with significant learning disabilities or problems of attention span may have difficulty in these tasks and subsequently may receive negative reinforcement from teachers and even parents. Such children may develop a poor self-image manifested as behavioral difficulties. The pediatrician must evaluate potential learning disabilities in any child who is not developing adequately at this stage or who presents with emotional or behav-

ioral problems. The developmental status of school-age children is not documented as easily as that of younger children because of the complexity of the milestones. In the school-age child, the quality of the response, the attentional abilities, and the child's emotional approach to the task can make a dramatic difference in success at school. The clinician must consider all of these aspects in the differential diagnosis of learning disabilities.

the parents' understanding of the child and the child's relationship to the environment. These strategies also facilitate the parents' care of the growing infant and child.

The last section of this chapter discusses developmental disorders of cognitive and social competence. Diagnosis and management of these conditions requires a comprehensive and often multidisciplinary approach. The health care provider can play a major role in diagnosis, in coordinating the child's evaluation, in interpreting the results to the family, and in providing reassurance and support.

II. BEHAVIORAL & DEVELOPMENTAL VARIATIONS

Behavioral and developmental variations and disorders encompass a wide range of issues of importance to pediatricians. Practitioners will be familiar with most of the problems discussed in this chapter; however, with increasing knowledge of the factors controlling normal neurologic and behavioral development in childhood, new perspectives on these disorders and novel approaches to their diagnosis and management are emerging.

Variations in children's behavior reflect a blend of intrinsic biologic characteristics and the environments with which the children interact. The next section focuses on some of the more common complaints about behavior encountered by those who care for children. These behavioral complaints are by and large normal variations in behavior, a reflection of each child's individual biologic and temperament traits and the parents' responses. There are no cures for these behaviors, but management strategies are available that can enhance

NORMALITY & TEMPERAMENT

The physician confronted by a disturbance in physiologic function rarely has doubts about what is abnormal. Variations in temperament and behavior are not as straightforward. Labeling such variations as disorders implies that a disease entity exists.

The behaviors described in this section are viewed as part of a continuum of responses by the child to a variety of internal and external experiences. Variations in temperament have been of interest to philosophers and writers since ancient times. The Greeks believed there were four temperament types: choleric, sanguine, melancholic, and phlegmatic. In more recent times, folk wisdom has defined temperament as a genetically influenced behavioral disposition that is stable over time. Although a number of models of temperament have been proposed, the one usually used by pediatricians in clinical practice is that of Thomas and Chess, who describe temperament as being the "how" of behavior as distinguished from the "why" (motivation) and the "what" (ability). Temperament is an independent psychological attribute that is expressed as a response to an external stimulus. The influence of tem-

perament is bidirectional: The effect of a particular experience will be influenced by the child's temperament, and the child's temperament will influence the responses of others in the child's environment. Temperament is the style with which the child interacts with the environment.

The perceptions and expectations of parents must be considered when a child's behavior is evaluated. A child that one parent might describe as hyperactive might not be characterized as such by the other parent. This truism can be expanded to include all the dimensions of temperament. Thus, the concept of "goodness of fit" comes into play. For example, if the parents want and expect their child to be predictable but that is not the child's behavioral style, the parents may perceive the child as being bad or having a behavioral disorder rather than as having a developmental variation. An appreciation of this phenomenon is important because the physician may be able to enhance the parents' understanding of the child and influence their responses to the child's behavior. When there is goodness of fit, there will be more harmony and a greater potential for healthy development not only of the child but also of the family. When goodness of fit is not present, tension and stress can result in parental anger, disappointment, frustration, and conflict with the child.

Other models of temperament include those of Rothbart, Buss and Plomin, and Goldsmith and Campos (Table 2-4). All models seek to identify intrinsic behavioral characteristics that lead the child to respond to the world in particular ways. One child may be

highly emotional and another less so (ie, calmer) in response to a variety of experiences, stressful or pleasant. The clinician must recognize that each child brings some intrinsic, biologically based traits to its environment and that such characteristics are neither good nor bad, right nor wrong, normal nor abnormal; they are simply part of the child. Thus, as one looks at variations in development, one should abandon the illness model and consider this construct as an aid to understanding the nature of the child's behavior and its influence on the parent-child relationship.

COMMON DEVELOPMENTAL CONCERNS

COLIC

Infant colic is characterized by severe and paroxysmal crying that occurs mainly in the late afternoon. The infant's knees are drawn up and its fists are clenched, flatus is expelled, the facies is "pained," and there is minimal response to attempts at soothing. Studies in the United States have shown that among middle-class infants, crying occupies about 2 hours per day at 2 weeks of age, about 3 hours per day by 6 weeks, and gradually decreases to about 1 hour per day by 3 months. The word "colic" is derived from Greek *kolikos* ("pertaining to the colon"). Although colic has traditionally been attributed to gastrointestinal disturbances, this has never been proved. Colic is a behavioral sign or symptom that begins in the first few weeks of life and peaks at age 2-3 months. In about 30-40% of cases, colic continues into the fourth and fifth months.

A colicky infant, as defined by Wessel, is one who is healthy and well fed but cries for more than 3 hours a day, for more than 3 days a week, and for more than 3 weeks—commonly referred to as the rule of threes. The important word in this definition is "healthy." Thus, before the diagnosis of colic can be made, the pediatrician must rule out diseases that might cause crying. With the exception of the few infants who respond to elimination of cow's milk from its own or the mother's diet, there has been little firm evidence of an association of colic with allergic disorders. Gastroesoph-

Table 2-4. Theories of temperament.

Thomas and Chess	Temperament is an independent psychological attribute, biologically determined, which is expressed as a response to an external stimulus. It is the child's behavioral style: an interactive model.
Rothbart	Temperament is a function of biologically based individual differences in reactivity and self-regulation. It is subsumed under the concept of "personality" and goes beyond mere "behavioral style."
Buss and Plomin	Temperament is a set of genetically determined personality traits that appear early in life and are different from other inherited and acquired personality traits.
Goldsmith and Campos	Temperament is the individual's differences in the probability of experiencing emotions and arousal.

ageal reflux is often suspected as a cause of colicky crying in young infants. Undetected corneal abrasion, urinary tract infection, and unrecognized traumatic injuries including child abuse must be among the physical causes of crying considered in evaluating these infants. Some attempts have been made to eliminate gas with simethicone and to slow gut motility with dicyclomine. Simethicone has not been shown to ameliorate colic. Dicyclomine has been associated with apnea in infants and is contraindicated.

This then leaves characteristics intrinsic to the child (ie, temperament) and parental caretaking patterns as contributing to colic. Behavioral states have three features: (1) they are self-organizing—that is, they are maintained until it is necessary to shift to another one; (2) they are stable over several minutes; and (3) the same stimulus elicits a state-specific response that is different from other states. The behavioral states are (among others) a crying state, a quiet alert state, an active alert state, a transitional state, and a state of deep sleep. The states of importance with respect to colic are the crying state and the transitional state. During transition from one state to another, infant behavior may be more easily influenced. Once an infant is in a stable state (eg, crying), it becomes more difficult to bring about a change (eg, to soothe). How these transitions are accomplished is probably influenced by the infant's temperament and neurologic maturity. Some infants move from one state to another easily and can be diverted easily; other infants sustain a particular state and are resistant to change.

The other component to be considered in evaluating the colicky infant is the feeding and handling behavior of the caregiver. Colic is a behavioral phenomenon that involves interaction between the infant and the caregiver. Different caregivers perceive and respond to crying behavior differently. If the caregiver perceives the crying infant as being spoiled and demanding and is not sensitive to or knowledgeable about the infant's cues and rhythms—or is hurried and “rough” with the baby—the infant's ability to organize and soothe itself or respond to the caregiver's attempts at soothing may be compromised. Alternatively, if the temperament of an infant with colic is understood and the rhythms and cues deciphered, crying can be anticipated and the caregiver can intervene before the behavior becomes “organized” in the crying state and more difficult to extinguish.

Management of Colic

A number of approaches can be taken to the management of colic.

1. Parents may need to be educated about the developmental characteristics of crying behavior and

made aware that crying increases normally into the second month and abates by the third to fourth month.

2. Parents may need reassurance, based on a complete history and physical examination, that the infant is not sick. Although these behaviors are stressful, they are a normal variant and are usually self-limited. This discussion can be facilitated by having the parent keep a diary of crying and weight gain. If there is a diurnal pattern and adequate weight gain, an underlying disease process is less likely to be present. Parental anxiety must be relieved, because it may be contributing to the problem.
3. For parents to effectively soothe and comfort the infant, they need to understand the baby's cues. The pediatrician can help by observing the infant's behavior and devising interventions aimed at calming both the infant and the parents. One can encourage a quiet environment without excessive handling. Rhythmic stimulation such as gentle swinging or rocking, soft music, drives in the car, or walks in the stroller may be helpful, especially if the parents are able to anticipate the onset of crying. Another approach is to change the feeding habits so that the infant is not rushed, has ample opportunity to burp, and, if necessary, can be fed more frequently so as to decrease gastric distention if that seems to be contributing to the problem.
4. Medications such as phenobarbital elixir and dicyclomine have been found to be somewhat helpful, but their use is to be discouraged because of the risk of adverse reactions and overdose. A trial of ranitidine hydrochloride might be of help if gastroesophageal reflux is contributing to the child's discomfort.
5. For colic that is refractory to behavioral management, a trial of changing the feedings, eliminating cow's milk from the formula, or from the mother's diet if she is nursing, may be indicated.

FEEDING DISORDERS IN INFANTS & YOUNG CHILDREN

Children have feeding problems for various reasons. The common denominator, however, is usually food refusal. Infants and young children may refuse to eat if they find eating painful or frightening. They may have had unpleasant experiences (emotional or physiologic) associated with eating, they may be depressed, or they may be engaged in a developmental conflict with the caregiver that is being played out in the arena of feeding. The infant may refuse to eat if the rhythm of the feeding experience with the caregiver is not harmonious. The child who has had an esophageal atresia repair and has a stricture may find eating uncomfortable. The very young infant with severe oral candidiasis may refuse to eat because of pain. The child who has had a choking experience associated with feeding may be terrified to eat (oral motor dysfunction or aspiration). The child who is forced to eat by a maltreating parent or an overzealous caregiver may refuse feeds. Children who have required nasogastric feedings or who have required periods of fasting and intravenous nutrition in the first 1–2 months of life are more likely to display food refusal behavior upon introduction of oral feedings.

Depression in children may be expressed through food refusal. Food refusal may develop when the infant's cues around feeding are not interpreted correctly by the parent. The baby who needs to burp more frequently or who needs time between bites but instead is rushed will often passively refuse to eat. Some will be more active refusers, turning their heads away to avoid the feeder, spitting out food, or pushing away food.

Chatoor and coworkers have proposed a developmental and interactive construct of the feeding experience. The stages through which the child normally progresses are establishment of homeostasis (0–2 months), attachment (2–6 months), and separation and individuation (6 months to 3 years). During the first stage, feeding can be accomplished most easily when the parent allows the infant to determine the timing, amount, pacing, and preference of food intake. During the attachment phase, allowing the infant to control the feeding permits the parent to engage the infant in a positive manner. This paves the way for the separation and individuation phase. When a disturbance occurs in the parent–child relationship at any of these developmental levels, difficulty in feeding may ensue, with both the parent and the child contributing to the dysfunctional

interaction. One of the most striking manifestations of food refusal occurs during the stage of separation and individuation. Conflict may arise if the parent seeks to dominate the child by intrusive and controlling feeding behavior at the same time the child is striving to achieve autonomy. The scenario then observed is of the parent forcing food on the child while the child refuses to eat. This often leads to extreme parental frustration and anger, and the child may be inadequately nourished and developmentally and emotionally thwarted.

When the pediatrician is attempting to sort out the factors contributing to food refusal, it is essential first to obtain a complete history, including a social history. This should include information concerning the parents' perception of the child's behavior and their expectations of the child. Second, a complete physical examination should be performed, with emphasis on oral–motor behavior and other clues suggesting neurologic, anatomic, or physiologic abnormalities that could make feeding difficult. The child's emotional state and developmental level must be determined. This is particularly important if there is concern about depression or a history of developmental delays. If evidence of oral–motor difficulty is suspected, evaluation by an occupational therapist is warranted. Third, the feeding interaction needs to be observed live, if possible. Finally, the physician needs to help the parents understand that infants and children may have different styles of eating and different food preferences and may refuse foods they do not like. This is not necessarily abnormal but reflects temperamental differences and variations in the child's way of processing olfactory, gustatory, and tactile stimuli.

Management of Feeding Disorders

The goal of intervention is to identify factors contributing to the disturbance and to work to overcome them. The parents may be encouraged to view the child's behavior differently and try not to impose their expectations and desires. Alternatively, the child's behavior may need to be modified so that the parents can provide adequate nurturing.

When the chief complaint is failure to gain weight, a different approach is required. The differential diagnosis should include not only food refusal but also medical disorders and maltreatment. The most common reason for failure to gain weight is inadequate caloric intake. Excessive weight loss may be due to vomiting or diarrhea, to malabsorption, or to a combination of these factors. In this situation more extensive diagnostic evaluation may be needed. Laboratory studies may include a complete blood count; erythrocyte sedimentation rate; urinalysis and urine culture; blood urea nitrogen; serum electrolytes and creatinine; and stool

examination for fat, occult blood, and ova and parasites. Some practitioners also include liver and thyroid profiles. Occasionally an assessment of swallowing function or evaluation for the presence of gastroesophageal reflux may be indicated. Because of the complexity of the problem, a team approach to the diagnosis and treatment of failure to thrive, or poor weight gain, may be most appropriate. The team should include a physician, nurse, social worker, and dietitian. Occupational and physical therapists, developmentalists, and psychologists may be required.

The goals of treatment of the child with poor weight gain are to establish a normal pattern of weight gain and to establish better family functioning. Guidelines to accomplishing these goals include the following: (1) establish a comprehensive diagnosis that considers all factors contributing to poor weight gain; (2) monitor the feeding interaction and ensure appropriate weight gain; (3) monitor the developmental progress of the child and the changes in the family dynamics that facilitate optimal weight gain and psychosocial development; and (4) provide support to the family as they seek to help the child.

SLEEP DISORDERS

Sleep is a complex physiologic process influenced by intrinsic biologic properties, temperament, cultural norms and expectations, and environmental conditions. Between 20% and 30% of children experience sleep disturbances at some point in the first 4 years of life. The percentage decreases to 10–12% in school-age children. Sleep disorders fall into two categories. Dysomnias refer to problems with initiating and maintaining sleep or to excessive sleepiness. Parasomnias refer to abnormalities of arousal, partial arousal, and transitions between stages of sleep.

Sleep is controlled by two different biologic clocks. The first is a circadian rhythm—sleep occurs daily. The second is an ultradian rhythm that occurs several times per night—the stages of sleep. Sleep stages cycle every 50 to 60 minutes in infants to every 90 minutes in ado-

lescents. The circadian clock has a 25-hour cycle. Environmental cues entrain the sleep-wake cycle into a 24-hour cycle. The cues are light-dark, ambient temperature, core body temperature, noise, social interaction, hunger, pain, and hormone production. Without the ability to perceive these cues (ie, blindness, autism) a child might have difficulty entraining a 24-hour sleep-wake cycle. Two major sleep stages have been identified clinically and with the use of polysomnography (electroencephalography, electro-oculography, and electromyography): rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. In REM sleep, muscle tone is relaxed, the sleeper may twitch and grimace, and the eyes move erratically beneath closed lids. In adults and children, REM sleep occurs throughout the night but is increased during the latter half of the night. NREM sleep is divided into four stages. In the process of falling asleep, the individual enters stage 1, light sleep, characterized by reduced bodily movements, slow eye rolling, and sometimes opening and closing of the eyelids. Stage 2 sleep is characterized by slowing of eye movements, slowing of respirations and heart rate, and relaxation of the muscles but with repositioning of the body. Some dreaming may occur in this stage. Most mature individuals spend about half of their sleep time in this stage. Stages 3 and 4 (also called delta or slow-wave sleep) are the deepest NREM sleep stages, during which the body is relaxed, breathing is slow and shallow, and the heart rate is slow.

The deepest NREM sleep occurs during the first 1–3 hours after going to sleep. Parasomnias occur during deep NREM sleep. Dreams and nightmares occur during REM sleep.

Sleep is clearly a developmental phenomenon. Infants are not born with a sleep-wake cycle. REM sleep is more common than NREM sleep in newborns and decreases by 3 to 6 months of age. Sleep spindles and vertex waves are usually not seen until 9 weeks of age. By 3 to 6 months, stage 1 through 4 NREM sleep can be seen. By 6 to 12 months an infant's electroencephalogram (EEG) can be read using adult criteria. Infants also do not make melatonin until 9 to 12 weeks of age. Melatonin is a hormone that decreases core body temperature and that appears to play a role in sleep onset and sleep maintenance. This hormone is sensitive to light, does cross the placenta, and is present in breast milk.

1. Parasomnias

Parasomnias, consisting of arousal from deep NREM sleep, are probably the most frightening for parents. They include night terrors, sleepwalking, and sleepwalking (somnambulism) (see Chapter 22).

Night Terrors & Sleepwalking

Night terrors commonly occur within 2 hours after falling asleep, during the deepest stage of NREM sleep, and are often associated with sleepwalking. They occur in about 3% of children. During a night terror, the child may sit up in bed screaming, thrashing about, and exhibiting rapid breathing, tachycardia, and sweating. The child is often incoherent and unresponsive to comforting. The episode may last up to half an hour, after which the child goes back to sleep and has no memory of the event the next day. The parents must be reassured that the child is not in pain and that they should let the episode run its course.

Management of night terrors is by reassurance of the parents plus measures to avoid emotional and psychosocial stressors that might be contributing to the problem. Because sleepwalking can result in injury, the parents should determine, if possible, when the attacks usually occur and awaken the child to full arousal about 15 minutes before that time. After 4–5 minutes, the child may be allowed to return to sleep. The waking is discontinued once the terrors stop, which is usually within a week. In severe cases, pharmacologic interventions may be needed temporarily. Imipramine (25–50 mg at bedtime) may be useful. However, behavioral approaches to increase the total amount of sleep and to address the sources of anxiety and stress are of more long-term benefit.

Nightmares

Nightmares are frightening dreams during REM sleep, typically followed by awakening, which usually occur in the latter part of the night. The peak occurrence is between ages 3 and 5 years, with an incidence between 25% and 50%. A child who awakens during these episodes is usually alert. He or she can often describe the frightening images, recall the dream, and talk about it during the day. The child seeks and will respond positively to parental reassurance. The child will often have difficulty going back to sleep and will want to stay with the parents. Nightmares are usually self-limited and need little treatment. If the child has recurrent nightmares, the pediatrician may have to make a more extensive investigation. Nightmares are often associated with stressful or frightening daytime events or anxieties such as frightening television programs, traumatic life events, and chronic stresses in the family. In severe cases, a psychologist or psychiatrist should be consulted.

2. Dyssomnias

The dyssomnias include problems going to sleep and nighttime awakenings. Although parasomnias are

frightening, dyssomnias tend to be only annoying and frustrating. They can result in daytime fatigue for both the parents and the child, parental discord about management, and family disruption. A number of factors contribute to these disturbances. The quantity and timing of feeds in the first years of life will influence nighttime awakening. Most infants beyond age 6 months can go through the night without being fed. Thus, under normal circumstances, night waking for feeds is probably a learned behavior and is a function of the child's arousal and the parents' response to that arousal. Cosleeping (ie, sleeping with the parents) can play a role in night waking. In many cultures, cosleeping is accepted behavior. It is inappropriate behavior when it intrudes on the parents' rest and their sexual relationship. Bedtime habits can influence settling in for the night as well as nighttime awakening. If the child learns that going to sleep is associated with pleasant parental behavior such as rocking, singing, reading, or nursing, going back to sleep after nighttime arousal without these pleasant parental attentions may be difficult. The child's temperament is another factor contributing to sleep. It has been reported that children with low sensory thresholds and less rhythmicity are more prone to night waking. Children who have had perinatal difficulties such as intracranial hemorrhage and hyaline membrane disease have a greater incidence of night waking and difficulties returning to sleep. Finally, psychosocial stressors can play a role in night waking.

Management of Sleep Disorders

A complete medical and psychosocial history should be obtained and a physical examination performed. A detailed sleep history and diary should be maintained to which both parents contribute. Some clinicians use polysomnography to complete the evaluation. Problems often arise when parents try to put the child to bed before he or she is biologically ready. The child might then lie awake and cry. In managing sleep difficulties, the child's individual sleep behavior characteristics must be taken into account and the parents' expectations and fears identified and addressed. Counseling is then provided on the following basis:

1. Sleep is a highly active and organized process that matures during the first years of life. One-week-old infants sleep about 16 hours a day, 6 of those hours during the daylight hours. A 2-year-old child sleeps a total of 13 hours a day, only 1 hour during the day.
2. Individual circadian rhythms do not change immediately; they require consistency and regularity over a period of time before change will occur.

3. The duration of sleep for a given individual does not vary significantly from day to day, but there is a wide range of normal.
4. The duration of nighttime sleep is correlated inversely with daytime sleep, and bedtimes and awakening times are correlated positively with each other.
5. Night waking occurs in 40–60% of infants and young children. If the child does not cry or wake up the parents, such behavior should not be considered a sleep disturbance.

Parents need to set limits for the child while acknowledging the child's individual biologic rhythms. They should resist the child's attempts to put off bedtime or to engage them during nighttime awakenings. Putting a child to bed after prolonged rocking, feeding, or when the child has already fallen asleep frequently results in disturbances of settling down at night or going back to sleep after a nighttime awakening. The goal is to establish clear bedtime rituals, to put the child to bed while still awake, and to create a quiet, secure bedtime environment.

For the child who has a delayed sleep phase—that is, difficulty in falling asleep and waking at desired times but no difficulty at a later hour—a regular schedule and consistent, nonstimulating bedtime rituals must be provided. Approaches used to alter the child's behavior include having the parents withdraw the attention elicited by the wakeful child and having them offer positive reinforcement of the desired behavior. Another strategy to alter this sleep pattern is to gradually move the bedtime to an earlier hour and awaken the child earlier in the morning. However, there is nothing intrinsically normal or abnormal in the delayed sleep phase. It becomes a problem only when it differs from parental expectations.

Some children are afraid to go to sleep. The parents need to help the child identify what is frightening about going to sleep and may need to stay near the child, reassuring the child that he or she is safe. Over a period of time, the child can be reassured and the parents may not need to be so involved. This also applies to nighttime awakenings.

The key to treatment of children who have difficulty going to sleep or who awaken during the night and disturb others is to recognize that both the child and the parents play significant roles in initiating and sustaining what may be an undesirable behavior. Thus, it becomes important for the physician and parents to understand normal sleep patterns, the parents' responses that inadvertently reinforce undesirable sleep behavior, and the child's individual temperament traits.

TEMPER TANTRUMS & BREATH-HOLDING SPELLS

1. Temper Tantrums

Temper tantrums are common between ages 12 months and 4 years, occurring about once a week in 50–80% of children in this age group. The child may throw himself or herself down, kick and scream, strike out at people or objects in the room, and hold his or her breath. These behaviors may be considered normal as the young child seeks to achieve autonomy and mastery over the environment. They are often a reflection of immaturity as the child strives to accomplish age-appropriate developmental tasks and meets with difficulty because of inadequate motor and language skills, impulsiveness, or parental restrictions. In the home, these behaviors may be annoying. In public, they are embarrassing.

Some children tolerate frustration well, are able to persevere at tasks, and cope easily with difficulties; others have a much greater problem dealing with experiences beyond their developmental level. Parents can minimize tantrums by understanding the child's temperament and what he or she is trying to communicate. Parents must also be committed to supporting the child's drive to master his or her feelings.

Management of Temper Tantrums

Appropriate intervention can provide an opportunity for enhancing the child's growth. The tantrum is a loss of control on the child's part that may be a frightening event and a blow to the child's self-image. The parents and the physician need to view these behaviors within

the child's developmental context rather than from a negative, adversarial, angry perspective.

Several suggestions can be offered for parents and physicians in managing tantrums:

1. Minimize the need to say "no" by "child-proofing" the environment so that fewer restrictions need be enforced.
2. Use distraction when frustration increases; direct the child to other, less frustrating activities; and reward the positive response.
3. Present options within the child's capabilities so that he or she can achieve mastery and autonomy.
4. Fight only those battles that need to be won, and avoid those that arouse unnecessary conflict.
5. Do not abandon the preschool child when a tantrum occurs. Stay nearby during the episode without intruding. A small child may need to be restrained. An older child can be asked to go to his or her room. Threats serve no purpose and should not be used.
6. Do not use negative terms when the tantrum is occurring. Instead, point out that the child is out of control and give praise when he or she regains control.
7. Never let a child hurt himself or herself, or others.
8. Do not "hold a grudge" after the tantrum is over, but do not grant the child's demands that led to the tantrum.
9. Seek to maintain an environment that provides positive reinforcement for desired behavior. Do not overreact to undesired behavior, but set reasonable limits and provide responsible direction for the child.
10. Approximately 5–20% of young children have severe temper tantrums that are frequent and disruptive. Such tantrums may result from a disturbance in the parent–child interaction, poor parenting skills, lack of limit-setting, and permissiveness. They may be part of a larger behavioral or developmental disorder or may emerge under adverse socioeconomic conditions, in circumstances of maternal depression and family dysfunction, or when the child is in poor health. Referral to a psychologist or psychiatrist is appropriate while the pediatrician continues to support and work with the family.

2. Breath-Holding Spells

Whereas temper tantrums can be frustrating to parents, breath-holding spells can be terrifying. The name for this behavior may be a misnomer in that it connotes

prolonged inspiration. In fact, breath-holding occurs during expiration and is reflexive—not volitional—in nature. It is a paroxysmal event occurring in 0.1–5% of healthy children from age 6 months to 6 years. The spells usually start during the first year of life, often in response to anger or a mild injury. The child is provoked or surprised, starts to cry—briefly or for a considerable time—and then falls silent in the expiratory phase of respiration. This is followed by a color change. Spells have been described as either pallid (acyanotic) or cyanotic, with the latter usually associated with anger and the former with an injury such as a fall. The spell may resolve spontaneously, or the child may lose consciousness. In severe cases, the child may become limp and progress to opisthotonos, body jerks, and urinary incontinence. Only rarely does a spell proceed to asystole or a seizure.

Management of Breath-Holding Spells

For the child with frequent spells, underlying disorders such as seizures, orthostatic hypotension, obstructive sleep apnea, abnormalities of the CNS, tumors, familial dysautonomia, and Rett syndrome need to be considered. An association exists among breath-holding spells, pica, and iron deficiency anemia. These conditions can be ruled out on the basis of the history, physical examination, and laboratory studies. Once it has been determined that the child is healthy, the focus of treatment is behavioral. Parents should be taught to handle the spells in a matter-of-fact manner and monitor the child for any untoward events. The reality is that parents cannot completely protect the child from upsetting and frustrating experiences and probably should not try to do so. Just as in temper tantrums, parents need to help the child control his or her responses to frustration. Parents need to be careful not to be too permissive and submit to the child's every whim for fear the child might have a spell. If loss of consciousness occurs, the child should be placed on his or her side to protect against head injury and aspiration. Maintaining a patent oral airway is essential, but cardiopulmonary resuscitation should be avoided. There are no prophylactic medications. Atropine, 0.01 mg/kg given subcutaneously, has been used with some benefit in spells accompanied by bradycardia or asystole.

III. DEVELOPMENTAL DISORDERS

Developmental disorders include problems with one or more aspects of development, such as verbal, motor, visual-spatial, attentional, and social abilities. These problems are diagnosed by comparing the child's performance level with norms accumulated from observation and testing of children of the same age. Problems with development are often noted by parents when a child does not meet normal motor and language milestones. Developmental disorders may also include difficulties with behavior or attention. Attention-deficit/hyperactivity disorder (ADHD) is the most common neurodevelopmental problem known. ADHD occurs in 2–10% of school-age children and may occur in combination with a variety of other learning or developmental problems. Mild developmental disorders are often not noted until the child is of school age.

Many biologic and psychosocial factors may influence a child's performance on developmental tests. In the assessment of the child, it is important to document adverse psychosocial factors, such as neglect or poverty, which can negatively influence developmental progress. Many of the biologic factors that influence development are genetic and are discussed throughout this section.

Evaluation

The neurodevelopmental evaluation must focus on (1) defining the child's level of developmental abilities in a variety of domains, including language, motor, visual-spatial, attentional, and social abilities; (2) characterizing the reason for the child's developmental delays; and (3) planning a treatment program for the developmental problems. These objectives are best achieved by a multidisciplinary team that includes the physician, a psychologist, a speech or language therapist, an occupational therapist, and an educational specialist. The psychologist will usually carry out standardized testing of intellectual ability appropriate to the child's age. The motor and language specialists will also carry out clinical testing to document the deficits in their areas and to organize a treatment program. The educational specialist will usually carry out academic testing for the school-age child and plan a course of special education support through the school. The physician is usually the integrator of the information from the team and

must also obtain a detailed medical and developmental history and conduct the physical and neurologic exam.

Medical and Neurodevelopmental Examination

The medical history should begin with pregnancy, labor, and delivery to identify conditions that might compromise the child's CNS. The physician must ask the child's parents about exposures to toxins, alcohol, drugs, smoking, and infections; maternal chronic illness; prematurity; subsequent newborn course; and complications (eg, intraventricular hemorrhage or hypoxic insult). Problems such as failure to thrive, chronic illnesses, hospitalizations, and abuse can interfere significantly with normal development. If the newborn course has been complicated, then information should be obtained from the hospital where treatment was provided. The occurrence of problems such as apnea, bradycardic episodes, and hyperbilirubinemia should be documented.

The physician should review and document the child's temperament, difficulties with feeding, and subsequent developmental milestones. The child's development in expressive and receptive language skills, motor coordination, and emotions should be discussed in detail. The child's difficulties with tantrums, attentional problems, impulsivity, hyperactivity, or aggression should be documented.

Major illnesses or hospitalizations should be discussed. Any CNS problems, such as trauma, infection, or encephalitis should be documented. The presence of metabolic diseases, such as diabetes or phenylketonuria, and exposure to environmental toxins such as lead should be determined. Chronic diseases such as chronic otitis media infections, hyper- or hypothyroidism, and chronic renal failure can interfere with normal development. The presence of motor or vocal tics, seizures, or sleep disturbances should be documented. In addition, parents should be questioned about any motor, cognitive, or behavioral regression.

A detailed history of school-related events should be recorded, including previous special education support, evaluations through the school, history of repeating grades, difficulties with specific academic areas, problems with peers, and the teacher's impressions of the child's difficulties, particularly related to attentional problems, impulsivity, or hyperactivity.

Perhaps the most important aspect of the medical history is a detailed family history of learning strengths and weaknesses, emotional or behavioral problems, learning disabilities, or mental retardation. The presence of more severe psychopathology, such as schizophrenia, bipolar disorder, depression, anxiety, or ADHD, should be noted for all family members.

Parental learning strengths and weaknesses, temperament difficulties, or attentional problems may be passed on to the child. For instance, dyslexia (deficits in decoding skills resulting in reading difficulties) may be genetic. Autosomal dominant genes on chromosomes 6 and 15 have been associated with dyslexia.

The neurodevelopmental examination should include a careful assessment of dysmorphic features such as epicanthal folds, palpebral fissure size, shape of the philtrum, low set or posteriorly rotated ears, prominent ear pinnae, unusual dermatoglyphics (eg, a single palmar crease), hyperextensibility of the joints, syndactyly, clinodactyly, or other unusual features. A detailed physical and neurologic examination needs to be carried out with an emphasis on both soft and hard neurologic findings. Soft signs can include motor incoordination, which can relate to handwriting problems and academic delays in written language or drawing. Visual motor coordination abilities can be assessed by having the child write, copy designs, or draw a person.

The child's growth parameters, including height, weight, and head circumference, need to be assessed, along with hearing and visual acuity. Cranial nerve abnormalities and oral motor coordination problems need to be noted. The examiner should watch closely for motor or vocal tics, which are quite common in individuals with Tourette syndrome. Both fine and gross motor abilities should be assessed. Dyspraxic movements in fine motor coordination are fairly common. Tandem walking, one-foot balancing, and coordinating a skip may often show surprising abnormalities.

The developmental aspects of the examination can include an assessment of auditory processing and perceptual ability with simple tasks, such as twofold to fivefold directions, assessing right and left directionality, memory for a series of spoken words or digit span, and comprehension of a graded paragraph. In assessing expressive language abilities, the examiner should look for difficulties with word retrieval, formulation and articulation, and adequacy of vocabulary. Visual-perceptual abilities can be assessed by simple visual memory tasks, puzzles, or object assembly, evaluating the child's ability to decode words or organize math problems. Visual motor integration and coordination can be assessed again with handwriting, design copying, and drawing a person. Throughout the assessment the clinician should pay special attention to the child's ability to focus attention and concentrate, and to other aspects of behavior such as evidence of depression or anxiety.

Additional questionnaires and checklists—such as the Child Behavior Checklist by Achenbach; ADHD scales such as the Conners' (or Parent/Teacher) Rating Scale; and the SNAP-IV, which includes the *Diagnostic and Statistical Manual* (DSM-IV) criteria for ADHD—can be used to help with this assessment.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

ADHD is a common neurodevelopmental disorder that may affect 2–10% of school-age children and may persist into adolescence and adulthood. It is associated with a triad of symptoms: impulsivity, inattention, and hyperactivity. DSM-IV has described two ADHD subtypes: impulsive and inattentive. To be classified according to either subtype, the child must exhibit six or more of the symptoms listed in Table 2–5. The majority of children with ADHD have a combined type with symptoms of inattention as well as hyperactivity and impulsivity. Although symptoms begin in early childhood, they can diminish between ages 10 and 25 years. Hyperactivity declines more quickly, and impulsivity and inattentiveness often persist in adolescence and adulthood. ADHD may be combined with other psychiatric condi-

Table 2–5. Attention deficit/hyperactivity disorder subtypes.

Subtype	Symptoms ^a
Impulsivity-hyperactivity	Fidgetiness Difficulty remaining seated in the class Excessive running or climbing Difficulty in engaging quiet activities Excessive talking and blurting out answers before questions have been completed Difficulty awaiting turns Interrupting and intruding on others
Inattentive	Failure to give close attention to detail Difficulty sustaining intention in task Failure to listen when spoken to directly Failure to follow instructions Difficulty organizing tasks and activities Reluctance to engage in tasks Losing utensils necessary for tasks or activities Easy distractibility Forgetfulness in daily activities

^aThe child must exhibit six or more of these symptoms. Adapted, with permission, from American Psychiatric Association, 1994.

tions, such as mood disorder in approximately 20% of patients, conduct disorders in 20%, and oppositionally defiant disorder in up to 40%. Approximately 25% of children with ADHD seen in a referral clinic have tics or Tourette syndrome. Conversely, well over 50% of individuals with Tourette syndrome also have ADHD.

ADHD has a substantial genetic component, with a heritability of 0.75 to 0.91. Several candidate genes have been identified, although there is strong evidence that ADHD is a disorder involving multiple genes. ADHD is also associated with a variety of genetic disorders related to developmental disorders, including fragile X syndrome, Williams syndrome, Angelman syndrome, XXY syndrome (Klinefelter syndrome), and Turner syndrome. Fetal alcohol syndrome (FAS) is also strongly associated with ADHD. CNS trauma, CNS infections, prematurity, and a difficult neonatal course with brain injury can also be associated with later ADHD. Metabolic problems such as hyperthyroidism can sometimes cause ADHD. These organic causes of ADHD should be considered in the evaluation of any child presenting with attentional problems, hyperactivity, or impulsivity. However, in the majority of children who have ADHD the cause remains unknown.

Treatment

The treatment of ADHD varies depending on the complexity of the individual case. It is important to educate the family regarding the symptoms of ADHD and to clarify that this is a neurologic disorder that at times is difficult for the child to control. Behavior modification techniques usually help these children and should include structure with consistency in daily routine, positive reinforcement whenever possible, and time out for negative behaviors. It is important to try to boost the child's self-esteem because psychological complications are common in this disorder.

A variety of educational interventions can be helpful, including preferential seating in the classroom, a system of consistent positive behavior reinforcement, consistent structure, the repetition of information when needed, and the use of instruction that incorporates both visual and auditory modalities. Many children with ADHD have significant social difficulties, and social skills training can be helpful. Individual counseling is beneficial in alleviating poor self-esteem, oppositional behavior, and conduct problems.

The use of medication, specifically stimulant medication such as methylphenidate (Ritalin) and dextroamphetamine, can be helpful. A new medication, atomoxetine a noncontrolled substance, has been found to be effective in some children with ADHD. Pemoline is no longer recommended because of its association with liver injury.

It is most important that, no matter what medication is used, the diagnosis is correct and the correct dosage is prescribed. A recent study has demonstrated that one of the major factors contributing to treatment failure is inadequate dosing or the failure to recognize the presence of comorbid conditions such as learning disability, anxiety disorders, and depression.

In children with normal intellectual abilities, 70–90% respond well to stimulant medications. Stimulants enhance both dopamine and norepinephrine neurotransmission, which seems to improve impulse control, attention, and hyperactivity. Metabolic studies of the CNS (eg, using positron emission tomography scanning) have demonstrated enhanced metabolism in several areas of the brain, including the caudate and the frontal regions.

The side effects of methylphenidate and dextroamphetamine include appetite suppression and resulting weight loss as well as sleep disturbances. Some individuals experience increased anxiety, particularly with higher doses of stimulant medications. Stimulants may exacerbate psychotic symptoms. They may also exacerbate motor tics in 30% of patients, but in 10% motor tics may be improved. Long-acting and short-acting forms of stimulant medication are available. The initial dose of methylphenidate is 0.3 mg/kg/dose given two or three times daily. Adderall is a relatively new stimulant that combines four dextro and levo amphetamine salts. This is a long-acting medication, and often a single morning dose suffices for the day.

Alternative medications for the treatment of ADHD include clonidine or guanfacine, which are α_2 -adrenergic presynaptic agonists that decrease norepinephrine levels. They are particularly helpful for individuals who are hyperreactive to stimuli and may be helpful in decreasing motor tics in patients who have Tourette syndrome. Tricyclic antidepressant medications such as imipramine may also be an effective treatment for ADHD, but the cardiovascular side effects at high dosage can include severe arrhythmias. Bupropion is an antidepressant medication that can also be effective for treatment of ADHD symptoms. Its use is contraindicated in patients with a history of seizures, because it will lower the seizure threshold. It has also been known to cause seizures in individuals who have anorexia or bulimia. It is used more commonly in adolescents and adults with ADHD than in children with the disorder.

MENTAL RETARDATION

Severe deficits in the development of language, motor skills, attention, abstract reasoning, visual-spatial skills, and academic or vocational achievement are associated with mental retardation. Deficits on standardized testing in cognitive and adaptive functioning greater than 2 standard deviations below the mean for the population are considered to fall in the range of mental retardation (Table 2-6). The most common way of reporting the results of these tests is by using an intelligence quotient (IQ). The IQ is a statistically derived number reflecting the ratio of age-appropriate cognitive function and the child's level of cognitive function. A number of accepted standardized measurement tools, such as the Wechsler Intelligence Scale for Children, 3rd edition (WISC-III), can be used to assess these capacities. To receive a diagnosis of mental retardation a child must not only have an IQ of less than 70, but also must demonstrate adaptive skills more than 2 standard deviations below the mean. Adaptive function refers to the child's ability to function in his or her environment and can be measured by a parent or teacher interview-recorded using an instrument such as the Vineland Adaptive Behavior Scales.

The prevalence of mental retardation is approximately 3% in the general population, although some

states have reported a prevalence of less than 2%. Mild levels of mental retardation are more common and more likely to have a sociocultural cause than are more severe levels. Poverty, deprivation, or a lack of exposure to a stimulating environment can contribute to developmental delays and poor performance on standardized tests. In addition, physical problems such as hearing loss, blindness, and brain trauma can lead to developmental delays and low IQ test scores. Great strides in our identification of genetic causes of mental retardation have been made since the 1990s because of the Human Genome Project. Over 750 genetic disorders have been associated with mental retardation, and over 200 of those disorders are carried on the X chromosome alone. In approximately 60% of cases, the cause of the mental retardation can be identified. Table 2-7 summarizes the findings of several studies on the causes of mental retardation.

Evaluation

Children who present with developmental delays should be evaluated by a team of professionals as described at the beginning of this section. For children 0-3½ years of age, the Bayley Scales of Infant Development, second edition, is a well-standardized developmental test. For children older than 3 years of age standardized cognitive testing, such as the Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R), the WISC-III, the Stanford-Binet IV, or the Kaufman Assessment Battery for Children (K-ABC) should be administered to assess cognitive function over a broad range of abilities, including verbal and

Table 2-6. Categories of mental retardation.

Mental Retardation Range	Intelligence Quotient (IQ)
Mild mental retardation	50-69
Moderate mental retardation	35-49
Severe mental retardation	20-34
Profound mental retardation	< 20

Table 2-7. Causes of mental retardation.

Cause	Percentage of Cases
Chromosomal abnormalities	4-28
Fragile X syndrome	2-5
Monogenetic conditions	4-14
Structural CNS abnormalities	7-17
Complications of prematurity	2-10
Environmental or teratogenic causes	5-13
"Cultural-familial" mental retardation	3-12
Metabolic or endocrine causes	1-5
Unknown	30-50

nonverbal scales. For the nonverbal patient, a scale such as the Leiter-R will assess skills that do not involve language.

A full psychological evaluation in school-age children should include an emotional assessment if psychiatric or emotional problems are suspected. Such problems are common in children with developmental delays or mental retardation. A hearing test and a vision screening or ophthalmologic evaluation are important to determine whether hearing and vision are normal.

Diagnostic testing should be carried out in an effort to find the cause of mental retardation. Because chromosomal abnormalities occur in 4–28% of patients with mental retardation, cytogenetic testing is important in cases without a known cause. A consensus panel has recommended a high-resolution karyotype so that small deletions or duplications can be visualized. In addition, fluorescent in situ hybridization (FISH) studies are available. These studies use a fluorescent DNA probe that hybridizes to a region of DNA where a deletion or duplication is suspected. Microdeletion syndromes—such as Prader–Willi syndrome or Angelman syndrome, caused by a deletion at 15q; velocardiofacial syndrome, caused by a deletion at 22q; Smith–Magenis syndrome, caused by a deletion at 17p; and Williams syndrome, caused by a 7p deletion—can be assessed with FISH studies. Sometimes the deletion is so small that it may not be visualized through the microscope even with high-resolution cytogenetic studies. If clinical features consistent with any of the microdeletion syndromes are present, then FISH studies should be ordered to look for a small deletion in a specific region. In addition, duplications may be present. For example, a duplication at 15q has been associated with pervasive developmental disorder or autistic spectrum disorders and with general mental retardation. This duplication can be identified by FISH testing.

Structural abnormalities of the brain can occur in many individuals with mental retardation. Magnetic resonance imaging (MRI) is superior to computed tomography (CT) in identifying structural and myelination abnormalities. CT is the study of choice in evaluation of intracranial calcifications, such as those seen in congenital infections or tuberous sclerosis. The value of CT and MRI studies in a child with a normal-sized head and no focal neurologic signs is unclear, and they are not routinely carried out. Neuroimaging is important in patients with microcephaly, macrocephaly, seizures, loss of psychomotor skills, or specific neurologic signs such as spasticity, dystonia, ataxia, or abnormal reflexes. Neuroimaging is not routinely carried out in known genetic disorders such as Down syndrome, fragile X syndrome, or microdeletion syndromes because the CNS abnormalities have been well described

and documentation of the abnormalities usually does not add to management.

Metabolic screening has a relatively low yield (0–5%) in children who present with developmental delay or mental retardation. Many patients with metabolic disorders such as hypothyroidism, phenylketonuria, and galactosemia are identified through newborn screening. Most patients with metabolic problems will present with specific indications for more focused testing, such as failure to thrive, recurrent unexplained illnesses, plateauing or loss of developmental skills, coarse facial features, cataracts, recurrent coma, abnormal sexual differentiation, arachnodactyly, hepatosplenomegaly, deafness, structural hair abnormalities, muscle tone changes, and skin abnormalities. Thyroid function studies should be carried out in any patient who has a palpably abnormal thyroid or exhibits clinical features associated with hypothyroidism. Serum amino acids, urine organic acid, and mucopolysaccharide screens should be considered in children with developmental delays and a suggestive history. Preliminary laboratory findings such as lactic acidosis, hyperuricemia, hyperammonemia, or a low or high cholesterol level require additional metabolic work-up.

Serial follow-up of patients is important because the physical and behavioral phenotype changes over time and diagnostic testing improves with time. Although cytogenetic testing may have been negative 10 years earlier, advances in high-resolution techniques, FISH testing, and fragile X DNA testing may now reveal an abnormality that was not identified previously. A stepwise approach to diagnostic testing may also be more cost-effective, so that the test most likely to be positive is done first.

Treatment

Once a diagnosis of mental retardation is made, treatment should include a combination of individual therapies, such as speech and language therapy, occupational therapy or physical therapy, special education support, behavioral therapy or counseling, and medical intervention, which may include psychopharmacology. To illustrate how these interventions work together, three disorders are described in detail in the next section.

<http://www/TheArc.org>

SPECIFIC FORMS OF MENTAL RETARDATION & ASSOCIATED TREATMENT ISSUES

1. Fragile X Syndrome

The most common inherited cause of mental retardation is fragile X syndrome, which is caused by a trinucleotide expansion (CGG repeated sequence) within the fragile X mental retardation I (*FMR1*) gene. Individuals with mental retardation of unknown origin should receive *FMR1* DNA testing to see if they have an expansion of the CGG repeat causing dysfunction of this gene. The CGG sequence at *FMR1* in the normal population includes 5–50 repeats. Carriers of the premutation have 54–200 repeats, and have been considered unaffected. However, there is mounting evidence for a specific phenotype in these individuals. Women with the premutation have a higher incidence of premature ovarian failure, anxiety, and mild facial dysmorphism. Individuals with the premutation have normal levels of FMR1 protein but increased levels of mRNA. It should be noted that seemingly unaffected females can pass an expansion of the CGG repeat to the next generation. Approximately 1 in 250 women and 1 in 700 men in the general population are premutation carriers. When a premutation of more than 90 repeats is passed on by a female to her offspring, it will expand to a full mutation (more than 200 repeats) 100% of the time, which usually causes mental retardation or learning disabilities. The full mutation is associated with methylation of the gene, which turns off transcription, resulting in a deficiency in the FMR1 protein product. These deficiencies result in mental retardation or significant learning and emotional problems.

Fragile X syndrome includes a broad range of symptoms. Patients can present with shyness, social anxiety, and learning problems, or they can present with mental retardation. Girls are usually less affected by the syndrome because they have a second X chromosome that is producing FMR1 protein. Approximately 70% of girls with the full mutation have cognitive deficits in addition to emotional problems, such as mood lability, ADHD, anxiety, and shyness. Approximately 85% of males with the syndrome have mental retardation and autistic-like features, such as poor eye contact, hand flapping, hand biting, and tactile defensiveness. About 20% of fragile X males meet the criteria for autism.

Children with fragile X syndrome usually present with language delays, hyperactivity, and tantrum behavior in early childhood. Although prominent ears and hyperextensible finger joints are common, approximately 30% of children with the syndrome may not have these features, and the diagnosis must be suspected because of behavioral problems and developmental de-

lays alone. As the boys move into puberty, macroorchidism develops with an average adult volume of 50 mL, or twice the normal volume. The child's face may become longer during puberty, and the majority of these children continue to have prominent ears.

Treatment

All young children with fragile X syndrome benefit from language and motor therapy because delays in these areas are universal. Because approximately 10% of boys with the syndrome will be nonverbal at age 5 years, the use of augmentative communication techniques—such as signing; the use of pictures to represent food, toys, or activities; or the use of computers that can be programmed for communication—are helpful. Tantrums and hyperarousal to stimuli, along with hyperactivity, are common. Sensory integrative occupational therapy can be helpful in calming hyperarousal to stimuli and in improving the child's fine and gross motor coordination and motor planning. Speech and language therapy can decrease oral hypersensitivity, improve articulation, enhance verbal output and comprehension, and stimulate abstract reasoning skills.

If the behavioral problems are severe, it can be helpful to involve a behavioral psychologist who emphasizes positive reinforcement, time outs, consistency in routine, and the use of both auditory and visual modalities, such as a picture sequence, to help with difficult transition times and new situations.

Psychopharmacology can also be useful to treat ADHD, aggression, anxiety, or severe mood instability. Clonidine or guanfacine may be helpful in low doses, beginning in the preschool period to treat hyperarousal, tantrums, or severe hyperactivity. Stimulant medications such as methylphenidate, dextroamphetamine, and Adderall are usually beneficial by age 5 years and occasionally earlier. Relatively low doses are used (eg, 0.2–0.3 mg/kg/dose of methylphenidate) because irritability is often a problem with higher doses.

Shyness and social anxiety combined with mild ADHD are commonly seen in girls who have fragile X syndrome. The social anxiety is sometimes so severe that selective mutism (refusal to speak in some environments, especially school) is seen in girls who have the full mutation. The treatment for selective mutism includes fluoxetine, language therapy, and counseling.

Anxiety may also be a significant problem for boys with fragile X syndrome, and the use of a selective serotonin reuptake inhibitor (SSRI) such as fluoxetine, sertraline, fluvoxamine, or paroxetine is often helpful. SSRIs may also decrease aggression or moodiness, although in approximately 25% of cases, an increase in agitation or even hypomania may occur. The use of a more limited serotonin agent, buspirone, may also be

helpful for anxiety, particularly if the patient cannot tolerate SSRIs.

Anticonvulsants such as carbamazepine, valproic acid, and gabapentin can be used to treat seizures, which occur in 20% of children with fragile X syndrome. They can also be helpful in treating more severe mood instability that does not improve with an SSRI, clonidine, or a stimulant medication. The use of carbamazepine and valproic acid requires careful monitoring of blood levels, liver function studies, electrolytes, blood count, and platelet level.

Aggression may become a significant problem in childhood or adolescence for boys with fragile X syndrome. Counseling can often be helpful, although medication may be needed. Stimulants, clonidine, and an SSRI may decrease aggression, although sometimes an atypical antipsychotic may be needed. If psychotic features are present, such as paranoia, delusions, or hallucinations, or if thinking is severely disorganized, then an atypical antipsychotic is usually helpful. Risperidone has been used most frequently in pediatrics and has a low risk for extrapyramidal symptoms. Side effects include sedation, excessive appetite and subsequent weight gain, and an increase in prolactin, which can cause breast tenderness and gynecomastia in boys. Usually a low dose of risperidone is well tolerated, and 0.5–2 mg at bedtime usually improves aggression, decreases hyperactivity, and stabilizes mood.

An important component of treatment is genetic counseling. Parents should meet with a genetic counselor after the diagnosis of fragile X syndrome is made because there is a high risk that other family members are carriers or may be affected by the syndrome. A detailed family history is essential, and all siblings of the proband should have *FMRI* DNA testing. If the mother received the gene from her father, then all of her sisters are obligate carriers, and their children are at 50% risk of having the fragile X mutation.

It is also helpful to link up a newly diagnosed family to a parent support group. Educational materials and parent support information may be obtained by calling The National Fragile X Foundation at 1-800-688-8765.

2. Fetal Alcohol Syndrome

Significant alcohol exposure in utero is associated with a broad spectrum of developmental problems, ranging

from learning disabilities to severe mental retardation. The Institute of Medicine has carefully defined diagnostic categories in patients with documented prenatal maternal alcohol consumption as follows:

A. FETAL ALCOHOL SYNDROME

The diagnosis of FAS requires growth retardation; evidence of CNS neurodevelopmental abnormalities; and a characteristic pattern of facial anomalies, including short palpebral fissures, thin upper lip, indistinct or smooth philtrum, and midface hypoplasia.

B. PARTIAL FETAL ALCOHOL SYNDROME

The diagnosis of partial fetal alcohol syndrome (PFAS) requires the presence of some but not all components of the facial anomalies as well as growth retardation, CNS neurodevelopmental abnormalities, or behavioral or cognitive abnormalities that are inconsistent with the child's developmental level and cannot be explained by familial background or environment.

C. ALCOHOL-RELATED NEURODEVELOPMENTAL DISORDER

Alcohol-related neurodevelopmental disorder (ARND) does not require the presence of facial dysmorphic features, but it does require the presence of CNS neurodevelopmental abnormalities (eg, microcephaly, CNS structural defects, neurologic hard and soft signs) or evidence of a complex pattern of behavioral or cognitive abnormalities as outlined earlier. These abnormalities may include learning disabilities; poor impulse control; and problems in memory, attention, or judgment.

D. ALCOHOL-RELATED BIRTH DEFECTS

The diagnosis of alcohol-related birth defects (ARBD) requires the presence of congenital anomalies including malformations and dysplasias in cardiac, skeletal, renal, ocular, or auditory areas (ie, sensorineural hearing loss). Strong animal and human evidence supports all of these diagnostic categories, including the controversial ARND diagnosis, which does not involve dysmorphic features. The prevalence of FAS, PFAS, and ARND combined is approximately 1 per 100 in the general population. These are common problems, and the physician must always ask about alcohol intake during pregnancy in a nonjudgmental way to obtain an accurate answer. The exact amount of alcohol consumption that leads to teratogenesis remains unclear. There is strong evidence that binge drinking during early critical periods of embryogenesis leads to alcohol-related syndromes.

Evaluation & Treatment

The majority of children with alcohol-related syndromes present with ADHD symptoms, with or without significant developmental delays. To adequately assess involvement in other organs the following tests are recommended: an ophthalmologic examination, a hearing test, and a careful cardiac examination, with ultrasonography if abnormalities are detected. A careful examination for dysmorphic features and bony abnormalities is necessary. Renal function studies (ie, creatinine) should be conducted and a renal ultrasound obtained. Mental health problems are observed in over 90% of children and adolescents affected by alcohol in utero. Depression, panic attacks, anxiety, and mood instability are common. Because psychotic ideation is present in 20–40% of individuals with alcohol-related syndromes, a thorough emotional or psychiatric evaluation is essential. Long-term therapy and special education services are usually needed, and psychopharmacologic intervention may be helpful.

For treatment of ADHD symptoms, a dextroamphetamine preparation should be tried initially, although methylphenidate may also be helpful. SSRI agents can help relieve anxiety, panic attacks, and depression, although mania or hypomanias, a side effect, may occur in 25–50% of patients. Mood instability may be severe, although it usually responds to a mood stabilizer, such as valproate, or carbamazepine. One should be cautious with lithium because kidney dysfunction, secondary to malformations or hypoplasia, occasionally occurs. Psychotic features should be treated with an atypical antipsychotic such as risperidone. Consultation with a psychiatrist is helpful because the mental health problems associated with these syndromes are complex.

A speech and language evaluation and an occupational therapy evaluation in childhood usually lead to documentation of problems, and ongoing therapy is usually helpful. The most significant problem in alcohol-related syndromes is the high rate of legal problems, incarceration, and alcohol or drug abuse in adolescence and adulthood. An intensive treatment program must be mobilized to improve the outcome of this disorder. Long-term counseling and advocacy, along with intensive job training, usually keeps these adolescents out of trouble, but the failure rate is high.

3. Autistic Spectrum Disorders

Autism is a neurologic disorder characterized by (1) qualitative impairments in social interaction; (2) qualitative impairments in communication; and (3) restricted repetitive and stereotyped patterns of behavior, interests, and activities. It is a relatively common disorder, occurring in approximately 1 in 500 children. There is a higher incidence of autistic spectrum disorders in disorders such as fragile X syndrome, tuberous sclerosis, Cornelia de Lange syndrome, Down syndrome, and 15q duplication. Despite this, in as many as 90% of cases of autism, no cause can be identified. There is a strong familial component. Parents of one child with autism have a 2–9% chance of having a second child with autism. The concordance rate among monozygotic twins is high, and there is an increased incidence of speech, language, reading, attention, and affective disorders in family members of children with autism.

Evaluation & Treatment

Children with autism are often not diagnosed until age 3 to 4 years, when their disturbances in reciprocal social interaction and communication become more apparent. However, impairments in communication and behavior can sometimes be recognized in the first 12 to 18 months of life. Behaviors noted during this period include a lack of motor imitation, a lack of joint attention and social referencing, a lack of affect sharing, poor eye contact, and a lack of symbolic play. The three most striking characteristics during the first year are a consistent failure to orient to one's name, failure to regard people directly, and failure to develop speech. Because of evidence that early intervention is particularly important for children with autism, great interest has arisen in developing a screening instrument that can be used in very young children. The Checklist for Autism in Toddlers (CHAT) is administered at 18 months and includes a short parent questionnaire and direct observation. It evaluates pretend play and joint attention (which includes pointing for interest and following gaze). This instrument is quick and easy to administer and has good specificity and positive predictive value (83%). Unfortunately, its sensitivity is poor (18%). Work is being done to modify this test or develop others with greater sensitivity. When behaviors consistent with autism are noted, the child should be referred to a team of specialists experienced in the assessment of autistic spectrum disorders as soon as possible.

All children with autism should have a formal audiology evaluation because of their language disorder. For children with autism and mental retardation, tests for high-resolution chromosomes, DNA for fragile X syndrome, FISH for 15q duplication, as well as metabolic screening, lead level, and thyroid studies should be considered. A Woods lamp test for tuberous sclerosis may also be done. Other tests should be considered as indicated by findings in the history and physical examination. Neuroimaging is not routinely indicated even in the presence of macrocephaly since children with autism often have relatively large heads. Approximately 15–30% of children with autism demonstrate plateauing or loss of skills (usually language and social skills only) between 12 and 24 months of age. This usually occurs before attaining 10 words. Children who have a history of regression should have a sleep-deprived EEG, or an overnight EEG, with adequate sampling of slow-wave sleep to rule out epileptiform discharges during slow-wave sleep. It should be noted that the recommendations for treatment of that type of EEG abnormality are still being debated.

Much controversy surrounds the appropriate treatment and educational approaches for children with autistic spectrum disorders. As with any child, treatment should be based on the individual needs of the child. It is clear, however, that intervention must begin early and must be comprehensive and intensive. Some advocate 25 hours or more per week of treatment that targets development of social attention, peer interactions, functional language, and appropriate play. It should be noted that psychotropic medications have been helpful in some children with autism. However, these medications should not take the place of behavioral interventions.

Adolescence

3

David W. Kaplan, MD, MPH, & Kathryn Love-Osborne, MD

Adolescence is a period of rapid physical, emotional, cognitive, and social growth and development. Generally, adolescence begins at age 11–12 years and ends between ages 18 and 21. Most teenagers complete puberty by age 16–18 years; in western society, however, for educational and cultural reasons, the adolescent period is prolonged to allow for further psychosocial development before the individual assumes adult responsibilities.

The developmental passage from childhood to adulthood encompasses the following steps: (1) completing puberty and somatic growth; (2) developing socially, emotionally, and cognitively, moving from concrete to abstract thinking; (3) establishing an independent identity and separating from the family; and (4) preparing for a career or vocation.

DEMOGRAPHY

In the United States in 2003, there were 20.3 million adolescents between ages 15 and 19 years and 19.8 million between ages 20 and 24 years. Adolescents and young adults (ages 15–24 years) constitute 14% of the US population. Over the next several decades, the proportion of racial and ethnic minority adolescents is expected to increase. It is projected that by 2040 the percentage of non-Hispanic whites will drop below 50%. Hispanics are becoming the second most populous racial/ethnic group.

MORTALITY DATA

For the adolescent population, cultural and environmental rather than organic factors pose the greatest threats to life. The three leading causes of death in the adolescent population (ages 15–19 years) in 2000 were unintentional injury (49.8%), homicides (14.1%), and suicides (12.0%). These three causes of violent death accounted for 76.0% of all adolescent deaths. Deaths resulting from homicide among black 15- to 19-year-olds increased 328% between 1983 and 1993. Although the homicide rate has decreased significantly since the high in 1993, homicide is still the leading cause of death for black adolescents age 15–19 years, accounting for 38.0% of all deaths. Although deaths from automobile crashes have decreased over the last

decade, alcohol use remains the underlying cause of most teenage motor vehicle deaths. Almost two thirds of motor vehicle deaths involving young drinking drivers occur on Friday, Saturday, or Sunday, and 70% occur between 8:00 PM and 4:00 AM.

There is continued concern in the United States with the problem of youth violence. This concern is rooted in the high rate of homicides involving handguns among young males, the number of firearm-related suicides, and school shootings. Youths ages 12 to 17 are twice as likely as adults to be victims of serious violent crimes, which include aggravated assault, rape, robbery, and homicide. Violent crimes committed by juveniles constitute about 1 in 4 of all violent crimes. Nationally, 17.4% of high-school students reported carrying a weapon at least once in the preceding 30 days. However, since the peak rate of serious violent crime involving juvenile offenders in 1993, the rate has decreased. The rate of serious violent crimes among youth victims decreased from 37.6 in 1980 to 16.0 in 2000.

MORBIDITY DATA

Demographic and economic changes in the American family since the mid-1970s have had a profound effect on children and adolescents. Between 1955 and 1990, the divorce rate rose from about 400,000 to nearly 1.2 million a year. Between 1960 and 1990, the number of children involved in divorce each year increased from 460,000 to 1.1 million. The percentage of children and adolescents living in two-parent households has decreased significantly, from 79% in 1980 to 69% in 2001. Sixty-five percent of Hispanic and 38% of black children and adolescents younger than age 18 lived in a two-parent household in 2001. In 2002, 16.7% of children and adolescents younger than age 18 years in the United States were living below the poverty level, compared with 12% in 1970. Forty percent of children in mother-only families were living in poverty.

The major causes of morbidity during adolescence are psychosocial: unintended pregnancy, sexually transmitted infections (STIs), substance abuse, smoking, dropping out of school, depression, running away from home, physical violence, and juvenile delinquency.

High-risk behavior in one area is often associated with problems in another (Figure 3–1). For example, teenagers who live in a dysfunctional family (eg, problems related to drinking or physical or sexual abuse) are much more likely than other teenagers to be depressed. A depressed teenager is at greater risk for drug and alcohol abuse, academic failure, inappropriate sexual activity, STIs, pregnancy, and suicide.

Early identification of the teenager at risk for these problems is important in preventing immediate complications and future associated problems. Early indicators for problems related to depression include the following:

1. Decline in school performance.
2. Excessive school absences or cutting class.
3. Frequent or persistent psychosomatic complaints.
4. Changes in sleeping or eating habits.
5. Difficulty in concentrating or persistent boredom.
6. Signs or symptoms of depression, extreme stress, or anxiety.
7. Withdrawal from friends or family, or change to a new group of friends.
8. Unusually severe violent or rebellious behavior, or radical personality change.

9. Conflict with parents.
10. Sexual acting-out.
11. Conflicts with the law.
12. Suicidal thoughts or preoccupation with themes of death.
13. Drug and alcohol abuse.
14. Running away from home.

DELIVERY OF HEALTH SERVICES

How, where, why, and when adolescents seek health care depends on ability to pay, distance to health care facilities, availability of transportation, accessibility of services, time away from school, and privacy. Many common teenage health problems, such as unintended pregnancy and the need for contraception; STIs; and substance abuse, depression, and other emotional problems, have moral, ethical, and legal implications. Teenagers are often reluctant to confide in their parents for fear of punishment or disapproval. Recognizing this reality, health care providers have established many specialized programs such as teenage family planning clinics, drop-in centers, STI clinics, hotlines, and adolescent clinics. For the physician, establishing a trusting and confidential relationship is basic to meeting an adolescent patient's health care needs. A patient who senses that the physician will inform the parents about a confidential problem may lie or fail to disclose information essential for proper diagnosis and treatment.

GUIDELINES FOR ADOLESCENT PREVENTIVE SERVICES

The American Medical Association guidelines for adolescent preventive services (GAPS) and the National Center for Education in Maternal and Child Health *Bright Futures* cover health screening and guidance, immunization, and health care delivery. The goals of these guidelines are (1) to deter adolescents from participating in behaviors that jeopardize health; (2) to detect physical, emotional, and behavioral problems early and intervene promptly; (3) to reinforce and encourage behaviors that promote healthful living; and (4) to provide immunization against infectious diseases. The guidelines recommend that adolescents between ages 11 and 21 years have annual routine health visits. Health services should be developmentally appropriate and culturally sensitive, and confidentiality between patient and physician should be ensured. A complete schedule of the recommended guidelines is shown in Figure 3–2A.

RELATING TO THE ADOLESCENT PATIENT

Adolescence is one of the physically healthiest periods in life. The challenge of caring for adolescents lies not in managing complex organic disease but in accommodating to the cognitive, emotional, and psychosocial growth that influences health behavior.

How the physician initially approaches the adolescent may determine the success or failure of the visit. The physician should behave simply and honestly, without an authoritarian or excessively professional manner. Because the self-esteem of many young adolescents is fragile, the physician must be careful not to overpower and intimidate the patient. To establish a comfortable and trusting relationship, the physician should strive to present the image of an ordinary person who has special training and skills.

Because individuals vary greatly in the onset and termination of puberty, chronologic age may be a poor indicator of physical, physiologic, and emotional development. In communicating with an adolescent, the physician must be sensitive to the patient's developmental level, recognizing that outward appearance and chronologic age may not give an accurate assessment of cognitive development.

Working with teenagers can be emotionally draining. Adolescents have a unique ability to identify hidden emotional vulnerabilities. The physician who has a personal need to control patients or foster dependency may be disappointed in caring for teenagers. Because teenagers are consumed with their own emotional needs, they rarely provide the physician with the ego rewards that younger or older patients do.

The physician should be sensitive to the issue of countertransference, the emotional reaction elicited in the physician by the adolescent. How the physician relates to the adolescent patient often depends on the physician's personal characteristics. This is especially true of physicians who treat families that are experiencing parent-adolescent conflicts. It is common for young physicians to overidentify with the teenage patient and for older physicians to see the conflict from the parents' perspective.

Overidentification with the parents is readily sensed by the teenager, who is likely to view the physician as just another authority figure who cannot understand the problems of being a teenager. Assuming a parental-authoritarian role may jeopardize the establishment of a working relationship with the patient. In the case of the young physician, overidentification with the teenager may cause the parents to become defensive about their parenting role and discount the physician's experience and ability.

Preventive Health Services by Age and Procedure

Adolescents and young adults have a unique set of health care needs. The recommendations for Guidelines for Adolescent Preventive Services (GAPS) emphasize annual clinical preventive services visits that address both the developmental and psychosocial aspects of health, in addition to traditional biomedical conditions. These recommendations were developed by the American Medical Association with contributions from a Scientific Advisory Panel, comprised of national experts, as well as representatives of primary care medical organizations and the health insurance industry. The body of scientific evidence indicates that the periodicity and content of preventive services can be important in promoting the health and well-being of adolescents.

1. Screening test performed once if family history is positive for early cardiovascular disease or hyperlipidemia.
2. Screen if positive for exposure to active TB or lives/works in high-risk situation, eg homeless shelter, jail, health care facility.
3. Screen at least annually if sexually active.
4. Screen if high risk for infection.
5. Screen annually if sexually active or if 18 years or older.
6. Vaccinate any adolescent not previously vaccinated.

7. Vaccinate if at risk for hepatitis A infection.
 8. Offer vaccine if no reliable history of chickenpox or previous immunization.
- * A parent health guidance visit is recommended during early and middle adolescence.
- ** Includes counseling regarding sexual behavior and avoidance of tobacco, alcohol, and other drug use.
- *** Includes history of unintended pregnancy and STD.
- Do not give if administered in last five years.

- 44. Have you begun dating? YES NO
- 45. Do you currently have a boyfriend or girlfriend? YES NO
If YES, how old is he/she? _____
- 46. Do you think you might be gay/lesbian/homosexual? YES NO
- 47. Have you ever had sex (sexual intercourse)? YES NO
- 48. Are you interested in receiving information on preventing pregnancy? YES NO
- 49. If you have had sex, are you (or your partner) using any kind of birth control? YES NO
- 50. If you have had sex, have you ever been treated for gonorrhea or chlamydia or any other sexually transmitted disease? YES NO

For males only

- 51. Have you been taught how to use a condom correctly? YES NO
- 52. If you have had sex, do you use a condom every time or almost every time? YES NO
- 53. Have you ever fathered a child? YES NO

For females only

- 54. How old were you when your periods began? _____
- 55. What date did your last period start? _____
- 56. Are your periods regular (once a month)? YES NO
- 57. Do you have painful or excessively heavy periods? YES NO
- 58. Have you ever had a vaginal infection or been treated for a female disorder? YES NO
- 59. Do you think you might be pregnant? YES NO
- 60. Have you ever been pregnant? YES NO

Everyone

- 61. Do you have any other problems you would like to discuss with the caregiver? YES NO

Past Medical History

- 62. Were you born prematurely or did you have any serious problems as an infant? YES NO
- 63. Are you allergic to any medicines? YES NO
If YES, what? _____

- 64. List any medications that you are taking and the problems for which the medication was given:

MEDICATION	REASON	HOW LONG
_____	_____	_____
_____	_____	_____
_____	_____	_____

- 65. Have you ever been hospitalized? YES NO
If YES, describe your problem and your age at the time.

AGE	PROBLEM
_____	_____
_____	_____
_____	_____

- 66. Have you had any injuries? YES NO
If YES, describe the injury and your age when it occurred.

AGE	KIND OF INJURY
_____	_____
_____	_____
_____	_____

- 67. Have you had any serious illnesses? YES NO
If YES, state the kind of illness and your age when it started.

AGE	ILLNESS
_____	_____
_____	_____
_____	_____

Family History

Have any members of your family, alive or dead (parents, grandparents, uncles, aunts, brothers or sisters), had any of the following problems? If YES, please state the age of the person when the condition occurred and the person's relationship to you.

PROBLEM	YES	NO	DON'T KNOW	AGE	RELATIONSHIP
A. Seizure disorder Epilepsy					
B. Mental retardation Birth defects					
C. Migraine headaches					
D. High blood pressure High cholesterol					
E. Heart attack or stroke at less than age 60					
F. Lung disease Tuberculosis					
G. Liver or intestinal disease					
H. Kidney disease					
I. Allergies Asthma Eczema					
J. Arthritis					
K. Diabetes					
L. Endocrine problems Other glandular problems					
M. Obesity Eating disorder					
N. Cancer					
O. Blood disorders Sickle cell anemia					
P. Emotional problems Suicide					
Q. Alcoholism Drug problems					

Figure 3-2. Continued

THE SETTING

Adolescents respond positively to a setting and to services that communicate a sensitivity to their age. A pediatrician's waiting room with toddlers' toys and examination tables too short for a young adult make adolescent patients feel they have outgrown the practice. Similarly, a waiting room filled with geriatric or pregnant patients can make a teenager feel out of place.

It is not uncommon to see a teenage patient who has been brought to the office against his or her wishes, especially for evaluations of drug and alcohol use, parent-child conflict, school failure, depression, or a suspected eating disorder. Even in cases of acute physical illness, the adolescent may feel anxiety about having a physical examination. If future visits are to be successful, the physician must spend time on the first visit to foster a sense of trust and an opportunity to feel comfortable.

CONFIDENTIALITY

It is helpful at the beginning of the visit to talk with the adolescent and the parents about what to expect. The physician should address the issue of confidentiality, telling the parents that two meetings, one with the teenager alone and one with only the parents, will take place. Adequate time must be spent with both the patient and the parents, or important information may be missed. At the beginning of the interview with the patient, it is useful to say, "I am likely to ask you some personal questions. This is not because I am trying to pry into your personal affairs but because these questions may be important to your health. I want to assure you that what we talk about is confidential, just between the two of us. If there is something I feel we should discuss with your parents, I will ask your permission first unless I feel it is life-threatening."

THE STRUCTURE OF THE VISIT

Caring for adolescents is a time-intensive process. In many adolescent practices, a 40–50% no-show rate is not unusual. The stated chief complaint may conceal the patient's real concern. For example, a 15-year-old girl may say she has a sore throat but actually may be worried about being pregnant.

By age 11 or 12 years, patients should be seen alone. This gives them an opportunity to ask questions they may be embarrassed to ask in front of a parent. Because of the physical changes that take place in early puberty, some adolescents are too self-conscious to undress in front of a parent. If an adolescent comes in willingly, either for an acute illness or for a routine physical examination, it may be helpful to meet with the adolescent

and parent together to obtain the history. In the case of angry adolescents, brought in against their will, it is useful to meet with the parents and patient just long enough to have the parents describe the conflict and voice their concerns. This meeting should last no longer than 3–5 minutes, and the adolescent should then be seen alone. This approach conveys that the physician is primarily interested in the adolescent patient, yet gives the physician an opportunity to acknowledge the parents' concerns.

The Interview

The first few minutes may dictate the success of the visit, whether or not a trusting relationship can be established. A few minutes just getting to know the patient is time well spent. For example, immediately asking, "Do you smoke marijuana?" when a teenager is brought in for suspected marijuana use confirms the adolescent's negative preconceptions about the physician and the purpose of the visit.

It is preferable to spend a few minutes asking non-threatening questions. "Tell me a little bit about yourself so I can get to know you." "What do you like to do most?" "Least?" "What are your friends like?" Neutral questions help defuse some of the patient's anger and anxiety. Toward the end of the interview, the physician can ask more directed questions about psychosocial concerns.

Medical history questionnaires for the patient and the parents are useful in collecting historical data (Figure 3–2B).

The history should include an assessment of progress with psychodevelopmental tasks and of behaviors potentially detrimental to health. The review of systems should include questions about the following:

1. Nutrition: Number and balance of meals; calcium, iron, cholesterol intake, body image.
2. Sleep: Number of hours, problems with insomnia or frequent waking.
3. Seat belt or helmet: Regularity of use.
4. Self-care: Knowledge of testicular or breast self-examination, dental hygiene, and exercise.
5. Family relationships: Parents, siblings, relatives.
6. Peers: Best friend, involvement in group activities, gangs, boyfriends, girlfriends.
7. School: Attendance, grades, activities.
8. Educational and vocational interests: College, career, short-term and long-term vocational plans.
9. Tobacco: Use of cigarettes, snuff, chewing tobacco.
10. Substance abuse: Frequency, extent, and history of alcohol and drug use.

- 11. Sexuality: Sexual activity, contraceptive use, pregnancies, history of sexually transmitted disease, number of sexual partners, risk for HIV infection.
- 12. Emotional health: Signs of depression and excessive stress.

The physician’s personal attention and interest is likely to be a new experience for the teenager, who has probably received medical care only through a parent. The teenager should leave the visit with a sense of having a personal physician.

Physical Examination

During early adolescence, many teenagers may be shy and modest, especially with a physician of the opposite sex. The examiner should address this concern directly, because it can be allayed by acknowledging the uneasiness verbally and by explaining the purpose of the examination, for example, “Many boys that I see who are your age are embarrassed to have their penis and testes examined. This is an important part of the examination

for a couple of reasons. First, I want to make sure that there aren’t any physical problems, and second, it helps me determine if your development is proceeding normally.” This also introduces the subject of sexual development for discussion.

A pictorial chart of sexual development is useful in showing the patient how development is proceeding and what changes to expect. Figure 3–3 shows the relationship between height, penis and testes development, and pubic hair growth in the male, and Figure 3–4 shows the relationship between height, breast development, menstruation, and pubic hair growth in the female. Many teenagers do not openly admit that they are interested in this subject, but they are usually attentive when it is raised. This discussion is particularly useful in counseling teenagers who lag behind their peers in physical development.

Because teenagers are sensitive about their changing bodies, it is useful to comment during the examination: “Your heart sounds fine. I feel a small lump under your right breast. This is very common during puberty in boys. It is called gynecomastia and should disappear in

BOYS

GIRLS

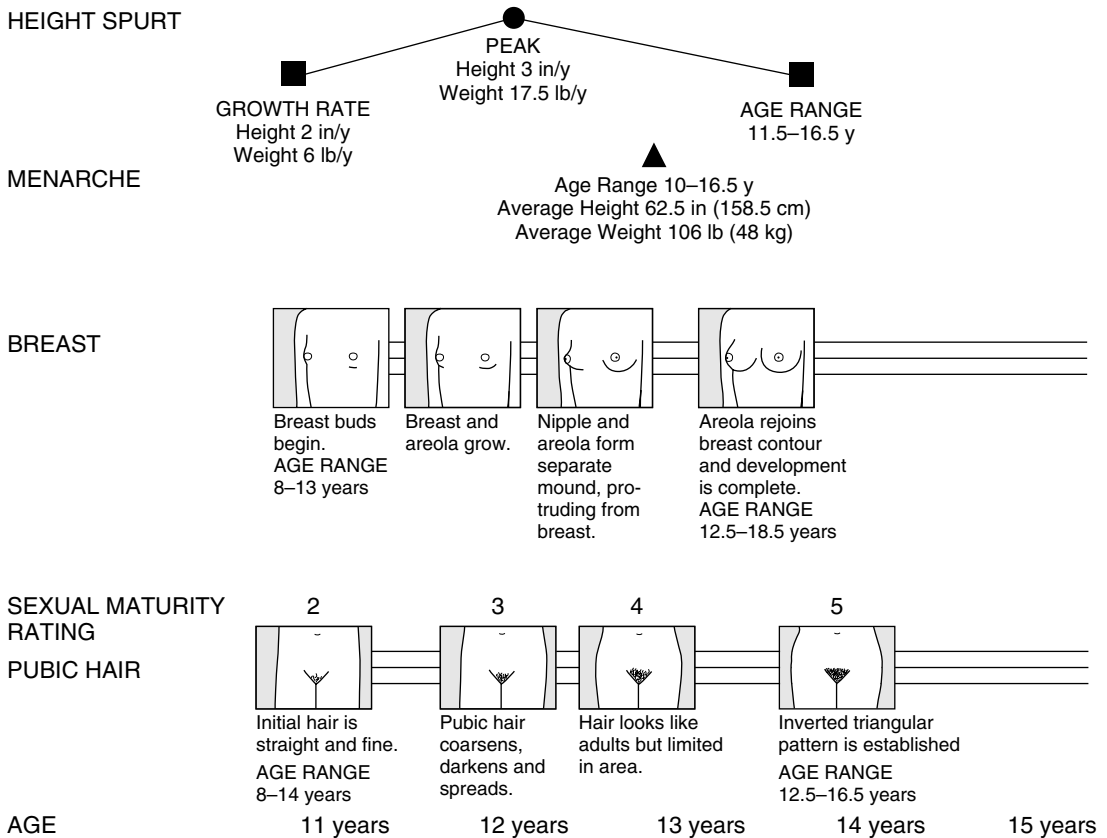

Figure 3–4. Adolescent female sexual maturation and growth. (Adapted and reproduced, with permission, from Tanner JM: *Growth at Adolescence*. Blackwell Scientific, 1962.)

6 months to a year. Don't worry, you are not turning into a girl."

If a teenage girl has not been sexually active and has no gynecologic complaints or abnormalities, a pelvic examination is usually not necessary until about age 18 years. The following are indications for a pelvic examination in a younger teenage girl:

1. A history of sexual intercourse. (The pelvic examination should be done for purposes of contraceptive counseling and to rule out sexually transmitted disease.)
2. Abnormal vaginal discharge.
3. Menstrual irregularities.
4. Suspicion of anatomic abnormalities, such as imperforate hymen.
5. Pelvic pain.
6. Patient request for an examination.

GROWTH & DEVELOPMENT

PUBERTY

Pubertal growth and physical development are a result of activation of the hypothalamic–pituitary–gonadal axis in late childhood. Before the onset of puberty, pituitary and gonadal hormone levels are low. With the onset of puberty, the inhibition of gonadotropin-releasing hormone (GnRH) in the hypothalamus is removed, allowing pulsatile production and release of the gonadotropins: luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In early to middle adolescence, pulse frequency and amplitude of LH and FSH secretion increase, which stimulates the gonads to produce sex steroids (estrogen or testosterone). In the female, FSH stimulates ovarian maturation, granulosa cell function, and estradiol secretion. LH is important in ovulation and is involved also in corpus luteum formation and progesterone secretion. Initially, estradiol has an inhibitory effect on the release of LH and FSH. Eventually, estradiol becomes stimulatory, and the secretions of LH and FSH become cyclic. Estradiol levels progressively increase, resulting in maturation of the female genital tract and breast development.

In the male, LH stimulates the interstitial cells of the testes, which produce testosterone. FSH stimulates the production of spermatocytes in the presence of testosterone. The testes also produce inhibin, a Sertoli cell protein that also inhibits the secretion of FSH. During puberty, circulating testosterone levels increase more than 20-fold. Levels of testosterone correlate with the physical stages of puberty and the degree of skeletal maturation.

PHYSICAL GROWTH

During adolescence, a teenager's weight almost doubles, and height increases by 15–20%. During puberty, major organs double in size, with the exception of lymphoid tissue, which decreases in mass. Before puberty, there is little difference in the muscular strength of boys and girls. The body's musculature increases both in size and in strength during puberty, with maximal strength lagging behind the increase in size by many months. Boys attain greater strength and mass, and strength continues to increase into late puberty. Although motor coordination lags behind growth in stature and musculature, it continues to improve as strength increases.

The pubertal growth spurt begins nearly 2 years earlier in girls than in boys. Girls reach their peak height velocity (PHV) between ages 11½ and 12 years; boys, between ages 13½ and 14 years. Linear growth at peak velocity is 9.5 cm/y ± 1.5 cm for boys and 8.3 cm/y ±

1.2 cm for girls. Pubertal growth usually takes 2–4 years and continues longer in boys than in girls. By age 11 years in girls and age 12 years in boys, 83–89% of ultimate height has been attained. An additional 18–23 cm in females and 25–30 cm in males will be achieved during further pubertal growth. Following menarche, growth is rarely more than 5–7.5 cm.

In boys, the quantity of body fat increases before onset of the height spurt. They then lose fat until the growth spurt has finished and gradually again increase in fat. Muscle mass doubles between ages 10 and 17 years. Girls, by contrast, gradually store fat from about age 6 years and do not decrease the quantity of fat, although its location changes, with an increase of subcutaneous fat in the region of the pelvis, breasts, and upper back.

SEXUAL MATURATION

Sexual maturity rating (SMR) is useful clinically for categorizing genital development. SMR staging includes age ranges of normal development and specific descriptions for each stage of pubic hair growth, penis and testis development in boys, and breast maturation in girls. Figures 3–3 and 3–4 graphically represent this chronologic development with reference to each sexual maturity stage. SMR 1 is prepuberty; SMR 5, adult maturity. In SMR 2 is the pubic hair is sparse, fine, non-pigmented, and downy; in SMR 3, the hair becomes pigmented and curly and increases in amount; and in SMR 4, the hair is adult in texture but limited in area. The appearance of pubic hair precedes that of axillary hair by more than 1 year. Male genital development begins with SMR 2, in which the testes become larger and the scrotal skin reddens and coarsens. In SMR 3, the penis lengthens; and in SMR 4, the penis enlarges in overall size and the scrotal skin becomes pigmented.

Female breast development follows a predictable sequence. Small, raised breast buds appear in SMR 2. In SMR 3, the breast and areolar tissue generally enlarge and become elevated. The areola and papilla (nipple) form a separate mound from the breast in SMR 4, and in SMR 5 the areola assumes the same contour as the breast.

Great variability exists in the timing and onset of puberty and growth, and psychosocial development does not necessarily parallel physical changes. Because of this variability, chronologic age may be a poor indication of physiologic and psychosocial development. Skeletal maturation correlates well with growth and pubertal development.

Teenagers have been entering puberty at increasingly earlier ages during the last century because of better nutrition and improved socioeconomic conditions. In the United States, the average age at menarche is 12.16 years in African American girls and 12.88 in

white girls. Among girls reaching menarche, the average weight is 48 kg, and the average height is 158.5 cm. However, menarche may be delayed until age 16 years or may begin as early as age 10. Although the first measurable sign of puberty in girls is the beginning of the height spurt, the first conspicuous sign usually is development of breast buds between ages 8 and 11 years. Although breast development usually precedes the growth of pubic hair, in some girls the sequence may be reversed. A common concern for girls at this time is whether the breasts will be of the right size and shape, especially because it is not unusual for one breast to grow faster than the other. Among girls, the growth spurt starts at about age 9 years and reaches a peak at age 11½, usually at SMR 3–4 breast development and stage 3 pubic hair development. The spurt usually ends by age 14 years. Girls who mature early will reach their PHV sooner and attain their final height earlier. Girls who mature late will attain a greater ultimate height because of the longer period of growth before the growth spurt. Final height is related to skeletal age at onset of puberty as well as genetic factors. The height spurt correlates more closely with breast developmental stages than with pubic hair stages.

The first sign of puberty in the male, usually between ages 10 and 12 years, is scrotal and testicular growth. Pubic hair usually appears early in puberty but may do so any time between ages 10 and 15 years. The penis begins to grow significantly a year or so after the onset of testicular and pubic hair development, usually between ages 10 and 13½. The first ejaculation usually occurs about 1 year after initiation of testicular growth, but its timing is highly variable. About 90% of boys have this experience between ages 11 and 15 years. Gynecomastia, a hard nodule under the nipple, occurs in a majority of boys, with a peak incidence between ages 14 and 15 years. Gynecomastia usually disappears within 6 months to 2 years. The height spurt begins at age 11 years but increases rapidly between ages 12 and 13, with the PHV reached at age 13½ years. The period of pubertal development lasts much longer in boys and may not be completed until age 18 years. The height velocity is higher in males (8–11 cm/y) than in females (6.5–9.5 cm/y). The development of axillary hair, deepening of the voice, and the development of chest hair in boys usually occur in mid-puberty, about 2 years after onset of growth of pubic hair. Facial and body hair begin to increase at age 16–17 years.

PSYCHOSOCIAL DEVELOPMENT

Adolescents are struggling to find out who they are, what they want to do in the future, and, in relation to that goal, what their personal strengths and weaknesses are. These questions arise primarily because teenagers are in the process of establishing their own identity. Adolescence is a period of progressive individuation and separation from the family. Because of the rapid physical, emotional, cognitive, and social growth occurring during adolescence, it is useful to divide the period into three sequential phases of development. Early adolescence occurs roughly between ages 10 and 13 years; middle adolescence, between ages 14 and 16 years; and late adolescence, at age 17 years and later.

Early Adolescence

Early adolescence (ages 10–13 years) is characterized by rapid growth and development of secondary sex characteristics. Because of the rapid physical changes during this period, body image, self-concept, and self-esteem fluctuate dramatically. Concerns about how personal growth and development deviate from that of peers may be a great worry, especially short stature in boys and delayed breast development or delayed menarche in girls. Although there is a certain curiosity about sexuality, young adolescents tend to feel more comfortable with members of the same sex. Peer relationships become increasingly important. Young teenagers still think concretely and cannot easily conceptualize about the future. They may have vague and unrealistic professional goals, such as becoming a movie star or a lead singer in a rock group.

Middle Adolescence

During middle adolescence (ages 14–16 years), as the rapid pubertal growth rate subsides, teenagers become more comfortable with their new bodies. Intense emotions and wide swings in mood are typical. Although some teenagers go through this experience relatively peacefully, others struggle desperately. Cognitively, teenagers move from concrete thinking to formal operations and develop the ability to think abstractly. With this new mental power comes a sense of omnipotence and a belief that the world can be changed by merely thinking about it. Sexually active teenagers may believe they do not need to worry about using contraception

because they can't get pregnant, "it won't happen to me." Sixteen-year-old drivers believe they are the best drivers in the world and think the insurance industry is conspiring against them by charging such high rates for automobile insurance. With the onset of the ability to think abstractly, teenagers begin to see themselves as others see them and may become extremely self-centered. Because they are establishing their own identities, relationships with other people, including peers, are primarily narcissistic, and experimenting with different images is quite common. Peers determine the standards for identification, behavior, activities, and fashion and provide emotional support, intimacy, empathy, and the sharing of guilt and anxiety during the struggle for autonomy. The struggle for independence and autonomy is often a difficult and stressful period for both the teenager and the parents.

As sexuality increases in importance during this time, adolescents may begin dating and experimenting with sex. Relationships usually tend to be one-sided and narcissistic.

Late Adolescence

During late adolescence (age 17 years and older), the young person generally becomes less self-centered and begins caring more about others. Social relationships shift from the peer group to the individual. Dating becomes much more intimate. By age 18 years, nearly half of American girls and two-thirds of boys have had sexual intercourse. The older adolescent becomes more independent from the family. The ability to think abstractly allows older adolescents to think more realistically in terms of future plans, actions, and careers. Older adolescents have rigid concepts of what is right or wrong. This is a period of idealism.

Sexual Orientation

Sexual orientation develops during early childhood. One's gender identity is established by age 2 years, and a sense of masculinity or femininity usually solidifies by age 5 or 6 years. Homosexual adults describe homosexual feelings during late childhood and early adolescence, years before engaging in overt homosexual acts.

Although only 5–10% of American young people acknowledge having had homosexual experiences and only 5% feel that they are or could be gay, homosexual experimentation is common, especially during early and middle adolescence. Experimentation may include mutual masturbation and fondling the genitals and does not by itself cause or lead to adult homosexuality. Theories about the causes of homosexuality include genetic, hormonal, environmental, and psychological models.

The development of homosexual identity in adolescence commonly progresses through two stages. The adolescent feels different, develops a crush on a person of the same sex without clear self-awareness of a gay identity, and then goes through a coming-out phase in which the homosexual identity is defined for the individual and revealed to others. The coming-out phase may be a very difficult period for the young person and the family. The young adolescent is afraid of society's bias and seeks to reject homosexual feelings. This struggle with identity may include episodes of both homosexual and heterosexual promiscuity, STIs, depression, substance abuse, attempted suicide, school avoidance and failure, running away from home, and other crises.

In a clinical setting, the issue of homosexual identity most often surfaces as a result of a teenager being seen for an STI, family conflict, school problem, attempted suicide, or substance abuse rather than as a result of a consultation about sexual orientation. Pediatricians should be aware of the psychosocial and medical implications of homosexual identity and be sensitive to the possibility of these problems in gay adolescents. Successful management depends on the physician's ability to gain the trust of the gay adolescent and on the physician's knowledge of the wide range of medical and psychological problems for which gay adolescents may be at risk. Pediatricians must be nonjudgmental in posing sexual questions if they are to be effective in encouraging the teenager to share concerns. Physicians who for religious or other personal reasons cannot be objective must refer the homosexual patient to another professional for treatment and counseling.

■ BEHAVIOR & PSYCHOLOGICAL HEALTH

It is not unusual for adolescents to seek medical attention for seemingly minor complaints. During early ado-

lence, teenagers may worry about normal developmental changes such as gynecomastia. They may present with vague symptoms, whereas the hidden agenda may be concerns about pregnancy or an STI. Adolescents with emotional disorders often present with somatic symptoms, for example, abdominal pain, headaches, dizziness or syncope, fatigue, sleep problems, and chest pain, that appear to have no biologic cause. The emotional basis of such complaints may be varied: somatoform disorder, depression, or stress and anxiety.

PSYCHOPHYSIOLOGIC SYMPTOMS & CONVERSION REACTIONS

The most common somatoform disorders during adolescence are conversion disorders or conversion reactions. (A conversion reaction is a psychophysiologic process in which unpleasant feelings, especially anxiety, depression, and guilt, are communicated through a physical symptom.) Psychophysiologic symptoms result when anxiety activates the autonomic nervous system, resulting in tachycardia, hyperventilation, and vasoconstriction. The emotional feeling may be threatening or unacceptable to the individual, who expresses it as a physical symptom rather than verbally. This process is unconscious, and the anxiety or unpleasant feeling is dissipated by the somatic symptom. The degree to which the conversion symptom lessens anxiety, depression, or the unpleasant feeling is referred to as primary gain. Conversion symptoms not only diminish unpleasant feelings but also release the adolescent from conflict or an uncomfortable situation. This is referred to as secondary gain. Secondary gain may intensify the symptoms, especially with increased attention from concerned parents and friends. Adolescents with conversion symptoms tend to have overprotective parents and become increasingly dependent on their parents as the symptom becomes the major focus concern in the family.

Clinical Findings

The symptom may appear at times of stress. Nervous, gastrointestinal, and cardiovascular symptoms are common and include paresthesias, anesthesia, paralysis, dizziness, syncope, hyperventilation, abdominal pain, nausea, and vomiting. Specific symptoms may reflect existing or previous illness (eg, pseudoseizures in adolescents with epilepsy) or modeling of a close relative's symptom (eg, chest pain in a boy whose grandfather died of a heart attack).

Conversion symptoms are more common in girls than boys. They occur in patients from all socioeconomic levels; however, the complexity of the symptom

may vary with the sophistication and cognitive level of the patient.

Differential Diagnosis

The history and physical findings are usually inconsistent with anatomic and physiologic concepts. Conversion symptoms are exhibited most frequently at times of stress and in the presence of individuals meaningful to the patient. The patient often exhibits a characteristic personality pattern, including egocentricity, emotional lability, and dramatic and attention-seeking behaviors.

Conversion reactions must be differentiated from hypochondriasis, which is a preoccupation with developing or having a serious illness despite medical reassurance that there is no evidence of disease. Over time, the fear of one disease may give way to concern about another. In contrast to patients with conversion symptoms, who seem relieved if an organic cause is considered, patients with hypochondriasis become more anxious when such a cause is considered.

Malingering is uncommon during adolescence. The malingering patient consciously and intentionally produces false or exaggerated physical or psychological symptoms. Such patients are motivated by external incentives such as avoiding work, evading criminal prosecution, obtaining drugs, or obtaining financial compensation. These patients may be hostile and aloof. Parents of patients with conversion disorders and malingering have a similar reaction to illness. They have an unconscious psychological need to have sick children and reinforce their child's behavior.

Somatic delusions are physical symptoms, often bizarre, that accompany other signs of mental illness. Examples are visual or auditory hallucinations, delusions, incoherence or loosening of associations, rapid shifts of affect, and confusion.

Treatment

The physician must emphasize from the onset that both physical and emotional causes of the symptom need to be considered. The relationship between physical causes of emotional pain and emotional causes of physical pain should be described to the family, using examples such as stress causing an ulcer or making a severe headache worse. The patient should be encouraged to understand that the symptom may persist and that at least a short-term goal is to continue normal daily activities. Medication is rarely helpful. If the family will accept it, psychological referral is often the best initial step toward psychotherapy. If the family resists psychiatric or psychological referral, the pediatrician may need to begin to deal with some of the emotional fac-

tors responsible for the symptom while building rapport with the patient and family. Regular appointments should be scheduled. During the sessions, the teenager should be seen first and encouraged to talk about school, friends, the relationship with the parents, and the stresses of life. Discussion of the symptom itself should be minimized; however, the physician should be supportive and must never suggest that the pain is not real. As the parents gain further insight into the cause of the symptom, they will become less indulgent of the complaints, facilitating the resumption of normal activities. If management is successful, the adolescent will increase coping skills and become more independent, while decreasing secondary gain.

If the symptom continues to interfere with daily activities and if the patient and parents feel that no progress is being made, psychological referral is indicated. A psychotherapist experienced in treating adolescents with conversion reactions is in the best position to establish a strong therapeutic relationship with the patient and family. After referral is made, the pediatrician should continue to follow the patient to ensure compliance with psychotherapy.

DEPRESSION (See also Chapter 6.)

Symptoms of clinical depression (lethargy, loss of interest, sleep disturbances, decreased energy, feelings of worthlessness, and difficulty concentrating) are common during adolescence. The intensity of feelings, often in response to seemingly trivial events such as a poor grade on an examination or not being invited to a party, makes it difficult to differentiate severe depression from normal sadness or dejection. In less severe depression, sadness or unhappiness associated with problems of everyday life is generally short-lived. The symptoms usually result in only minor impairment in school performance, social activities, and relationships with others. Symptoms respond to support and reassurance.

Clinical Findings

The presentation of serious depression in adolescence may be similar to that in adults, with vegetative signs such as depressed mood, crying spells or inability to cry,

discouragement, irritability, a sense of emptiness and meaninglessness, negative expectations of oneself and the environment, low self-esteem, isolation, a feeling of helplessness, diminished interest or pleasure in activities, weight loss or weight gain, insomnia or hypersomnia, fatigue or loss of energy, feelings of worthlessness, and diminished ability to think or concentrate. However, it is not unusual for a serious depression to be masked because the teenager cannot tolerate the severe feelings of sadness. Such a teenager may present with recurrent or persistent psychosomatic complaints, such as abdominal pain, chest pain, headache, lethargy, weight loss, dizziness and syncope, or other nonspecific symptoms. Other behavioral manifestations of masked depression include truancy, running away from home, defiance of authorities, self-destructive behavior, vandalism, drug and alcohol abuse, sexual acting out, and delinquency.

Differential Diagnosis

A complete history and physical examination, including a careful review of the patient's medical and psychosocial history, should be performed. The family history should be explored for psychiatric problems.

The teenager should be questioned about the previously listed symptoms of depression, and specifically about suicidal ideation or preoccupation with thoughts of death. The history should include an assessment of school performance, looking for signs of academic deterioration, excessive absence or cutting class, changes in work or other outside activities, and changes in the family (eg, separation, divorce, serious illness, loss of employment by a parent, a recent move to a new school, increasing quarrels or fights with parents, the death of a close relative). The teenager may have withdrawn from friends or family or switched allegiance to a new group of friends. The physician should seek to develop a history of drug and alcohol abuse, conflicts with the police, sexual acting out, running away from home, unusually violent or rebellious behavior, or radical personality changes. Patients with vague somatic complaints or concerns about having a fatal illness may have an underlying affective disorder.

Adolescents presenting with symptoms of depression require a thorough medical evaluation to rule out any contributing or underlying medical illness. Among the medical conditions associated with affective disorders are eating disorders, organic central nervous system (CNS) disorders (tumors, vascular lesions, closed head trauma, and subdural hematomas), metabolic and endocrinologic disorders (systemic lupus erythematosus, hypothyroidism, hyperthyroidism, Wilson disease, hyperparathyroidism, Cushing syndrome, Addison disease, premenstrual syndrome), infections (infectious

mononucleosis, syphilis), and mitral valve prolapse. Marijuana use, phencyclidine abuse, amphetamine withdrawal, and excessive caffeine intake can cause symptoms of depression. Common prescription and over-the-counter medications, including birth control pills, anticonvulsants, and β -blockers, may cause depressive symptoms.

Some routine laboratory studies are indicated in the depressed patient to rule out organic disease: a complete blood count (CBC) and erythrocyte sedimentation rate (ESR), urinalysis, serum electrolytes, blood urea nitrogen (BUN), serum calcium, thyroxine and thyroid-stimulating hormone (TSH), Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR), and liver enzymes. Although metabolic markers such as abnormal secretion of cortisol, growth hormone, and thyrotropin-releasing hormone have been useful in confirming major depression in adults, these neurobiologic markers are less reliable in adolescents.

The risk of depression appears to be greatest in families with a history of early onset and chronic depression. Depression of early onset and bipolar illness are more likely to occur in families with a strong multigenerational history of depression. The lifetime risk of depressive illness in first-degree relatives of adult depressed patients has been estimated to be between 18% and 30%.

Treatment

The primary care physician may be able to counsel adolescents and parents if depression is mild or is the result of an acute personal loss or frustration and if the patient is not contemplating suicide or other life-threatening behaviors. If, however, there is evidence of a long-standing depressive disorder, suicidal thoughts, or psychotic thinking, or if the physician does not feel competent or has no interest in counseling the patient, psychological referral should be made.

Counseling involves establishing and maintaining a positive supportive relationship; following the patient at least weekly; remaining accessible to the patient at all times; encouraging the patient to express emotions openly, defining the problem and clarifying negative feelings, thoughts, and expectations; setting realistic goals; helping to negotiate interpersonal crises; teaching assertiveness and social skills; reassessing the depression as it is expressed; and staying alert to the possibility of suicide.

Patients with a clinical course consistent with bipolar disease or those who have a significant depression that is unresponsive to supportive counseling should be referred to a psychiatrist for evaluation of antidepressant medication.

ADOLESCENT SUICIDE (See also Chapter 6.)

In 2000, 3994 people age 15–24 years committed suicide, 1621 suicides among those age 15–19 years and 2378 among those age 20–24 years. In the younger group, males had a suicide rate 5 times higher than females, and white males had the highest rate, 15.5 per 100,000. The incidence of unsuccessful suicide attempts is three times higher in females than in males. The estimated ratio of attempted suicides to actual suicides is estimated to be 100:1–50:1. Firearms account for 67% of suicide deaths in both males and females.

With the normal mood swings of adolescence, short periods of depression are common, and a teenager may have thoughts of suicide. Normal mood swings during this period rarely interfere with sleeping, eating, or participating in normal activities. Acute depressive reactions (transient grief responses) to the loss of a family member or friend may result in depression lasting for weeks or even months. An adolescent who is unable to work through this grief can become increasingly depressed. A teenager who is unable to keep up with schoolwork, does not participate in normal social activities, withdraws socially, has sleep and appetite disturbances, and has feelings of hopelessness and helplessness should be considered to be at increased risk for suicide.

Another group of suicidal adolescents is composed of angry teenagers attempting to influence others by their actions. They may be only mildly depressed and may not have a long-standing wish to die. Teenagers in this group, usually females, may attempt suicide or make a suicidal gesture as a way of getting back at someone or gaining attention by frightening another person.

The last group at risk for suicide are adolescents with a serious psychiatric problem such as acute schizophrenia or a true psychotic depressive disorder.

Risk Assessment

The physician must determine the extent of the teenager's depression and assess the risk of inflicting self-harm. The evaluation should include interviews with both the teenager and the family. The history

should include the medical, social, emotional, and academic background (see Table 6–16). The physician should inquire about

1. Common signs of depression
2. Recent events that could be the cause of an underlying depression
3. Evidence of long-standing problems in the home, at school, or with peers
4. Drug or substance use and abuse
5. Signs of psychotic thinking, such as delusions or hallucinations
6. Evidence of masked depression, such as rebellious behavior, running away from home, reckless driving, or other acting-out behavior.

When seeing depressed patients, the physician should always inquire about thoughts of suicide, for example, by asking, “Are things ever so bad that life doesn’t seem worth living?” If the response is affirmative, a more specific question should be asked, for example, “Have you thought of taking your life?” If the patient has thoughts of suicide, the immediacy of risk can be assessed by determining if the patient has a concrete, feasible plan. Although patients who are at greatest risk have a concrete plan that can be carried out in the near future, especially if they have rehearsed the plan, the physician should not dismiss the potential risk of suicide in the adolescent who does not describe a specific plan. The physician should pay attention to his or her gut feelings. Subtle nonverbal signs may indicate that the patient is at greater risk than may be apparent.

Treatment

The primary care physician is often in a unique position to identify an adolescent at risk for suicide, because many teenagers who attempt suicide seek medical attention in the weeks preceding the attempt. These visits are often for vague somatic complaints. If the patient shows evidence of depression, the physician must assess the severity of the depression and suicidal risk. The pediatrician should always seek emergency psychological consultation for any teenager who is severely depressed, psychotic, or acutely suicidal. It is the psychologist’s or psychiatrist’s responsibility to assess the seriousness of suicidal ideation and decide whether hospitalization or out-patient treatment is most appropriate. Adolescents with mild depression and at low risk for suicide should be followed closely, and the extent of the depression should be assessed on an ongoing basis. If at any point it appears that the patient is worsening or the teenager is not responding to supportive counseling, referral should be made.

SUBSTANCE ABUSE

Substance abuse is a complex problem for adolescents and the broader society. See Chapter 4 for an in-depth look at this issue.

EATING DISORDERS (See Chapter 5.)

EXOGENOUS OBESITY (See Chapter 10: Normal Childhood Nutrition & Its Disorders)

Overweight, or at risk for obesity, is defined as body mass index (BMI) greater than the 85th percentile for age (Figures 3–5 and 3–6). It is important to note that mean BMI changes dramatically with age. For a 13-year-old, a BMI greater than 25 constitutes obesity, whereas in adolescents older than 18, the adult standard of BMI greater than 30 accurately defines obesity (Figure 3–7).

Background

Recent data from the National Health and Nutrition Examination Survey (NHANES)-IV showed an increase in obesity in adolescents ages 12–19 from 5% in 1966–1970 to 14% in 1999. The changes in BMI during and after adolescence have been shown to be important predictors of adult adiposity. In general, the longer a child remains obese, the more likely obesity will persist into adulthood. The medical risks associated with obesity are discussed in Chapter 10. The psychosocial hazards of obesity tend to be the greatest consequence for adolescents, who may experience alienation, distorted peer relations, poor self-esteem, guilt, depression, or altered body image.

Figure 3–7. Nomogram for determining body mass index (BMI) from height and weight. A straight-edge connecting weight and height allows one to read BMI (weight in kg ÷ [height in m²]). The three dots on the left side of the BMI line represent 50th percentile values for females age 20 years (top), 15 years (middle), and 10 years (bottom). The dots on the right side are for similar-aged males. (Reproduced, with permission, from Forbes GR: Nutrition and growth. In: McAnarney ER et al [eds]: *Textbook of Adolescent Medicine*. WB Saunders, 1992.)

Diagnosis

An adolescent with a BMI above the 85th percentile is considered at risk for obesity; BMI above the 95th percentile is considered obese. Patients can be identified as at risk for obesity based on current weight relative to height, growth and weight trend, and weight of family members. In addition, the provider needs to assess a patient's readiness to make lifestyle changes. When obesity is diagnosed, the following database can be col-

lected: height; weight; BMI; blood pressure; condition of the skin, thyroid, heart, and abdomen; hematocrit; and urinalysis. Acanthosis nigricans is a cutaneous finding characterized by velvety hyperpigmentation, most prominent behind the neck, in the axilla, and in the groin. Acanthosis is more commonly seen in dark-skinned persons and is a marker for insulin resistance. Endocrine causes of obesity, such as hypothyroidism and Cushing disease, can generally be excluded on the basis of the history and physical examination. If an adolescent is healthy and has no delay of growth or sexual maturation, an underlying endocrinologic, neurologic, or genetic cause is unlikely.

Treatment

Poorly motivated adolescents may be alienated by an aggressive discussion of weight loss. Instead, providers may give basic information about healthy diet and regular exercise and be available for future visits if patients become interested in weight loss. For the highly motivated patient, treatment should be appropriate to age and developmental level. The adolescent should be taught appropriate eating and exercise habits to maintain weight reduction yet meet nutritional needs for growth and development. You may be more likely to engage the average adolescent by helping him or her to choose concrete, obtainable goals (eg, decreasing soda from three to two per day, or walking with a friend 3 days a week instead of watching television). Appetite-suppressing drugs, fasting, and bypass surgery have no role in the management of obese adolescents unless severe comorbidities of obesity are present. An age-appropriate behavior modification program incorporating good dietary counseling and exercise is optimal. Studies indicate that increased activity may be more important than dietary changes in long-term weight management. Lifestyle activity recommendations, such as walking and taking the stairs, may be more effective in the long run than regimented exercise programs. Avoiding labeling any food as "forbidden" may improve long-term success with healthy eating behaviors. Behavioral treatment involving parents has been shown to improve long-term maintenance of weight loss in children; parental involvement in adolescent weight loss programs has shown mixed results. In general, the most important factor in successful weight loss and weight maintenance is motivation of the adolescent. Monthly follow-up visits may help to maintain motivation, especially initially. Unfortunately, no program has been proven effective for long-term weight reduction.

SCHOOL AVOIDANCE

Any teenager who has missed more than 1 week of school for a physical illness or symptom, and whose clinical picture is inconsistent with a serious illness, should be suspected of harboring primary or secondary emotional factors that contribute to the absence. Investigation of absences may show a pattern, such as missing morning classes or missing the same days at the beginning or end of the week. Emotional factors for school absenteeism are usually attributed to physical symptoms in this age group.

School avoidance should be suspected in children who are consistently absent in spite of parents' and professionals' attempts to encourage school attendance. Adolescents with school avoidance problems often have a history of excessive absences or separation difficulties as a younger child. They may also have a record of recurrent somatic complaints. Parents of a school avoider often feel helpless to compel their adolescent to attend school, may lack the sophistication to distinguish malingering from illness, or may have an underlying need to keep the teenager at home.

A complete history and physical examination should be performed, reviewing the patient's medical, educational, and psychiatric history. Signs of emotional problems should be explored. After obtaining permission from the patient and parents, the physician may find it helpful to speak directly with school officials and some key teachers. The adolescent may be having problems with particular teachers or subjects or experiencing adversity at school (eg, schoolyard bullying, an intimidating instructor). Some students get so far behind academically that they see no way of catching up and feel overwhelmed. Separation anxiety, sometimes of long duration, may be manifested in subconscious worries that something may happen to the mother while the teenager is at school.

The school nurse may give useful information, including the number of visits to the nurse during the last school year. An important part of the history is how the parents respond to the absences and somatic complaints. The parent(s) may be making a subconscious attempt to keep the adolescent at home, which may be coupled with secondary gains for the patient, such as increased parental attention.

Treatment

The importance of returning to school quickly after a period of school avoidance needs to be emphasized. The pediatrician should facilitate this process by offering to speak with school officials to excuse missed examina-

tions, homework, and papers. The pediatrician should speak directly with teachers who are punitive. The objective is to make the transition back to school as easy as possible. The longer adolescents stay out of school, the more anxious they may become about returning and the more difficult the return becomes. If an illness or symptom becomes so severe that an adolescent cannot go to school, the patient and the parents must be informed that a visit to a medical office is necessary. The physician focuses visits on the parents as much as on the adolescent to alleviate any parental guilt about sending the child to school. If the adolescent cannot stay in school, hospitalization should be recommended for an in-depth medical and psychiatric evaluation. Parents should be cautioned about the possibility of relapse after school holidays, summer vacation, or an acute illness.

Klerman LV: School absence: A health perspective. *Pediatr Clin North Am* 1988;35:1253 [PMID: 3059298].

SCHOOL FAILURE

When children graduate from grade school to middle school or junior high school, the amount and complexity of course work increase significantly. This occurs at about the same time as the rapid physical, social, and emotional changes of puberty. To perform well academically, young adolescents must have the necessary cognitive capacity, study habits, concentration, motivation, interest, and emotional focus. Academic failure presenting at adolescence has a broad differential:

1. Limited intellectual abilities
2. Specific learning disabilities
3. Depression or emotional problems
4. Physical causes such as visual or hearing problems
5. Excessive school absenteeism secondary to chronic disease such as asthma or neurologic dysfunction
6. Lack of ability to concentrate
7. Attention-deficit/hyperactivity disorder
8. Lack of motivation
9. Drug and alcohol problems.

Each of these possible causes must be explored in depth (Table 3-1). Evaluation of this differential requires a careful history, physical examination, and appropriate laboratory tests as well as standardized educational and psychological testing.

Treatment

Treatment depends on the cause. Management must be individualized to address specific needs, foster strengths, and implement a feasible program. For children with specific learning disabilities, an individual prescription

Table 3–1. A classification of common developmental dysfunctions in adolescence.

Dysfunction	Subtypes	Frequent Manifestations ^a
1. Attention deficits	a. Primary b. Secondary (to anxiety or poor information processing) c. Situational (only evident in certain settings)	Weak attention to detail; distractibility; impulsivity, restlessness; task impersistence; performance inconsistency; organizational problems; reduced working capacity
2. Memory impairments	a. Generalized retrieval problems b. Modality-specific retrieval problems c. Attention-retention deficiencies	Deficient, undependable, or slow recall of data from long- or short-term memory Problems with revisualization or auditory, motor, or sequential recall Poor recall associated with superficial initial registration
3. Language disorders	a. Receptive b. Expressive	Poor verbal and reading comprehension; poor listening; trouble following directions and explanations Problems with word finding, sentence formulation Difficulty with written expression
4. Higher-order cognitive disabilities	a. Inferential weakness b. Poor verbal reasoning c. Poor nonverbal reasoning d. Difficulty with abstraction, symbolization e. Weak generalization and rule application	Problems understanding and assimilating new concepts; tendency to think “concretely,” delays in mathematics, reading comprehension, science, social studies
5. Fine motor incoordination	a. Eye:hand coordination problems b. Impaired proprioceptive feedback c. Dyspraxia d. Motor memory impairment	Slow, labored, sometimes illegible writing; awkward pencil grip; dyssynchrony between cognitive tempo and writing speed; output failure—reduced productivity
6. Organizational deficiencies	a. Temporal-sequential disorientation b. Material disarray c. Integrative dysfunction d. Resynthesis problems e. Attentional disorganization	Problems with time allocation, schedules, planning, arranging ideas in writing Tendency to lose, misplace, forget books, papers; trouble organizing notebook Varying inability to integrate data from multiple sources or sensory modalities Trouble extracting most salient details, retelling and adapting data to current demands Impulsivity, erratic tempo, poor self-monitoring, careless errors
7. Socialization disabilities	a. Wide range of subtypes, including conduct disorder, social impulsivity, impaired social cognition or feedback, egocentricity	Antisocial behaviors; delinquency; withdrawal; excessive dependency on peer support

^aManifestations are likely to vary somewhat depending on compensatory strengths, quality of educational experience, and motivation. Modified and reproduced, with permission, from Levine MD, Zallen BG: Learning disorders of adolescence. *Pediatr Clin North Am* 1984;31:2.

for regular and special education courses, teachers, and extracurricular activities is important. Counseling helps these adolescents gain coping skills, raise self-esteem, and develop socialization skills. If the patient has a history of hyperactivity or attention deficit disorder along with poor ability to concentrate, a trial of stimulant medication (eg, methylphenidate, dextroamphetamine) may be useful. If the teenager appears to be depressed or if other serious emotional problems are uncovered, further psychological evaluation should be recommended.

BREAST DISORDERS

The breast examination should become part of the routine physical examination in girls as soon as breast budding occurs. The preadolescent thus comes to accept breast examination as a routine part of health care, and the procedure serves as an opportunity to offer reassurance about any concerns she may have. The breast examination begins with inspection of the breasts for symmetry and Tanner or sexual maturity rating (SMR) stage. Asymmetrical breast development is common, especially in young adolescents, and is generally transient, although 25% of women may continue to have some degree of asymmetry into adulthood. Unusual causes of breast asymmetry include unilateral breast hypoplasia, amastia, absence of the pectoralis major muscle, and unilateral virginal hypertrophy (massive enlargement of the breast during puberty).

Palpation of the breasts can be performed with the patient in the supine position and the patient's ipsilateral arm placed behind her head. The examiner palpates the breast tissue with the flat of the fingers in concentric circles from the sternum, clavicle, and axilla in to the areola. The areola should be compressed gently to check for discharge.

Instructions for breast self-examination and its purpose can be given to older adolescents approaching age 18 years during this portion of the physical examination, and the patient should be encouraged to begin monthly self-examination after each menstrual flow after age 18 years. Because the vast majority of breast lesions in teens are benign, teaching young adolescents breast self-examination may lead to unnecessary anxiety and overconcern with normal variants.

BREAST MASSES

Most breast masses in adolescents are benign (Table 3–2); however, cancer does occasionally occur in adolescents. A large study in Greece of 684 females ages 14–20 with breast masses showed only 2.5% to be malignant. The malignant cases included hemangiosarcoma, rhabdomyosarcoma, ductal carcinoma, cystosarcoma phyllodes, and metastatic tumor.

Fibroadenoma

Fibroadenoma (which accounts for approximately two-thirds of all breast masses in adolescents) presents as a rubbery, well-demarcated, slowly growing, nontender

Table 3–2. Breast masses in adolescent females.

Common
Fibroadenoma
Fibrocystic changes
Breast cysts
Breast abscess/mastitis
Less common or rare (benign)
Lymphangioma
Hemangioma

Rhabdomyosarcoma
Lymphosarcoma
Hemangiosarcoma
Metastatic cancer

mass that may occur in any quadrant, but is most commonly found in the upper outer quadrant. The average size is 2–3 cm in diameter. In 10–25% of cases, multiple or recurrent lesions occur. Quiescence can be expected after the teenage years.

Cysts

Breast cysts are generally tender and spongy, with exacerbation of symptoms premenstrually and improvement after menses. Often they are multiple. Spontaneous regression occurs over two or three menstrual cycles in about 50% of cases.

It is reasonable to follow breast masses that are consistent with fibroadenoma or cyst in adolescents for two or three menstrual cycles. Approximately 25% of fibroadenomas become smaller, and approximately 50% of cysts resolve. If a presumed fibroadenoma does not change after this time, ultrasound will differentiate a solid tumor from a cyst. Patients with solid tumors larger than 2.5 cm in diameter should be referred for fine-needle aspiration or excisional biopsy. Those with tumors less than 2.5 cm in diameter may be followed every 3–6 months, because many of these tumors will shrink or remain the same. Persistent cystic lesions may be drained by needle aspiration. Patients with suspicious lesions should be referred immediately to a breast surgeon (Table 3–3).

Table 3–3. Breast lesions.

Fibroadenoma	Rubbery, well demarcated, nontender, slowly growing; most commonly found in the upper outer quadrant of the breast. Usually < 5 cm.
Adenocarcinoma	Hard, nonmobile, well-circumscribed, painless mass; generally indolent clinical course; occurs also in males but less frequently.
Cystosarcoma phyllodes	Firm, rubbery mass that may suddenly enlarge; associated with skin necrosis; most often benign.
Giant juvenile fibroadenoma	Remarkable large fibroadenoma with overlying dilated superficial veins; accounts for 5–10% of fibroadenomas in adolescents; benign but requires excision to prevent breast atrophy and for cosmetic reasons.
Intraductal papilloma	A cylindric tumor arising from the ductal epithelium; often subareolar but may be in the periphery of the breast in adolescents, with associated nipple discharge. Most are benign but require excision for cytologic diagnosis.
Fat necrosis	Localized inflammatory process in one breast; follows trauma in about half of cases. Subsequent scarring may be confused with cancer.
Virginal or juvenile hypertrophy	Massive enlargement of both breasts or, less often, one breast; attributed to end-organ hypersensitivity to normal hormonal levels just before or within a few years after menarche.
Miscellaneous	Fibroma, galactocele, hemangioma, intraductal granuloma, interstitial fibrosis, keratoma, lipoma, granular cell myoblastoma, papilloma, sclerosing adenosis.

Fibrocystic Breasts

Fibrocystic breast disease sometimes occurs in older adolescents and becomes more common with age. It is characterized by cyclic tenderness and nodularity bilaterally and is believed to be influenced by the estrogen–progesterone balance.

Reassuring the young woman about the benign nature of the process and emphasizing the importance of breast self-examination as she becomes an adult may be all that is needed. Support bras may provide sympto-

matic relief. Oral contraceptives (OCPs) often improve symptoms. Studies have shown no association between methylxanthines and fibrocystic breasts; however, some women report reduced symptoms when they discontinue caffeine intake. The efficacy of vitamins E, B₁, and A is unknown. Evening primrose oil has been beneficial in 44% of patients. A trial of 1000 mg three times a day for 3 months may be helpful.

Breast Abscess

The female with a breast abscess usually complains of unilateral breast pain, and examination reveals overlying inflammatory changes. Often the examination is misleading in that the infection may extend much deeper than suspected. A palpable mass is found only late in the course. Although breast feeding is the most common cause of mastitis, trauma and eczema involving the areola are frequent factors in teenagers. *Staphylococcus aureus* is the most common pathogen, but other aerobic and anaerobic organisms have also been implicated.

Cyclic mastodynia, fibrocystic disease, or chest wall pain may also be causes of breast pain, but no associated inflammatory signs should be present.

Fluctuant abscesses should be surgically incised and drained. Oral antibiotics with appropriate coverage (dicloxacillin or a cephalosporin) should be given for 2–4 weeks. Ice packs for the first 24 hours and heat thereafter may relieve symptoms.

GALACTORRHEA

In teenagers, galactorrhea is most often benign; however, a careful history and work-up are necessary. Prolactinomas are the most common pathologic cause of galactorrhea in adolescents of both sexes and generally present as amenorrhea or failure of sexual maturation. Hypothyroidism is the second most common cause in the adolescent years but has been reported only in girls, usually prepubertally.

Galactorrhea may be present after spontaneous or induced abortions as well as postpartum. Numerous prescribed and illicit drugs are associated with galactorrhea (Table 3–4). In addition, stimulation of the intercostal nerves (following surgery or due to herpes zoster infection), stimulation of the nipples, CNS disorders (hypothalamic injury), or significant emotional distress may produce galactorrhea.

Clinical Findings

If the teenager has no history of pregnancy or drug use, TSH and serum prolactin levels should be determined. An elevated TSH confirms the diagnosis of hypothy-

roidism. An elevated prolactin and normal TSH, often accompanied by amenorrhea, suggest a hypothalamic or pituitary tumor, and magnetic resonance imaging (MRI) scan is indicated. When the prolactin level is normal, uncommon causes such as adrenal, renal, or ovarian tumors should be considered. Males with a negative work-up and normal puberty need to be followed intensively. Males with elevated prolactin levels require an MRI scan every 12–18 months even if the galactorrhea resolves, because of the significant risk of a small pituitary adenoma that may become apparent with serial examinations.

Treatment

Treatment depends on the underlying cause. Prolactinomas may be removed surgically or suppressed with bromocriptine. Bromocriptine may also be beneficial to some amenorrheic females with normal serum prolactin levels. The female with a negative work-up and persistent galactorrhea may be followed with menstrual history and serum prolactin level every 6–12 months. In many cases, symptoms resolve spontaneously and no diagnosis is made. The female with an elevated serum prolactin concentration but negative prolactinoma work-up may be treated with bromocriptine if her symptoms are bothersome or may be observed with MRI scan every 1–2 years for several years.

GYNECOMASTIA

Gynecomastia is a common concern of male adolescents, most of whom (60–70%) develop transient subareolar breast tissue during SMR stages 2 and 3. Proposed causes include testosterone–estrogen imbalance, increased serum prolactin level, and abnormal serum protein binding levels.

Clinical Findings

In type I idiopathic gynecomastia, the adolescent presents with a unilateral (20% bilateral) tender, firm mass beneath the areola. More generalized breast enlargement is classified as type II. Pseudogynecomastia is the term for excessive fat tissue or prominent pectoralis muscles.

Differential Diagnosis

Gynecomastia may be drug-induced (Table 3–5). Testicular, adrenal, or pituitary tumors, Klinefelter syndrome, primary hypogonadism, thyroid or hepatic dysfunction, or malnutrition may also be associated with gynecomastia (Table 3–6). Onset of gynecomastia in late (rather than early or middle) adolescence is more likely indicative of pathology.

Treatment

If gynecomastia is idiopathic, reassurance about the common and benign nature of the process can be given. Resolution may take up to 2 years. Medical reduction has been achieved with pharmacotherapeutic agents, such as dihydrotestosterone, danazol, clomiphene, and tamoxifen, but these agents should be reserved for patients in whom no decrease in breast size occurs after 2 years. Surgery is reserved for those with significant psychological trauma or severe breast enlargement.

■ GYNECOLOGIC DISORDERS IN ADOLESCENCE

PHYSIOLOGY OF MENSTRUATION

The ovulatory menstrual cycle is divided into three consecutive phases: follicular (the first 14 days), ovulatory (midcycle), and luteal (days 16–28). During the follicular phase, pulsatile GnRH from the hypothalamus stimulates anterior pituitary secretion of FSH and LH. Under the influence of FSH and LH, a dominant ovarian follicle emerges by days 5–7 of the menstrual cycle, and the other follicles become atretic. Rising estradiol levels produced by the maturing follicle cause proliferation of the endometrium. By the midfollicular phase, FSH is beginning to decline secondary to estradiol-mediated negative feedback, whereas LH continues to rise as a result of estradiol-mediated positive feedback.

The rising LH initiates progesterone secretion and luteinization of the granulosa cells of the follicle. Progesterone in turn further stimulates LH and FSH. This leads to the LH surge, which causes the follicle to rupture and expel the oocyte.

During the luteal phase, LH and FSH gradually decline. The corpus luteum secretes progesterones. The endometrium enters the secretory phase in response to rising levels of estrogen and progesterone, with maturation 8–9 days after ovulation. If no pregnancy occurs or placental human chorionic gonadotropin (HCG) is released, luteolysis begins; estrogen and progesterone levels decline; and the endometrial lining is shed as menstrual flow approximately 14 days after ovulation (Figure 3–8).

During the first 2 years after menarche, the majority of cycles are anovulatory (50–80%). Between 10% and 20% of cycles remain anovulatory for up to 5 years after menarche.

PELVIC EXAMINATION

A pelvic examination may be indicated to evaluate abdominal pain or menstrual disorders or to detect a suspected STI in the adolescent. It has previously been recommended that a routine pelvic examination be done at age 18 years to obtain the first Papanicolaou (Pap) smear and to evaluate reproductive anatomy. Recently recommendations have changed to delay the first Pap smear until age 21 years in the absence of menstrual problems in patients who have never had intercourse. The first Pap smear should be performed within 3 years of the initiation of sexual activity. Pap smears should be performed earlier in adolescents with a history of sexual abuse with penile penetration. The adolescent may be apprehensive about the first examination. It should not be rushed, and an explanation of the procedure and its purpose should precede it. The patient can be encour-

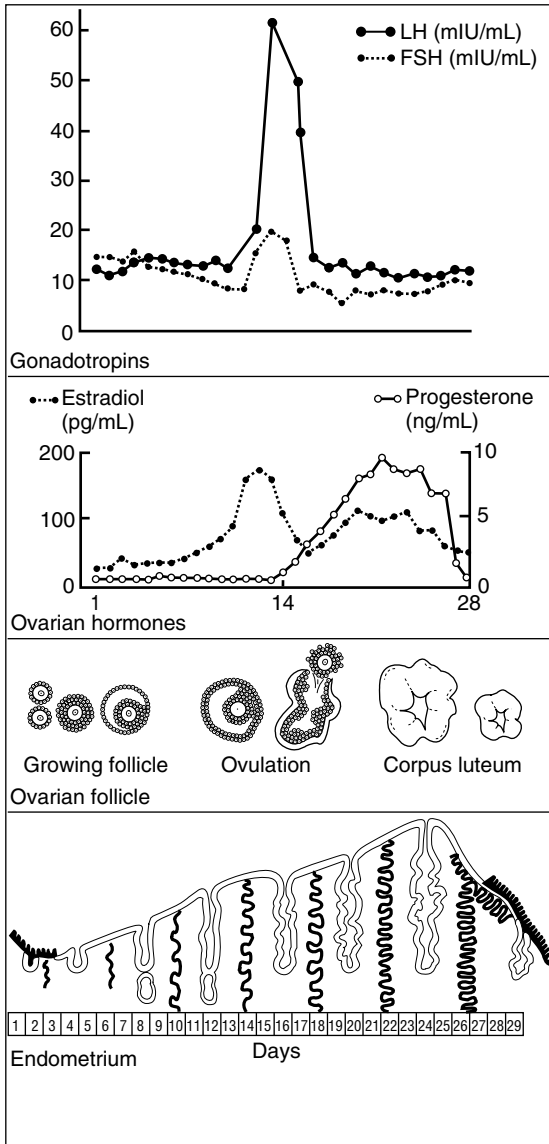

Figure 3-8. Physiology of the normal ovulatory menstrual cycle; gonadotropin secretion, ovarian hormone production, follicular maturation, and endometrial changes during one cycle. FSH = follicle-stimulating hormone, LH = luteinizing hormone. (Reproduced, with permission, from Emans SJH et al: *Pediatric and Adolescent Gynecology*, 4th ed. Little, Brown, 1998.)

aged to relax by slow, deep breathing and by relaxation of her lower abdominal and inner thigh muscles. A young adolescent may wish to have her mother present during the examination, but the history should be taken privately. A female chaperone should be present with male examiners.

The pelvic examination begins by placing the patient in the dorsal lithotomy position after equipment and supplies are ready (Table 3-7). The examiner inspects the external genitalia, noting the pubic hair maturity rating, the size of the clitoris (2-5 mm is normal), Skene glands just inside the urethral meatus, and Bartholin glands at 4 o'clock and 8 o'clock outside the hymenal ring. In cases of alleged sexual abuse or assault, the horizontal measurement of the relaxed prepubertal hymenal opening should be recorded and the presence of any lacerations, bruises, scarring, or synechiae about the hymen, vulva, or anus should be noted.

A vaginal speculum is then inserted at a 45-degree twist and angled 45 degrees downward. (A medium Pedersen speculum is most often used in sexually experienced patients; a narrow Huffman is used for virginal patients.) The vaginal walls are inspected for estrogen effects, inflammation, or lesions. The cervix should be dull pink. Cervical ectropion is commonly observed in adolescents; the columnar epithelium extends outside the cervical os onto the face of the cervix until later adolescence, when it recedes.

Specimens are obtained, including a wet preparation for leukocytes, trichomonads, and clue cells (vaginal epithelial cells stippled with adherent bacteria); potassium hydroxide (KOH) preparation for yeast and whiff test; cervical swab for gonorrhea and *Chlamydia*; and endocervical and cervical samples for Pap smear. A cervical brush provides a higher yield of cells for the endocervi-

 - Lubricant
 - Kleenex
-

cal Pap slide. Pap smears should be interpreted by a cytopathologist at a laboratory using the Bethesda system of classification.

The speculum is then removed, and bimanual examination is performed to assess uterine size and position, adnexal enlargement or tenderness, or cervical motion tenderness. Bimanual examination may reveal beading in the adnexa secondary to endometriosis.

MENSTRUAL DISORDERS

1. Amenorrhea

Amenorrhea is the lack of onset of menses when normally anticipated. Primary amenorrhea is no menstrual periods or secondary sex characteristics by age 14 years or no menses in the presence of secondary sex characteristics by age 15 years. Constitutional delay is normal pubertal progression at a delayed onset or rate. Secondary amenorrhea is defined as the absence of menses for at least three cycles after regular cycles have been present. In some instances, evaluation should begin immediately, without waiting for the specified age or duration of lapsed periods, such as in patients with suspected pregnancy, short stature with the stigmata of Turner syndrome, or an anatomic defect.

Evaluation for Primary Amenorrhea

Primary amenorrhea may be the result of anatomic abnormalities, chromosomal deviations, or physiologic delay (Table 3–8).

The history should include whether puberty has commenced, level of exercise, nutritional intake, presence of stressors, and the age at menarche for female relatives. Adrenal androgens are largely responsible for axillary and pubic hair; estrogen is responsible for breast development, maturation of the external genitalia, vagina, and uterus, and menstruation.

A careful physical examination should be done, noting the percentage of ideal body weight for height and age, SMR stage, vaginal patency, presence of the uterus (assessed through rectoabdominal examination or ultrasonography if pelvic examination is not appropriate), signs of virilization (acne, clitoromegaly of > 5 mm, hirsutism), or stigmata of Turner syndrome (< 152 cm tall, shield-like chest, widely spaced nipples, increased carrying angle of the arms, webbed neck). If pelvic examination reveals normal female external genitalia and pelvic organs, the patient should be given a challenge of medroxyprogesterone, 10 mg orally bid for 5 days (or 10 mg/d for 7–10 days) (Figure 3–9). If withdrawal bleeding occurs within 7 days after administration of medroxyprogesterone, normal anatomy and adequate estrogen effect are implied. If physical examination reveals an absent uterus

Table 3–8. Causes of amenorrhea.

Hypothalamic–pituitary axis

 - Tuberculosis, brucellosis

Defect in hormone synthesis or action (virilization may be present)

- Adrenal hyperplasia^a
- Cushing disease
- Adrenal tumor
- Ovarian tumor (rare)
- Drugs (steroids, ACTH)

^aIndicates condition that usually presents as primary amenorrhea. ACTH = adrenocorticotropic hormone.

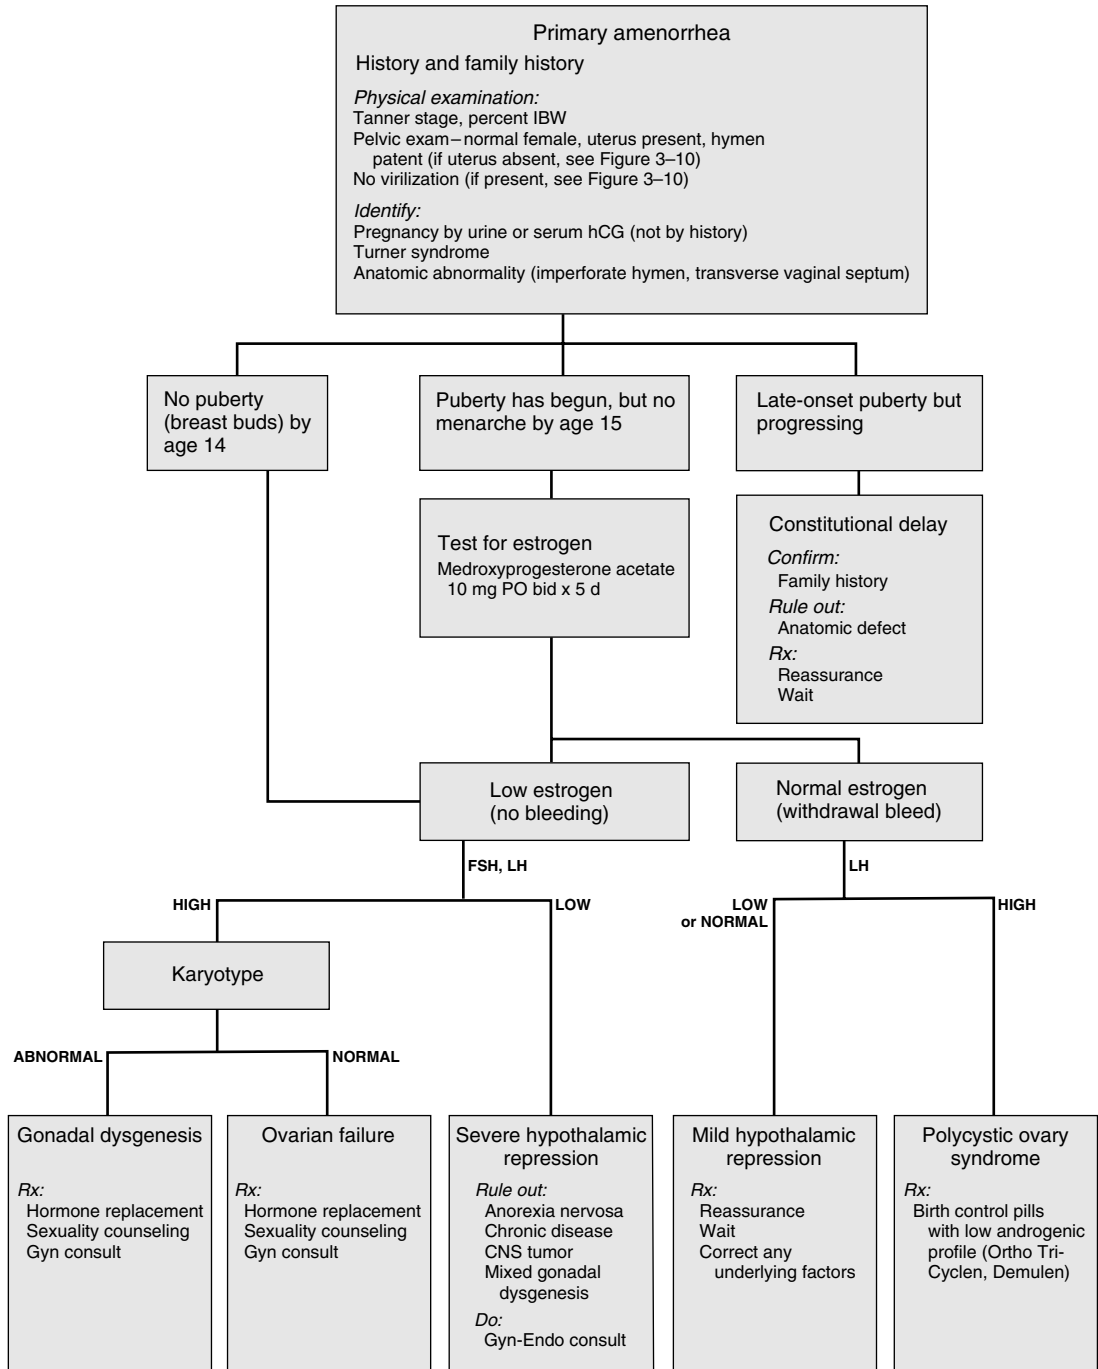

Figure 3–9. Evaluation of primary amenorrhea in a normal female. FSH = follicle-stimulating hormone, IBW = ideal body weight, LH = luteinizing hormone.

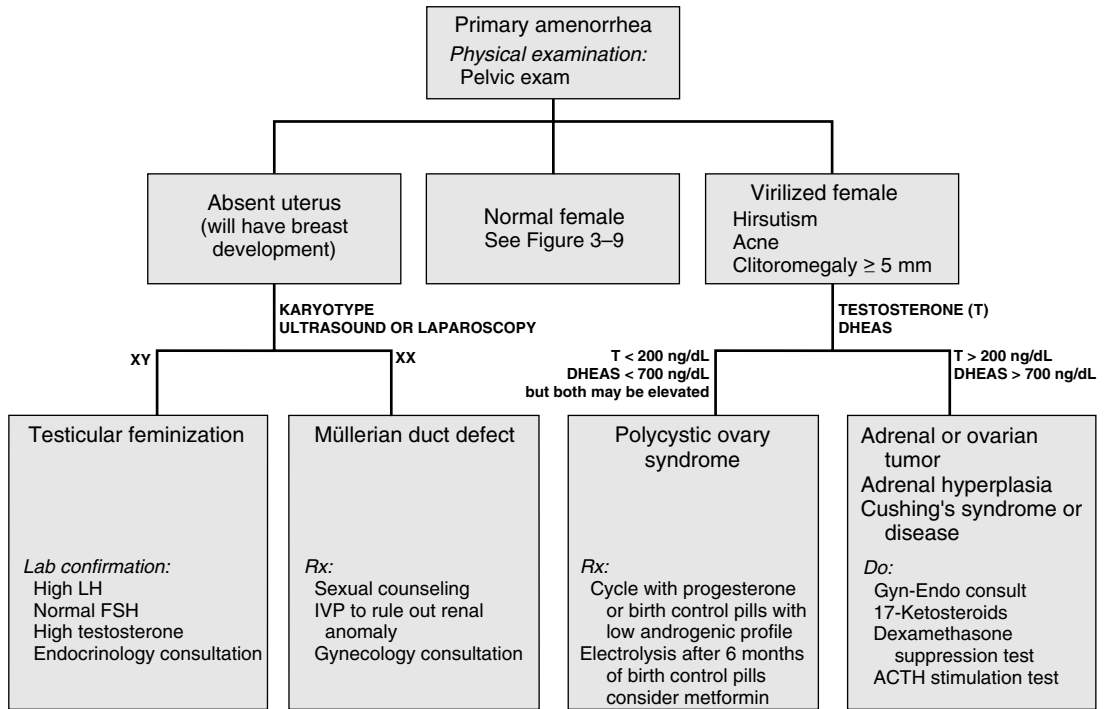

Figure 3–10. Evaluation of primary amenorrhea in a female without a uterus or with virilization. ACTH = adrenocorticotropic hormone, DHEAS = dehydroepiandrosterone sulfate, FSH = follicle-stimulating hormone, IVP = intravenous pyelogram, LH = luteinizing hormone.

(Figure 3–10), karyotyping should be performed to differentiate testicular feminization from müllerian duct defect, because these two entities are managed differently.

Laboratory studies should include CBC, ESR, and TSH. If systemic illness is suspected, a urinalysis and a chemistry panel including renal and liver function tests should be obtained. If short stature is present, a bone age should be done. If the diagnosis remains unclear after preliminary evaluation, or if no withdrawal bleed occurs after a medroxyprogesterone challenge, FSH, LH, and prolactin levels should be obtained. Low levels of gonadotropins indicate a more severe hypothalamic suppression, caused by anorexia nervosa, chronic disease, or a CNS tumor. Involvement of a gynecologist or endocrinologist is helpful at this point. If gonadotropin levels are high, ovarian failure or gonadal dysgenesis is implied, and karyotype should be obtained.

Evaluation & Treatment of Secondary Amenorrhea

Secondary amenorrhea results when estrogen stimulation is unopposed, maintaining the endometrium in

the proliferative phase. The most common causes are pregnancy, stress, and polycystic ovary syndrome (PCOS). Ovarian failure can also present as secondary amenorrhea, caused by mosaic Turner syndrome or autoimmune oophoritis.

The history should focus on issues of stress, chronic illness, drugs, weight change, strenuous exercise, sexual activity, and contraceptive use. A review of systems should include questions about headaches, visual changes, hirsutism, constipation, cold intolerance, and galactorrhea.

Physical examination should include ophthalmoscopic and visual field examination, palpation of the thyroid, determination of blood pressure and heart rate, compression of the areola to check for galactorrhea, and a search for signs of androgen excess (eg, hirsutism, clitoromegaly, severe acne, ovarian enlargement).

The first laboratory study obtained is a pregnancy test, even if the patient denies sexual activity. If the teenager is not pregnant, a progesterone challenge (medroxyprogesterone, 10 mg orally bid for 5 days or 10 mg/d for 7–10 days) should be done to determine whether the uterus is primed with estrogen (Figure 3–11).

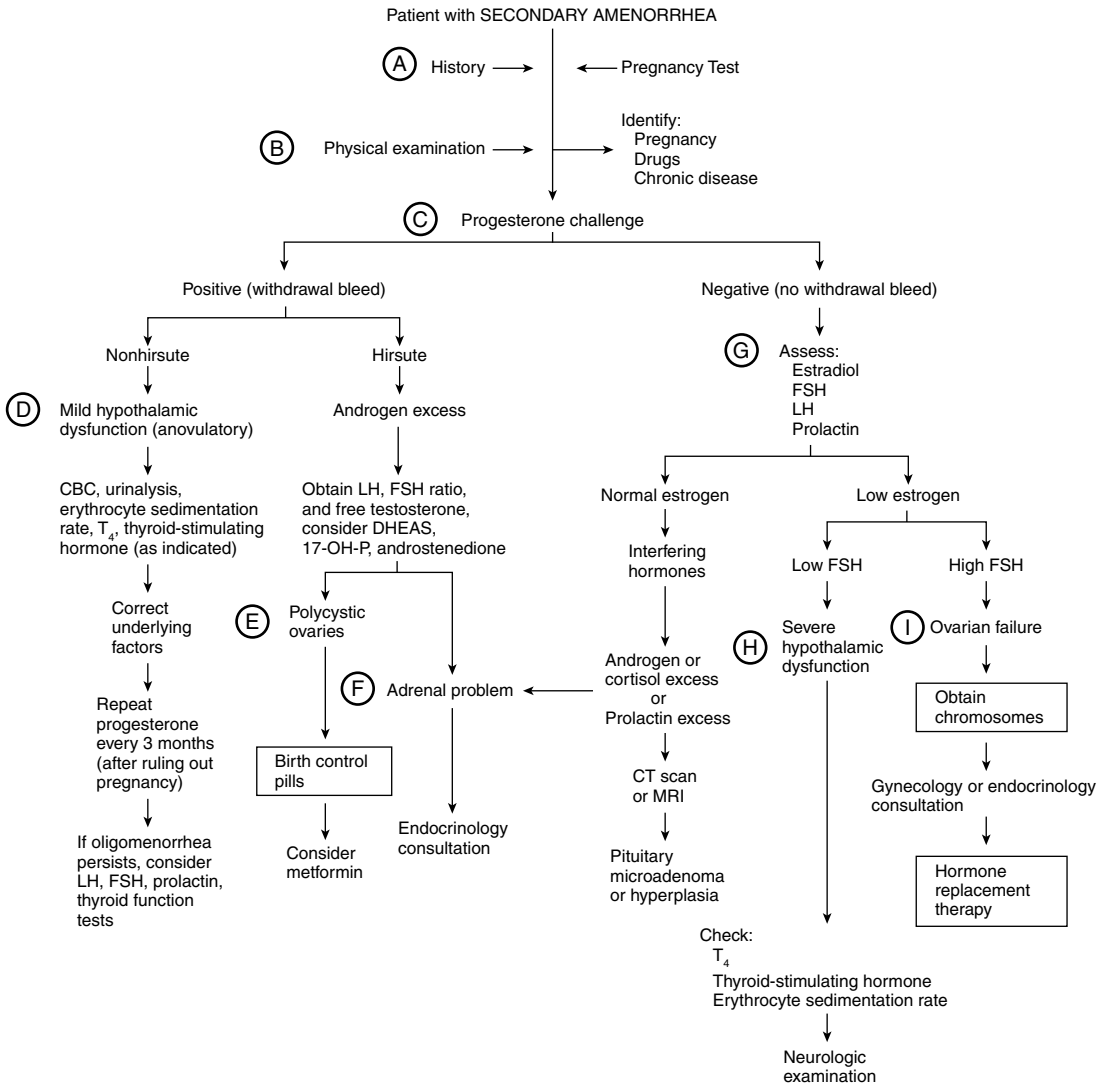

Figure 3–11. Evaluation of secondary amenorrhea. CBC = complete blood count, DHEAS = dehydroepiandrosterone sulfate, FSH = follicle-stimulating hormone, LH = luteinizing hormone, T₄ = thyroxine.

Most patients who have withdrawal flow after progesterone challenge have mild hypothalamic suppression due to weight change, athletics, stress, or illness; however, disorders such as PCOS, adrenal disorders, ovarian tumors, thyroid disease, and diabetes mellitus should be excluded by history and physical examination and appropriate laboratory studies. (See section on Primary Amenorrhea and Figure 3–11.)

If withdrawal flow occurs after the progesterone challenge (see Figure 3–11), serum levels of estradiol,

FSH, LH, and prolactin should be checked. An elevated FSH level accompanied by a low estrogen level implies ovarian failure, in which case blood for karyotype and anti-ovarian antibodies (if the karyotype is normal) should be obtained and laparoscopy considered. If gonadotropin levels are low or normal and the estradiol level is low, hypothalamic amenorrhea is likely; however, one must consider the possibilities of a CNS tumor (prolactinoma or craniopharyngioma), pituitary infarction from postpartum hemorrhage or

sickle cell anemia, uterine synechiae, or chronic disease. Further evaluation may be necessary.

If signs of virilization are present (see Figure 3–10), determining levels of free testosterone, 17-hydroxyprogesterone, and dehydroepiandrosterone sulfate (DHEAS) will help to distinguish PCOS from adrenal causes of virilization and amenorrhea. Although elevation of testosterone and DHEAS may occur in patients with PCOS, the elevation is not as dramatic as with androgen-producing adrenal or ovarian tumors, adrenal hyperplasia, or Cushing syndrome. Endocrinologic consultation will assist in differentiating the cause of significantly elevated androgens.

PCOS is a spectrum of disorders accompanied by symptoms of obesity, insulin resistance, hirsutism, acne, oligomenorrhea, and infertility. PCOS is very common, with a prevalence estimated at 5–10%. Although a classic LH:FSH ratio of greater than 2.5:1 is described in PCOS, up to 40% of patients do not have elevated LH levels. Because of insufficient FSH, androstenedione cannot be converted to estradiol in the ovarian follicle, and anovulation and production of excess androgens result. Thus another term for PCOS is functional hyperandrogenic anovulation.

Oral contraceptive pills containing a low androgenic progestin (desogestrel or norgestimate) such as Desogen or Ortho Tri-Cyclen help to regulate menses and improve acne and hirsutism. Patients who do not wish to take an oral contraceptive pill can be given progesterone, 10 mg daily, for the first 10 days of each month to allow withdrawal flow; however, this treatment does not suppress ovarian androgen production. Hirsute patients should have a lipid profile checked, because PCOS patients have an increased risk of dyslipidemias. OCPs may reduce terminal hair growth, but antiandrogens such as spironolactone reduce the growth and diameter of terminal hair and may be useful for more severe hirsutism. Weight loss in obese patients helps to suppress ovarian androgen production. Insulin sensitizing medications, such as metformin, have been shown in recent studies to improve menstrual regularities in adolescents with PCOS.

2. Dysmenorrhea

Dysmenorrhea is the most common gynecologic complaint of adolescent girls, with an incidence of about 80% by age 18 years. Yet many teenage girls do not seek help from a physician, relying instead on female relatives, friends, and the media for advice. Therefore, the physician should ask about menstrual cramps when taking a review of systems.

Dysmenorrhea can be divided into primary and secondary dysmenorrhea on the basis of whether underlying pelvic disease exists (Table 3–9). Primary dysmen-

orrhea accounts for 80% of cases of adolescent dysmenorrhea and most often affects women younger than age 25 years.

Pelvic examination is normal in females with primary dysmenorrhea. The pelvic examination has diagnostic benefits and provides an opportunity to educate and reassure the patient about her normal reproductive function. However, if the patient has never been sexually active and the history is consistent with primary dysmenorrhea, a trial of a nonsteroidal anti-inflammatory drug (NSAID) is justified. Patients should be instructed to begin NSAIDs at the first sign of menses or dysmenorrhea and continue them for 2–3 days. Recommended doses are ibuprofen 400–800 mg every 6 hours or naproxen (220–550 mg) twice a day. If the patient does not respond to NSAIDs, oral contraceptive pills are an effective treatment for primary dysmenorrhea. If patients do not respond to either of these treatments, secondary dysmenorrhea is more likely and a pelvic examination is indicated.

Secondary dysmenorrhea is menstrual pain due to an underlying pelvic lesion (see Table 3–9). Although uncommon in adolescents, when present it is most often due to infection or endometriosis. In one study of adolescent females with chronic pelvic pain, more than 40% who had not received a definitive diagnosis by the third visit were found to have endometriosis.

The clinician evaluating a patient with secondary dysmenorrhea should take a sexual history and conduct a pelvic examination even if the patient is not sexually active. Testing for gonorrhea and *Chlamydia*, a CBC and ESR, and a pregnancy test should be done. Gynecologic consultation is indicated to look for endometriosis or congenital problems by ultrasonography or laparoscopy. Treatment depends on the cause (see Table 3–9).

3. Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding may consist of menorrhagia (normal intervals with excessive flow) or metrorrhagia (irregular intervals with excessive flow). It results when an endometrium that has proliferated under unopposed estrogen stimulation finally begins to slough, but does so incompletely, causing irregular, painless bleeding. The unopposed estrogen stimulation occurs during anovulatory cycles, common in younger adolescents who have not been menstruating for long. Anovulation may also occur in older adolescents during times of stress or illness (Figure 3–12).

Clinical Findings

Typically, the adolescent has had several years of regular cycles and then begins to have menses every 2 weeks, or

Table 3–9. Dysmenorrhea in the adolescent.

Primary Dysmenorrhea—no pelvic pathology					
	Etiology	Onset and Duration	Symptoms	Pelvic Exam	Treatment
Primary	Excessive amount of prostaglandin F _{2α} , which attaches to myometrium, causing uterine contractions, hypoxia, and ischemia. Also, directly sensitizes pain receptors.	Begins with onset of flow or just prior and lasts 1–2 d. Does not start until 6–18 mos after menarche, when cycles become ovulatory.	Lower abdominal cramps radiating to lower back and thighs. Associated nausea, vomiting, diarrhea, and urinary frequency also due to excess prostaglandins.	Normal. May wait to examine if never sexually active and history is consistent with primary dysmenorrhea.	Mild—heating pad, warm baths, nonprescription analgesics. Moderate to severe—prostaglandin inhibitors at onset of flow or pain. Consider oral contraceptives.
Secondary Dysmenorrhea—underlying pathology present. (Always perform pelvic exam if secondary dysmenorrhea suspected or patient is sexually active. Tests for <i>Chlamydia</i> and gonorrhea, CBC, and ESR should be obtained.)					
Infection	Most often due to a sexually transmitted disease such as chlamydia or gonorrhea.	Recent onset of pelvic cramps.	Pelvic cramps, excessive bleeding, intermenstrual spotting or vaginal discharge.	Mucopurulent or purulent discharge from cervical os, cervical friability, cervical motion tenderness, adnexal tenderness, positive test for STI.	Appropriate antibiotics.
Endometriosis	Aberrant implants of endometrial tissue in pelvis or abdomen; may result from reflux.	Generally starts more than 2 y after menarche.	Pelvic pain, may occur intermenstrually.	Two thirds are tender on exam, especially during late luteal phase.	Hormonal suppression by oral contraceptives or danazol. Surgery may be necessary for extensive disease.
Complication of pregnancy	Spontaneous abortion, ectopic pregnancy.	Acute onset.	Pelvic cramps associated with a delay in menses.	Positive HCG, enlarged uterus or adnexal mass.	Immediate gynecologic consult.
Congenital anomalies	Transverse vaginal septum, septate uterus, or cervical stenosis.	Onset at menarche.	Pelvic cramps.	Underlying congenital anomaly may be apparent. May require exam under anesthesia.	Gynecologic consult for ultrasound, hysteroscopy, or laparoscopy.
IUD	Increased uterine contractions, or increased risk for pelvic infection.	Onset after placement of IUD or acutely if due to infection.	Pelvic cramps, heavy menstrual bleeding, may have vaginal discharge.	Normal, or see infection earlier.	Prostaglandin inhibitors of mefenamic acid may be drug of choice because they also reduce flow. Appropriate antibiotics and consider removal of IUD if infection is present.
Pelvic adhesions	Previous abdominal surgery or pelvic inflammatory disease.	Delayed onset after surgery or PID.	Abdominal pain, may or may not be associated with menstrual cycles; possible alteration in bowel pattern.	Variable.	Surgery. Consider a trial of tricyclic antidepressants.

CBC = complete blood count; ESR = erythrocyte sedimentation rate; HCG = human chorionic gonadotropin; STI = sexually transmitted infection; IUD = intrauterine device; PID = pelvic inflammatory disease.

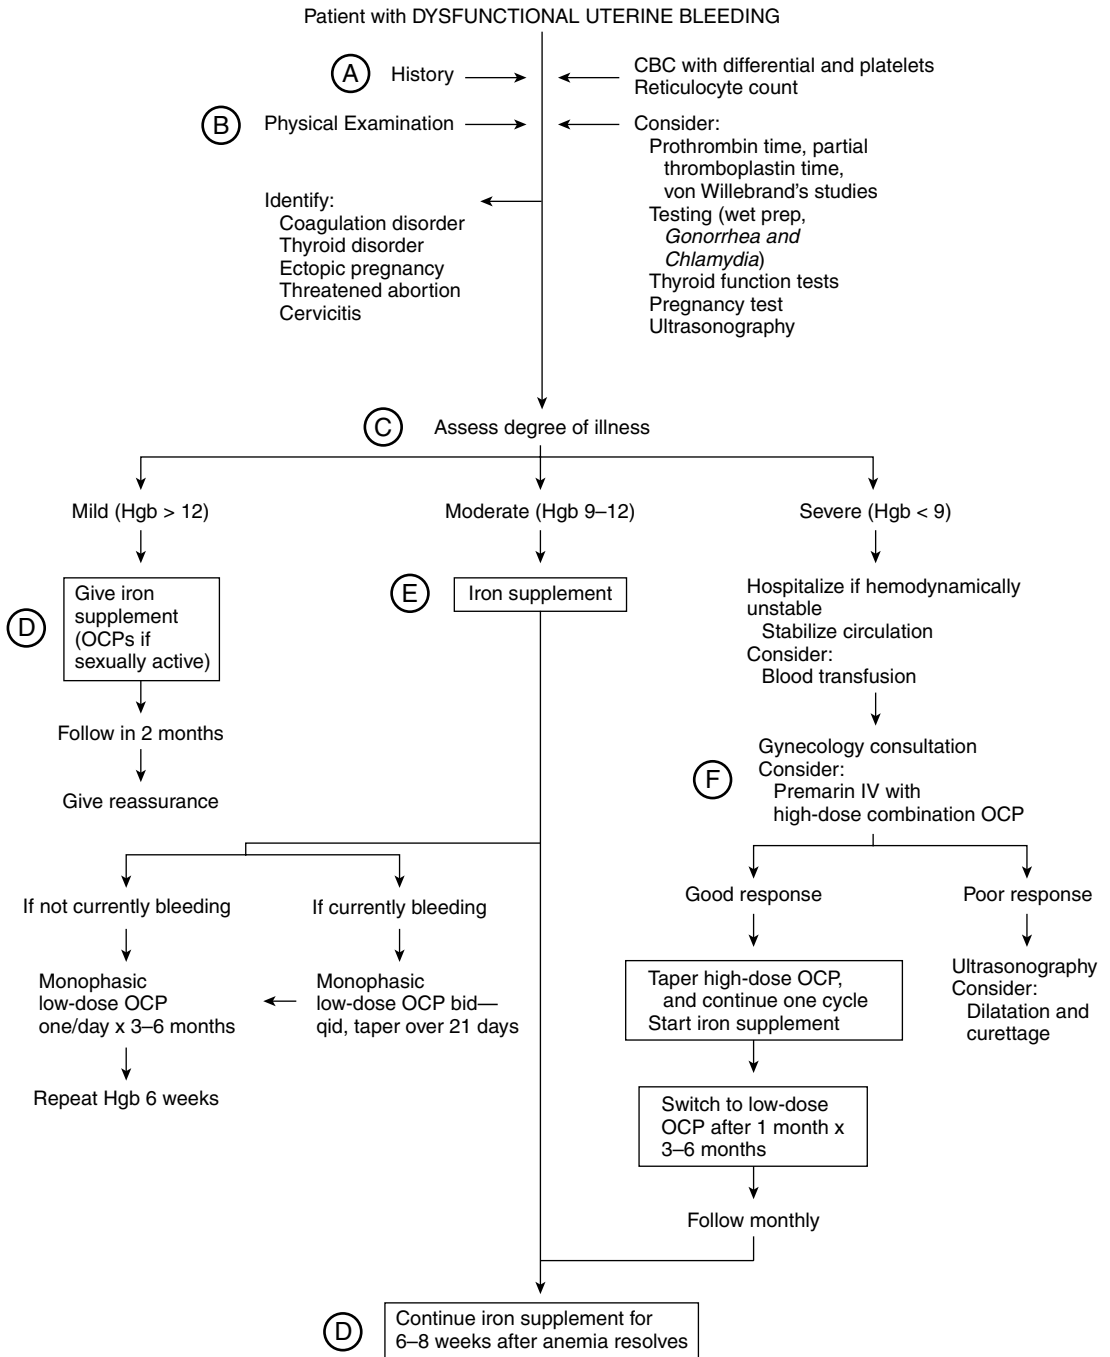

Figure 3-12. Evaluation of dysfunctional uterine bleeding. CBC = complete blood count, Hgb = hemoglobin, OCP = oral contraceptive pills.

complains of bleeding for 2–3 weeks after 2–3 months of amenorrhea. A history of painless, irregular periods at intervals of less than 3 weeks may also be elicited. Bleeding for more than 10 days should be considered abnormal. Dysfunctional uterine bleeding must be considered a diagnosis of exclusion (Table 3–10).

Management

A pregnancy test and pelvic examination with appropriate tests for sexually transmitted infections should be performed in sexually active patients. A CBC, including a platelet count, should be obtained. The history and physical findings may suggest the need for additional coagulation or hormonal studies. Coagulation studies should be done if the patient presents with severe anemia, especially within 1 year after menarche. Management depends on the severity of the problem (Table 3–11). It is important to treat for a minimum of 3–4 months to progressively reduce the endometrium to baseline thickness.

4. Mittelschmerz

Mittelschmerz is midcycle pain caused by irritation of the peritoneum due to spillage of fluid from the ruptured follicular cyst at the time of ovulation. The patient presents with a history of midcycle, unilateral dull or aching abdominal pain lasting a few minutes to as long as 8 hours. This pain rarely mimics the abdominal findings of acute appendicitis, torsion or rupture of an ovarian cyst, or ectopic pregnancy. The patient should be reassured and treated symptomatically. If the findings are severe enough to warrant consideration of the previously mentioned diagnoses, laparoscopy may be done.

5. Premenstrual Syndrome

Premenstrual syndrome (PMS) refers to a cluster of physical and psychological symptoms that are temporally related to the luteal phase of the menstrual cycle and are alleviated by the onset of menses. PMS should be distinguished from major depression, idiopathic cyclic edema, fibromyalgia, chronic fatigue syndrome, and psychosomatic disorders. This may be difficult because of the diversity of symptoms ascribed to PMS and the variability from month to month in the same patient. Premenstrual behavioral symptoms most commonly cited include emotional lability, anxiety, depression, irritability, impulsivity, hostility, and impaired social function. Physical symptoms include bloating, breast tenderness, fatigue, and appetite changes. Previously thought to be a disorder limited to adult women, studies indicate that adolescents also experience premenstrual symptoms. Although a number of causes have been proposed (progesterone deficiency, hyperprolactinemia, estrogen excess or imbalance of the estrogen–progesterone ratio, vitamin B₁₂ deficiency, fluid retention, low levels of endorphins and prostaglandins, hypoglycemia, psychosomatic factors), none has been proven. Hormones may play a role; women who have undergone hysterectomy but not oophorectomy may have cyclic symptoms resembling PMS, whereas postmenopausal women have no such symptoms.

Several treatments have been advocated but are without consistent benefits. OCPs or NSAIDs may be beneficial for some women. Sertraline (50–100 mg) has been shown to be significantly better than placebo for treatment of premenstrual dysphoria.

6. Ovarian Cysts

Functional cysts account for 20–50% of ovarian tumors in adolescents and are a result of the normal physiologic process of ovulation. They may be asymptomatic or may cause menstrual irregularity, constipation,

Table 3–11. Management of dysfunctional uterine bleeding.^a

	Mild	Moderate	Severe
	Hgb > 12 g/dL	Hgb 9–12 g/dL	Hgb < 9 g/dL (or dropping); orthostatic symptoms and signs
Acute treatment	Menstrual calendar Iron supplementation NSAID with menses may help reduce flow Consider oral contraceptive pills if patient is sexually active and desires contraception	Monophasic oral contraceptive pills up to four pills per day and taper over 2–3 wk; may need antiemetic. Bleeding should stop in a few days. Begin tapering dose 2–3 d after bleeding stops. Expect withdrawal flow a few days after last dose.	Fluids, blood transfusion as needed, admit to hospital if Hgb < 7 or patient is hemodynamically unstable For hemostasis, consider: conjugated estrogens (Premarin), 25 mg IV every 4–6 h for 24 h or until bleeding stops. Provide antiemetic medication. Then: oral contraceptive pills (1/50) cycle: 4 pills/d for 4 d 3 pills/d for 4 d 2 pills/d for 17 d withdrawal bleeding for 7 d ^b
Long-term management	Monitor menstrual calendar and Hgb Follow-up in 2–3 mos	Cycle with either: (1) Medroxyprogesterone acetate, 10 mg PO daily for 10 d starting on day 14 of each cycle for 3–6 mos, or (2) Oral contraceptive pills for 3–6 mos beginning the Sunday after withdrawal bleeding starts. Provide iron supplementation. Monitor Hgb Follow-up within 2–3 wk and every 3 mos	Next: Oral contraceptive pills cycle (using 28-d packs) for 3 mos Begin the Sunday after withdrawal bleeding begins. Length of use dependent on resolution of anemia. Monitor hemoglobin Follow-up within 2–3 wks and every 3 mos

^aDiagnosis: Prolonged (> 8 d) painless menses; heavy flow (> 6 tampons/pads per day); short cycles (< 21 d); no cause found.

^bThis schedule will use three 21-d packages.

Hgb = hemoglobin; PO = by mouth; NSAID = nonsteroidal anti-inflammatory drug.

Modified from Blythe M: Common menstrual problems. Part 3. Abnormal uterine bleeding. Adolescent Health Update 1992;4:1.

or urinary frequency. Functional cysts, unless large, rarely cause abdominal pain; however, torsion or hemorrhage of an ovarian cyst may present as an acute abdomen. Follicular cysts account for the majority of ovarian cysts. They are produced every cycle but occasionally are not resorbed. Follicular cysts are unilateral, usually not larger than 4 cm in diameter, and resolve spontaneously. If the patient is asymptomatic, she can be reexamined monthly. The patient should be referred to a gynecologist for laparoscopy if she is premenarcheal, if the cyst has a solid component or is larger than 5 cm by ultrasonography, if she has symptoms or signs suggestive of hemorrhage or torsion, or if the cyst fails to regress within 2 months. Luteal cysts occur less

commonly and may be 5–10 cm in diameter. The patient may have associated amenorrhea or, as the cyst becomes atretic, heavy vaginal bleeding. The patient may be monitored for 3 months but should have a laparoscopy if the cyst is larger than 5 cm, does not resolve within 2 months, or if there is pain or bleeding from the cyst.

Slap GB: Menstrual disorders in adolescence. *Best Pract Res Clin Obstet Gynaecol* 2003;17(1):75 [PMID: 12758227].

CONTRACEPTION

According to the Youth Risk Behavior Survey, by 12th grade 60.5% of adolescents in 2001 had had sexual intercourse. This percentage had decreased from 66.7 in 1991. For female adolescents, reported use of a condom at last intercourse increased from 38% in 1991 to 51.3% in 2001. For male adolescents, this percentage increased from 54.5% to 65.1%. However, the percentage of adolescents reporting use of alcohol or drugs before last intercourse increased 18% between 1991 and 2001.

Abstinence & Decision Making

Many adolescents have given little thought to how they feel about their developing sexuality or how they will handle sexual situations. By talking with teenagers about sexual intercourse and its implications, and alternatives to intercourse, providers can help teens make informed decisions before they find themselves with an unplanned pregnancy or a sexually transmitted infection.

If an adolescent chooses to remain abstinent, the clinician should reinforce that decision. Encouraging adolescents to use contraception when they do engage in sexual intercourse does not lead to higher rates of sexual activity. Another approach to decreasing teen pregnancy is to educate adolescent males on the importance of hormonal contraception and emergency contraception for their partners, in addition to condom use. The teen pregnancy, birth, and abortion rates are higher in the United States than in any other developed country, despite similar rates of sexual experience.

Emergency Contraception

A discussion of emergency contraception (EC), which could potentially prevent 50–90% of unintended pregnancies and elective abortions, should be part of anticipatory guidance given to both female and male teenagers. Indications for EC include unprotected intercourse within the past 120 hours (5 days), condom breakage, more than two missed oral contraceptive pills, and greater than 14 weeks since the last Depo-Provera injection. The pregnancy rate after EC is 1.8%, compared with 6.8% without such intervention. (See Table 3–12 for dosages.) EC works best within 24 hours of intercourse but can be taken up to 120 hours afterward. It should be verified that other instances of unprotected intercourse beyond 120 hours have not occurred. The only contraindication to the use of EC is pregnancy. Plan B is a progestin-only method that causes significantly less nausea and vomiting than combined estrogen/progesterone methods. Preven is a

Table 3–12. Emergency postcoital contraception regimens.

Pill	Dosage	Each Dose Achieves:
Plan B ^a	Two tablets orally	Levonorgestrel 1.5 mg
Preven ^b	Two tablets orally, repeat in 12 h	Levonorgestrel 0.5 mg
Nordette ^b	Four tablets orally and repeat in 12 h	Levonorgestrel 0.6 mg
Lo-Ovral ^b	Four tablets orally and repeat in 12 h	Norgestrel 1.2 mg
Alesse ^b	Five pink pills orally and repeat in 12 h	Levonorgestrel 0.5 mg
Triphasil ^b	Four yellow pills orally and repeat in 12 h	Levonorgestrel 0.5 mg

^aBoth doses can be given at the same time.

^bAn antiemetic drug taken 30 minutes before the dose may help reduce nausea.

combined estrogen/progesterone product marketed specifically for EC. If these methods are not available, certain combined OCPs can be used for EC. It is important to note that the newer progestin-containing contraceptives are **not** approved for EC. A follow-up appointment should be held in 2–3 weeks, to test for pregnancy if menses have not occurred, to screen for STI if indicated, and to counsel regarding contraceptive use.

Condoms & Spermicides

The use of condoms has gained popularity as a result of the educational and marketing efforts driven by the acquired immunodeficiency syndrome (AIDS) epidemic. Condom use has increased over the past several decades. Regardless of whether another method is used, all sexually active adolescents should be counseled to use condoms. Condoms offer protection against STIs by decreasing the transmission of gonorrhea, *Chlamydia*, syphilis, herpes simplex, hepatitis, and human immunodeficiency virus (HIV). Spermicides containing nonoxynol-9 are no longer recommended, as recent evidence has suggested that repeated use of spermicide may increase transmission of HIV. Aside from the diaphragm and cervical cap, barrier methods do not require a medical visit or prescription and are widely available. The polyurethane vaginal pouch, or female condom, is also available. Although it has pregnancy and STI prevention properties similar to those of the

male condom, its higher cost and greater difficulty of insertion make it less appealing to adolescents.

Oral Contraceptives

OCPs have a three-pronged mechanism of action: (1) suppression of ovulation; (2) thickening of the cervical mucus, thereby making sperm penetration more difficult; and (3) atrophy of the endometrium, which diminishes the chance of implantation. The latter two actions are progestin effects.

A. COMBINATION ORAL AND CUTANEOUS CONTRACEPTIVES

Combination OCPs contain both estrogen and progestin. Ethinyl estradiol is the estrogen currently used in nearly all OCPs in the United States. A number of progestins are used in OCPs and differ in their estrogenic, antiestrogenic, and androgenic effects. As estrogen doses decreased in OCPs, the androgenic side effects of progestins became more apparent, leading to the development of two progestins (desogestrel and norgestimate) with lower androgenic potential. Ortho Tri-Cyclen is being advertised as a treatment for acne. All of the lower androgenic pills improve acne and may especially benefit patients with polycystic ovary syndrome. Reports of increased risk of thromboembolism associated with the newer progestins are likely related to an excess of first-time users among desogestrel patients. Factor V Leiden has been identified as a risk factor for venous thrombosis; 5% of patients of European ancestry are carriers of factor V Leiden. Carriers have a 30- to 50-fold increased risk for thrombosis. Testing family members with a history of venous thrombosis for factor V Leiden and other conditions such as the prothrombin gene mutation, protein C and S, and antithrombin III before prescribing estrogen-containing OCPs to the adolescent may prevent these complications. OCPs have many noncontraceptive benefits, including improvement of dysmenorrhea, acne, and PMS; suppression of ovarian and breast cysts; and lower risk of anemia, pelvic inflammatory disease, and ectopic pregnancy. A pill containing 30–35 mg of ethinyl estradiol with norgestimate, desogestrel, or 0.5 mg norethindrone is recommended for adolescents beginning OCPs.

Ortho Evra is a newly released combined estrogen/progesterone patch, which is worn 3 weeks out of every 4. It releases 150 µg of norelgestromin and 20 µg of ethinyl estradiol per day. Side effects are similar to those of combined OCPs. Five percent of patients report having a patch come off. Two percent report skin irritation. Efficacy may be reduced in patients weighing more than 200 pounds. The patch is an attractive alternative to OCPs for adolescents who have difficulty re-

membering to take a pill every day, as compliance is increased. The failure rate for the patch is reported to be 1%.

B. PROGESTIN-ONLY PILLS

Progestin-only pills contain no estrogen. Their chief use is in women who experience unacceptable estrogen-related side effects with combination OCPs or who have a contraindication to estrogen-containing pills. Their lack of estrogen, however, is also responsible for the main side effect, less predictable menstrual patterns. For this reason, progestin-only pills are not often appropriate for adolescents. Their mechanism of action relies on the progestin-mediated actions, and ovulation is suppressed in only 15–40% of cycles.

C. INDICATIONS AND CONTRAINDICATIONS

Combined OCPs may be the method of choice for sexually active adolescents who frequently have unplanned intercourse; however, the patient must be able to comply with a daily dosing regimen. Most states allow OCPs to be prescribed to minors confidentially. Ideally, it is best to wait until 6–12 regular menstrual cycles have occurred before beginning hormonal contraception; however, if the teenager is already sexually active, the medical and social risks of pregnancy outweigh the risks of hormonal contraception.

OCPs or the contraceptive patch may also be used to treat dysmenorrhea, menorrhagia, dysfunctional uterine bleeding, and acne (see previous discussion).

Contraindications to combined OCPs or the contraceptive patch can be categorized as absolute and relative (Table 3–13). When use of estrogenic agents is contraindicated, progestin-only pills and Depo-Provera are alternatives.

D. BEGINNING BIRTH CONTROL PILLS OR THE CONTRACEPTIVE PATCH AND FOLLOW-UP

Before a patient begins taking OCPs or the patch, a careful menstrual history, medical history, and family medical history should be taken. In addition, baseline weight and blood pressure should be established; breast and pelvic examination should be performed; and specimens for urinalysis, Pap smear, and gonorrhea and *Chlamydia* testing should be obtained. If patients have not yet initiated intercourse, pelvic examination can be deferred until after intercourse is initiated. If time constraints are present and a patient has no symptoms suggesting an STI, OCPs or the patch may be started and a pelvic exam scheduled as soon as possible.

If the teen has no contraindications (see Table 3–13), she may begin her first pack of pills or the patch with her next menstrual period (either the first Sunday after flow begins or the first day of flow, depending on the brand). A low-dose monophasic combined oral

Table 3–13. Contraindications to combined birth control pills.

Absolute contraindications

- Pregnancy
- Lactation (wait 6 wk postpartum)
- History of thrombophlebitis, thromboembolic disorder, cerebrovascular disease, or ischemic heart disease
- Structural heart disease complicated by endocarditis, atrial fibrillation, or pulmonary hypertension
- Breast cancer
- Severe migraine headaches with neurologic changes (numbness, weakness)
- History of benign or malignant liver tumor, active hepatitis or severe cirrhosis
- Severe hypertension SBP > 160 mmHg or DBP > 100 mmHg
- Major surgery with prolonged immobilization or surgery on legs or pelvis

Relative contraindications

- Recent pregnancy (wait 3 wk postpartum)
- Lactation (6 wk–6 mos) OCPs may decrease milk supply
- Undiagnosed vaginal bleeding
- Active gallbladder disease
- Use of drugs that affect liver enzymes (rifampin, griseofulvin, phenytoin, carbamazepine, barbiturates)

SBP = systolic blood pressure; DBP = diastolic blood pressure; OCPs = oral contraceptives.

Reprinted with permission from Hatcher RA et al: *Contraceptive Technology*, 17th ed. Ardent Media, 1998.

contraceptive or a triphasic pill of low androgenic profile is used for those without contraindications to use of estrogen. With adolescents, it is wise to use 28-day packs rather than 21-day packs to reduce the chance of missing pills. The patient should be instructed on the use of her pills and on the possible risks and side effects and their warning signs. To ensure protection, she should use a back-up method, such as condoms, for the first 2 weeks. In addition, the patient should be advised to use condoms at every intercourse to prevent STIs. A follow-up visit every 3 months for the first year may improve compliance, because teenagers often discontinue birth control pills because of nonmedical reasons or minor side effects. Teenagers may need reassurance about the safety of birth control pills and their added benefits (Table 3–14).

E. MANAGEMENT OF SIDE EFFECTS

A different type of combined oral contraceptive should be tried if a patient has a persistent minor side effect for more than the first 2–3 months. Adjustments should be made on the basis of hormonal effects desired (Table

Table 3–14. Noncontraceptive health benefits of oral contraceptive pills.

Protection against life-threatening conditions

- Ovarian cancer
- Endometrial cancer
- Pelvic inflammatory disease
- Ectopic pregnancy
- Morbidity and mortality due to unintended pregnancies

Alleviate conditions affecting quality of life

- Iron deficiency anemia
- Benign breast disease
- Dysmenorrhea
- Irregular cycles
- Functional ovarian cysts
- Premenstrual syndrome
- Improved acne

Mounting evidence

- Improved bone density

3–15). Changes are most often made for persistent breakthrough bleeding not related to missed pills.

Injectable and Implantable Hormonal Contraceptives

The depot form of medroxyprogesterone acetate (DMPA), or Depo-Provera, is a long-acting injectable progestational contraceptive. It is given as a deep intramuscular injection of 150 mg into the gluteal or deltoid muscle every 12 weeks. The first injection should be given within the first 5 days of the menstrual cycle to ensure immediate contraceptive protection. Patients more than 1 week late for their injection should have two pregnancy tests 2 weeks apart before restarting DMPA, unless they have not been sexually active since missing the DMPA injection. DMPA works chiefly by blocking the LH surge, thereby suppressing ovulation, but it also thickens cervical mucus and alters the endometrium to inhibit implantation. With a failure rate of less than 0.3%, minimal compliance issues, long-acting nature, reversibility, lack of interference with intercourse, and lack of estrogen-related side effects, it may be an attractive contraceptive for many adolescents. Patients should be warned about unpredictable menstrual patterns, the possibility of weight gain or mood changes, and the potential for decreased bone density, which remains under investigation. DMPA may reduce intravascular sickling and increase hemoglobin and red cell survival in patients with sickle cell disease. Moreover, DMPA may be the preferred method for patients

Table 3–15. Estrogenic, progestogenic, and androgenic effects of oral contraceptive pills.

Estrogenic Effects	Progestogenic Effects	Androgenic Effects
Nausea	Both the estrogenic and the progestational components of oral contraceptives may contribute to the development of the following adverse effects: Breast tenderness Headaches Hypertension Myocardial infarction (rare)	All low-dose combined pills suppress a woman's production of testosterone, which has a beneficial effect on acne, oily skin, and hirsutism. The progestin component may have androgenic as well as progestational effects: Increased appetite and weight gain Depression, fatigue Decreased libido and/or enjoyment of intercourse Acne, oily skin Increased breast tenderness or breast size Increased LDL cholesterol levels Decreased HDL cholesterol levels Decreased carbohydrate tolerance; increased insulin resistance Pruritus
Increased breast size (ductal and fatty tissue)		
Cyclic weight gain due to fluid retention		
Leukorrhea		
Cervical eversion or ectopy		
Hypertension		
Rise in cholesterol concentration in gallbladder bile		
Growth of leiomyoma		
Telangiectasia		
Hepatocellular adenomas or hepatocellular carcinoma (rare)		
Cerebrovascular accidents (rare)		
Thromboembolic complications including pulmonary emboli (rare)		
Stimulation of breast neoplasia (exceedingly rare)		
(Most pills with less than 50 µg of ethinyl estradiol do not produce troublesome estrogen-mediated side effects or complications.)		

LDL = low-density lipoprotein; HDL = high density lipoprotein.

Reproduced with permission from Hatcher RA et al: *Contraceptive Technology*, 17th ed. Ardent Media, 1998.

with seizure disorders, because it has been found to reduce the number of seizures in some patients. DMPA may also be helpful for adolescents with von Willebrand disease, since amenorrhea (which decreases blood loss) is a common effect of DMPA. Studies have shown no increased risk of liver cancer, breast cancer, or invasive squamous cell cervical cancer among users of DMPA, and the risk of endometrial and ovarian cancers is reduced.

Lunelle is a monthly combined estrogen/progesterone injectable contraceptive that was approved in the United States in 2000; however, the manufacturer recently discontinued production of Lunelle. There is potential for another company to produce this contraceptive in the future. Lunelle contains 5 mg of estradiol cypionate and 25 mg of medroxyprogesterone acetate. Its advantages over progestin-only injectable contraceptives include faster return to fertility and less amenorrhea, which theoretically should lower the risk of osteoporosis. Side effects include weight gain, irregular

bleeding, breast pain, menorrhagia, and dysmenorrhea. Efficacy is excellent, with a reported failure rate of 0.2%. Monthly injections may make this method less attractive for adolescents.

The levonorgestrel-containing nonbiodegradable subdermal implant (Norplant System), which is inserted under the skin of the upper arm using a trocar, is effective for 5 years, with pregnancy rates ranging from 0.04 per 100 woman-years in the first year of use to 1.1 per 100 woman-years in the fifth year. It acts through ovulation inhibition and thickening of the cervical mucus. Menstrual irregularities (including prolonged bleeding, intermenstrual spotting, and amenorrhea) are the most common side effects, although headache, acne, weight gain or loss, and depression may occur. Its ease of use, lack of compliance issues, high efficacy, and long-term protection make the subdermal implant an ideal contraceptive for adolescents who can tolerate the menstrual irregularities. In 2000, Norplant was removed from the market because of concern over

decreased efficacy in the fifth year in some lots. No implantable contraceptive methods are currently marketed in the United States.

Implantable Contraceptive Methods Available Outside of the United States

Implanon is a single implant, effective for 3 years. It contains etonogestrel. It has been used in Europe and has a failure rate approaching 0%. Side effects include irregular bleeding, headache, nausea, breast pain, and depression. Return to fertility is rapid following removal. Insertion and removal are reportedly significantly easier than Norplant. Other implantable progestones used in other countries include Norplant II and Jadelle (levonorgestrel) and Uniplant and Surplant (norgestrol acetate).

Contraceptive Vaginal Ring

The Nuva Ring is a vaginal ring that releases 15 µg of ethinyl estradiol and 120 µg of etonogestrel per day. The ring is placed inside the vagina for 3 weeks, followed by 1 week without the ring to allow for withdrawal bleeding. A new ring is inserted each month. Failure rate is 1%. Side effects include vaginitis in 5%, headache in 6%, and foreign body sensation in 2.5%. The vaginal ring is easier to insert correctly than the diaphragm. However, like the diaphragm, adolescents are often reluctant to use contraception requiring insertion into the vagina.

Contraceptive Methods Not Usually Recommended for Teenagers

Adolescents should understand the menstrual cycle and be taught that ovulation typically occurs 2 weeks before the next menstrual period and may be difficult to predict. Because teenagers frequently have irregular cycles, the rhythm, or calendar, method is not effective. Adolescents also need to be taught that withdrawal is not a reliable method of contraception. Diaphragms and cervical caps require professional fitting and skill with insertion and are not popular among teenagers. Adolescents who have never been pregnant or who engage in behaviors that carry a risk of STIs should not use an intrauterine device. Sterilization is rarely appropriate for adolescents.

PREGNANCY

The teen birth rate in the United States has been steadily decreasing since the early 1990s, with a historic low in 2001. From 1991 to 2001, the birth rate for adolescents age 15–19 years decreased from 61.8 to 45.3/1000. Abortions have also decreased over the past decade. In 1997, 16.3% of pregnancies in 15- to 17-year-olds ended in abortion, as did 37.5% of pregnancies in 18- to 19-year-olds. Despite decreasing rates, the United States still has the highest adolescent pregnancy rate of any developed country. Over 800,000 adolescents younger than age 19 become pregnant every year. Young maternal age and associated maternal risk factors have been linked to adverse neonatal outcome, including higher rates of low-birth-weight babies (< 2500 g) and neonatal mortality. The psychosocial consequences for the teenage mother and her infant are listed in Table 3–16. Teenagers who are pregnant require additional support from their caregivers. Clinics for young mothers may be the best providers.

Presentation

Adolescents may present with delayed or missed menses or may even request a pregnancy test, but often they present with an unrelated concern or have a hidden agenda. Because of the high level of denial, they may come in with complaints of abdominal pain, urinary frequency, dizziness, or other nonspecific symptoms and have no concern about pregnancy. A history of symptoms such as weight gain, engorged breasts, an unusually light or mistimed period, and urinary frequency may be present. Denial contributes to the delay in seeking prenatal care. Clinicians need to have a low threshold for suspicion of pregnancy. If any suspicion exists, a urine pregnancy test should be obtained.

Diagnosis

The history and physical examination may assist in making the diagnosis. Bluish coloring and softening of the cervix may be noted on speculum examination. The uterine fundus may be palpable on abdominal examination if sufficient time has elapsed. If uterine size on bimanual examination does not correspond to dates, one

Table 3–16. Psychosocial consequences of pregnancy for the adolescent mother and her infant.

Mother	Infant
<p>Increased morbidity related to pregnancy</p> <p>Greater risk of toxemia, anemia, prolonged labor, premature labor</p> <p>Increased chance of miscarriages, stillbirths</p> <p>Increased change of maternal mortality</p>	<p>Greater health risks</p> <p>Increased chance of low birth weight or prematurity</p> <p>Increased risk of infant death</p> <p>Increased risk of injury and hospitalization by age 5</p>
<p>Decreased educational attainment</p> <p>Less likely to get high school diploma, go to college, or graduate</p>	<p>Decreased academic achievement</p> <p>Lower cognitive scores</p> <p>Decreased development</p> <p>Greater chance of being behind grade or needing remedial help</p>
<p>Lower occupational attainment and prestige</p> <p>Less chance of stable employment (some resolution over time)</p> <p>Lower job satisfaction</p> <p>Lower income/wages</p> <p>Greater dependence on public assistance</p>	<p>Lower chance of advanced academics</p> <p>Lower academic aptitude as a teenager and perhaps a higher probability of dropping out of school</p>
<p>Less stable marital relationships</p> <p>Higher rates of single parenthood</p> <p>Earlier marriage (though less common than in the past)</p> <p>Accelerated pace of marriage, separation, divorce, and remarriage</p>	<p>Psychosocial consequences</p> <p>Greater risk of behavior problems</p> <p>Poverty</p> <p>Higher probability of living in a nonintact home while in high school</p> <p>Greater risk of adolescent pregnancy</p>
<p>Faster pace of subsequent childbearing</p> <p>High rate of repeat unintended pregnancy</p> <p>More births out of marriage</p> <p>Closer spacing of births</p> <p>Larger families</p>	

must consider ectopic pregnancy, incomplete or missed abortion, twin gestation, or inaccurate dates.

Enzyme-linked immunoassay test kits specific for the β -HCG subunit and sensitive to less than 50 mIU/mL of HCG can be performed on urine (preferably the first morning-voided specimen, because it is more concentrated) in less than 5 minutes and are

accurate by the expected date of the missed period in almost 100% of patients. Serum radioimmunoassay is also specific for the β subunit, is accurate within 7 days after conception, and is helpful in ruling out ectopic pregnancy or threatened abortion.

The timing of pregnancy tests is important, because HCG levels rise initially after conception, peak at about 60–70 days, then drop to levels not detected by routine office slide tests after 16–20 weeks.

Special Issues in Management

When an adolescent presents for pregnancy testing, it is helpful, before performing the test, to find out what she hopes the result will be and what she thinks she will do if the test is positive. If she wants to be pregnant and the test is negative, further counseling about the implications of teen pregnancy should be offered. Prenatal vitamins should be prescribed. For those who do not wish to be pregnant, contraception should be discussed, because teens with a negative pregnancy test have a high risk of pregnancy within the next 2 years.

If the adolescent is pregnant, the physician must discuss her support systems and her options with her (abortion, adoption, raising the baby). Many teenagers need help in telling and involving their parents. It is important to remain available for further assistance with decision making. Patients should be informed of the gestational age and time frames required for the different options. If the patient knows what she wants to do, she should be referred to the appropriate resources. Because teenagers are often ambivalent about their plans and may have a high level of denial, it is prudent to follow up in 1 week to be certain that a decision has been made. Avoiding a decision reduces the adolescent's options and may result in poor pregnancy outcomes. Providers can help ensure that the patient obtains prenatal care if she has chosen to continue the pregnancy. In addition, brief counseling about healthy diet; folic acid supplementation (400 μ g/d); and avoiding alcohol, tobacco, and other drugs is helpful.

Young maternal age, low maternal prepregnancy weight, poor weight gain, delay in prenatal care, and low socioeconomic status contribute to low birth weight and poor fetal outcome. The poor nutritional status of some teenagers; their erratic diets, smoking, drinking, or substance abuse; and their high incidence of STIs also play a role. Teenagers are also at greater risk than adult women for pre-eclampsia, eclampsia, iron deficiency anemia, cephalopelvic disproportion, prolonged labor, premature labor, and maternal death. Early prenatal care and good nutrition can make a difference with a number of these problems.

Because of the high risk of a second unintended pregnancy within the next 2 years, postpartum contra-

ceptive counseling and follow-up are imperative. Combined OCPs or the contraceptive patch can be started 3 weeks after delivery in adolescents who are not breast feeding; progestin-only methods can be started immediately postpartum, even in breastfeeding adolescents. Pregnancy prevention is the most cost-effective means of reducing the consequences of teenage pregnancy. Sexual decision making, contraceptive counseling, and close follow-up of sexually active adolescents of both sexes can make a difference. Adolescents who receive sexuality and contraceptive education are not more likely to have intercourse but are less likely to become pregnant than their counterparts who do not receive such instruction.

Ectopic Pregnancy

In the United States, 100,000 ectopic pregnancies occur each year, accounting for 2% of pregnancies. Adolescents have the highest mortality rate from ectopic pregnancy, most likely related to delayed entry into health care. Risk factors include history of pelvic inflammatory disease or chlamydial infection. Conception while on progestin-only methods of contraceptives also increases risk of ectopic pregnancy, because of the progestin-mediated decrease in tubal motility. Providers should keep a high level of suspicion with any adolescent presenting with vaginal bleeding and abdominal pain.

VULVOVAGINITIS

Vaginitis may be due to pathogens or to indigenous flora after a change in milieu of the vagina. Candidal vulvovaginitis and bacterial vaginosis (formerly called *Gardnerella*, *Haemophilus*, or nonspecific vaginitis) may occur in patients who are not sexually active. These are examples of indigenous flora that may cause symptoms. Bacterial vaginosis, however, is more prevalent in those who are sexually active. In sexually active patients, *Trichomonas* infection or cervicitis due to sexually transmitted pathogens must be considered (see Chapter 40). For this reason, appropriate specimens should be taken from sexually active patients or suspected victims of sexual abuse in order to detect STIs, even if yeast forms are present or bacterial vaginosis is identified.

1. Physiologic Leukorrhea

Leukorrhea is the normal vaginal discharge that begins around the time of menarche. The discharge is typically clear or whitish, and its consistency may vary according to cyclic hormonal influences. There should be no odor. Girls in early adolescence may have concerns about such a discharge and need reassurance that it is normal. This may be a good time to tell girls that there is no need for douching. If a vaginal wet preparation is examined, a few squamous epithelial cells may be revealed, but there should be fewer than five polymorphonuclear cells per high-power field.

2. Candidal Vulvovaginitis

Candidal vulvovaginitis is caused by yeast (*Candida albicans*). It typically occurs after a course of antibiotics, after which the normal perineal flora are altered and yeast is allowed to proliferate. Diabetic patients, those with compromised immune systems, and those who are pregnant or receiving OCPs are more prone to develop candidal infections.

Clinical Findings

The patient usually complains of vulvar pruritus or dyspareunia and a thick vaginal discharge, frequently beginning the week before menses. Examination of the vulva reveals erythematous mucosa, sometimes with excoriation, and a thick, white, cheesy discharge. The discharge may be adherent to the walls of the vagina. Leukocytes may be seen on a wet preparation, and a KOH preparation may reveal budding yeast or mycelia. The vaginal preparations are often not helpful, and the patient should be treated on the basis of the clinical examination. Vaginal culture for yeast is usually unnecessary.

Treatment

Butoconazole, clotrimazole, miconazole, terconazole, or tioconazole vaginal creams or suppositories designed for seven nightly doses are effective in most patients. Fluconazole (150 mg once orally) is also effective and may be beneficial on a monthly prophylactic basis for women with recurring infections. Patients with recurrent episodes should be given prophylactic treatment whenever they take antibiotics. It may be helpful to simultaneously treat the partners of sexually active patients with recurrent candidal infections.

3. Bacterial Vaginosis

Bacterial vaginosis may be caused by any of the indigenous vaginal flora, such as *Gardnerella*, *Bacteroides*, *Pep-*

tococcus, *Mycoplasma hominis*, lactobacilli, or other anaerobes.

Clinical Findings

The patient generally complains of a malodorous discharge. On examination, a thin, homogeneous, grayish white discharge is found adhering to the vaginal wall. A whiff test, in which a drop of KOH is added to a smear of the discharge on a slide, results in the release of amines, causing a fishy odor. Wet preparation reveals an abundance of clue cells and small pleomorphic rods.

Treatment

Treatment for bacterial vaginosis is with metronidazole (500 mg orally bid for 7 days) or clindamycin (300 mg orally bid for 7 days). Topical metronidazole or clindamycin may also be effective. Ampicillin (500 mg orally four times a day for 7 days) is the alternative for pregnant patients.

4. Other Causes Of Vulvovaginitis

Sexually Transmitted Infections

STIs are a common cause of vaginal discharge in adolescents (see Chapter 40). *Chlamydia* and gonorrhea

testing should be done whenever a sexually active adolescent complains of vaginal discharge even when the cervix appears normal.

Foreign Body Vaginitis

Foreign bodies (most commonly retained tampons or condoms) cause extremely malodorous vaginal discharges. Treatment consists of removal, for which ring forceps may be useful. Further treatment is generally not necessary.

Allergic or Contact Vaginitis

Bubble baths, feminine hygiene sprays, or vaginal contraceptive foams or suppositories may cause chemical irritation of the vaginal mucosa. Discontinuing use of the offending agent is indicated.

Substance Abuse

4

Paritosh Kaul, MD, & Catherine Stevens-Simon, MD

The use and abuse of mood-altering substances—alcohol, marijuana, opioids, cocaine, amphetamines, sedative-hypnotics, hallucinogens, inhalants, nicotine, anabolic steroids, γ -hydroxybutyrate (GHB), and 3,4-methylenedioxymethamphetamine (ecstasy)—continues to be a serious public health problem. The short- and long-term health, social, emotional, legal, and behavioral consequences of substance abuse are particularly damaging during childhood and adolescence. Not only does early substance use portend chronic, severe polysubstance abuse later in life, but substance use may also compromise physical, cognitive, and psychosocial aspects of adolescent development if this maladaptive behavior becomes the preferred response to environmental stressors.

Substance abuse tends to be a chronic, progressive disease. The first or initiation stage—from nonuser to user—is such a common feature of becoming an American adult that many authorities call it normative behavior. At this stage, substance use is typically limited to experimentation with tobacco or alcohol (so-called gateway substances). During adolescence, young people are expected to establish an independent, autonomous identity. They try out a variety of behaviors within the safety of their family circles and peer groups. This process often involves experimentation with psychoactive substances, usually in culturally acceptable circumstances. Progression to the second or continuation stage of substance abuse is a nonnormative risk behavior with the potential to compromise adolescent development. The American Psychiatric Association criteria listed in Table 4–1 can be used to judge the severity of substance use that progresses beyond the experimentation stage to substance abuse or substance dependency. Maintenance and progression within a class of substances (eg, from beer to liquor) and progression across classes of substances (eg, from alcohol to marijuana) represent the third and fourth stages of substance abuse. Individuals at these stages are polysubstance abusers, and most manifest one or more of the symptoms of dependency listed in Table 4–1. The transition from one stage to the next is typically a cyclic process of regression, cessation, and relapse. Common symptoms and physiologic effects of intoxication (which can occur at any stage) and withdrawal (a symptom of dependency)

for the major classes of substances are presented in Tables 4–2 and 4–3.

US Department of Health and Human Services. *Healthy People 2010*, 2nd ed. With Understanding and Improving Health and Objectives for Improving Health (2 vols). Washington, DC: U.S. Government Printing Office, 2000.

SCOPE OF THE PROBLEM

The best source of information about the prevalence of substance abuse among American children and adolescents is the annual Monitoring the Future Study, which tracks health-related behaviors in a sample of 44,000 8th, 10th, and 12th graders in about 400 public and private schools across the United States. This study probably understates the magnitude of the problem of substance abuse because it excludes two of the most abuse-prone groups of young people—school dropouts and runaways. Although the exclusion of these youngsters may minimize prevalence estimates only moderately for the entire population, errors in estimating drug use among subgroups with high rates of school dropout (eg, urban minority youths) are thought to be substantial. Data from this survey and others show that alcohol is the most frequently abused substance in our society. Experimentation with alcohol typically begins in or before middle school; is more common among boys than girls; and is most common among whites, less common among Hispanics and Native Americans, and least common among blacks and Asians. Over 50% of children consume alcohol before high school, and over 90% do so before graduation. Over 25% of eighth graders and over 50% of high-school students seen in an average American pediatric practice have used alcohol within the last 30 days, and half have consumed five or more drinks on at least

Table 4–1. Substance abuse and substance dependency.**Diagnostic criteria for substance abuse**

- A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one or more of the following occurring within a 12-month period:
1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (eg, repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household).
 2. Recurrent substance use in situations in which it is physically hazardous (eg, driving an automobile or operating a machine when impaired by substance use).
 3. Recurrent substance-related legal problems (arrests for substance-related disorderly conduct).
 4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (eg, arguments with spouse about consequences of intoxication, physical fights).
- B. The symptoms have never met criteria for substance dependence for this class of substance.

Diagnostic criteria for substance dependency

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three or more of the following, occurring at any time in the same 12-month period:

1. Tolerance, as defined by either of the following:
 - a. Need for markedly increased amounts of the substance to achieve intoxication or desired effect.
 - b. Markedly diminished effect with continued use of the same amount of the substance.
2. Withdrawal, as manifested by either of the following:
 - a. The characteristic withdrawal syndrome for the substance (criteria A and B of the criteria for withdrawal from the specific substance).
 - b. The same (or closely related) substance taken to relieve or avoid withdrawal symptoms.
3. The substance often taken in larger amounts or over a longer period than was intended.
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use.
5. A great deal of time spent in activities necessary to obtain the substance (eg, visiting multiple doctors, driving long distances), use the substance (chain-smoking), or recover from its effects.
6. Important social, occupational, or recreational activities given up or reduced because of substance use.
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (eg, current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

one occasion. Use of tobacco, marijuana, and other mood-altering substances is less common (Table 4–4). Marijuana is the most commonly used illicit drug in the United States. First experiences with marijuana and the substances listed in Table 4–4 typically occur during middle school and early high school. Initiation of substance abuse is rare after age 20 years.

The level of substance abuse among American youth rose in the 1960s and 1970s, declined in the 1980s, reached a nadir in 1990, and rose again in the early and mid-1990s, peaking among eighth graders in 1996 (see Table 4–4). Use declined slightly in the late 1990s and was stable in 2000. Marijuana accounted for most of the increased drug use during the 1990s. Table 4–4 shows that marijuana use is still widespread among American youth. Use of most other drugs, including crack cocaine, declined during the 1990s. The major exception to this encouraging trend has been the increased use of ecstasy and anabolic steroids in 1999 and

2000. However, use of both drugs showed a decline in 2002. Overall drug and alcohol use also decreased in 2002. Studies indicate that the rise and fall in use of a substance is heralded by changes in the perceived risks and benefits of using the substance. Increased availability has been a major factor in the rising use of anabolic steroids and ecstasy. The age at initiation of alcohol and other substance abuse dropped significantly in the early 1990s. Currently, most first-time users are between 12 and 14 years of age. Inhalants such as glue and gasoline are predominantly a choice of younger adolescents. This statistic is particularly worrisome because early-onset substance use is one of the best predictors of persistent abuse later in life.

Table 4–2. Physiologic effects of commonly abused mood-altering substances.¹

EYES/PUPILS	
Mydriasis	Amphetamines, MDMA, or other stimulants, cocaine, glutethimide, jimsonweed, LSD Withdrawal from alcohol and opioids
Miosis	Alcohol, barbiturates, benzodiazepines, opioids, PCP
Nystagmus	Alcohol, barbiturates, benzodiazepines, inhalants, PCP
Conjunctival injection	LSD, marijuana
Lacrimation	Inhalants, LSD. Withdrawal from opioids.
CARDIOVASCULAR	
Tachycardia	Amphetamines, MDMA, or other stimulants, cocaine, LSD, marijuana, PCP. Withdrawal from alcohol, barbiturates, benzodiazepines.
Hypertension	Amphetamines, MDMA, or other stimulants, cocaine, LSD, marijuana, PCP. Withdrawal from alcohol, barbiturates, benzodiazepines.
Hypotension	Barbiturates, opioids. Orthostatic: marijuana. Withdrawal from depressants.
Arrhythmia	Amphetamines, MDMA, or other stimulants, cocaine, inhalants, opioids, PCP
RESPIRATORY	
Depression	Opioids, depressants, GHB
Pulmonary edema	Opioids, stimulants
CORE BODY TEMPERATURE	
Elevated	Amphetamines, MDMA, or other stimulants, cocaine, PCP. Withdrawal from alcohol, barbiturates, benzodiazepines, opioids.
Decreased	Alcohol, barbiturates, benzodiazepines, opioids, GHB
PERIPHERAL NERVOUS SYSTEM RESPONSE	
Hyperreflexia	Amphetamines, MDMA, or other stimulants, cocaine, LSD, marijuana, methaqualone, PCP Withdrawal from alcohol, barbiturates, benzodiazepines
Hyporeflexia	Alcohol, barbiturates, benzodiazepines, inhalants, opioids
Tremor	Amphetamines or other stimulants, cocaine, LSD Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine
Ataxia	Alcohol, amphetamines, MDMA, or other stimulants, barbiturates, benzodiazepines, inhalants, LSD, PCP, GHB
CENTRAL NERVOUS SYSTEM RESPONSE	
Hyperalertness	Amphetamines, MDMA, or other stimulants, cocaine
Sedation, somnolence	Alcohol, barbiturates, benzodiazepines, inhalants, marijuana, opioids, GHB
Seizures	Alcohol, amphetamines, MDMA, or other stimulants, cocaine, inhalants, methaqualone, opioids (particularly meperidine, propoxyphene) Withdrawal from alcohol, barbiturates, benzodiazepines
Hallucinations	Amphetamines, MDMA, or other stimulants, cocaine, inhalants, LSD, marijuana, PCP Withdrawal from alcohol, barbiturates, benzodiazepines
GASTROINTESTINAL	
Nausea, vomiting	Alcohol, amphetamines or other stimulants, cocaine, inhalants, LSD, opioids, peyote, GHB Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine, opioids

Table 4–3. Effects of commonly abused mood-altering substances.

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
Alcohol (ethanol)	Depressant; 10 g/drink Drink: 12 oz beer, 4 oz wine, 1½ oz liquor; one drink increases blood level by approxi- mately 0.025 g/dL (varies by weight)	Legal: 0.05–0.1 g/dL (varies by state) Mild: < 0.1 g/dL; disinh- bition, euphoria, mild sedation and impaired coordination Moderate: 0.1–0.2 g/dL; impaired mentation and judgment, slurred speech ataxia Severe: > 0.3 g/dL; con- fusion, stupor; > 0.4 g/dL; coma, depressed respiration	Mild: headache, tremors, nausea and vomiting ("hangover") Severe: fever, sweaty, seizure, agitation, hallucination, hyper- tension, tachycardia Delirium tremens (chronic use)	Hepatitis, cirrhosis, car- diac disease, Wer- nicke encephalop- athy, Korsakoff syndrome
Marijuana (cannabis)	Delta-9-tetrahydro- cannabinol (THC); 4–6% in marijuana; 20–30% in hashish	Low: euphoria, relaxation, impaired thinking High: mood changes, depersonalization, hallucinations Toxic: panic, delusions, paranoia, psychosis	Irritability, disturbed sleep, tremor, nystag- mus, anorexia, diarrhea, vomiting	Cough, gynecomastia, low sperm count, in- fertility, amotivational syndrome, apathy
Cocaine	Stimulant; releases biogenic amines; concentration varies with preparation and route of admin- istration	Hyperalert, increased energy, confident, in- somnia, anxiety, para- noia, dilated pupils, tremors, seizures, hy- pertension, arrhythmia, tachycardia, fever, dry mouth Toxic: coma, psychosis, seizure, myocardial in- farction, stroke, hyper- thermia, rhabdomy- olysis	Drug craving, depres- sion, dysphoria, irrita- bility, lethargy, trem- ors, nausea, hunger	Nasal septum ulceration, epistaxis, lung damage, intravenous drug use
Opioids (heroin, morphine, co- deine, metha- done, opium, fen- tanyl, meperidine, propoxyphene)	Depressant; binds central opioid recep- tor; variable con- centrations with sub- stance	Euphoria, sedation, im- paired thinking, low blood pressure, pin- point pupil, urinary re- tention Toxic: hypotension, ar- rhythmia, depressed respiration, stupor, coma, seizure, death	Only after > 3 weeks of regular use: drug crav- ing, rhinorrhea, lac- rimation, muscle aches, diarrhea, anx- iety, tremors, hyper- tension, tachycardia.	Intravenous drug use: cellulitis, endocarditis, embolisms, HIV
Amphetamines	Stimulant; sympatho- mimetic	Euphoria, hyperalert state, hyperactive, hy- pertension, arrhythmia, fever, flushing, dilated pupils, tremor, ataxia, dry mouth	Lethargy, fatigue, de- pression, anxiety, nightmares, muscle cramps, abdominal pain, hunger	Paranoia, psychosis

(continued)

Table 4–3. Effects of commonly abused mood-altering substances. (continued)

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
		Toxic: coma, circulatory collapse, hypertensive crisis, cerebral hemorrhage		
MDMA (ecstasy)	Stimulant, psychedelic; releases serotonin, dopamine, and nor-epinephrine; inhibits reuptake of neurotransmitters; increases dopamine synthesis; inhibits MAO	Enhanced empathy, euphoria, increased energy and self-esteem, tachycardia, hypertension, increased psychomotor drive, sensory enhancement, illusions, difficulty concentrating and retaining information, headaches, palpitations, flushing, hyperthermia Toxic: frank psychosis, coma, seizures, intracranial hemorrhage, cerebral infarction, asystole, pulmonary edema, multisystem organ failure, acute renal or hepatic failure, ARDS, DIC, SIADH, death	None	Paranoid psychosis
GHB (liquid ecstasy)	Depressant, endogenous CNS transmitter; influences dopaminergic activity, higher levels of GABA-B activity	10 mg/kg: sleep 30 mg/kg: memory loss 50 mg/kg: general anesthesia Toxic: CNS and respiratory depression, aggressiveness, seizures, bradycardia, apnea	Only after chronic use with dosing every 3 hrs Early: mild tremor, tachycardia, hypertension, diaphoresis, moderate anxiety, insomnia, nausea, vomiting Progressive: confusion, delirium, hallucinations, autonomic instability, death	Wernicke–Korsakoff
Sedative-hypnotics (barbiturates, benzodiazepines, methaqualone)	Depressant	Sedation, lethargy, slurred speech, pinpoint pupils, hypotension, psychosis, seizures Toxic: stupor, coma, cardiac arrest, seizure, pulmonary edema, death	Only after weeks of use: agitation, delirium, psychosis, hallucinations, fever, flushing, hyper- or hypotension, death	Paranoia

(continued)

Table 4–3. Effects of commonly abused mood-altering substances. (continued)

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
Hallucinogens (LSD, peyote, mescaline, mushrooms, nutmeg, jimsonweed)	Inhibition of serotonin release	Illusions, depersonalization, hallucination, anxiety, paranoia, ataxia, dilated pupils, hypertension, dry mouth Toxic: coma, terror, panic, “crazy feeling”	None	Flashbacks
Phencyclidine	Dissociative anesthetic	Low dose (< 5 mg): illusions, hallucinations, ataxia, hypertension, flushing Moderate dose (5–10 mg): hyperthermia, salivation, myoclonus High dose (> 10 mg): rigidity, seizure, arrhythmia, coma, death	None	Flashbacks
Inhalants (toluene, benzene, hydrocarbons and fluorocarbons)	Stimulation progressing to depression	Euphoria, giddiness, impaired judgment, ataxia, rhinorrhea, salivation, hallucination Toxic: respiratory depression, arrhythmia, coma, stupor, delirium, sudden death	None	Permanent damage to nerves, liver, heart, kidney, brain
Nicotine	Releases dopamine, 1 mg nicotine per cigarette	Relaxation, tachycardia, vertigo, anorexia	Drug craving, irritability, anxiety, hunger, impaired concentration	Permanent damage to lung, heart, cardiovascular system
Anabolic steroids ^a	Bind steroid receptor Stacking: use many types simultaneously; pyramiding: increase dosage	Increased muscle bulk, strength, endurance, increased drive, hypogonadism, low sperm count, gynecomastia, decreased libido, virilization, irregular menses, hepatitis, early epiphyseal closure, aggressiveness	Drug craving, dysphoria, irritability, depression	Tendon rupture, cardiomyopathy, atherosclerosis, peliosis hepatitis (orally active C17 derivatives of testosterone are especially hepatotoxic)

^aDespite conventional assumptions, scientific studies show that anabolic steroids do not improve aerobic athletic performance and improve strength only in athletes trained in weight lifting before they begin using steroids who continue to train and take a high-protein diet.

MORBIDITY ASSOCIATED WITH SUBSTANCE ABUSE

Use and abuse of alcohol or other mood-altering substances is associated with the leading causes of adolescent and young adult deaths and injuries in the United States (ie, motor vehicle accidents, other unintentional injuries, homicide, and suicide), which are typically

outcomes of high-risk or violent behaviors combined with impaired judgment. Substance abuse is also associated with physical and sexual abuse. Up to two thirds of sexual assaults and acquaintance or date rapes are linked to alcohol or other drug use. Drug use and abuse also contribute to other high-risk behaviors, such as unsafe and increased sexual activity, leading to unintended pregnancy and sexually transmitted diseases. The use of drugs during periods of low self-esteem and depression increases the risk of suicide.

The well-known long- and short-term risks associated with tobacco, alcohol, and cocaine are listed in Table 4-3. Less well known are the long- and short-term morbidities connected with the currently most popular illicit drugs among adolescents (eg, marijuana and ecstasy). The active ingredient in marijuana, δ -9-tetrahydrocannabinol (THC), transiently causes tachycardia, mild hypertension, and bronchodilation. Regular use can cause lung changes similar to those seen in tobacco smokers. Heavy use decreases fertility in both sexes, leads to immunosuppression, and can cause the destruction of hippocampal and basal ganglia nuclei, resulting in disruption in cognition, learning, coordination, and memory. This may explain the development of so-called amotivational syndrome in heavy users, characterized by decreased attention to environmental stimuli and impaired goal-directed thinking and behavior. Also of concern is the increasing potency of available marijuana. Recent analysis of confiscated mar-

ijuana has shown a three- to five-fold increase in the concentration of THC since the 1970s and 1980s.

Ecstasy, which is gaining in popularity with teens and becoming more accessible, can cause permanent brain damage. Chronic use destroys the serotonin system of the brain and has been associated with progressive decline of immediate and delayed memory and with alterations in mood, sleep, and appetite. Even first-time users may develop frank psychosis indistinguishable from schizophrenia. Irreversible cardiomyopathy, noncardiogenic pulmonary edema, and pulmonary hypertension may occur with long-term use. Overdose can cause hyperthermia and multiorgan system failure.

Environmental and prenatal exposure to abused substances carry significant health risks. Parental tobacco smoking has been associated with low birth weight in newborns, sudden infant death syndrome, bronchiolitis, asthma, otitis media, and fire-related injuries. Paternal use of marijuana during pregnancy is associated with an increase the risk of sudden infant death syndrome. In utero exposure to cocaine and alcohol can result in fetal malformations, intrauterine growth retardation, and brain injury.

SUPPLEMENT USE AND ABUSE

Use of supplements or special diets to enhance athletic performance dates back to antiquity, when warriors and athletes ate certain animals to acquire their characteristics. Today, many elite and casual athletes use ergogenic supplements in an attempt to improve performance. The most popular products among the pediatric population are protein supplements, creatine, and the prohormones. Strength athletes (ie, weight lifters) use protein powders and shakes to enhance muscle repair and mass. The typical amount of protein consumed by athletes far exceeds the recommended daily allowance for resistance-training athletes (1.6–1.7 g/kg/d). Excess consumption of protein provides no added strength or muscle mass and can provoke renal failure in teens with underlying renal dysfunction.

Creatine is the most popular nutritional supplement, with annual sales of \$400 million. It is a combination of glycine, arginine, and methionine. Creatine is produced naturally in the liver, kidneys, and pancreas. It facilitates the production of adenosine triphosphate and increases free energy for muscle contraction. It maximizes power during short-duration, intense exercise, and improves baseline strength in adults. In contrast, creatine does not improve performance in longer duration, aerobic exercise; nor has its effectiveness been analyzed in children. Although the American College of Sports Medicine discourages use of the synthetic product by people under 18 years of age, recent studies show that creatine is extensively used by athletes in grades 6–12. Use by high-school juniors and seniors mirrors that of collegiate athletes. Side effects include weight gain, headache, abdominal pain, diarrhea, and increased muscle strain. There are conflicting reports about the risk of renal damage.

Most disturbing for health care providers is the growing availability and use of prohormones, specifically dehydroepiandrosterone (DHEA) and androstene-

dione. Sold as dietary supplements, these precursors to testosterone and other sex hormones are sold without federal regulation. Endogenous DHEA is produced in the adrenal cortex as a precursor of gonadal hormones. Putative benefits of DHEA include increased fat catabolism; increased muscle mass; increased libido; “improved” immune function; and decreased memory loss, heart disease, cancer, type II diabetes mellitus, Alzheimer, and Parkinson disease. Although its effects on strength and performance in athletes remain unstudied and unproven, the advertised benefits are attractive to many athletes. Its effect on young, healthy individuals (ie, those with higher baseline DHEA levels) has not been studied. In adults, two studies have shown that usage at 50 mg/d and 100 mg/d increases androgenic steroid plasma levels and improves subjective perception of physical and psychological well-being. Users of DHEA report few adverse effects.

Androstenedione, which is banned by the International Olympic Committee, National Collegiate Athletic Association, and National Football League, is converted to testosterone by the liver. A recent study of young athletes concluded that oral androstenedione does not increase plasma testosterone concentrations and, in young eugonadal men, has no anabolic effect on muscle protein metabolism. Other studies have shown increased biologically active estrogen levels. No long-term studies of androstenedione have been conducted. Its side effects are believed to be similar to those of other anabolic and androgenic agents. Most side effects are secondary to androgen excess—hyperlipidemia, hypertension, insulin resistance, hyperinsulinism, depression, aggression, paranoia, acne, male pattern baldness, alopecia, priapism, and others. Most effects are reversible with cessation of the product’s use. Irreversible side effects include virilization in females (hair loss, clitoromegaly, hirsutism, voice-deepening) and gynecomastia in males.

As the use of supplements and herbs increases, it will be increasingly important for pediatric care providers to be familiar with their common side effects. The Internet has become a source of information and sales of these products, which could lead to their increased use. The easy accessibility, perceived low risk, and low cost of these products significantly increase the likelihood that they will become significant substances of abuse by the pediatric population.

RESPONSE TO THE PROBLEM

Federal, state, and local governments attempt to control the damage caused by substance abuse by prohibiting use and by legislating against associated high-risk behaviors (eg, enacting drunk-driving laws and nighttime curfews). However, neither these legal actions nor the large sums of money spent on school- and community-based drug abuse prevention and treatment programs have curbed the problem. Hence, the American Academy of Pediatrics (AAP) recommends that pediatricians become knowledgeable about the extent and nature of drugs used in their community, provide anticipatory guidance to parents starting with the first prenatal visit, and be aware of community referral and treatment resources for adolescents. The Internet makes this task more difficult. For example, poor methods for age verification make it easy for minors to purchase tobacco products online.

PREDICTING THE PROGRESSION FROM USE TO ABUSE

Most adolescents who use mood-altering substances do so only intermittently or experimentally. The challenge to pediatric health care providers is to recognize the warning signs, identify potential abusers early, and intervene in an effective and timely fashion before acute or chronic use results in morbidity. The best predictors of ethanol and drug abuse are male sex, young age at first use, and associating with drug-using peers. It is still unclear why only a minority of the young people exhibiting the high-risk characteristics listed in Table 4–5 go on to abuse substances. Substance abuse is a symptom of personal and social maladjustment as often as it is a cause. Because a direct relationship exists between the number of risk factors listed in Table

4–5 and the frequency of substance abuse, a combination of risk factors is the best indicator of risk. Even so, most teenagers who exhibit multiple risk characteristics never develop a substance abuse problem, presumably because the protective factors listed in Table 4–5 give them enough resiliency to cope with stress in more socially adaptive ways.

Being aware of the risk domains listed in Table 4–5 will help physicians identify youngsters most apt to need counseling about substance abuse. Theories concerning the mechanisms responsible for the association between the risk factors listed in Table 4–5 and substance abuse are listed in Table 4–6. These theories provide a framework for understanding why individual patients may be at risk for progressing from occasional to established or compulsive substance abuse. Most theories emphasize social influences as the most reliable predictors of both the onset and the progression of substance abuse. For example, most teenage smokers report smoking at home and cite smoking parents or relatives as a reason to continue smoking.

Problem behavior theory is one of the most frequently cited concepts in the substance abuse literature. Its main argument is that socially disapproved behaviors tend to cluster and to resist intervention because they have both negative and positive consequences for the individual. Expectancy theory, which takes up where problem behavior theory leaves off, proposes a potentially modifiable mechanism by which learning experiences influence substance abuse. Measuring alcohol- and drug-related expectations has been found to provide a more accurate assessment of risk than any of the factors listed in Table 4–5. Expectations about the effects of substances are important determinants of social and psychological reactions to them. Furthermore, these expectations are longitudinally related to different patterns of substance abuse. For example, within homogeneous groups of nondrinkers, low-risk drinkers, and high-risk drinkers, expectations about outcomes differ significantly both at entry into college and 3 years later. At each level alcohol abusers who progress to the next level of drinking expect more positive outcomes from the drinking. Conversely, evidence that negative experiences with alcohol transform some high-risk freshmen drinkers into nondrinking seniors suggests that it may be possible to influence indulgence patterns by altering expectancies. Here intervention is critical. Without guidance, most youngsters do not draw sobering conclusions from their negative experiences with drugs and alcohol. Despite serious accidents and socially unrewarding experiences, positive expectancies about the effects of alcohol tend to increase rather than decrease during the first 3 years of college. Similarly the expectation of weight loss and improved mood leads to initiation of smoking or reluctance to quit.

Table 4–5. Factors that influence the progression from substance use to substance abuse.

Enabling Risk Factors	Potentially Protective Factors
SOCIETAL AND COMMUNITY	
Experimentation encouraged by media Illicit substances available Extreme economic deprivation Neighborhood disorganization, crowding Tolerance of licit and illicit substance use	Regular involvement in church activities Support for norms and values of society Strict enforcement of laws prohibiting substance use among minors and abuse among adults Neighborhood resources, supportive adults
SCHOOL	
Lack of commitment to school or education Truancy Academic failure Early, persistent behavior problems	Strong commitment to school or education Future-oriented goals Achievement oriented
FAMILY	
Models of substance abuse and other unconventional behavior Dysfunctional parenting styles; excessive authority or permissiveness High family conflict; low bonding	Models of conventional behavior Attachment to parents Cohesive family Nurturing parenting styles
PEERS	
Peer rejection in elementary grades Substance use prevalent among peers Peer attitudes favorable to substance abuse and unconventional behavior	Popular with peers Abstinent friends Peer attitudes favor conventional behavior
INDIVIDUAL	
Genetic predisposition Psychological diagnoses (attention-deficit/hyperactivity disorder; antisocial personality) Depression and low self-esteem Alienation and rebelliousness Sexual or physical abuse Early onset of deviant behavior or delinquency Early onset of sexual behavior Aggressive	Positive self-concept, good self-esteem Intolerance of deviance Internally motivated, takes charge of problems

MANAGEMENT OF SUBSTANCE ABUSE

It is critical that pediatric care providers have the knowledge and skill to diagnose, treat, and advocate for their substance-using and abusing patients. The AAP Committee on Substance Abuse recommends that pediatricians include discussions of substance abuse as part of their anticipatory care, starting with parents at the prenatal visit.

Office Screening

Given the high incidence of substance abuse and the subtlety of its early signs and symptoms, a general psychosocial assessment is the best way to screen for substance abuse. Interviewing and counseling techniques and methods for taking a psychosocial history are discussed in Chapter 3. In an atmosphere of trust and confidentiality, physicians must ask routine screening questions of all patients and be alert for addictive diseases, especially in light of the high level of denial often present in addicted patients. The universal screening approach outlined in the American Medical Association guidelines for adolescent preventive services (GAPS) is a good guide for routine screening and diagnosis. Clues to possible substance abuse include truancy, failing grades, problems with interpersonal relationships, delinquency, depressive affect, chronic fatigue, recurrent abdominal pains, chest pains or palpitations, headache, chronic

Table 4–6. Theories accounting for the progression from substance use to substance abuse.^a

Theory	Key Constructs and Assumptions	Major Protagonist
Problem Behavior	Socially problematic behaviors ^b occur together and reflect a common underlying cause. The common antecedent is the reflection of the interaction among individual personality traits (eg, unconventionality), the perceived environment (eg, models of deviance), and a nondominant pattern of socialization (eg, low value on education).	Jessor R, Jessor R: <i>Problem Behavior and Psychosocial Development</i> . Academic Press, 1977.
Social Learning	Problem behavior theory plus a scheme to explain reinforcement of these behaviors. The risk of problem behavior increases when youngsters have the opportunity to become skillful in unconventional settings and are rewarded for doing so.	Bandura A: <i>Social Learning Theory</i> . Prentice-Hall, 1977.
Reasoned Action	Behavior is determined by the interaction between perceived consequences and attitudes toward those consequences. The risk of problem behavior increases when the perceived costs are low or the perceived benefits high.	Ajzen I, Fishbein M: <i>Understanding Attitudes and Predicting Behavior</i> . Prentice-Hall, 1980.
Health Belief	Health behaviors reflect assessments of perceived risk or harm, potential to avoid that harm through alternative behaviors, and ability to access requisite resources. The risk of unhealthy behavior increases when the perceived health risk is low or the ability to avoid that risk is perceived to be low or unrelated to the behavior.	Becker MH: The health belief model and personal health behavior. <i>Health Education Monograph</i> 1974;2:324.
Social Control	Behavior is determined by the bonds an individual establishes with society. The risk of problem behavior increases when attachment to those who express conventional values is weak, commitment to participation in conventional activities is low, little time is spent in these activities, and the central value system of society is not fully accepted.	Hirschi T: <i>Causes of Delinquency</i> . Univ California Press; 1969.
Peer Cluster	The socialization process that accompanies adolescent development results in the formation of peer clusters. Family sanctions, religious identifications, and school adjustment affect behavior indirectly through their effects on peer clusters.	Oetting ER, Beauvais F: Peer cluster theory. <i>Counseling Psychol</i> 1987; 34:205.
Expectancy	Problem behavior and reasoned action theories plus a mechanism by which learning experiences exert an influence on future behavior. The risk of problem behavior increases when experiences reinforce preexisting positive expectancies about the effects of deviant behavior.	Werner MJ: Relation of alcohol expectancies to change in problem drinking among college students. <i>Arch Pediatr Adolesc Med</i> 1995;149: 733.
Self-Medication	Individuals are predisposed to addiction when they experience painful affective states or psychiatric disorders; symptom relief perpetuates the use of specific substances.	Khantzian EJ: The self-medication hypothesis. <i>Am J Psychiatry</i> 1985;142:1259.

^aOrdered by frequency of citation in the literature.

^bA problem behavior is defined as any behavior compromising the accomplishment of normal developmental tasks of adolescence; most are hard to change because they also serve functions central to the psychosocial development of adolescents who lack conventional alternatives.

cough, persistent nasal discharge, and recurrent complaints of sore throat. Substance abuse should be included in the differential diagnosis of all behavioral, family, psychosocial, and medical problems. Pediatricians seeing patients in emergency departments, trauma units, or prison must have an especially high index of

suspicion. A family history of drug addiction or abuse should raise the level of concern about drug abuse in the pediatric patient. Possession of promotional products such as T-shirts and caps with cigarette or alcohol logos should also be a red flag as teenagers who own these items are more likely to use the products they advertise.

Diagnosis

Although few children and adolescents will have been abusing substances long enough to have developed overt signs and symptoms, it is important to look for them on physical examination. Positive physical findings can be a tool to penetrate a patient’s denial and convince him or her of the significant extent of the alcohol or drug use.

When the psychosocial history suggests the possibility of substance use, the primary tasks of the diagnostic interview are the same as the evaluation of other medical problems (Table 4–7).

First, specific information about the extent of the problem must be gathered. Eliciting multiple-choice answers is a useful technique. For example, “Has anything really good ever happened to you when you are high?” or “Some of my patients like to get high because they feel good; others find it helps them relax and be sociable with friends; and some find it helps them forget their problems. Are any of these things true for you?”

Second, the provider needs to determine why the patient has progressed from initiation to the continua-

Table 4–7. Diagnostic interview for substance abuse.

I. Define the extent of the problem by determining:

- Age at onset of substance use
- Which substances are being used
- Circumstances of use
 - Where?
 - When?
 - With whom?
- To what extent substances are being used
 - How frequently?
 - How much (quantity)?
 - With what associated symptoms (eg, tolerance, withdrawal)?
- With what result?
 - What does the patient gain from becoming high?
 - Does the patient get into risky situations while high?
 - Does the patient engage in behaviors while high that are later regretted?

II. Define the cause of the problem by developing a differential diagnosis

tion or maintenance phase of substance abuse. The cause may be different at different periods of development. Although peer group characteristics are one of the best predictors of substance use among early and middle adolescents, this is not so among older adolescents and young adults.

Brief questionnaires can be used if time does not allow for more detailed investigation. Two instruments evaluated rigorously in primary care settings are the CAGE questionnaire and the Perceived Benefits of Drinking Scale. CAGE is a mnemonic derived from the first four questions listed in Table 4–8. A score of 2 or more is highly suggestive of substance abuse. The Perceived-Benefits-of-Drinking Scale consists of the next five statements listed in Table 4–8. Patients who endorse more than three statements deserve further evaluation. Because CAGE is more predictive of substance use problems among males and the Perceived-Benefits-of-Drinking Scale is more predictive among females, many clinicians combine the two scales. Including an additional question about use of tobacco and a question about the patient’s best friend’s use of mood-altering

Table 4–8. Substance abuse screening questionnaires.

CAGE Questionnaire
CUT DOWN: Have you ever felt you ought to cut down on your drinking (drug use)?
ANNOYED: Have people annoyed you by criticizing your drinking (drug use)?
GUILTY: Have you ever felt bad about your drinking (drug use)?
EYE OPENER: Have you ever had a drink (used drugs) to steady your nerves in the morning?
(Score 1 point for each positive answer; refer if total points ≥ 2)
Used, with permission, from Ewing JE: Detecting alcoholism: The CAGE questionnaire. <i>JAMA</i> 1984;252:1905.
Perceived Benefits Scales
1. Drinking (drug use) helps me forget my problems.
2. Drinking (drug use) helps me be friendly.
3. Drinking (drug use) helps me feel good about myself.
4. Drinking (drug use) helps me relax.
5. Drinking (drug use) helps me be friends with others who drink (use drugs).
(Score 1 point for each positive answer; refer if total points ≥ 3)
Used, with permission, from Petchers MK, Singer MI: Perceived-Benefit-of-Drinking Scale. <i>J Pediatr</i> 1987;110:977.

substances further enhances the diagnostic accuracy of these screening tools.

Although constructed as screening tools for alcohol abuse in adults, the questions in Table 4–8 can be adapted to elicit similar information about use of other mood-altering substances by pediatric patients and by their close contacts (eg, parents and older siblings). Finally, clinicians may find it helpful to use these questionnaires to stimulate discussion of the patient's self-perception of his or her substance use. For example, if an adolescent admits to a previous attempt to cut down on drinking, this provides an opportunity to inquire about events that may have led to the attempt.

Additional screening instruments include the following:

1. The Simple Screening Instrument for Alcohol and Other Drug Abuse (SSI-AOD), from the Center for Treatment of Substance Abuse, is a quick, 16-item screen that has proven reliable among adolescent medical patients.
2. The Personal Experience Inventory is a comprehensive, standardized 260-item self-report measure of chemical involvement and the psychosocial aspect of substance use.
3. The Personal Experience Screening Questionnaire is a quick, 38-item screen that evaluates the severity of the problem and associated psychosocial risks.
4. The Adolescent Diagnostic Interview is a structured interview based on the American Psychiatric Association's diagnostic criteria for substance abuse (see Table 4–1).

Although these instruments may be too time-consuming for routine office use, they may prove helpful in the evaluation of patients who pose diagnostic or therapeutic dilemmas.

Comorbidity

It is important for pediatric care providers to recognize the possibility of multiple diagnoses in patients who are

abusing substances. Alcohol and substance abusers are more likely than are their nonabusing counterparts to have another psychiatric disorder. Affective disorders, anxiety disorders, and mania rank among the disorders most strongly associated with alcohol and drug dependence. Adolescents with depression are likely to use drugs in an attempt to feel pleasure, but this type of self-medication may exacerbate their condition. In addition to identifying psychiatric comorbidities, it is imperative that providers look for medical conditions that can mimic symptoms of drug withdrawal or intoxication. Patients with significant primary medical conditions may use illicit substances to relieve symptoms (severe pain, chemotherapeutic side effects). Although it is often difficult to determine which diagnosis is primary, it is important for pediatric health care providers to recognize the possibility of a comorbid condition and provide appropriate treatment.

Pharmacologic Screening

The use of urine and blood testing for detecting substance abuse is controversial. The consensus is that pharmacologic screening should be reserved for situations where behavioral dysfunction is of sufficient concern to outweigh the practical and ethical drawbacks of testing. The AAP recommends screening under certain circumstances (eg, an inexplicably obtunded patient in the emergency department) but discourages routine screening for the following reasons: (1) Voluntary screening programs are rarely truly voluntary owing to the negative consequences for those who decline to participate. (2) Infrequent users or individuals who have not used substances recently may be missed. (3) Confronting substance-abusing individuals with objective evidence of their use has little or no effect on their behavior. (4) The AAP reminds providers that their role is counseling and treatment, not law enforcement, so that drug testing should not be done for the purpose of detecting illegal use. If testing is to be performed, the provider should discuss the plan for screening with the patient, explain the reasons for it, and obtain informed consent. The AAP does not consider parental request and permission sufficient justification for involuntary screening of mentally competent minors.

Beyond the ethical concerns, there are also practical concerns. If testing is to be performed, it is imperative

that it be done accurately and that the limitations of testing be understood by all parties. Tests range from simple, inexpensive, chromatographic spot tests, which can be performed in the office, to gas chromatography and mass spectrometry, which require specialized laboratory equipment and are usually reserved for forensic investigations. Most commercial medical laboratories use the enzyme multiplication immunoassay technique, in which a sample of the fluid to be tested is added to a test reagent consisting of a known quantity of the radiolabeled index drug (ie, the drug being tested for). If the index drug is also present in the patient's urine or serum, it competes with the radiolabeled drug for binding sites on the test kit antibody. The unbound or excess drug can then be quantified with a spectrophotometer. Most of the commonly abused mood-altering substances, with the exception of solvents and inhalants, can be detected by this method.

Caution is necessary in interpreting results because false-positives may be obtained as a result of antibody cross-reactions with the medications and substances listed in Table 4-9 or from passive exposure to illicit substances. The most common cause of false-negative tests is infrequent use. Table 4-10 shows the duration of detectability in the urine after last use by class of substance and duration of use. Detectability ranges from a few hours for alcohol to several weeks for regular marijuana use. False-negative results can occur if the patient alters or adulterates the specimen, either by drinking a large volume of fluid or adding such substances as bleach, vinegar, or golden seal powder to the specimen. (Teenagers should be advised that despite street lore,

TREATMENT & REFERRAL

Office-Based Treatment

The AMA and the AAP recommend that all children and adolescents receive counseling about the dangers of substance use and abuse from their primary health care providers. By offering confidential health care services

and routinely counseling about the risks associated with drug abuse, pediatricians can help most of their patients avoid the adverse consequences of experimentation with mood-altering substances. However, more intervention is required for youngsters in environments where substance abuse is regarded as acceptable recreational behavior. Because substance use is often deeply embedded in the fabric of these young peoples' lives, most have little interest in prevention or treatment. Counseling strategies appropriate for patients who wish to change their behavior may be ineffective for a patient who does not consider use of mood-altering substances to be a problem. It may therefore be preferable to begin discussions about treatment by helping youngsters consider alternative ways of meeting the needs that substance use is currently providing. The clinician may in this way help the patient devise alternatives that are more attractive than substance use. Realistically, few substance-abusing teenagers will choose to quit because of a single conversation with even a highly respected health care provider. The message is most effective when offered repeatedly from a variety of sources—family, peers, guidance counselors, and teachers.

Because an assessment of the patient's readiness to change is the critical first step in office-based intervention, clinicians should consider the construct presented in Table 4–11. In theory, individuals pass through this series of stages in the course of changing problem behaviors. Thus, to be maximally effective, providers should tailor their counseling messages to the patient's stage of readiness to change.

Once it has been established that a patient is prepared to act on information about treatment, the next step is to select the program that best fits his or her individual needs. Most drug treatment programs are not designed to recognize and act on the individual vulnerabilities that have predisposed the patient to substance abuse. When programs are individualized, even brief (5- to 10-minute) counseling sessions may promote reductions in cigarette smoking and drinking. This strategy appears to be most effective when the health care provider's message is part of an office-wide program so that the entire staff reinforces the cessation message with every patient. Specific steps to help youngsters quit smoking are discussed in the next section and summarized in Table 4–12. These same strategies and principles can be applied to the treatment of drug and alcohol use.

Smoking Cessation in Pediatrics

Although more than half of adolescents who smoke regularly say they want to quit and have tried to quit, only a minority report that they have been advised or helped to do so by a health care provider. Practitioners unfa-

Table 4–11. Stages of change and intervention tasks.

Patient Stage	Motivation Tasks
Precontemplation	Create doubt, increase the patient's awareness of risks and problems with current patterns of substance use
Contemplation	Help the patient weigh the relative risks and benefits of changing substance use; evoke reasons to change and risks of not changing; strengthen the patient's self-efficacy for changing current use
Determination	Help the patient determine the best course of action to change substance use from among available alternatives
Action	Help the patient establish a clear plan of action toward changing substance use
Maintenance	Help the patient identify and use strategies to prevent relapse
Relapse	Help the patient renew the process of change starting at contemplation

miliar with approaches to smoking cessation may feel that smoking cessation interventions are time-consuming, nonreimbursable, and impractical in a busy office. In reality, studies conducted by the National Cancer Institute indicate that health care providers can help their patients stop smoking with short office interventions. Some of the most effective smoking cessation interventions are self-help programs consisting of a series of short (typically under 5 minutes) physician interventions reinforced by the entire office staff using the simple protocol outlined in Table 4–12.

The first step is motivational. Provide patients with a list of reasons for quitting. Suggest that they call 1-800-4CANCER to obtain the National Cancer Institute's "Quit for Good" or "Why Do You Smoke?" pamphlets and materials.

However, motivation alone is not enough. Learning to use coping skills to prevent relapse and to avoid discouragement at the time of relapse appear to be important to ultimate success. Smoking cessation is a process that takes time. Relapse must be regarded as a normal part of quitting rather than evidence of personal failure or a reason to forgo further attempts. Patients can actually benefit from relapses if they are helped to identify the circumstances that led to the relapse and to devise

Table 4–12. How to help your patients stop smoking.**Ask** about smoking at every opportunity.

1. Do you smoke? How old were you when you started?
2. How much?
3. How soon after waking do you have your first cigarette?
4. Do you have friends who smoke? family members? relatives? role models?
5. Are you interested in stopping smoking?
6. Have you ever tried to stop before? If so, what happened?

Advise all smokers to stop.

1. State your advice clearly, for example: “As your physician, I must advise you to stop smoking now.”
2. Personalize the message to quit. Refer to the patient’s clinical condition, smoking history, family history, personal interests, or social roles (see Table 4–13).

Assist the patient in stopping.

1. Set a quit date. Help the patient pick a date within the next 4 weeks, acknowledging that no time is ideal.
2. Provide self-help materials. The smoking cessation coordinator or support staff member can review the materials with the patient.
3. Discuss the importance of a smoke-free environment.
4. Rehearse through role-playing how to respond to social situations where others are smoking.
5. Elicit support of parents and relatives; encourage them to stop smoking with their teen.
6. Encourage participation in activities that are incompatible with smoking.
7. Consider prescribing replacement therapy (patch or gum) for highly addicted patients (those who smoke a pack or more daily or who smoke their first cigarette within 30 minutes after waking).
8. Consider signing a stop-smoking contract with the patient.
9. If the patient is not willing to quit now, provide motivating literature and flag the chart and do remember to ask again at the next visit.

Arrange follow-up visits.

1. Set a follow-up visit within 1–2 weeks after the quit date.
2. Have a member of the office staff call or write the patient within 7 days after the initial visit, reinforcing the decision to stop and reminding the patient of the quit date.
3. At the first follow-up visit, ask about the patient’s smoking status to provide support and help prevent relapse.
4. Set a second follow-up visit in 1 month.
5. Remind the teen that relapse is common—indeed the norm. When it happens, discuss the circumstances and encourage the patient to think of alternative responses and to try again.

Adapted, with permission, from Glynn T, Manley M: *How to Help Your Patients Stop Smoking: A National Cancer Institute Manual for Physicians*. National Institutes of Health, 1989.

strategies to prevent subsequent relapses or respond to them in a different manner. Because nicotine is a physically and psychologically addictive substance, replacement therapy may relieve withdrawal symptoms. Three types of nicotine replacement therapies (NRT) are available. Nicotine gum and transdermal nicotine patches are recommended for teens. NRT improves smoking cessation rates and provides relief from withdrawal symptoms. Providers should be aware that adolescents may not exhibit the same symptoms of nicotine dependence as adults, that symptoms may occur rapidly, with autonomy lost within as little as 4 weeks. Those who are not comfortable prescribing and monitoring NRT should limit their involvement with patients who smoke to those who do not exhibit signs of nicotine dependency (eg, patients who smoke less than a pack of cigarettes a day or do not feel a craving to smoke their first cigarette within 30 minutes after waking). In addition to NRT, sustained-release forms of the antidepressants bupropion, clonidine, and nortriptyline have been shown in randomized trials to help smokers quit and to decrease relapse rates fivefold.

Two tobacco-use prevention curricula have been selected by The Division of Adolescent and School Health (DASH) of the CDC for adoption by schools—Botvin’s Life Skills Training Program and Project Toward No Tobacco (TNT). The first is the more comprehensive of the two curricula. It is designed to target the primary causes of substance use, including tobacco, alcohol, and other drugs, by teaching a combination of health information, general life skills, and skills in resisting tobacco and other drugs. Program effectiveness has been demonstrated among white, African-American, and Hispanic youth.

Project TNT, the second curriculum and the more effective of the two, was designed to target the primary causes of cigarette smoking, smokeless tobacco use, and cigar and pipe smoking among teens. Compared with the subjects who received the standard school health education, subjects in Project TNT were less likely to start using smokeless tobacco or cigarettes, and less likely to use them regularly. The program was equally effective in boys and girls, and was effective during the transitional period from junior to senior high school.

Referral

There is no consensus about which substance-abusing patients can be adequately treated in the office, which require referral, and which require hospitalization. Factors to be considered are summarized in Table 4–13. When doubt exists about the seriousness of the problem or the advisability of office management, consultation with a specialist should be sought.

Although most primary pediatric providers will not assume responsibility for the treatment of substance-abusing youngsters, clinicians can be instrumental in motivating their patients to seek treatment and in guiding them to appropriate treatment resources. Substance-abusing teenagers must be treated in teen-oriented treatment facilities. Despite the similarities between adult and adolescent substance abuse, adult programs are usually developmentally inappropriate and ineffective for adolescents. As discussed in Chapter 3, many adolescents are concrete thinkers. Their inability to reason deductively, especially about emotionally charged issues, makes it difficult for them to understand the abstract concepts (such as denial) that are an

integral component of most adult-oriented programs. This invariably frustrates counselors who misinterpret lack of comprehension as resistance to therapy, and concrete responses as evidence of deceit.

Treatment programs range from low-intensity, outpatient, school-based student assistance programs, which rely heavily on peers and nonprofessionals, to residential, hospital-based programs staffed by psychiatrists and other professionals. Outpatient counseling programs are most appropriate for motivated patients who do not have significant mental health or behavioral problems and are not at risk for withdrawal. Some investigators have raised the concern that in pediatric settings, low-problem users may actually experience a strengthening of the drug subculture by associating with high-problem users in group therapy. More intensive day treatment programs are available for those who require a structured environment. Inpatient treatment should be considered for patients who need medical care and detoxification in addition to counseling, education, and family therapy.

Finally, special dual-diagnosis facilities are available for substance-abusing patients who also have other psychological conditions. These patients are difficult to diagnose and treat because it is often unclear whether their symptoms are a consequence of substance use or a symptom of a comorbid psychological disorder. Recognition of such disorders is critical because they must be treated in programs that include psychiatric expertise.

Approaches to the treatment of substance abuse in children and adolescents are typically modeled after adult treatment programs. Most notable are the 12-step programs modeled after Alcoholics Anonymous. These programs are attractive because they demand total abstinence and acknowledge that substance abuse is a chronic disease requiring a lifelong commitment to abstinence and long-term support from family, peers, and community. Although treatment is usually effective, relapse is common. Because efficacy research has lagged behind practice and implementation (especially among low-intensity programs), there is little empirical evidence on which to base recommendations for one program or another. Various forms of treatment appear to have the potential to be effective. Thus, in practice, referral recommendations should be based on the significance of the problem for the individual and the availability of affordable programs in the community.

Table 4–13. Factors to consider prior to referral for substance abuse.

PREVENTION OF SUBSTANCE ABUSE

Prevention of substance abuse has been a public health priority since the 1980s. Pediatric health care providers are important as advocates and educators of the community and government on developmentally appropriate programs. *Primary level* programs focus on preventing the initiation of substance use. The Drug Awareness and Resistance Education (DARE) program is a familiar example of a primary prevention program that attempts to educate elementary and middle school students about the adverse consequences of substance abuse and enable them to resist peer pressures.

Secondary level programs target populations at increased risk for substance use. The aim is to prevent progression from initiation to continuance and maintenance, relying on individualized intervention to reduce the risk and enhance the protective factors listed in Table 4–5. This approach enables the provider to focus scarce resources on those who are most likely to benefit from them. Alateen, which supports the children of alcoholic parents typifies secondary level prevention.

Tertiary level prevention programs target young people who have been identified as substance abusers. The aim is to prevent the morbid consequences of substance use. One example is identifying adolescents who misuse alcohol and drugs at parties and providing them with a safe ride home. Because prevention is more effective when targeted at reducing the initiation of substance use than at decreasing use, tertiary prevention is the least effective approach.

Very few population-based programs undergo rigorous scientific evaluation. It is the consensus among drug educators that primary prevention programs, such as DARE, have minimal effect in decreasing the use of illicit substances. During the 1990s, when these programs were most popular, a smaller proportion of middle- and high-school students perceived illicit drug and alcohol use as dangerous, and substance use actually increased. Even when knowledge- and resistance-based programs do increase student understanding of adverse consequences, there is no evidence that they change attitudes or abuse rates.

The failure of resistance education programs has fostered interest in a potentially more effective type of program, exemplified by the Adolescents Training and Learning to Avoid Steroids (ATLAS) program. This

program, a same-sex, peer-educator program designed to simultaneously reduce the use of steroids and improve dietary and exercise habits of teen athletes has proven effective in randomized controlled trials. Pediatric health care providers should promote developmentally appropriate prevention programs like this one that address the social and psychological problems predisposing youngsters to substance abuse and which provide realistic alternative solutions.

Parents and others should understand that most adolescents who abuse alcohol and drugs do not do so just for the high. Rather, these behaviors are often purposeful, developmentally appropriate coping strategies. To the extent that these behaviors meet young peoples' developmental needs, they are not apt to be abandoned unless equally attractive alternatives are available. For example, even though many teenagers cite stress and anxiety as reasons for smoking, teen-oriented smoking cessation programs rarely address the young smoker's need for alternative coping strategies by offering stress management training. Similarly, for the youngster growing up in an impoverished urban environment, the real costs of substance abuse may be too low and the rewards too high to be influenced by talk and knowledge alone. It is unreasonable to expect a talk-based intervention to change attitudes and behaviors in a direction that is opposite to that of the child's own social milieu. The efficacy of the most promising prevention models and interventions is apt to decay over time unless changes in the social environment provide substance-abusing children and adolescents with realistic alternative ways to meet their developmental needs.

Eric J. Sigel, MD

Teenagers and younger children continue to develop eating disorders at an alarming rate. The spectrum of eating disorders includes anorexia nervosa, bulimia nervosa, eating disorders not otherwise specified, and binge-eating disorder. The relationship between biology and environment in the development of eating disorders is complex, so these disorders are best defined in a biopsychosocial context.

ETIOLOGY

Some evidence supports a genetic predisposition for eating disorders. There is a 7% incidence of anorexia nervosa in first-degree relatives of anorexic patients compared with a 1–2% incidence in the general population. Twin studies have shown a 55% concordance rate in monozygotic twins, compared with 7% in dizygotic twins. A study of males with anorexia nervosa showed a relative risk of 20 for first-degree female relatives. Most studies have found a higher incidence of eating disorders among first-degree relatives of bulimic patients as well. Several genetic markers have been associated with an increased susceptibility to anorexia nervosa, though no clinically relevant genetic test is available to date. Genetics and eating disorders continue to be an active area of investigation, with a national study underway that will define the genetic aspect more specifically.

Leptin, a hormone produced in adipocytes and involved with satiety signaling, may play a role in the evolution of eating disorders. Anorexic patients have a decreased amount of leptin initially, which increases to excessive levels as they regain weight. One hypothesis is that there may be an abnormality in leptin receptors, with satiety indicators not responding normally. Other neurotransmitters, such as serotonin and neuropeptide Y, which are involved in satiety, are abnormal in some anorexic patients. An alteration in dopamine has also been recognized, though its significance has not been elucidated. Ghrelin, a gut peptide, has been shown to be elevated in patients with anorexia nervosa and is also hypothesized to play a role in the pathophysiology of anorexia. Patients with bulimia nervosa or binge-eating disorder appear to have a blunted serotonin response to eating and satiety. With a decreased satiety response, patients continue to eat, leading to a binge. Treatment with selective serotonin reuptake inhibitors (SSRIs)

tends to equilibrate satiety regulation. More research is needed to determine which factors are causative and which are results of the eating disorder.

Traditional psychological theory has suggested many factors that might lead to the development of eating disorders. Enmeshment of mother with daughter to the point that the teenager cannot develop her own identity (a key developmental marker of adolescence) may be a predisposing factor. The teenager may cope by asserting control over food, as she senses her lack of control in the developmental realm. A second theory involves father–daughter distancing. As puberty progresses and a girl's sexuality blossoms, a father may experience difficulty in dealing with his daughter as a sexual being and may respond by withdrawing both emotionally and physically. The teenage girl may intuitively recognize this and subconsciously decrease her food intake in order to become prepubertal again. A third theory is related to puberty itself. Some teenagers may fear or dislike their changing bodies. By restricting food intake they lose weight, stop menstruating, and effectively reverse pubertal development.

In addition, society has provided the message that being thin or muscular is necessary for attractiveness and success. The ease of access to diet products—foods and diet pills—as well as Internet instructions (proanorexia sites) makes it simple for adolescents to embark on a quest for thinness or muscularity.

Genetic predisposition, psychological factors, and environmental factors combine to create a milieu that promotes adolescent eating disorders.

INCIDENCE

Among teenage girls in the United States, anorexia nervosa is the third most common chronic illness. The incidence in the United States has been increasing steadily since the 1930s. Ascertaining exact incidence is difficult. It is thought that 1–2% of teenagers have anorexia nervosa and 2–4% have bulimia nervosa. Adolescents outnumber adults 5 to 1, although the number of adults with eating disorders is rising. The incidence is also increasing among younger children. Often prepubertal patients have significant associated psychiatric diagnoses. Females outnumber males 8 to 1. The number of males diagnosed with eating disorders has also increased, which correlates with the increased media emphasis on muscular, chiseled appearance as the male ideal. In the recent Youth Risk Behavior Survey (2001) of US teenagers, 62% of females and 29% of males were attempting to lose weight, a 3% increase compared with 1999. Fourteen percent of youth did not eat for more than 24 hours to lose weight. Overall, 9.2% of youth had used diet pills as a weight loss method in the previous 30 days—12.6% of girls and 5.5% of boys. Self-induced vomiting or laxative use (or both) was also common; 7.8% of females and 2.9% of males were using one or the other to lose weight. Concern about weight, and harmful attempts to lose weight all increased from 1999 to 2001. Binge-eating disorder has a 1.1% incidence in the teenage population. Forty-six percent of females and 30% of males report at least one bingeing episode during their lifetime.

PREDISPOSING FACTORS

In the past, the typical anorexic patient was described as a high-achieving, athletic, straight-A student from a middle class socioeconomic background. Demographics have changed somewhat, and anorexia nervosa now occurs in all races and socioeconomic classes. Children involved in gymnastics, figure skating, and ballet—activities that emphasize (and in which coaches often require) thin bodies—are at higher risk for anorexia than are children in sports that do not emphasize body

image. Sudden changes in dietary habits, such as becoming vegetarian, may be a first sign of anorexia, especially if the change is abrupt and without good reason.

The typical bulimic patient is more impulsive, tending to engage in risk-taking behavior such as alcohol use, drug use, and sexual experimentation. Bulimic patients are often an appropriate weight for height or slightly overweight, and they get average grades. Some studies have found that 50% of bulimic patients have been sexually abused. In males, wrestling and homosexual orientation predispose to bulimia nervosa.

DIAGNOSIS

1. Anorexia Nervosa

Table 5–1 lists the diagnostic criteria for anorexia nervosa, according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV). There are two forms of anorexia nervosa. In the restricting type, patients do not regularly engage in binge eating or purging. In the purging type, classic anorexia nervosa is combined with binge eating or purging behavior (or both). Differentiating the two is important because of differing implications for prognosis and treatment.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinicians should recognize the early symptoms and signs of anorexia nervosa because intervention may pre-

Table 5–1. Diagnostic criteria for anorexia nervosa.

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (eg, weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
- B. Intense fear of gaining weight or becoming fat, even though underweight.
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- D. In postmenarchal females, amenorrhea, ie, the absence of at least three menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, eg, estrogen, administration.)

Reprinted, with permission, from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Text Revision. Copyright 2000. American Psychiatric Association.

vent the full-blown syndrome from developing. Patients may show some of the behaviors and psychology of anorexia nervosa, such as reduction in dietary fat and intense concern with body image, even before weight loss or amenorrhea occurs.

Making the diagnosis of anorexia nervosa can be challenging because adolescents may try to conceal their illness. Assessing the patient's body image is essential to determining the diagnosis. Table 5-2 lists screening questions that help to tease out a teenager's perceptions of body image. Additional diagnostic screening tools include the Eating Attitudes Test (EAT) or other questionnaires that assess a range of eating and dieting behaviors. Parental observations are critical in determining whether a patient has expressed dissatisfaction over body habitus as well as revealing what weight loss techniques the child has attempted. In the teenager who is not ready to share his or her concerns about body image, the clinician may find clues to the diagnosis by carefully considering other presenting symptoms. Weight loss from a baseline of normal body weight is an obvious red flag and should raise the clinical suspicion of an eating disorder. Additionally, anorexia nervosa should be considered in any girl with secondary amenorrhea who has lost weight.

Physical symptoms are usually secondary to weight loss and proportional to the degree of malnutrition. The body effectively goes into hibernation, becoming functionally hypothyroid (euthyroid sick) to save as much energy as possible. Body temperature decreases, and patients report being colder than normal. Patients become bradycardic, especially in the supine position. Dizziness, lightheadedness, and occasional syncope may

Table 5-2. Screening questions to help diagnose anorexia and bulimia nervosa.

How do you feel about your body?
Are there parts of your body you might change?
When you look at yourself in the mirror, do you see yourself as overweight, underweight, or satisfactory?
If overweight, how much do you want to weigh?
If your weight is satisfactory, has there been a time that you were worried about being overweight?
If overweight/underweight, what would you change?
Have you ever been on a diet?
What have you done to help yourself lose weight?
Do you count calories or fat grams?
Do you keep your intake to a certain number of calories?
Have you ever used nutritional supplements, diet pills, or laxatives to help you lose weight?
Have you ever made yourself vomit to get rid of food or lose weight?

ensue, as orthostasis and hypotension secondary to impaired cardiac function occur. Left ventricular mass is decreased, (as all striated muscle throughout the body loses mass), stroke volume is compromised, and peripheral resistance is increased. Patients can develop prolonged QT syndrome, putting them at risk for cardiac arrhythmias. Peripheral circulation is reduced. Hands and feet may be blue and cool. Hair thins, nails become brittle, and the skin is dry. Lanugo develops as a primitive response to starvation. The gastrointestinal tract may be affected. Inability to take in normal quantities of food, early satiety, and gastroesophageal reflux can develop as the body adapts to reduced intake. The normal gastrocolic reflex may be temporarily lost due to lack of stimuli, leading to delayed gastric emptying and constipation.

Neurologically, patients may experience decreased cognition, inability to concentrate, increased irritability, and depression, which may be related to structural brain changes and decreased cerebral blood flow.

A combination of malnutrition and stress causes hypothalamic hypogonadism. The hypothalamic-pituitary-gonadal axis shuts down as the body struggles to survive, directing finite energy resources to support more vital functions. Both males and females experience decreased libido and interruption of pubertal development, depending on the timing of the illness. Skeletal growth may be interrupted as well.

Nutritional assessment is vital. Often patients eliminate fat from their diets and may eat as little as 100-200 kcal/d. A gown-only weight after urination is the most accurate way to assess weight. Patients tend to wear bulky clothes and may hide weights in their pockets or drink excessive amounts of fluid (water-loading) to trick the practitioner. Calculating body mass index (BMI)—weight in kilograms divided by height in meters squared—is an efficient way to interpret degree of malnutrition. A BMI less than the fifth percentile (using the new BMI growth curves) indicates significant malnutrition. Additionally, ideal body weight (IBW) for height should be calculated. A weight less than 85% IBW is one of the diagnostic criteria for anorexia nervosa. Ideal body weight should be calculated using the 50th percentile of BMI for age.

A hallmark physical feature of anorexia nervosa in girls is amenorrhea, which occurs for two reasons. The hypothalamic-pituitary-ovarian axis shuts down under stress, causing hypothalamic amenorrhea. Additionally, adipose tissue is needed to convert estrogen to its activated form. When weight loss is significant, adipose tissue is lost and there is not enough substrate to activate estrogen. Resuming normal menses depends on increasing both body weight and body fat. Approximately 73% of postmenarcheal girls will resume menstruating if they reach 90% of their IBW. An adolescent female

needs, on average, 17% body fat to restart menses and 22% body fat if she has primary amenorrhea.

B. LABORATORY FINDINGS

Most organ systems can potentially suffer some degree of damage in the anorexic patient, related both to severity and duration of illness (Table 5–3). Initial screening should include complete blood count with differential, and serum levels of electrolytes, blood urea nitrogen/creatinine, phosphorus, calcium, magnesium, and thyroid-stimulating hormone, as well as liver function tests and urinalysis. An electrocardiogram should be performed, because significant electrocardiographic abnormalities may be present, most importantly prolonged QT syndrome. Bone densitometry should be done if amenorrhea has persisted for 6 months, as patients begin to accumulate risk for osteoporosis.

Differential Diagnosis

If the diagnosis is unclear (ie, the patient has lost a significant amount of weight but does not have typical body image distortion or fat phobia), then the clinician must consider the differential diagnosis for weight loss in adolescents. This includes inflammatory bowel disease, diabetes, hyperthyroidism, malignancy, and depression. Less common diagnoses include adrenal insufficiency and malabsorption syndromes such as celiac

Table 5–3. Laboratory findings: anorexia nervosa.

Increased blood urea nitrogen/creatinine secondary to renal insufficiency
Decreased white blood cells, platelets, and less commonly red blood cells/hematocrit secondary to bone marrow suppression or fat atrophy of the bone marrow
Increased AST and ALT secondary to malnutrition.
Increased cholesterol, thought to be related to fatty acid metabolism
Decreased alkaline phosphatase secondary to zinc deficiency
Low to low-normal thyroid-stimulating hormone and thyroxine
Decreased follicle-stimulating hormone, luteinizing hormone, estradiol, and testosterone secondary to shutdown of hypothalamic–pituitary–gonadal axis
Abnormal electrolytes related to hydrational status
Decreased phosphorus
Decreased insulin-like growth factor
Increased cortisol
Decreased urine specific gravity in cases of intentional water intoxication

ALT = alanine aminotransferase; AST = aspartate aminotransferase.

disease. The history and physical examination should direct laboratory and radiologic evaluation.

2. *Bulimia Nervosa*

Table 5–4 lists the diagnostic criteria for bulimia nervosa. Binge eating is either eating excessive amounts of food during a normal mealtime or having a meal (or other eating episode) last longer than usual, consuming food throughout. Bulimic individuals feel out of control while eating, unable or unwilling to recognize satiety signals. Any type of food may be included in a binge, though typically it is either carbohydrates or junk food. Extreme guilt is often associated with the episode. At some point, either prior to or during a binge, bulimic individuals often decide to purge. The amount of food consumed feels overwhelming, and they do not want to gain weight. The most common ways to purge are self-induced vomiting, exercise, and laxative use. Some individuals will vomit multiple times during a purge episode, after using large amounts of water to cleanse their system. This can induce significant electrolyte abnormalities such as hyponatremia and hypokalemia, which may put the patient at acute risk for arrhythmia or seizure. Other methods of purging include diuretics, diet pills, cathartics, and nutritional supplements, including Metabolife.

Table 5–4. Diagnostic criteria for bulimia nervosa.

-
- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 - (1) eating, in a discrete period of time (eg, within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
 - (2) a sense of lack of control over eating during the episodes (eg, a feeling that one cannot stop eating or control what or how much one is eating)
 - B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
 - C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
 - D. Self-evaluation is unduly influenced by body shape and weight.
 - E. The disturbance does not occur exclusively during episodes of anorexia nervosa.
-

Reprinted, with permission, from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Text Revision. Copyright 2000. American Psychiatric Association.

Diagnosing bulimia nervosa can be difficult unless the teenager is forthcoming or parents or caregivers can supply direct observations. Often bulimic patients are average or slightly above average in body weight, without any physical abnormalities. Screening all teenagers for body image concerns is crucial. If the teenager expresses concern about being overweight, then the clinician needs to screen the patient about dieting methods. Asking whether patients have binged, feel out of control while eating, or whether they cannot stop eating can clarify the diagnosis. Parents may report that significant amounts of food are missing or disappearing more quickly than normal. If the physician is suspicious, direct questioning about all the ways to purge should follow. Indicating first that the behavior in question is not unusual can make the questioning less threatening and more likely to elicit a truthful response. For example, the clinician might say, "Some teenagers who try to lose weight make themselves vomit after eating. Have you ever considered or done that yourself?"

Clinical Findings

A. SYMPTOMS AND SIGNS

Symptoms are related to the mechanism of purging. Gastrointestinal problems are most prominent. Abdominal pain is a frequent complaint. This can be due to gastroesophageal reflux, because frequent vomiting may result in esophagitis. Early satiety, involuntary vomiting, and complaints of food "coming up" on its own are frequent. Less common but more serious is hematemesis or esophageal rupture. Patients may report bowel problems—diarrhea or constipation—if laxatives have been used. Sialadenosis—parotid pain and enlargement—may occur secondary to frequent vomiting. Erosion of dental enamel may result from increased exposure to acidity during vomiting. Because comorbid depression is common in bulimia nervosa, patients may report difficulty sleeping, decreased energy, decreased motivation, and headaches. Lightheadedness or syncope may develop secondary to dehydration.

It is important to note that most purging methods are ineffective. When patients binge, they may consume thousands of calories. Digestion begins rapidly. Although the patient may be able to vomit some of the food, much is actually digested and absorbed. Laxatives work on the large intestine, leading to fluid and electrolyte loss. Consumed calories are still absorbed from the small intestine. Use of diuretics may result in decreased fluid weight and electrolyte imbalance.

On physical examination, bulimic patients may be dehydrated and have orthostatic hypotension. Sialadenosis, tooth enamel loss, dental caries, and abdominal tenderness are the most common findings.

Abrasion of the proximal interphalangeal joints may occur secondary to scraping the fingers against teeth while inducing vomiting. Rarely a heart murmur is heard. An irreversible cardiomyopathy can develop secondary to ipecac use. Tachycardia and hypertension may occur secondary to caffeine and diet pill use.

B. LABORATORY FINDINGS

Electrolyte disturbances are characteristic of bulimic patients. The method of purging results in specific abnormalities. Vomiting causes metabolic alkalosis, hypokalemia, and hypochloremia. If laxatives are used, then a metabolic acidosis develops with hypokalemia and hypochloremia. Amylase may be increased secondary to chronic parotid stimulation.

Panagiotopoulos C et al: Electrocardiographic findings in adolescents with eating disorders. *Pediatrics 2000*;105(5):1100 [PMID: 10790469].

3. Binge-Eating Disorder

The diagnostic category of binge-eating disorder was created in DSM-IV. Officially, it is still considered a research diagnosis. Studies show that most adults who have binge-eating disorder (a prevalence of 2–4%) develop symptoms during adolescence Table 5–5 lists the diagnostic criteria.

Clinical Findings

A. SYMPTOMS AND SIGNS

Binge-eating disorder is a new eating disorder category. It occurs most often in patients who are overweight or obese. Eighteen percent of such patients report bingeing at least once in the past year. Patients with binge-eating disorder have an increased incidence of depression and substance abuse. Using the DSM-IV diagnostic criteria as a guide for evaluation, the suspicion of binge-eating disorder should be raised for any significantly overweight patient. Specific questionnaires are available for evaluating patients suspected of having binge-eating disorder.

B. LABORATORY FINDINGS

The clinician should assess causes and complications of obesity, and laboratory evaluation should include thyroid function tests and measurement of cholesterol and triglyceride levels.

Table 5–5. Diagnostic criteria for binge-eating disorder.

-
- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
- (1) eating, in a discrete period of time (eg, within any 2-hour period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances.
 - (2) a sense of lack of control over eating during the episode (eg, a feeling that one cannot stop eating or control what or how much one is eating)
- B. The binge-eating episodes are associated with three (or more) of the following:
- (1) eating much more rapidly than normal
 - (2) eating until feeling uncomfortably full
 - (3) eating large amounts of food when not feeling physically hungry
 - (4) eating alone because of being embarrassed by how much one is eating
 - (5) feeling disgusted with oneself, depressed, or very guilty after overeating
- C. Marked distress regarding binge eating at present.
- D. The binge eating occurs, on average, at least 2 days a week for 6 months.
- E. The binge eating is not associated with regular use of inappropriate compensatory behaviors (eg, purging, fasting, excessive exercise) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa.
-

Schneider M: Bulimia nervosa and binge eating disorder in adolescents. *Adolesc Med State of the Art Reviews* 2003;14(1):119 [PMID: 12529196].

4. Eating Disorder Not Otherwise Specified

An additional diagnostic category found in DSM-IV is eating disorder not otherwise specified. Patients do not meet all the criteria for either anorexia nervosa or bulimia nervosa, but have features of either or both. Table 5–6 lists the diagnostic criteria. Individuals require similar treatment intervention depending on the clinical features.

Table 5–6. Diagnostic criteria for eating disorder not otherwise specified.

The eating disorder not otherwise specified category is for disorders of eating that do not meet the criteria for any specific eating disorder. Examples include

1. For females, all of the criteria for anorexia nervosa are met except that the individual has regular menses.
 2. All of the criteria for anorexia nervosa are met except that, despite significant weight loss, the individual's current weight is in the normal range.
 3. All of the criteria for bulimia nervosa are met except that the binge eating and inappropriate compensatory mechanisms occur at a frequency of less than twice a week or for a duration of less than 3 months.
 4. The regular use of inappropriate compensatory behavior by an individual of normal body weight after eating small amounts of food (eg, self-induced vomiting after the consumption of two cookies).
 5. Repeatedly chewing and spitting out, but not swallowing, large amounts of food.
-

COMPLICATIONS (Table 5–7)

1. Anorexia Nervosa

Short-Term Complications

A. EARLY SATIETY

Patients may have significant difficulty digesting modest quantities as their bodies adapt to increased caloric intake. Patients may benefit from a gastric-emptying agent such as metoclopramide. This complication usually resolves after a patient has become used to larger meals.

B. SUPERIOR MESENTERIC ARTERY SYNDROME

As patients become malnourished, the fat pad between the superior mesenteric artery and the duodenum may shrink, compressing the transverse duodenum and causing vomiting and intolerance of oral intake, especially solids. Diagnosis is made by an upper GI series, which shows to and fro movement of barium in the descending and transverse duodenum proximal to the obstruction. Treatment involves a liquid diet or nasoduodenal feedings until restoration of the fat pad has occurred, coincident with weight gain.

C. CONSTIPATION

Patients may have prolonged constipation, often not having a bowel movement for a week or longer. Two

Table 5–7. Complications of anorexia and bulimia nervosa.

Cardiovascular	Hematologic
Bradycardia	Leukopenia
Postural hypotension	Anemia
Arrhythmia, sudden death	Thrombocytopenia
Congestive heart failure (during refeeding)	↓ESR
Pericardial effusion	Impaired cell-mediated immunity
Mitral valve prolapse	Metabolic
ECG abnormalities (prolonged QT, low voltage, T-wave abnormalities, conduction defects)	Dehydration
Endocrine	Acidosis
↓LH, FSH	Hypokalemia
↓T ₃ , ↑rT ₃ ; ↓T ₄ , TSH	Hyponatremia
Irregular menses	Hypochloremia
Amenorrhea	Hypochloremic alkalosis
Hypercortisolism	Hypocalcemia
Growth retardation	Hypophosphatemia
Delayed puberty	Hypomagnesemia
Gastrointestinal	Hypercarotenemia
Dental erosion	Neurologic
Parotid swelling	Cortical atrophy
Esophagitis, esophageal tears	Peripheral neuropathy
Delayed gastric emptying	Seizures
Gastric dilatation (rarely rupture)	Thermoregulatory abnormalities
Pancreatitis	↓REM and slow-wave sleep
Constipation	Renal
Diarrhea (laxative abuse)	Hematuria
Superior mesenteric artery syndrome	Proteinuria
Hypercholesterolemia	↓Renal concentrating ability
↑Liver function tests (fatty infiltration of the liver)	Skeletal

mechanisms contribute to this symptom: loss of gastrocolic reflex and loss of colonic muscle tone. Typically stool softeners do not help because the colon has decreased peristaltic amplitude. Agents that induce peristalsis, such as bisacodyl and polyethylene glycol-electrolyte solution (Miralax), are helpful. Constipation can persist for up to 6–8 weeks after refeeding. Occasionally patients need enemas.

D. REFEEDING SYNDROME

Described in the Treatment section.

Long-Term Complications

A. OSTEOPOROSIS

Approximately 90% of females with anorexia nervosa have reduced bone mass at one or more sites. The development of osteopenia and osteoporosis is multifactorial. Estrogen and testosterone are essential to potentiate bone development. Teenagers are particularly at risk as they accrue 40% of their bone mineral during adolescence. Low body weight is most predictive of bone loss. Amenorrhea, an indicator of estrogen deficiency, is also highly correlated with osteoporosis. Bone minerals begin to resorb without estrogen. Elevated cortisol levels and decreased insulin-like growth factor-1 (IGF-1) also contribute to bone resorption. Studies show that as little as 6 months of amenorrhea can lead to osteopenia or osteoporosis. In one study, 44% of adolescents with anorexia had osteopenia of the lumbar spine. Males also can develop osteoporosis due to decreased testosterone.

The only proven treatment for osteoporosis in anorexia nervosa in girls is regaining sufficient weight and body fat to restart the menstrual cycle. Controversy exists regarding the use of hormone replacement therapy (HRT). Most studies do not support use of HRT to improve bone recovery; however, some evidence indicates that use of HRT may stop further bone loss and may be of particular benefit for patients with extremely low body weight (less than 70% IBW). Some practitioners use HRT if amenorrhea is prolonged (> 1 year) and the patient is not able to achieve normal body weight. The bisphosphonates used to treat postmenopausal osteoporosis are currently being studied in adolescents. Newer treatments in research trials have shown some promise, including recombinant IGF-1 injection and use of dehydroepiandrosterone, though they are both still under investigation.

B. BRAIN CHANGES

As malnutrition becomes more pronounced, brain tissue—both white and gray matter—is lost and a concomitant increase in cerebrospinal fluid occurs in the sulci and ventricles. Follow-up studies of weight-recovered anorexic patients show a persistent loss of gray matter, although white matter returns to normal. Functionally there does not seem to be a specific relationship between cognition and brain tissue loss, though studies have shown a decrease in cognitive ability, as well as decreased cerebral blood flow in more severe malnourished states. Communicating to the patient and the family that brain tissue can be lost can have a signifi-

cant effect on the perception of the seriousness of this disorder.

Mortality

Patients with eating disorders are at a higher risk of dying than the general population. Meta-analysis has shown the risk of dying to be 5.9% in such patients. Mortality estimates vary between 0% and 18%, depending on the patient population studied and the length of the study. One study showed the risk of dying to be 0.56% per year. Death in anorexic patients is due to suicide, abnormal electrolytes, and resultant cardiac arrhythmias.

Herzog DB et al: Mortality in eating disorders: A descriptive study. *Int J Eat Dis* 2000;28(1):20 [PMID: 10800010].

2. *Bulimia Nervosa*

Short-Term & Long-Term Complications

Complications for normal-weight bulimic patients are related to their mechanisms of purging, and many of these complications were listed earlier in the Symptoms and Signs section. If the bulimic patient is significantly malnourished, the complications may be the same as those encountered in the anorexic patient. Other complications of bulimia include esophageal rupture, acute or chronic esophagitis, and, rarely, Barrett syndrome. Chronic vomiting can lead to metabolic alkalosis, and laxative abuse may cause metabolic acidosis. Patients may develop aspiration pneumonia from vomiting. Diet pill use can cause insomnia, hypertension, tachycardia, palpitations, seizures, and sudden death.

Patients who stop taking laxatives can have trouble with bowel function, most often constipation. Treating constipation can be difficult psychologically, because the practitioner may need to prescribe agents similar to the drugs of abuse used during the eating disorder.

Mortality

The mortality rate in bulimic patients is similar to that in anorexic patients. Death usually results from suicide or electrolyte derangements.

TREATMENT

Many treatment modalities are available. Factors that determine treatment interventions are severity of illness, length of illness, specific manifestations of disease, previous treatment approaches and outcomes, program availability, financial resources, and insurance coverage. Treatment options include outpatient management, day treatment hospitalization, and inpatient hospitalization of either a medical or psychiatric nature. Residential treatment is most often used when outpatient management or short-term hospitalization fails and the eating disorder becomes chronic. Residential treatment usually lasts 2–6 months. Day treatment programs are a good intervention for patients who do not yet need inpatient care but who are not improving with outpatient management. Treatment is costly. Many patients do not have insurance benefits that adequately cover the cost of treatment, leaving parents and practitioners with profound dilemmas as to how to best provide treatment in the face of financial constraints.

Regardless of type of treatment program, a multidisciplinary approach is most effective. Treatment should include medical monitoring, nutrition therapy, and individual and family psychotherapy by practitioners experienced with eating disorder patients. Family therapy is especially helpful with younger teenagers, whereas older teenagers tend to benefit more from individual therapy, although both should be encouraged. Family therapy is an important means by which to help families understand the development of the disease and address the issues that may be barriers to recovery. Both types of therapy are encouraged in most treatment programs, and recovery without psychotherapy is unusual. The average length of therapy is roughly 6–9 months, although some individuals continue therapy for extended periods. Adjunctive modalities include art and horticulture therapy, therapeutic recreation, and massage therapy.

Careful instruction in nutrition is important in helping the teenager dispel misconceptions about nutrition, identify realistic nutritional goals, and normalize eating. Initially, nutrition education may be the most important intervention as the teenager slowly works through his or her fears of fat-containing foods and weight gain. The teenager begins to trust the nutrition therapist and begins to restore body weight, by eventually eating in a well-balanced, healthy manner.

1. Anorexia Nervosa

The key to determining level of intervention depends on the degree of malnutrition, the rapidity of weight loss, the degree of medical compromise, and presence of life-threatening electrolyte abnormalities. No absolute criteria determine level of intervention. The practitioner must examine the degree of medical compromise, consider immediate risks, and the potential for an individual to reverse the situation on his or her own.

A. INPATIENT TREATMENT

Table 5–8 lists the criteria for hospital admission generally used in the medical community. It is usually quite difficult for a patient who is losing weight rapidly (> 2 lb/wk) to reverse the weight loss because the body is in a catabolic state.

If a patient is hospitalized the initial goal is to stop weight loss. The clinician can begin a meal plan containing approximately 250 kcal more than the patient has been routinely eating. Depending on the sophistication of the program and support staff, this can usually be accomplished orally. Ideally, with the help of a nutritionist, patients should start with a well-balanced meal plan, with appropriately divided carbohydrates, proteins, and fats. Usually patients tolerate oral meals. If the patient resists, a nasogastric tube or intravenous alimentation can be used for a short time. Aside from caloric needs, the clinician needs to pay attention to the patient's hydration status, including the appropriate amount of fluid with the meal plan. Dehydration should be corrected slowly. The oral route is usually adequate. Aggressive intravenous fluid administration should be avoided because left ventricular mass is compromised and rapid increase in volume may not be tolerated. Regulating fluid intake is important, because water intoxication can contribute to abnormal electrolytes and falsified weights.

During the initial introduction of food, the clinician needs to monitor the patient for refeeding syndrome, a phenomenon that occurs if caloric intake is increased too rapidly. Signs of refeeding syndrome are decreased

serum phosphate (as the body finally starts making adenosine triphosphate), decreased serum potassium (as increased insulin causes shifting of K^+ from extracellular fluid into K^+ -depleted cells), and edema related to fluid shifts as well as from congestive heart failure.

Caloric intake can be increased 250 kcal/d as long as refeeding syndrome does not occur. Weight goals vary depending on programmatic approach. Typically intake is adjusted to reach a goal of 0.1–0.25 kg/d weight gain.

Overnight monitoring for bradycardia is helpful in assessing degree of metabolic compromise. Usually the more rapid and severe the weight loss, the worse the bradycardia. Improving bradycardia correlates with weight recovery. Orthostatic hypotension is most severe around hospital day 4, improving steadily and correcting by the third week of nutritional rehabilitation. An electrocardiogram should be obtained because the patient is at risk for prolonged QT syndrome and junctional arrhythmias related to the severity of bradycardia.

It usually takes 2–3 weeks to reach the initial goals of hospitalization—steady weight gain, toleration of oral diet without signs of refeeding syndrome, corrected bradycardia (heart rate > 45/min for three consecutive nights), and orthostasis. Specific weight criteria are used by many programs when considering discharge. This depends partly on admission weight. Ideally a patient gains at least 5% of his or her ideal weight. Some programs set discharge at 80%, 85%, or 90% IBW. Patient outcomes are improved with discharge at a higher body weight. One study has shown that patients do better if discharged at 95% IBW. Frequently, insurance companies do not cooperate and will not pay beyond strict medical stabilization (normal vital signs and normal electrolytes). In many practitioners' experience, relapse rate is high if patients are discharged at less than 75% IBW.

Extremely malnourished patients may not benefit from individual psychotherapy or nutritional instruction initially because they may be cognitively impaired. Beginning family psychotherapy at first, with the addition of individual psychotherapy after the first week of refeeding, may prove more effective.

Medications (specifically SSRIs) are not helpful in treating anorexia nervosa independently. Once the patient has achieved approximately 85% IBW, then SSRIs (fluoxetine, citalopram, or sertraline) help prevent relapse.

Several open label trials support the use of atypical antipsychotics (risperidone, olanzapine), which target specifically the body image distortion that these patients experience.

To help address the malnourished state, a multivitamin with iron and zinc supplementation may be beneficial. Zinc has been found to be depleted in anorexia nervosa. Supplementation helps restore appetite as well

Table 5–8. Criteria for inpatient treatment of anorexia nervosa.

Body weight < 75% of ideal body weight
Supine heart rate < 45/min
Symptomatic hypotension or syncope
Hypokalemia: K^+ < 2.5 mEq/L
Rapid weight loss that cannot be interrupted as outpatient
Failure of outpatient management
Acute food refusal

as improve depressive moods. Symptomatic treatment for disturbances in the gastrointestinal system should be used appropriately until symptoms resolve.

B. OUTPATIENT TREATMENT

Not all patients diagnosed with anorexia nervosa need inpatient treatment, especially if parents and clinicians recognize the warning signs early. These patients can receive treatment in the outpatient setting, employing the same multidisciplinary team approach. Appropriate nutrition counseling is vital in guiding a patient and family through the initial stages of recovery. As the nutrition therapist is working at increasing the patient's caloric intake, a practitioner needs to monitor the patient's weight and vital signs. Often activity level needs to be decreased to help reverse the catabolic state. A reasonable weight gain goal may be 0.2–0.5 kg/wk. If weight loss persists, careful monitoring of vital signs, including supine heart rate, is important in determining whether an increased level of care is needed. Concomitantly, the patient should be referred to a psychotherapist, and, if indicated, assessed by a psychiatrist.

2. Bulimia Nervosa

Treatment of bulimia nervosa depends on the frequency of bingeing and purging and the severity of biochemical and psychiatric derangement. If K^+ is less than 3.0 mEq/L, then inpatient medical admission is warranted. Typically extracellular K^+ is spared at the expense of intracellular K^+ , so that a patient may become hypokalemic several days after the serum K^+ concentration appears to be corrected. Usually cessation of purging is sufficient to correct K^+ concentration and is the recommended intervention for K^+ greater than 3.0 mEq/L; if K^+ is 2.5–2.9 mEq/L, oral supplementation is suggested; if K^+ is less than 2.5 mEq/L, then intravenous therapy is recommended. Supplements can be stopped once K^+ levels are greater than 3.5 mEq/L. Once serum K^+ corrects and remains normal 2 days after supplements are stopped, the clinician can be confident that total body K^+ has returned to normal. Continued hospitalization depends on the patient's psychological status.

Many of these patients abuse laxatives and may be chronically dehydrated. The renin–angiotensin–aldosterone axis, as well as the antidiuretic hormone level, may be elevated to compensate. These systems do not shut down automatically when laxatives are stopped, and fluid retention of up to 10 kg/wk may result. This puts patients at risk for congestive heart failure and can scare them as their weight increases dramatically. A diuresis often occurs after approximately 7–10 days. Parents and patients should be advised of this possible

complication of initial therapy to help maintain their confidence in the care plan.

Another reason to hospitalize bulimic patients is failure of outpatient management. The binge–purge cycle is addictive and can be difficult for patients to interrupt on their own. Hospitalization can offer a forced break from the cycle, allowing patients to normalize their eating, interrupt the addictive behavior, and regain ability to recognize satiety signals.

Outpatient management can be pursued if patients are medically stable. Cognitive-behavioral therapy is crucial to help bulimic patients understand their disease and to offer suggestions for decreasing bingeing and purging. Nutrition therapy offers patients ways to regulate eating patterns so that they can avoid the need to binge. Medical monitoring should be done to check electrolytes periodically, depending on the purging method used.

SSRIs are generally quite helpful in treating the binge–purge cycle. Fluoxetine has been studied most extensively; a dose of 60 mg/day is most efficacious in teenagers. Other SSRIs are thought to work similarly and are worth trying if the patient experiences side effects while taking fluoxetine. Treatment for gastroesophageal reflux and gastritis should be used when appropriate. The pain and swelling of enlarged parotid glands can be helped by sucking on tart candy and by the application of heat.

Newman-Toker J: Risperidone in anorexia nervosa. *J Am Acad Child Adolesc Psychiatry* 2000;39(8):941 [PMID: 10939220].

3. Binge-Eating Disorder

A combination of cognitive-behavioral therapy and antidepressant medication has been helpful in treating binge-eating disorder in adults. Use of SSRIs for binge-eating disorder in adolescents has not been studied, but in adults, fluoxetine and citalopram help decrease binge episodes, improve depression, and the decreased appetite that contributes to weight loss. This evidence suggests that SSRIs in adolescents with binge eating disorder may be helpful as well.

McElroy SL et al: Citalopram in the treatment of binge-eating disorder: A placebo-controlled trial *J Clin Psychiatry* 2003; 64(7):807 [PMID: 12934982].

PROGNOSIS

Outcome in eating disorders, especially anorexia nervosa, has been studied extensively. Unfortunately, most studies have focused on specific inpatient treatment programs, and few have evaluated the less ill patients who do not need hospitalization. About 40–50% of patients receiving treatment recover; 20–30% have intermittent relapses; and 20% have chronic, unremitting illness. As time from initial onset lengthens, the recovery rate decreases and mortality associated with anorexia nervosa and bulimia nervosa increase.

The course of anorexia nervosa often includes significant weight fluctuations over time, and it may be a matter of years until recovery is certain. The course of bulimia nervosa often includes relapse episodes of bingeing and purging, although bulimic patients initially recover faster than do anorexic patients. Up to 50% of anorexic patients may develop bulimia, as well as major psychological sequelae, including depression, anxiety, and substance abuse disorders. Bulimic patients also develop similar psychological illness but rarely develop anorexia. Long-term medical sequelae, aside from low body weight and amenorrhea, have not been studied in an outcome format, although anorexia nervosa is known to have multiple medical consequences including osteoporosis and structural brain changes.

It is unclear whether age at onset affects disease course. Shorter length of time between symptom onset and therapy tends to improve outcome. Various treatment modalities can be equally effective. Favorable out-

comes have been found with brief medical hospitalization and long psychiatric or residential hospitalization. Higher discharge weight seems to improve the initial outcome. It is difficult to compare treatment regimens, because the numbers are small and the type of patient and illness varies between studies. No existing studies compare outpatient to inpatient treatment or the effects of day treatment on recovery.

Binge-eating disorder has been recognized only recently, and outcomes have not been studied. Intervention with an SSRI appears to help the bingeing, but little is known regarding long-term prognosis.

Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

6

Jennifer Hagman, MD, & Donald W. Bechtold, MD

The task of the primary care provider is often to discern when symptoms are indicative of a problem versus a normal variant of development. When the symptoms include changes in behavior, thoughts, and emotions, the task becomes one of determining if a psychiatric disorder is present and what the contributing role of genetic and biologic factors, family and peer relationships, and environment may be.

■ PSYCHOSOCIAL ASPECTS OF CHILD DEVELOPMENT AND FAMILY LIFE

FAMILY LIFE

The structure of families has changed significantly over the past two decades, with an increase in the number of single-parent homes, mothers who work outside the home, blended families, alternative lifestyles including gay and lesbian parents, and a decline in extended families living in close proximity. The family serves the following functions: (1) rearing children to become autonomous adults and eventually competent parents and (2) meeting the needs of family members for nurturing, protection, feedback, recognition (mirroring), promoting adaptive behaviors, and emotional closeness and support. Evidence suggests that the lifestyle preferences of the parent figures are less important to healthy development than is the parents' ability to serve parental functions consistently.

THE PARENTAL UNIT

The cornerstone of family functioning is the parental unit, which optimally serves as the primary source of stability, consistency, and authority during childhood and adolescence. Effective parents (or adults in the parental role) should be aware of and responsive to the

emotional and physical needs of other, more dependent family members while defining the norms of behavior that will lead to independent adaptive functioning in the future. The ways in which parents function in their roles within the family determines in large part the health or impairment of the family and its individual members.

Support systems, which include relatives, friends, and caregivers, serve an important function to help parents through life transitions from birth to the young adult years and beyond. In the case of a two-parent unit, the partners in a healthy relationship can provide the necessary emotional support, respite, and adult companionship for each other. The women's movement has helped men expand their parental roles and personal identities to include more nurturing activities. Because single parents often have no in-house source of adult support, relatives, friends, and other external support systems such as church, school, and childcare providers are critical. In single-parent families or families in which the parents are not able to meet each other's needs, the child is at risk of becoming a pseudoadult companion, thus completing the parental unit.

The lack of a solid parental partnership or effective support system for the family can be an important factor in virtually any child-centered problem. To function successfully as a couple, both partners must find the relationship satisfying through mutual nurturing and affirmation, trust and respect, conflict recognition and resolution, and intimacy and sexual satisfaction.

When the parental unit is weakened by dissatisfaction or by persistent conflict, children are at risk of becoming the focus of heightened parental attention and concern, thus displacing the conflict from within the relationship onto the child. Concern about the child distracts the parents from their own problems, and the child may function as a buffer between the adults. Questions designed to screen the quality of the marital and parental relationship are outlined in Table 6-6.

EFFECTS OF MARITAL SEPARATION AND DIVORCE

Currently, about 40% of marriages will end in divorce. Seventy-five percent of divorced parents remarry, and another 50% divorce a second time. Approximately 90% of single parents are mothers, and in about half of such cases the children have little or no contact with the father.

Clinical Effects of Separation and Divorce

The adverse emotional effects of divorce can be far-reaching for both adults and children. Many women who have been through a divorce report that it takes a minimum of 3 years for a sense of order and stability to return.

Effects on the parent-child relationship include a decrease in parenting capacity manifested by irregularity of schedules, flares of temper, lessening of emotional sensitivity and support of the child, inconsistent discipline, and decreased pleasure in the parent-child relationship. A tendency exists for the divorced parent to look to the child as a source of emotional support or even as a surrogate spouse. In the course of separation and divorce one parent may not be able to contain their angry thoughts about the other, and the child is subjected to a litany of complaints and negative statements, which can be confusing and painful for the child and significantly affect his or her ability to cope with the divorce. Some children may become inappropriately close to their parents by acting as little helpers and parental advisors. Adolescents, in contrast, may rebel in order to distance themselves from the emotional needs of their distressed parents.

The effects of divorce on children are seen most dramatically in the 2 years following dissolution of the

marriage and depend largely on the parents' ability to maintain a working relationship with respect to parenting and financial issues related to the children. Few children experience the dissolution of even turbulent marriages as a relief, because the breakup of the nuclear family is perceived as a loss of the structure that provides for their safety and support. Children would rarely choose divorce as a solution for their parents' problems.

The effects of divorce on a child vary with the child's age and developmental level. Preschoolers may display symptoms of behavioral regression, expressing fears of separation at night and when they are with babysitters, sleep disturbances, and irritability. Children age 5-8 years may express their grief with sadness and weeping. Children often wish for reconciliation of the parents and may develop symptoms or behaviors that serve a secondary purpose of causing the parents to communicate or be together.

Approximately 50% experience a decrease in school performance, and some may become aggressive. Children age 9-12 years often respond with anger and blame and are at greatest risk of becoming a surrogate companion. In adolescence, anger often is accompanied by depression. Teenagers rely heavily on their peers during this time and can become pessimistic about their own future involvement in intimate relationships.

Outcome

The most favorable outcome is for the parents to avoid discussion of their personal conflicts in the presence of the child and resume caregiving relationships with their children in a collaborative manner. Children do not cope well in a setting of unremitting marital strife, and overall development can be significantly affected. It is important that parents develop predictable routines for the children despite the challenges of separation and divorce. Younger children fare best, particularly when they have a support network (eg, siblings, grandparents) while the parents are preoccupied with their own problems. A brief course of psychotherapy should be considered for all parents and children who are going through separation and divorce. Therapy will assist with coping and communication during this difficult time and give the parents and children a place to discuss their fears and emotions with someone who is not directly involved in the situation.

Children of divorced parents experience increased rates of depression and anxiety, especially if the parents are not able to maintain a nonhostile working relationship regarding visitation and decisions related to the children's needs. At 10-year follow-up, 40% of such children report worry, underachievement, self-deprecation, and lingering anger. The effect of divorce on chil-

dren may be far-reaching in scope and long-term in duration.

On reaching adulthood, children often fear repeating their parents' unhappy marriages and may struggle with issues of commitment and trust in intimate relationships.

CAREGIVER DYSFUNCTION

Primary Caregiver Dysfunction

Primary caregiver dysfunction can be defined as a failure to provide parenting functions (usually, but not necessarily, by the mother) because of parental vulnerability or disability. Caregiver dysfunction can result from domestic violence, mental illness, and substance abuse. Caregivers can experience significant impairment because of anxiety, depression, exhaustion, anger, or indifference in relation to the demands of child care. Caregiver dysfunction can lead to a number of symptoms in the child (Table 6–1) and includes the risk of

Table 6–1. Signs and symptoms suggesting primary caregiver dysfunction.

Failure to thrive
Feeding problems
Delays in development
Signs of abuse
Frequent physician visits, especially for nonspecific concerns
Excessive parental worry about illness in the child
Inadequate physical care
Child perceived as “difficult to deal with”
Sleep problems

another generation of children who may themselves display caregiver dysfunction as parents.

These individuals frequently have difficult psychosocial histories, find themselves without emotional or physical support, and have unmet personal needs (Table 6–2). Characteristics of the child may also contribute to the parent's failure to nurture and meet the child's needs. Risk factors from the child include prematurity, perinatal complications, birth defects, multiple births, chronic medical or mental illness, and a difficult temperament. These characteristics frequently define the child as different, defective, or disappointing in the parent's eyes.

Caregiver dysfunction is identified by interviewing the parents and observing the interaction between parent and child. The child should be evaluated for organic disorders that could explain the presenting symptoms. A history aimed at identifying specific parental risk factors should be obtained directly from the parent (see Table 6–2), with emphasis on feelings of stress or of being overwhelmed by the needs of the child or the demands of daily life. Attention should be paid to the parent's description of the child and to parental symptoms of anxiety or depression manifested by tension, irritability, fatigability, tearfulness, sleep disturbance, and a wish to avoid or withdraw from daily activities.

In observing the parent–child interaction, the physician should look for reciprocity, mutual enthusiasm, and enjoyment in the relationship, as opposed to pathologic signs of tension, irritability, or apathy on either side of the relationship. Physical disorders that may explain the presenting symptoms must be ruled out, but it should also be noted that caregiver dysfunction and organic disease often coexist.

Interventions are focused primarily on supporting and educating the parents and arranging referrals for as-

Table 6–2. Parental risk factors contributing to primary caregiver dysfunction.

History of inadequate relations with own mother
Isolation from an adult support system (eg, single parent)
Psychiatric disorders (particularly acute or chronic depression)
Chronic psychosocial or cognitive dysfunctions (eg, unstable relationships, school problems, legal problems, employment problems)
Unresolved grief over past losses
Marital discord
Poverty or financial problems
Personal or family illnesses
Unwanted or difficult pregnancy
Current life stresses (eg, loss of a relationship, recent illness, job loss)

assessment and treatment of physical or mental illness when appropriate. The physician should empathize, explaining that being a parent is difficult and tiring work and that it requires health, energy, and emotional support. The task is to help the parent feel well physically and emotionally and then to facilitate the development of appropriate childcare skills. A social support system should be sought through friends, family, and community resources. Parenting skills can be taught and positively reinforced over time. Referrals can be made to parenting classes in the community or through mental health centers. Reports are necessary to the department of social services in cases where neglect or abuse is suspected.

The prognosis depends on the parent's receptiveness to professional interventions, support, and education. Follow-up by the physician's office regarding recommendations will increase the chance that interventions to support optimal family functioning will be successful.

■ CHALLENGES IN PARENTING RELATED TO CHILD AND ADOLESCENT DEVELOPMENT

Parenting is challenging, rewarding, and frustrating. Physical and emotional exhaustion as well as unfulfilled expectations about parenting and family life can be avoided or mitigated if both partners share the parenting responsibilities, or if there is a strong support system available to the parents. Primary caregivers are also partly replenished emotionally by the child's positive

responses and by memories of their own positive experiences as children. Children who are developmentally disabled or temperamentally difficult may be more unpredictable and challenging for the parent to respond to, and difficulty in the parent-child relationship may result. A mild consequence may be a state of tension in the family. In extreme situations, child abuse and neglect may result. Some parents have unrealistic fantasies about the children that may reflect their own unmet needs. Children with illnesses, disabilities, or temperamental difficulties call for modified expectations so that the parents can meet the special needs of the child.

Developmental disturbances are variations in normal child development that cause distress or concern. Parents frequently contact their physicians with questions about the terrible twos, childhood fears and anxieties, and adolescent rebellion. The health care provider is faced with making the correct diagnosis, educating the parents about normal developmental variations, and developing strategies to facilitate optimal parent-child interactions.

Each new phase of child development presents unique challenges. The infancy years are a time of irregular sleep-wake cycles and a need for almost constant care and attendance. During the toddler years, the child's strivings for autonomy and independence should be supported and encouraged within appropriate limits and without letting the child become the family tyrant. In the subsequent years, parents are faced with competitive challenges, requiring a balanced respect for the child's evolving wishes to be independent while still setting limits that maintain safety and respect for others.

THE PUSHY PRESCHOOLER

The push for independence and autonomy that begins in the second year of life can pose problems for parents who are insecure in the parental role. Preschool children typically want to have their way even when it poses a danger or is not in their best interest. Children may try to decide when and what the family eats, what time is bedtime, and who sleeps in which bed, all as part of their rudimentary push to become independent. The parents' task is to respect the child's wish for self-determination while setting limits and providing guidance so that the child does not become tyrannical or out of control.

Parents who are having difficulty placing limits on behavior will come in with one of the following types of complaints:

1. Discipline won't work with this child.
2. I can't get her to do what I ask without getting mad.

3. He says, “I don’t have to do it if I don’t want to.”
4. She won’t sleep in her own bed.
5. Other children his age don’t like him. He always wants his own way.

Parents who have difficulty saying no may be emotionally drained or may believe that confrontation must be avoided. In the former case, parental depression or emotional exhaustion from working and single parenthood is common. In the latter case, the parent typically overidentifies with the frustrated child’s distress and is then reminded of painful conflicts or unhappiness in his or her own life. Keeping the child happy (ie, avoiding conflict) keeps the parent from feeling distressed and unhappy, but inevitably leads to more power struggles and defiant behavior.

In planning interventions, the physician must educate the parents about the sometimes pushy nature of preschool children within a healthy developmental context. With that explanation comes the need for external limits, because a child’s judgment and self-control are as yet underdeveloped. Parents need to know that a child’s disappointment and frustration with limits are a necessary component of growth and development.

Parents who are emotionally depleted or depressed need to be cared for themselves, either through rest, emotional support, and assistance with parenting or through referrals for therapy. In the case of a parent who avoids conflict, the physician should suggest addressing one or two discipline problems. For example, if toys are not picked up after a reminder, they are put away out of the child’s reach for some specific period of time. As the parent begins to feel more comfortable with providing limits and appropriate consequences, the child’s behavior typically becomes less oppositional; at this point, the parent should use positive reinforcement, such as, “I like the way you picked up your toys; let’s read a story together.”

CHILDHOOD FEARS & ANXIETIES

During the elementary school years, parents must begin to let their children experience the challenges that await them outside the home. Parental support of development of these social and emotional skills must be balanced with realistic definitions of success. Persistent separation anxiety on the part of parents and unrealistic standards of performance can contribute to problems for the child in regulating anxiety and developing self-esteem during these years.

The vast majority of childhood fears are not associated with psychological disorders; in fact, the fearful stimuli tend to evolve and change with age in a devel-

Table 6-3. Sequence of developmental anxieties.

Age at First Appearance	Source of Anxieties
Early infancy	Sudden loud noises, unpredictable stimuli, loss of postural support, heights.
1 year	Stranger, unfamiliar situations and objects. Beginning of separation distress.
2–6 years	Animals, darkness, imaginary creatures (ghosts and monsters).
School age	Bodily injury, physical danger. Fear of loss of loved one.
Teens and adulthood	Fear of failure (eg, test anxiety), concerns about social acceptance, loss of a loved one, physical danger, natural disasters.

opmental sequence (Table 6-3) and, overall, tend to decrease in frequency and intensity with age.

Although the manifestations of many developmental anxieties, such as separation distress and fear of the dark, may wax and wane over months or years, most specific childhood fears are transient (days to weeks in duration) and not associated with substantial interference with daily life. In most cases, all that is needed is to reassure the parents about the developmental nature of fears; the parents can then reassure their children that they will be fine even though they feel frightened at times. Fears become a source of greater concern to health care providers when they appear outside the normal developmental sequence of fears, when they are persistent, when they cause severe distress, or when they interfere with adaptive functioning such as poor attendance at school or avoidance of peer relationships. Approximately 2–3% of preschool age children have fears troublesome enough to require specific mental health interventions such as referral to a child and adolescent psychiatrist.

ADOLESCENT REBELLION & TURMOIL

Adolescence is a time of considerable physical and emotional change. General theoretic impressions and sampling bias at one time tended to exaggerate the turmoil of normal adolescence. A longitudinal study of normal suburban middle-class boys through their high-school years identified only 21% as experiencing tumultuous unrest. On closer examination, this segment was distinguished from the remainder of the sample by lower socioeconomic status, more overt marital conflicts in the family, and a higher than normal incidence of mental illness in the family. Overall, approximately 20% of adolescents have a stormy course; another 20% progress continuously and smoothly through adolescence; and the remainder show normal overall adjustment but have transient difficulties during times of stress.

The early adolescent has unpredictable changes of mood, intense attachment to peers, and a self-centered point of view, all of which can diminish positive aspects of the parent-child relationship and lead to increased tension between the parent and the adolescent. Not since infancy and the toddler years have parents received so little gratitude for their efforts. Like parents of toddlers, the parents of young adolescents need to support autonomy while providing the structure and limits necessary to maintain safety and promote good decision making on the part of the adolescent.

The sexual interests of the middle adolescent can elicit parental reactions related to the parent's own comfort or concerns about sexuality and can range from pride to fear to envy or even confusion about sexual boundaries with the adolescent. The parents' own past experience may influence their reactions and ability to negotiate this developmental phase in a manner that facilitates communication while helping the teen make responsible decisions.

Finally, as the late adolescent prepares to leave home for college or other independent living, parents face, in addition to anxiety and excitement, the sense of loss and grief associated with their child going out into the world.

Of particular concern to physicians today, as well as to society at large, is the tragic increase in teen violence, including school shootings. Although the prediction of violent behavior remains a difficult and imprecise endeavor, physicians can support and encourage several important prevention efforts.

- The vast majority of the increase in youth violence including suicides and homicides involves the use of firearms. Thus the presence of firearms within the home, the method of storage and safety measures when present, and access to firearms outside the

home should be explored regularly with all adolescents as part of their routine medical care.

- Although violence toward others remains difficult to predict, its association with suicidal impulses should not be overlooked. In general, the suicidal youth is somewhat easier to identify than the homicidal youth, and in many cases may be one and the same (see the section on Suicide in Children & Adolescents). Any comment about wishes to be dead or hopelessness should be taken seriously and help sought.
- Parents and guardians should be aware of their child's school attendance and performance and peer groups. They should know their children's friends and be aware of who they are going out with, where they will be, what they will be doing, and when they will be home. Any concerns should be discussed with the teen and interventions sought if necessary.
- Most students involved in school violence could have benefited from earlier interventions to address problems in social and educational functioning in the school environment. Many communities and school districts have increased their efforts to identify and intervene with students whom teachers, peers, or parents recognize as having difficulty.

■ THE CHRONICALLY ILL CHILD

Reactions to Chronic Physical or Mental Illness and Disability

Between 5% and 10% of individuals experience a prolonged period of medical illness or disability during childhood, and another 5–10% experience the onset of mental illness in childhood. The psychosocial effects for the child and the family are often profound. Although the specific effect of illness on children and their families depends on the characteristics of the illness, the age of the child, and premorbid functioning, it can be expected that both the child and the parents will go through predictable stages toward eventual acceptance of the disease state. Shock and disbelief at the time of diagnosis give way in time to anger and to mourning the loss of the normal, healthy child. It may take months for a family to accept the disease, to cope with the stresses, and to resume normal life to the extent possible. These stages resemble those that follow the loss of a loved one. If anxiety and guilt remain prominent within the family, a pattern of overprotection can evolve. Likewise, when the illness is not accepted as a reality to be dealt with, a pattern of denial may become prominent. The clinical manifestations of these patterns of behavior are presented in Table 6–4.

Children are very observant and intuitive when it comes to understanding their illness and its general

prognosis. At the same time, their primary concerns are the effects of the illness on everyday life, feeling sick, and limitations on normal activities. Children are also keenly aware of the family's reactions and may be reluctant to bring up issues they know are upsetting to their parents. Whenever possible, parents should be encouraged to discuss the child's illness and to answer questions openly and honestly, including exploration of the child's fears and fantasies. Such interactions promote closeness and relieve the child's sense of isolation. Even with these active attempts to promote effective sharing between the child and the family, ill children frequently experience fear, anxiety, irritability, and anger over their illness and guilt over causing family distress. Sleep disturbances, tears, and clinging, dependent behavior are not infrequent or abnormal.

THE TERMINALLY ILL CHILD

The diagnosis of fatal illness in a child is a severe blow even to families who have reason to suspect that outcome. The discussion with parents (and the child) about terminal illness is one of the most difficult tasks for a physician working with children and adolescents. Although parents want and need to know the truth, they are best told in stepwise fashion beginning with temporizing phrases such as, "The news is not good" and "This is a life-threatening illness." The parent's reactions and questions can then be observed for clues to how much they want to be told at any one time. The physician must also attempt to gauge how much of the information the parents are able to comprehend during the initial discussion and consider involvement of appropriate support services. Parent's reactions may proceed in a grief sequence including initial shock and disbelief lasting days to weeks, followed by anger, despair, and guilt over weeks to months, and ending in acceptance of the reality of the situation. These responses vary in intensity, duration, and sequence within the family.

Although children probably do not fully understand the permanency of death until about age 8, most ill children experience a sense of danger and doom that is associated with death before that age. Even so, the question of whether to tell a child about the fatal nature of a disease should in most cases be answered in the affirmative unless the parents object. When the parents object, this should alert the physician to involve the unit social worker, who can work with the family to ensure their decision is in the best interest of the child. Refusal of the adults to tell the child, especially when the adults themselves are very sad, leads to a conspiracy of silence that increases fear of the unknown in the child and leads to feelings of loneliness and isolation at the time of greatest need. In fact, children who are able

Table 6–4. Patterns of coping with chronic illness.

Overprotection

- Persistent anxiety or guilt
- Few friends and peer activities
- Poor school attendance
- Overconcern with somatic symptoms
- Secondary gain from the illness

Effective coping

- Realistic acceptance of limits imposed by illness
- Normalization of daily activities with peers, play, and school

Denial

- Lack of acceptance of the illness
- Poor medical compliance
- Risk-taking behaviors
- Lack of parental follow-through with medical instructions
- General pattern of acting-out behavior

to discuss their illness with family members are less depressed, have fewer behavior problems, have higher self-esteem, feel closer to their families, and adapt better to the challenges of their disease and its treatment.

The siblings of dying children are also significantly affected. They may feel neglected and deprived because of the time their parents must spend with the sick child. Anger and jealousy may then give rise to feelings of guilt over having such feelings about their sick sibling. Awareness of the emotional responses, coping abilities, and available resources for support of other family members can diminish these feelings and make a significant difference in the family's overall ability to cope with the illness.

After the child dies, the period of bereavement may last for years. Family members may need outside help in dealing with their grief through supportive counseling services or peer-support groups. Bereavement usually does not substantially interfere with overall life functioning for more than 2–3 months. Most parents and siblings are able to return to work and school within a month, although their emotional state and thoughts may continue to be dominated by the loss for some time. When the individual is unable to function in his or her societal and family role beyond this time frame, a diagnosis of complicated bereavement, major depression, posttraumatic stress disorder (PTSD), or adjustment disorder should be considered and appropriate interventions recommended, such as referral for counseling or psychotherapy and possibly antidepressant medication.

Long-Term Coping

The process of coping with a chronic or terminal illness is complex and varies with the dynamics of each individual child and family. Each change in the course of the illness and each new developmental stage for the child present different challenges. It is important for health care providers to continually assess the family and child's needs and coping abilities over time and to provide appropriate support, information, and access to interventions.

Assistance from Health Care Providers

A. EDUCATE THE PATIENT AND FAMILY

Children and their families should be given information about the illness, including its course and treatment, at frequent intervals. Factual, open discussions minimize anxieties. The explanation should be comprehensible to all, and time should be set aside for questions and answers. The setting can be created with an invitation such as, "Let's take some time together to review the situation again."

B. PREPARE THE CHILD FOR CHANGES AND PROCEDURES

The physician should explain, in an age-appropriate manner, what could be expected with a new turn in the illness or with upcoming medical procedures. This explanation enables the child to anticipate and in turn to master the new development and promotes trust between the patient and the health care providers.

C. ENCOURAGE NORMAL ACTIVITIES

The child should attend school and play with peers as much as the illness allows. Individual education plans (IEP) should be requested from the school if accommodation beyond the regular classroom is necessary. At the same time, parents should be encouraged to apply the same rules of discipline and behavior to the ill child as are applied to well siblings.

D. ENCOURAGE COMPENSATORY ACTIVITIES, INTERESTS, AND SKILL DEVELOPMENT

For example, a child whose athletic development has been interrupted by the disability might pursue the acquisition of computer skills.

E. PROMOTE SELF-RELIANCE

The health care provider should guide and encourage parents in helping ill children assume responsibility for some aspects of their medical care.

F. PERIODICALLY REVIEW FAMILY COPING

From time to time, the physician should ask, "How is everyone doing with this?" The feelings of the patient, the parents, and other children in the family are explored, as well as concerns about finances and the status of the marriage. Feelings of fear, guilt, anger, and grief should be watched for and accepted as normal reactions to difficult circumstances.

G. RECOMMEND SUPPORT GROUPS

Appropriate lay support groups for the patient and family should be recommended. Many hospitals have such groups, and hospital social workers can facilitate participation for the patient and family.

SCREENING FOR PSYCHOSOCIAL PROBLEMS & PSYCHIATRIC DISORDERS WITHIN THE CONTEXT OF HEALTH MAINTENANCE VISITS

Between 5% and 15% of children in the United States have psychiatric disorders, and nearly 50% of pediatric office visits are related to psychosocial or developmental problems. These statistics underscore the importance of screening for mental illness and psychosocial problems in children and their families.

Most families seek help from their primary care providers when they are concerned about a child's health, growth, or development. It is thus critical that primary care providers be able to identify the need for, and initiate the evaluation of, mental health problems in children and adolescents.

The most efficient indicator in screening for psychosocial problems is the history provided by caregivers. Psychosocial information can be obtained from checklists, general questioning, and direct questioning. The most effective method is a combination of these three information-gathering techniques. Questions can be incorporated into the general pediatric office screening forms, or specific questionnaires can be used. The 34-item pediatric symptom checklist (Table 6-5) screens children age 6-12 years for psychosocial dysfunction. The checklist is to be completed in the waiting room by a parent or other caregiver. Each item is rated by the parents as often present (2 points), sometimes present (1 point), or never present (0 points). The information can be used in two ways: first, as a psychosocial review of symptoms and point of depart-

ture for the discussion of problems that often or sometimes occur; and second, as a general screening device, with a total score of 28 or higher indicating a need for in-depth psychosocial evaluation of the child.

Five questions forming the mnemonic PSYCH can be addressed to parents as a means of uncovering areas of concern. The questions can be rephrased slightly and then directed to children as well.

1. **Parent-child interaction:** How are things going with you and your child?
2. **School:** How are things going in school? (Academically and behaviorally.)
3. **Youth:** How are things going with peer relationships?
4. **Casa:** How are things going at home? (Including siblings, the marriage, and parents as individuals.)
5. **Happiness:** How would you describe your child's mood? (Comfortable and happy versus tense and unhappy.)

Direct questions regarding age-appropriate behavior norms can then be reviewed. Concerns about infant attachment, the terrible twos, childhood fears, school problems, and adolescent behavioral problems can in this way be brought into the open for further discussion.

ASSESSMENT OF BEHAVIORAL AND EMOTIONAL SIGNS AND SYMPTOMS

When an emotional or behavioral sign or symptom is present, a thorough evaluation is indicated. Information must be collected from caregivers, the child, and sometimes school personnel and others acquainted with the child's functioning. At least 30 minutes should be scheduled, and additional appointments may be necessary. Screening questions and guidelines for observation are given in Table 6-6.

It is useful to see both parents and the child first together, then the parents alone, and then the child alone. This sequence enables the physician to observe interactions among family members and gives the parents and the child an opportunity to talk confidentially about their concerns. Parents and children often feel shame and guilt about some personal inadequacy they perceive to be causing the problem. The physician can ease that burden and facilitate the assessment by acknowledging that the family is trying to cope and that the ultimate task of assessment is to seek solutions and not to assign blame. An attitude of nonjudgmental inquiry can be communicated with supportive statements such as, "Let's see if we can figure out what might be happening here and find some ways to make things better."

Table 6–5. Pediatric symptom checklist.^a

	Never	Sometimes	Often
1. Complains of aches or pains			
2. Spends more time alone			
3. Tires easily, little energy			
4. Fidgets, is unable to sit still			
5. Has trouble with a teacher			
6. Is less interested in school			
7. Acts as if driven by a motor			
8. Daydreams too much			
9. Is distracted easily			
10. Is afraid of new situations			
11. Feels sad, unhappy			
12. Is irritable, angry			
13. Feels hopeless			
14. Has trouble concentrating			
15. Has less interest in friends			
16. Fights with other children			
17. Is absent from school			
18. Experiences a drop in school grades			
19. Is down on himself or herself			
20. Visits doctor, with doctor finding nothing wrong			
21. Has trouble with sleeping			
22. Worries a lot			
23. Wants to be with you more than before			
24. Feels he or she is bad			
25. Takes unnecessary risks			
26. Gets hurt frequently			
27. Seems to be having less fun			
28. Acts younger than children the same age			
29. Does not listen to rules			
30. Does not show feelings			
31. Does not understand other people’s feelings			
32. Teases others			
33. Blames others for his or her troubles			
34. Takes things that belong to others			

^aParents are asked to indicate which category—Never, Sometimes, or Often—best fits their child, with 0, 1, or 2 points assigned to each answer, respectively. For interpretation of scores, see text.

Table 6–6. Screening for psychosocial problems.**Developmental history**

1. Review the landmarks of psychosocial development
2. Summarize the child's temperamental traits
3. Review stressful life events and the child's reactions to them
 - a. Separations
 - b. Losses
 - c. Marital conflict
 - d. Illnesses, injuries, and hospitalizations
4. Obtain details of past mental health problems and their treatment

Family history

1. Marital history
 - a. Overall satisfaction with the marriage
 - b. Conflicts or disagreements within the relationship
 - c. Quantity and quality of time together away from children
 - d. Whether the child comes between or is a source of conflict between the parents
 - e. Marital history prior to having children
2. Parenting history
 - a. Feelings about parenthood
 - b. Whether parents feel united in dealing with the child
 - c. "Division of labor" in parenting
 - d. Parental energy or stress level
 - e. Sleeping arrangements
 - f. Privacy
 - g. Attitudes about discipline
 - h. Interference with discipline from outside the family (eg, ex-spouses, grandparents)
3. Stresses on the family
 - a. Problems with employment
 - b. Financial problems
 - c. Changes of residence
 - d. Illness, injuries, and deaths
4. Family history of mental health problems
 - a. Depression? Who?
 - b. Suicide attempts? Who?
 - c. Psychiatric hospitalizations? Who?
 - d. "Nervous breakdowns"? Who?
 - e. Substance abuse or problems? Who?
 - f. Nervousness or anxiety? Who?

Observation of the parents

1. Do they agree on the existence of the problem or concern?
2. Are they uncooperative or antagonistic about the evaluation?
3. Do the parents appear depressed or overwhelmed?
4. Can the parents present a coherent picture of the problem and their family life?
5. Do the parents accept some responsibility for the child's problems, or do they blame forces outside the family and beyond their control?
6. Do they appear burdened with guilt about the child's problem?

Observation of the child

1. Does the child acknowledge the existence of a problem or concern?
2. Does the child want help?
3. Is the child uncooperative or antagonistic about the assessment?
4. What is the child's predominant mood or attitude?
5. What does the child wish could be different (eg, "three wishes")?
6. Does the child display unusual behavior (activity level, mannerisms, fearfulness)?
7. What is the child's apparent cognitive level?

Observation of parent-child interaction

1. Do the parents show concern about the child's feelings?
2. Does the child control or disrupt the joint interview?
3. Does the child respond to parental limits and control?
4. Do the parents inappropriately answer questions addressed to the child?
5. Is there obvious tension between family members?

Data from other sources

1. Waiting room observations by office staff
2. School (teacher, nurse, social worker, counselor)
3. Department of social services

History of the Presenting Problem

First, obtain a detailed description of the problem.

- When did it start?
- Were there unusual stresses at that time?
- How are the child's life and the family's functioning affected?
- What does the child say about the problem?

- What attempts have been made to alleviate the problem?
- Do the parents have any opinions about the cause of the problem?

Questions to screen for other psychosocial problems, listed in Table 6–6, can be asked when additional information is sought.

Interviewing the Preschool Child

Preschool children should be interviewed with their parents. As the parents discuss their concerns, the physician can look for the following behaviors:

1. Does the child use the parents as a source of security and support?
2. Does the 2- to 5-year-old child warm up to the strange environment and begin to explore the room and even interact with the physician from a distance?
3. How does the child relate to toys that are offered?
4. What is the child's activity level?
5. Does the child display unusual mannerisms (eg, intense clinging, stereotypical motor behaviors)?
6. Does the child disrupt or attempt to control the interview?
7. Do the parents attempt to place appropriate limits on behavior? How does the child respond?

It is helpful to have toy human figures, animals, or puppets, and crayons and paper available that the child can use to portray emotional states and interpersonal interactions. After hearing the history from the parents and after observing the child, the physician may question the 3- to 5-year-old child about toy figures who appear to be feeling sad, worried, angry, or bossy. Children age 3–5 years are frequently able to confirm important interpersonal relationships and attitudes in such symbolic play activities.

Interviewing the School-Age Child

Most school-age children have mastered separation anxiety sufficiently to tolerate at least a brief interview alone with the physician. In addition, they may have important information to share about their own worries. The child should be told beforehand by the parents or physician (or both) that the doctor will want to talk to the child about his or her feelings. School-age children understand and even appreciate parental concern about unhappiness, worries, and difficulty in getting along with people. At the outset, it is useful to confirm that the purpose of the interview is to explore the child's own opinions about certain issues raised by the parents. Rapport can be enhanced by asking if the child has ever talked with anyone else about how he or she feels. If the answer is affirmative, the child may explain more about what he or she liked or did not like about that discussion. If the child has never before talked about personal feelings with a professional, the physician can acknowledge that it is often not easy to talk with a stranger about some kinds of problems. The physician should then ascertain whether the child

agrees that a problem exists (eg, unhappiness, anxiety, sleep disturbance).

- The physician should ask the child to describe the problem in his or her own words, or ask what he or she thinks is causing the problem.
- It is important to ask the child how the problem affects the child and the family.
- Asking directly about how mom and dad get along can yield information about parental conflicts.
- Questions about school can yield information about life outside the home and with peers.
- Questions about worries, unhappy feelings, and what makes the child angry can elicit clues to the child's emotional life.
- Asking a child to make three wishes can uncover important concerns that may not have been apparent from the history: Let's pretend you could have anything or change anything. What would you wish for and why?

At the end of the interview with the child, it is important to share or reiterate the central points derived from the interview and to state that the next step is to talk with the parents about ways to make things better for the child. At that time, it is good to discuss any concerns or misgivings the child might have about sharing information with parents so that the child's right to privacy is not arbitrarily violated. Most children want to make things better and thus will allow the physician to share appropriate concerns with the parents.

Interviewing the Adolescent

Because the central developmental task of adolescence is to create an identity separate from that of the parents, the physician must show respect for the teen's point of view. That process usually begins with the physician meeting briefly with the parents and adolescent together to define the concerns. The physician should then meet alone with the adolescent. After the physician has interviewed the adolescent and talked further with the parents, he or she should formulate thoughts and recommendations. Whenever possible, it is helpful to discuss these with the adolescent before presenting them to the parents and teen together. The issue of confidentiality must be approached during the first interview. A good policy is to say, "What we talk about today is between you and me unless we decide someone should know or unless it appears to me that you might be in a potentially dangerous situation."

The interview with the adolescent alone might then start with a restatement of the parents' concern. The patient is then encouraged to describe the situation in

his or her own words. The physician should then ask questions about:

1. Predominant mood state
2. Nature of relationships with family members
3. Level of satisfaction with school and peer relationships
4. Plans for the future
5. Drug and alcohol use
6. Sexual activity
7. Worries or concerns
8. What the adolescent would like to be different

In concluding the interview, the physician should summarize his or her thoughts and develop a plan with the teenager to present to the parents. If teenagers participate in the solution, they are more likely to work with the family in improving the situation. This should include a plan either for further investigation or for ways of dealing with the problem and arranging subsequent appointments with the physician or an appropriate referral to a mental health provider.

DIAGNOSTIC FORMULATION AND INTERPRETATION OF FINDINGS

Diagnosis starts with a description of the presenting problem, which is then evaluated within the context of the child's age, developmental needs and tasks, and temperament; the stresses and strains on the child and the family; and the functioning of the family system and family history of mental illness. The physician then develops an etiologic hypothesis based on the information gathered:

1. The behavior falls within the range of normal given the child's developmental level.
2. The behavior is a temperamental variation.
3. The behavior is related to central nervous system impairment (eg, prematurity, exposure to toxins in utero, seizure disorder, genetic disorders).
4. The behavior is a normal reaction to stressful circumstances (eg, medical illness, change in family structure, loss of a loved one).
5. The problem is primarily a reflection of family dysfunction (eg, the child is the symptom bearer, or scapegoat, or the identified patient for the family).
6. The problem indicates a possible psychiatric disorder.
7. The problem is complicated by an underlying medical condition.
8. Some combination of the preceding.

The physician's first task is to decide whether a problem exists. For example, how hyperactive must a 5-year-old child be before he or she is too hyperactive? Functional impairment may be the single best marker of the difference between symptomatology and normal variation. When a child's function is impaired in major domains of life, such as learning, peer relationships, family relationships, authority relationships, and recreation, or when a substantial deviation from the trajectory of normal developmental tasks occurs, a differential diagnosis should be sought based on the symptom profile. The physician's interpretation is then presented to the family. The interpretive process includes the following components:

1. An explanation of how the presenting problem or symptom is a reflection of a suspected cause
2. A suggested plan of intervention based on the presumed cause
3. A discussion of any further evaluation necessary to confirm or refine a diagnosis

A joint plan involving the physician, parents, and child is then negotiated to address the child's symptoms and developmental needs in light of the family structure and stresses. If an appropriate plan cannot be developed, or if the physician feels that further diagnostic assessment is required, referral to a mental health practitioner should be recommended.

PSYCHIATRIC DISORDERS OF CHILDHOOD & ADOLESCENCE

A psychiatric disorder is defined as a characteristic cluster of signs and symptoms (eg, emotions, behaviors,

thought patterns, and mood states) that are associated with subjective distress or maladaptive behavior. This definition presumes that the individual's symptoms are of such intensity, persistence, and duration that the ability to adapt to life's challenges is compromised.

Psychiatric disorders have their origins in neurobiology, genetics, psychological (life experience), or environmental sources. The neurobiology of childhood disorders is today one of the most active areas of investigation in child and adolescent psychiatry. Although much remains to be clarified, data from genetic studies point to heritable transmission of attention-deficit/hyperactivity disorder (ADHD), schizophrenia, mood and anxiety disorders, pervasive developmental disorders, learning disorders, and tic disorders, among others. About 3–5% of children and 10–15% of adolescents are personally affected by psychiatric disorders and will benefit from psychiatric treatment.

The Diagnostic and Statistical Manual IV—text revision (DSM-IV-TR) is the formal reference text for psychiatric disorders and includes the criteria for each of the mental illnesses, including those that begin in childhood and adolescence. Psychiatric diagnoses are given on five axes to allow the physician to address the developmental, medical, psychosocial, and overall adaptive issues that contribute to the primary diagnosis on axis I or II.

Axis I: Clinical disorders and other conditions that may be a focus of clinical attention

Axis II: Personality disorders, mental retardation, learning disabilities

Axis III: General medical conditions

Axis IV: Psychosocial and environmental problems

Axis V: Global assessment of functioning (on a scale of 0–100, with 100% being the highest level of functioning)

Primary care physicians often are the first to identify and recommend treatment for mental illness in children and adolescents. Criteria for referral to a child and adolescent psychiatrist are listed in Table 6–7.

American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders—Text Revision*. American Academy of Pediatrics, 2000.

PERVASIVE DEVELOPMENTAL DISORDERS & AUTISM

Pervasive developmental disorders (PDD) and childhood autism are early-onset, severe neuropsychiatric disorders that were once referred to as childhood psychoses. PDD (including autistic disorder) are now distinguished from childhood schizophrenia on the basis

Table 6–7. When to consider consultation or referral to a child and adolescent psychiatrist.

Diagnosis is not clear
Pediatrician feels further assessment is needed
Pediatrician believes medication may be needed, but will not be prescribing
Pediatrician has started medications and needs further psychopharmacologic consultation
Individual, family, and/or group psychotherapy is needed.
Psychotic symptoms (hallucinations, paranoia) are present
Bipolar affective disorder is suspected.

of clinical differences and family histories. The term PDD denotes a group of disorders with the common findings of impairment of socialization skills and characteristic behavioral abnormalities. Speech and language deficits are common as well.

1. Autistic Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Severe deficits in social responsiveness and interpersonal relationships.
- Abnormal speech and language development.
- Behavioral peculiarities such as ritualized, repetitive, or stereotyped behaviors; rigidity; and poverty of age-typical interests and activities.
- Onset in infancy or early childhood (before age 3 years).

General Considerations

Autistic disorder is uncommon, with an incidence of approximately 4 cases per 10,000 school-age children. More boys than girls are affected (3:1). Although the cause of autistic disorder is unknown, central nervous system dysfunction is suggested by its higher incidence in populations affected by perinatal disorders: rubella, phenylketonuria, tuberous sclerosis, infantile spasms, encephalitis, and fragile X syndrome. Studies of twins reveal over 90% concordance for autistic disorder in monozygotic twins compared with 24% in dizygotic twins. Twenty-five percent of families with an autistic child have other family members with language-related disorders. (See also Chapter 2.)

Clinical Findings

Severe deficits in reciprocal social interaction (eg, delayed or absent social smile, failure to anticipate interaction with caregivers, and a lack of attention to a primary caregiver's face) are often evident even in the first year of life. In toddlers, findings include deficiencies in imitative play and a relative lack of interest in interactions with others. Language development is often quite delayed. In fact, children are often first referred for audiologic evaluation because of failure to respond as expected to sounds. When speech does begin to develop, it may be echolalic or nonsensical. Autistic children often display peculiar interests; bizarre responses to sensory stimuli; repetitive, stereotypical motor behaviors (eg, twirling, hand-flapping); odd posturing; self-injurious behavior; abnormal patterns of eating and sleeping; and unpredictable mood changes. Thematic pretend play is often impaired. An intense preoccupation with an age-unusual interest (eg, power poles) may replace the usual broad range of interests of the child's age-mates. About 70% of autistic children have intelligence quotients under 70.

Differential Diagnosis

Although most autistic children function at the mentally retarded level, the vast majority of mentally retarded children do not show the essential characteristics of autistic disorder. A hearing or visual impairment must be ruled out with appropriate screening. Children with developmental speech and language disorders typically show better interpersonal interactions than autistic children. Evaluation should include investigations for metabolic disorders and fragile X syndrome.

Complications

Approximately 25% of autistic individuals eventually develop a seizure disorder. Comorbid psychiatric disorders such as mood disorders should be screened for if significant changes in behavior occur. Some autistic adolescents who have higher cognitive skills become depressed as they become partially aware of their deficits.

Treatment

Parents and families need strong support as well as education in caring for a child with autism. Early interventions to facilitate the development of reciprocal interactions, language, and social skills are critical. Occupational therapy for sensory integration is also an integral component of the comprehensive assessment. Sensory integration interventions help the autistic child and help the family better support the child and adapt the environment to their specific needs.

Behaviorally oriented special education classes or day treatment programs are vital in helping the autistic child acquire more appropriate social, linguistic, self-care, and cognitive skills.

No specific medications are available to treat autistic disorder. Pharmacotherapy is aimed at reducing specific target symptoms and must be continually assessed and reevaluated for efficacy and side effects. Coexisting diagnoses must be carefully considered. Neuroleptic medications (eg, risperidone, olanzapine, and haloperidol) may modify a variety of disruptive symptoms, including hyperactivity, aggressiveness, and negativism. Fenfluramine may help the subset of autistic children with low serotonin levels (although serotonin levels are very difficult to measure). Psychostimulants may benefit concurrent ADHD symptoms but can sometimes worsen behavior or mood. Antidepressants—especially the selective serotonin reuptake inhibitors (SSRIs)—may benefit both mood symptoms and symptoms of excessive rigidity or obsessive behavior. Mood stabilizers may diminish irritability, lability, or episodic dyscontrol. Naltrexone may help control severe self-injurious behavior or stereotypes. Controlled studies do not support the use of secretin for autism.

Parents and families need strong support as well as education in caring for a child with autism. Early interventions to facilitate the development of reciprocal interactions, language, and social skills are critical. Occupational therapy for sensory integration is also an integral component of the comprehensive assessment. Sensory integration interventions help the autistic child and help the family better support the child and adapt the environment to their specific needs.

Prognosis

Autism is a lifelong disorder. The best prognosis is for children who have normal intelligence and have developed symbolic language skills by age 5 years. Most individuals with autism will not be able to live independently and will require significant support and supervision throughout their lives. Approximately one sixth of autistic children become gainfully employed as adults, and another one sixth are able to function in sheltered workshops or special work and school environments. The remainder need ongoing supervision and support, often in a milieu-based therapeutic environment to provide a structured day. Placement in specialized residential homes or programs may be necessary for some individuals whose guardians are unable to meet their special needs or provide a secure and safe home environment.

2. Nonautistic Pervasive Developmental Disorders

Asperger syndrome, childhood disintegrative disorder, pervasive developmental disorder not otherwise specified (PDD-NOS), and Rett syndrome (Table 6–8).

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Substantial social impairment, either primary or representing a loss of previously acquired social skills.*
- *Abnormalities in speech and language development or behavior resembling autistic disorder.*
- *Onset by early childhood (may be as late as age 9 years in childhood disintegrative disorder).*

General Considerations

Children with nonautistic PDDs display a wide range of deficits in social, language, and behavioral skills that are similar to those in children with autistic disorder. However, these children deviate from the clinical profile for autistic disorder by failing to meet all the necessary diagnostic criteria, by failing to fulfill severity threshold (ie, milder functional impairment), by manifesting atypical symptomatology (eg, the characteristic hand-wringing or gender distribution in Rett syndrome), or by experiencing onset at a later age. In the past, many of these children would have been classified in the group manifesting so-called atypical development. Children with nonautistic PDDs probably outnumber autistic children by as much as 2–3:1.

Differential Diagnosis

Specific developmental speech and language disorders should be distinguished. Hearing impairment should be ruled out with appropriate screening.

Treatment

The backbone of treatment for Asperger syndrome and PDD-NOS is an adaptive behavioral approach aimed at teaching and reinforcing more appropriate social and language skills and behaviors. Rett syndrome and childhood disintegrative disorder have much worse prognoses and call for multidisciplinary, often milieu-based interventions (as for autistic disorder). Occupational therapy for sensory integration interventions may be helpful. In all cases, family education and support are important.

Children should be screened for the presence of other psychiatric conditions, including mood disorders, obsessive-compulsive disorder (OCD), ADHD, and

Table 6–8. Characteristics of nonautistic pervasive developmental disorders.

Disorder	Age at Onset	Clinical Features
Asperger's syndrome	Early childhood	"Odd" individuals (probably more common in males) with normal intelligence, motor clumsiness, eccentric interests, and a limited ability to appreciate social nuances
Childhood disintegrative disorder	3–4 years	Profound deterioration to severe autistic disorder
Pervasive developmental disorder	Early childhood	Two to three times more common than autistic disorder, with similar but less severe symptoms
Rett syndrome	5 months to 4 years old	Females with reduced head circumference and loss of social relatedness who develop stereotyped hand movements and have impaired language and mental functioning

anxiety disorders, and appropriate interventions should be initiated. Psychoactive medications may be helpful for treating specific target symptoms as described for autistic disorder.

Prognosis

These are lifelong disorders. The prognosis is variable depending on the severity of social and language deficits and response to treatment interventions.

MOOD DISORDERS

1. Depression in Children & Adolescents

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Dysphoric mood, mood lability, irritability or depressed appearance, persisting for days to months at a time.*
- *Characteristic neurovegetative signs and symptoms (changes in sleep, appetite, concentration, and activity levels).*
- *Suicidal ideation, feeling of hopelessness*

General Considerations

The incidence of depression in children increases with age, from 1–3% before puberty to around 8% for adolescents. The rate of depression in females approaches adult levels by age 15. The lifetime risk of depression ranges from 10–25% for women and 5–12% for men. The incidence of depression in children is higher when other family members have been affected by depressive disorders. The sex incidence is equal in childhood, but with the onset of puberty the rates of depression for females begin to exceed those for males by 5:1.

Clinical Findings

Clinical depression can be defined as a persistent state of unhappiness or misery that interferes with pleasure or productivity. The signs and symptoms of depression are surprisingly constant from early childhood to adolescence and adulthood (Table 6–9). The dysphoria of depression in children and adolescents is as likely to be an irritable mood state accompanied by tantrums or verbal outbursts, as it is to be a sad mood. Typically, a child or adolescent with depression begins to look unhappy and may make comments such as “I have no friends,” “Life is boring,” “There is nothing I can do to make things better,” or “I wish I were dead.” A change in behavior patterns usually takes place that includes social isolation, deterioration in schoolwork, loss of interest in usual activities, and flashes of anger and irritability. Sleep and appetite patterns commonly change, and the child may complain of tiredness and nonspecific pain such as headaches or stomachaches.

Differential Diagnosis

Clinical depression can be identified by asking about the symptoms. Children are often more accurate than their caregivers in assessing their own mood state. When several depressive symptoms cluster together over time and are persistent (2 weeks or more) and severe, a diagnosis of major depressive disorder is appropriate. When symptoms are fewer and of lesser severity

Table 6–9. Clinical manifestations of depression in children and adolescents.

Depressive Symptom	Clinical Manifestations
Anhedonia	Loss of interest and enthusiasm in play, socializing, school, and usual activities; boredom; loss of pleasure
Dysphoric mood	Tearfulness; sad, downturned expression; unhappiness; slumped posture; quick temper; irritability; anger
Fatigability	Lethargy and tiredness; no play after school
Morbid ideation	Self-deprecating thoughts, statements; thoughts of disaster, abandonment, death, suicide, or hopelessness
Somatic symptoms	Changes in sleep or appetite patterns; difficulty in concentrating; bodily complaints, particularly headache and stomachache

but have persisted for months or years, a diagnosis of dysthymic disorder is justified. Milder symptoms of short duration in response to some stressful life event warrant a diagnosis of adjustment disorder with depressed mood (See Table 6–9).

Rating scales of mood can be helpful in assessing child and adolescent patients. The Child Depression Inventory (CDI), the BECK Depression Rating Scale, and the Reynolds Adolescent Depression Scale are easily used in primary care.

Substantial rates of comorbidity of depression are associated with ADHD, conduct disorders, anxiety disorders, eating disorders, and substance abuse disorders. Medically ill patients also have an increased incidence of depression. Every child and adolescent with a depressed mood state should be asked directly about suicidal ideation and physical and sexual abuse. Depressed adolescents should also be screened for hypothyroidism and substance abuse.

Complications

Because the emotional pain associated with depression can be intensely distressing, the child or adolescent may consider suicide (see section on Suicide in Children & Adolescents). In addition, adolescents have a propensity to avoid the pain of depression through substance abuse or excitement-seeking behaviors (eg, partying, negativism and defiance, reckless behavior). School performance usually suffers during a depressive episode as children are unable to concentrate or motivate themselves to complete homework or projects. The irritability, isolation, and withdrawal that often result from the depressive episode can lead to loss of peer relationships and tense dynamics within the family.

Treatment

Treatment includes identifying the symptoms of depression and developing a comprehensive plan to treat the depressive episode and help the caregivers to respond more effectively to the patient's emotional needs. Referrals should be made for individual and family therapy. In therapy, efforts are made to resolve conflicts between family members, improve communication skills within the family, and increase the opportunity for enjoyable time spent together. Attitudes, expectations, and disciplinary methods are evaluated. The child is encouraged to become involved in activities and to pursue opportunities for maximizing skills and talents. Individual psychotherapy aimed at identifying pervasively negative thoughts and correcting negativistic cognitive distortions can increase the patient's awareness of care and concern on the part of adults. It

also helps the young person to identify, label, and verbalize feelings and misperceptions.

Antidepressant medications should be considered for all patients with a depressive diagnosis (Table 6–10). When the symptoms of depression are moderate to severe and persistent and have begun to interfere with relationships and school performance, antidepressant medications may be indicated. Mild depressive symptoms often do not require antidepressant medications and may improve with psychotherapy alone. A positive family history of depression increases the risk of early-onset depression in children and adolescents and chances of a positive response to antidepressant medication.

Prognosis

A comprehensive treatment intervention, including psychotherapy, medication assessment, and evaluation of school and home environments, often leads to complete remission of depressive symptoms over a 1- to 2-month period. If medications are started and prove effective, they must be continued for 6–9 months after remission of symptoms to prevent relapse. Early-onset depression (before age 15) is associated with increased risk of recurrent episodes and the potential need for longer term treatment with antidepressants. Education of the family and child (or adolescent) will help them identify depressive symptoms sooner and limit the severity of future episodes with earlier interventions. Some studies suggest that up to 30% of preadolescents with major depression manifest bipolar disorder at 2-year follow-up. It is important to reassess the child or adolescent with depressive symptoms regularly for at least 6 months and to maintain awareness of the depressive episode in the course of well-child care.

American Academy of Child and Adolescent Psychiatry: Practice parameters for the assessment and treatment of children and

Table 6–10. Interventions for the treatment of depression.

Adjustment disorder	Refer for psychotherapy	Medications usually not needed
Mild depression	Refer for psychotherapy	Medications may not be needed

2. Bipolar Affective Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Periods of abnormally and persistently elevated, expansive, or irritable mood, and heightened levels of energy and activity.*
- *Not caused by prescribed or illicit drugs.*
- *Associated symptoms: grandiosity, diminished need for sleep, pressured speech, racing thoughts, impaired judgment.*

General Considerations

Bipolar affective disorder (previously referred to as manic-depressive disorder) is an episodic mood disorder manifested by alternating periods of mania or hypomania and depressive episodes or, less commonly, manic episodes alone. Children and adolescents often exhibit a variable course of mood instability combined with misconduct and impulsivity. At least 20% of bipolar adults experience onset of symptoms before age

20 years. Onset of bipolar disorder before puberty is thought to be uncommon, whereas the lifetime prevalence of bipolar disorder in middle to late adolescence approaches 1%.

Clinical Findings

In about 70% of patients, the first symptoms are primarily those of depression; in the remainder, manic, hypomanic, or mixed states dominate the presentation. Manic patients display a variable pattern of elevated, expansive, or irritable mood along with more rapid speech, higher energy levels, some difficulty in sustaining concentration, and a decreased need for sleep. Patients often do not acknowledge any problem with their mood or behavior. The clinical picture can be quite dramatic, with florid psychotic symptoms of delusions and hallucinations (a full-blown manic psychosis), more subtle changes and lability in mood or behavior (cyclothymia), or milder symptoms of psychomotor activation (hypomania).

Differential Diagnosis

ADHD is thought to be highly comorbid with bipolar disorder in prepubertal children. Physical or sexual abuse and exposure to domestic violence can often cause children to appear mood labile, hyperactive, and aggressive, and PTSD should be considered by reviewing the history for traumatic life events in children with these symptoms. Diagnostic considerations should also include an acute organic process, particularly substance abuse disorder. Individuals with manic psychosis may resemble those with schizophrenia. Psychotic symptoms associated with bipolar disorder should clear with resolution of the mood symptoms, which should also be prominent. Hyperthyroidism should be ruled out. In prepubescent children, mania may be difficult to differentiate from ADHD and other disruptive behavior disorders. Preoccupation with violence, decreased need for sleep, intense and prolonged rages or dysphoria, and some periodicity of symptom activity suggest bipolar disorder. Table 6-11 further defines points of differentiation between ADHD, conduct disorder, and bipolar disorder.

Complications

Children and adolescents with bipolar disorder are more likely to be aggressive or assaultive toward peers and family members. This may also result in significant interference with academic learning and peer relationships. The poor judgment associated with manic episodes predisposes to dangerous, impulsive, and sometimes criminal activity. Legal difficulties can arise

Table 6–11. Differentiating behavior disorders.

	ADHD	Conduct Disorder	Bipolar Disorder
School problems	Yes	Yes	Yes
Behavior problems	Yes	Yes	Yes
Defiant attitude	Occasional	Constant	Episodic
Motor restlessness	Constant	May be present	May wax and wane
Impulsivity	Constant	May be present	May wax and wane
Distractibility	Constant	May be present	May wax and wane
Anger expression	Short-lived (minutes)	Plans revenge	Intense rages (minutes to hours)
Thought content	May be immature	Blames others	Morbid or grandiose ideas
Sleep disturbance	May be present	No	May wax and wane
Self-deprecation	Briefly, with criticism	No	Prolonged, with or without suicidal ideation
Obsessed with ideas	No	No	Yes
Hallucinations	No	No	Diagnostic, if present
Family history	May be a history of school problems	May be a history of antisocial behavior	May be a history of mood disorders

ADHD = attention-deficit/hyperactivity disorder.

from impulsive acts, such as excessive spending, acts of vandalism, theft, or aggression, associated with grandiose thoughts. Affective disorders are associated with a 30-fold greater incidence of successful suicide. Substance abuse may be a further complication, often representing an attempt at self-medication for the mood problem.

Treatment & Prognosis

Most patients with bipolar disorder respond to pharmacotherapy with mood stabilizers such as lithium, carbamazepine, or valproate, either alone or in combination. The atypical neuroleptic, olanzapine, has been approved by the Food and Drug Administration (FDA) for the treatment of bipolar affective disorder. Neuroleptic medications may be necessary in addition to a mood stabilizer if psychotic symptoms or significant aggression is present. In cases of severe impairment, hospitalization is required to maintain safety and initiate treatment. Although it is often possible to discontinue the neuroleptic medication after remission of symptoms, it is usually necessary to continue the mood stabilizer for at least a year, and longer if the individual has had recurrent episodes. It is not uncommon for the patient to need lifelong medication. Supportive psychotherapy for the patient and family and education about the recurrent nature of the illness are critical. In its adult form, bipolar

disorder is an illness with a remitting course of alternating depressive and manic episodes. The time span between episodes can be years or months depending on the severity of illness and ability to comply with medication interventions. In childhood, the symptoms may be more pervasive and not fall into the intermittent episodic pattern until after puberty.

SUICIDE IN CHILDREN & ADOLESCENTS

The suicide rate in young people has remained high for several decades. In 1997, suicide was the third leading cause of death among children and adolescents age 10–24 years in the United States. The suicide rate among adolescents age 15–19 years quadrupled from approximately 2.7 to 11.3 per 100,000 since the 1960s. It is estimated that each year, approximately 2 million US adolescents attempt suicide, yet only 700,000 receive medical attention for their attempt. Suicide and homicide rates for children in the United States are two to five times higher than those for the other 25 industrialized countries combined, primarily due to the prevalence of firearms in the United States. For children younger than 10 years old, the rate of completed suicide is low, but from 1980 to 1992 it increased by 120%, from 0.8 to 1.7 per 100,000.

Adolescent girls make three to four times as many suicide attempts as boys of the same age, but the number of completed suicides is three to four times greater in boys. Firearms are the most commonly used method in successful suicides, accounting for 40–60% of cases; hanging, carbon monoxide poisoning, and drug overdoses each account for approximately 10–15% of cases.

Suicide is almost always associated with a psychiatric disorder and should not be viewed as a philosophic choice about life or death or as a predictable response to overwhelming stress. Most commonly it is associated with a mood disorder and the hopelessness that accompanies a severe depressive episode. Suicide attempts are often an angry, impulsive, and retaliatory act of aggression in an individual who is unable to exercise better insight and judgment because of an impaired state due to either mental illness or substance abuse. Although suicide attempts are more common in individuals with a history of behavior problems and academic difficulties, other suicide victims are high achievers who are temperamentally anxious and perfectionistic and who commit suicide impulsively after a failure or rejection, either real or perceived. Mood disorders (in both sexes, but especially in females), substance abuse disorders (especially in males), and conduct disorders are commonly diagnosed at psychological autopsy in adolescent suicide victims. Some adolescent suicides reflect an underlying psychotic disorder, with the young person usually committing suicide in response to auditory hallucinations or psychotic delusions.

The vast majority of young people who attempt suicide give some clue to their distress or their tentative plans to commit suicide. Most show signs of dysphoric mood (anger, irritability, anxiety, or depression). Over 60% make comments such as “I wish I were dead” or “I just can’t deal with this any longer” within the 24 hours prior to death. In one study, nearly 70% of subjects ex-

perienced a crisis event such as a loss (eg, rejection by girlfriend or boyfriend), a failure, or an arrest prior to completed suicide.

Assessment of Suicide Risk

Any clinical assessment for depression must include questions about suicidal ideation. If a child or adolescent expresses suicidal thinking, the physician must ask if he or she has an active plan. Suicidal ideation accompanied by any plan warrants immediate referral for a psychiatric crisis assessment. This can usually be accomplished at the nearest emergency room.

Assessment of suicide risk calls for a high index of suspicion and a direct interview with the patient and significant others such as family members, peers, and teachers. A format for the interview is provided in Table 6–12. The highest risk of suicide is among older white adolescent boys. High-risk factors include previous suicide attempts, a suicide note, and a viable plan for suicide with the availability of lethal means, close personal exposure to suicide, conduct disorder, and substance abuse. Other risk factors are signs and symptoms of major depression or dysthymia, a family history of suicide, a recent death in the family, and a view of death as a relief from the pain in their lives. Persons who have little or no family support, those who are facing a crisis in their lives at work or school, and those who refuse to agree not to commit suicide are also at high risk.

Principles of Intervention

Any suicide attempt must be considered a serious matter. The patient should not be left alone, and one should show understanding of the young person’s pain and convey a desire to help. The physician should meet with the patient and the family, both alone and together, and listen carefully to their problems and perceptions. It should be made clear that with the assistance of mental health professionals, solutions can be found.

These patients should be referred for psychiatric evaluation and possible hospitalization if there appears to be a high potential for suicide, if they are severely depressed or intoxicated, if the family does not appear appropriately concerned, or if there are practical limitations on providing supervision and support to ensure safety. Any decision to send the patient home without hospitalization should be made only after consultation with a mental health expert. The decision should rest on a perceived lessening of the risk of suicide and assurance of the family’s ability to follow through with outpatient therapy and provide appropriate support and supervision. Guns, pills, knives, and razor blades must

Table 6–12. Clinical interview to assess suicide risk.

1. An observation or change has been noted.
2. How have you been feeling (inside, emotionally)?
3. Have you had periods of feeling down or discouraged?
 - a. How often?
 - b. How long?
 - c. How severe?
4. Do they interfere with your life?
 - a. Daily activities?
 - b. School or work?
 - c. Sleep or appetite? Both?
 - d. Family life?
5. Do you have feelings of—
 - a. Self-criticism or worthlessness?
 - b. Helplessness?
 - c. Hopelessness?
 - d. Wanting to give up?
6. Are the feelings ever so strong that life does not seem worth living? Have you had thoughts of suicide?
 - a. Are you having thoughts of suicide now?
 - b. How persistent are they?
 - c. How much effort does it take to resist?
 - d. Can you tolerate the pain you are feeling?
7. Have you made any plans to carry out suicide?
 - a. What are the plans?
 - b. Have you taken any tentative action (eg, obtaining a gun or rope, stockpiling pills)?
 - c. As you have thought about suicide, how have you viewed the idea of death?
8. What deters you from trying suicide?
9. If the suicidal feelings are subsiding, could you resist the feelings if they returned?
10. Is there someone you can turn to for help at those times? Who?
11. Has the idea of suicide come up in the past?
 - a. How often?
 - b. When and under what circumstances?
 - c. What has happened at those times?
12. Can you tolerate the pain that you are feeling right now?

be removed from the home entirely, and, as much as possible, access to them outside the home must be denied. The patient should be restricted from driving for at least the first 24 hours to lessen the chance of impulsive motor vehicle accidents. Instructions and phone numbers for crisis services should be given, and the family must be committed to a plan for mental health treatment.

Suicide prevention should be a community- and school-based effort to increase awareness and provide access to services, including hotlines. Restricting young people's access to firearms is also a critical factor, as

firearms are responsible for 85% of deaths due to suicide or homicide in youth in the United States.

Finally, the physician should be aware of his or her own emotional reactions to dealing with potentially suicidal adolescents and their families. Because the assessment takes considerable time and energy, the physician should be on guard against becoming tired, irritable, or angry. The physician need not be afraid of precipitating suicide by direct and frank discussions of suicidal risk.

ADJUSTMENT DISORDERS

The most frequent and most disturbing stresses for children and adolescents are marital discord, separation and divorce, family illness, the loss of a loved one, a change of residence, and, for adolescents, peer relationship problems. When faced with stress, children can experience many different symptoms, including changes in mood, changes in behavior, anxiety symptoms, and physical complaints. Key findings include the following:

- The precipitating event or circumstance is identifiable.
- The symptoms have appeared within 3 months after the occurrence of the stressful event.
- Although the child experiences distress or some functional impairment, the reaction is not severe or disabling.
- The reaction does not persist more than 6 months after the stressor has terminated.

The range of symptoms associated with adjustment disorders is listed in Table 6–13.

Differential Diagnosis

When symptoms are a reaction to an identifiable stressor but are severe, persistent, or disabling, depressive disorder, anxiety disorder, and conduct disorders must be considered.

Table 6–13. Signs and symptoms of adjustment reactions.

Irritable, angry mood
Anxious, worried mood
Unhappy, depressed mood
Angry resistance to authority
Fatigue
Aches and pains
Decreased school performance
Social withdrawal
Any combination of the above

Treatment

The mainstay of treatment is the doctor’s assurance that the emotional or behavioral change is a predictable consequence of the stressful event. This validates the child’s reaction and encourages the child to talk about the stressful occurrence and its aftermath. Parents are asked to understand the child’s reaction and encourage appropriate verbal expression of feelings, while defining boundaries for behavior that prevent the child from feeling out of control.

Prognosis

The duration of symptoms in adjustment reactions depends on the severity of the stress; the child’s personal sensitivity to stress and vulnerability to anxiety, depression, and other psychiatric disorders; and the available support system.

SCHIZOPHRENIA

The incidence of schizophrenia is about 1 per 10,000 per year. The onset of schizophrenia is typically between the mid- to late teens and early 30s, with onset before puberty being relatively rare. Symptoms usually begin after puberty, although a full “psychotic break” may not occur until the young adult years. Childhood onset (before puberty) of psychotic symptoms due to schizophrenia is uncommon and usually indicates a more severe form of the spectrum of schizophrenic disorders. It affects only one or two children in every 10,000 of the population younger than age 15 years, and boys outnumber girls by approximately 2:1. Childhood schizophrenia appears to be genetically related to the adult type of schizophrenia. Schizophrenia is a biologically based disease with a strong genetic component. Other psychotic disorders that may be encountered in childhood or adolescence include schizoaffective disorder and psychosis not otherwise specified (NOS). Psychosis NOS may be used as a differen-

tial diagnosis when psychotic symptoms are present, but the cluster of symptoms is not consistent with a schizophrenia diagnosis.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Delusional thoughts.*
- *Disorganized speech (rambling or illogical speech patterns).*
- *Disorganized or bizarre behavior.*
- *Hallucinations (auditory, visual, tactile, olfactory), negative symptoms (ie, flat affect, avolition, alogia).*

Clinical Findings

Children and adolescents display many of the symptoms of adult schizophrenia. Hallucinations or delusions, bizarre and morbid thought content, and rambling and illogical speech are typical. Affected individuals tend to withdraw into an internal world of fantasy and may then equate fantasy with external reality. They generally have difficulty with schoolwork and with peer relationships. Adolescents may have a prodromal period of depression prior to the onset of psychotic symptoms. The majority of patients with childhood-onset schizophrenia have had nonspecific psychiatric symptoms or symptoms of delayed development for months or years prior to the onset of their overtly psychotic symptoms.

Differential Diagnosis

Obtaining the family history of mental illness is critical when assessing children and adolescents with psychotic symptoms. Psychological testing is often helpful in identifying or ruling out psychotic thought processes. Psychotic symptoms in children younger than age 8 years must be differentiated from manifestations of normal vivid fantasy life or abuse-related symptoms. Children with psychotic disorders often have learning disabilities and attention difficulties in addition to disorganized thoughts, delusions, and hallucinations. In psychotic adolescents, mania is differentiated by high levels of energy, excitement, and irritability. Any child or adolescent exhibiting new psychotic symptoms requires a medical evaluation that includes physical and neurologic examinations (including consideration of magnetic resonance imaging and electroencephalo-

gram), drug screening, and metabolic screening for endocrinopathies, Wilson disease, and delirium.

Treatment

The treatment of childhood and adolescent schizophrenia focuses on four main areas: (1) decreasing active psychotic symptoms, (2) supporting development of social and cognitive skills, (3) reducing the risk of relapse of psychotic symptoms, and (4) providing support and education to parents and family members. Antipsychotic medications (eg, risperidone, olanzapine, haloperidol) are the primary psychopharmacologic intervention. In addition, a supportive, reality-oriented focus in relationships can help to reduce hallucinations, delusions, and frightening thoughts. A special school or day treatment environment may be necessary depending on the child's or adolescent's ability to tolerate the school day and classroom activities. Support for the family emphasizes the importance of clear, focused communication and an emotionally calm climate in preventing recurrences of overtly psychotic symptoms.

Prognosis

Schizophrenia is a chronic disorder with exacerbations and remissions of psychotic symptoms. It is generally believed that earlier onset (prior to age 13 years) and poor premorbid functioning (oddness or eccentricity) generally predict a poorer outcome.

Shaffer JL, Ross RG: Childhood onset schizophrenia: Premorbid and prodromal diagnostic and treatment histories. *J Am Acad Child Adolesc Psychiatry* 2002;41:538 [PMID: 12014786].

- *Violating the rights of others or society's norms.*
- *Aggressive behavior toward persons, animals, or property.*

General Considerations

Disorders of conduct affect approximately 9% of males and 2% of females younger than 18 years. This is a very heterogeneous population, and overlap occurs with ADHD, learning and other neuropsychiatric disorders, mood disorders, and family dysfunction. Many of these individuals come from homes where domestic violence, child abuse, drug abuse, shifting parental figures, and poverty are environmental risk factors. Although social learning partly explains this correlation, the genetic heritability of aggressive conduct and antisocial behaviors is currently under investigation.

Clinical Findings

The typical child with conduct disorder is a boy with a turbulent home life and academic difficulties. Defiance of authority, fighting, tantrums, running away, school failure, and destruction of property are common symptoms. With increasing age, fire-setting and theft may occur, followed in adolescence by truancy, vandalism, and substance abuse. Sexual promiscuity, sexual perpetration, and other criminal behaviors may develop. Hyperactive, aggressive, and uncooperative behavior patterns in the preschool and early school years tend to predict conduct disorder in adolescence with a high degree of accuracy, especially when ADHD goes untreated. A history of reactive attachment disorder is an additional childhood risk factor. The risk for conduct disorder increases with inconsistent and severe parental disciplinary techniques, parental alcoholism, and parental antisocial behavior.

Differential Diagnosis

Young people with conduct disorders, especially those with more violent histories, have an increased incidence of neurologic signs and symptoms, psychomotor seizures, psychotic symptoms, mood disorders, ADHD, and learning disabilities. Efforts should be made to identify these associated disorders (see Table 6–11) because they may suggest specific therapeutic interventions. Conduct disorder is best conceptualized as a final common pathway emerging from a variety of underlying psychosocial, genetic, environmental, and neuropsychiatric conditions. Other diagnoses that may be present or should be differentiated include intermittent explosive disorder and oppositional defiant disorder.

CONDUCT DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

A persistent pattern of behavior that includes the following:

- *Defiance of authority.*

Treatment

Effective treatment can be complicated by the problematic psychosocial problems often found in the lives of children and adolescents with conduct disorders and difficulty achieving compliance with treatment recommendations. Efforts should be made to stabilize the environment and improve functioning within the home, particularly as it relates to parental functioning and disciplinary techniques. Identification of learning disabilities and placement in an optimal school environment is also critical. Any associated neurologic and psychiatric disorders should be addressed. In severe cases, residential treatment may be needed, often through the juvenile justice system. Medications such as mood stabilizers, neuroleptics, stimulants, and antidepressants have all been studied in youth with conduct disorders, yet none has been found to be consistently effective in this population. Early involvement in programs such as Big Brothers and Sisters, Scouts, and team sports in which consistent adult mentors and role models interact with youth decreases the chances that the youth with conduct disorders will develop antisocial personality disorder. Multisystemic therapy (MST) is being used increasingly as an intervention for youth with conduct disorders and involvement with the legal system. MST is an intensive home-based model of care that seeks to stabilize and improve the home environment and to strengthen the support system and coping skills of the individual and family.

Prognosis

The prognosis is based on the ability of the child's support system to mount an effective treatment intervention consistently over time. The prognosis is generally worse for children in whom the disorder presents before age 10 years; those who display a diversity of antisocial behaviors across multiple settings; and those who are raised in an environment characterized by parental antisocial behavior, alcoholism or other substance abuse, and conflict. Nearly half of such children become antisocial as adults. Persistent antisocial behavior in childhood or adolescence tends to predict a diagnosable psychiatric disorder in adulthood.

1. Oppositional Defiant Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *A pattern of negativistic, hostile, and defiant behavior lasting at least 6 months.*

- *Loses temper, argues with adults, defies rules.*
- *Blames others for own mistakes and misbehavior.*
- *Angry, easily annoyed, vindictive.*
- *Does not meet criteria for conduct disorder.*

Oppositional defiant disorder (ODD) usually is evident before 8 years of age and may be an antecedent to the development of conduct disorder. The symptoms usually first emerge at home, but then extend to school and peer relationships. The disruptive behaviors of ODD are generally less severe than those associated with conduct disorder and do not include hurting other individuals or animals, destruction of property, or theft.

ODD is more common in families where caregiver dysfunction is present, and in children with a history of multiple changes in caregivers; inconsistent, harsh, or neglectful parenting; or serious marital discord.

Interventions include careful assessment of the psychosocial situation and recommendations to support parenting skills and optimal caregiver functioning. Assessment for comorbid psychiatric diagnoses such as learning disabilities, depression, and ADHD should be pursued and appropriate interventions recommended.

ANXIETY DISORDERS

1. Anxiety-Based School Refusal (School Avoidance)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A persistent pattern of school avoidance related to symptoms of anxiety.
- Somatic symptoms on school mornings, with symptoms resolving if the child is allowed to remain at home.
- No organic medical disorder that accounts for the symptoms.
- High levels of parental anxiety are commonly observed.

General Considerations

Anxiety-based school refusal is a persistent behavioral symptom rather than a diagnostic entity. It refers to a pattern of school nonattendance resulting from anxiety, which may be related to a dread of leaving home (separation anxiety), a fear of some aspect of school, or a fear of feeling exposed or embarrassed at school (social phobia). In all cases, a realistic cause of the fear (eg, an intimidating teacher or a playground bully) should be ruled out. In most cases, anxiety-based school refusal is related to developmentally inappropriate separation anxiety. The incidence between males and females is about equal, and there appear to be peaks of incidence at ages 6–7 years, again at ages 10–11 years, and in early adolescence.

Clinical Findings

In the preadolescent years, school refusal often begins after some precipitating stress in the family. The child's anxiety is then manifested either as somatic symptoms or in displacement of anxiety onto some aspect of the school environment. The somatic manifestations of anxiety include dizziness, nausea, and stomach distress. Characteristically, the symptoms become more severe as the time to leave for school approaches and then remit if the child is allowed to remain at home for the day. In older children, the onset is more insidious and often as-

sociated with social withdrawal and depression. The incidence of anxiety and mood disorders is increased in these families.

Differential Diagnosis

The differential diagnosis of school nonattendance is presented in Table 6–14. Medical disorders that may be causing the somatic symptoms must be ruled out. Children with learning disorders may wish to stay home to avoid the sense of failure they experience at school. Children may also have transient episodes of wanting to stay at home during times of significant family stress or loss. The onset of school avoidance in middle or late adolescence may herald the onset of schizophrenia or other psychotic disorder. Children who are avoiding school for reasons related to ODD or conduct disorder can be differentiated on the basis of their chronic non-compliance with adult authority and their preference for being with peers rather than at home.

Table 6–14. Differential diagnosis of school nonattendance.^a

I. Emotional or anxiety-based refusal^b	
A.	Separation anxiety disorder (50–80% of anxious refusers)
B.	Generalized anxiety disorder
C.	Mood/depressive disorder (with or without combined anxiety)
D.	Social phobia
E.	Specific phobia
F.	Panic disorder
G.	Psychosis (“voices” say not to attend)
II. Truancy^c behavior disorders	
A.	Oppositional defiant disorder, conduct disorder
B.	Substance abuse disorders
III. “Realistic” school refusal	
A.	Learning disability, unaddressed or undetected
B.	Marauding students (including gangs)
C.	Psychologically abusive teacher
D.	Family-sanctioned nonattendance
1.	For companionship
2.	For child care
3.	To care for the parent (role-reversal)
4.	To supplement family income
E.	Socioculturally sanctioned nonattendance (school is not valued)
F.	Homosexual attraction, gender concerns
IV. Undiagnosed medical condition (including pregnancy)	

^aMedically unexplained absence of more than 2 weeks.

^bSubjectively distressed child who generally stays at home.

^cNonsubjectively distressed and not at home.

Complications

The longer a child remains out of school, the more difficult it is to return and the more strained the relationship between child and parent becomes. Many parents of nonattending children feel tyrannized by their defiant, clinging child. Children often feel accused of making up their symptoms, leading to further antagonism between the child, parents, and medical caregivers.

Treatment

The goal of treatment is to help the child confront anxiety and overcome it by returning to school. This requires a strong alliance between the parents and the health care provider. The parent must understand that no underlying medical disorder exists, that the child's symptoms are a manifestation of anxiety, and that the basic problem is anxiety that must be faced to be overcome. Parents must be reminded that being good parents in this case means helping a child cope with a distressing experience. Children must be reassured that their symptoms are caused by worry and that they will be overcome on return to school.

A plan for returning the child to school is then developed with parents and school personnel. Firm insistence on full compliance with this plan is essential. The child is brought to school by someone not likely to give in, such as the father or an older sibling. If symptoms develop at school, the child should be checked by the school nurse and then returned to class after a brief rest. The parents must be reassured that school staff will handle the situation at school and that school personnel can reach the primary health care provider if any questions arise.

If these interventions are ineffective, increased involvement of a therapist and consideration of a day treatment program may be necessary. For children with persistent symptoms of separation that do not improve with behavioral interventions, medications such as SSRIs should be considered. Comorbid diagnoses of panic disorder, generalized anxiety, or major depression should be carefully screened for and, if identified, treated appropriately.

Prognosis

The vast majority of preadolescent children improve significantly with behavioral interventions and return to school. The prognosis is worsened by the length of time the child remains out of school. Long-term outcomes are influenced by comorbid diagnoses and responsiveness to behavioral or medication interventions. A history of school refusal is more common in adults with panic and anxiety disorders and agoraphobia than in the general population.

2. Generalized Anxiety Disorder & Panic Disorder

Transient developmental fears are common in early childhood. Therefore, the person evaluating the clinical significance of anxiety symptoms in children must consider the age of the child, the developmental fears that can normally be expected at that age, the form of the symptoms and their duration, and the degree to which the symptoms disrupt the child's life.

Anxiety can be manifested either directly or indirectly, as shown in Table 6–15. The characteristics of anxiety in childhood are listed in Table 6–16. Community-based studies of school-age children and adolescents suggest that nearly 10% of children have some type of anxiety disorder. The differential diagnosis of symptoms of anxiety is presented in Table 6–17.

The child's family and school environment should be evaluated for marital discord, family violence, harsh or inappropriate disciplinary methods, sexual abuse, ne-

Table 6–15. Signs and symptoms of anxiety in children.

Psychological

- Fears and worries
- Increased dependence on home and parents
- Avoidance of anxiety-producing stimuli
- Decreased school performance
- Increased self-doubt and irritability
- Frightening themes in play and fantasy

Psychomotor

- Motoric restlessness and hyperactivity
- Sleep disturbances
- Decreased concentration
- Ritualistic behaviors (eg, washing, counting)

Psychophysiologic

- Autonomic hyperarousal
- Dizziness and lightheadedness
- Palpitations
- Shortness of breath
- Flushing, sweating, dry mouth
- Nausea and vomiting
- Panic
- Headaches and stomachaches

Table 6–16. Anxiety disorders in children and adolescents.

Disorder	Major Clinical Manifestations
Generalized anxiety disorder	Intense, disproportionate or irrational worry, often about future events
Panic disorder	Unprovoked, intense fear with sympathetic hyperarousal, and often palpitations or hyperventilation
Posttraumatic stress disorder	Fear of a recurrence of an intense, anxiety-provoking traumatic experience, causing sympathetic hyperarousal, avoidance of reminders, and the re-experiencing of aspects of the traumatic event
Separation anxiety disorder	Developmentally inappropriate wish to maintain proximity with caregivers; morbid worry of threats to family integrity or integrity of self upon separation; intense homesickness
Social phobia	Painful shyness or self-consciousness; fear of humiliation with public scrutiny
Specific phobia	Avoidance of specific feared stimuli

glect, and emotional overstimulation. The child's experience of anxiety and its relationship to life events should be explored, and therapy to incorporate specific cognitive and behavioral techniques to diminish the anxiety should be recommended. Finally, when panic attacks or anxiety symptoms do not remit with cognitive, behavioral, and environmental interventions, and they significantly affect life functioning, psychopharmacologic agents may be helpful. SSRIs may be effective across a broad spectrum of anxiety symptoms.

Prognosis

There appears to be continuity between high levels of childhood anxiety and anxiety disorders in adulthood. Anxiety disorders are thus likely to be lifelong conditions, yet with effective interventions, individuals can minimize their influence on overall life functioning.

OBSESSIVE–COMPULSIVE DISORDER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent obsessive thoughts, impulses, or images that cause marked anxiety or distress and

are not simply excessive worries about real-life problems.

- *The individual attempts to ignore or suppress the thoughts or impulses.*
- *Repetitive compulsive behaviors or mental acts that the person feels driven to perform in response to the obsessive thought aimed at preventing or reducing distress.*
- *The obsessions and compulsions cause marked distress, are time-consuming, and interfere with normal routines.*

Obsessive-compulsive disorder (OCD) is an anxiety disorder that often begins in early childhood, but may not be diagnosed until the teen or even young adult years. The essential features of OCD are recurrent obsessions or compulsions that are severe enough to be time-consuming or cause marked distress and functional impairment. Obsessions are persistent ideas, thoughts, or impulses that are intrusive and often inappropriate. Children may have obsessions about contamination or cleanliness; ordering and compulsive behaviors will follow, such as frequent hand-washing, counting, or ordering objects. The goal of the compulsive behavior for the individual with OCD is to reduce anxiety and distress. There may be significant avoidance of situations due to obsessive thoughts or fears of contamination. OCD is often associated with major depressive disorder. The prevalence of OCD is estimated to be around 2%, and the rates are equal between males and females.

Treatment

OCD is best treated with a combination of cognitive-behavioral therapy (CBT) specific to OCD and medications in more severe cases. SSRIs are effective in diminishing OCD symptoms. Fluvoxamine and sertraline have FDA approval for the treatment of pediatric OCD. The tricyclic antidepressant (TCA) clomipramine has FDA approval for the treatment of OCD in adults.

Prognosis

Although OCD is usually a lifelong condition, most individuals can achieve significant remission of symptoms with the combination of CBT and medications. A minority of individuals with OCD are completely disabled by their symptoms.

POSTTRAUMATIC STRESS DISORDER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Signs and symptoms of autonomic hyperarousal such as easy startle, increased heart rate, and hypervigilance.*
- *Avoidant behaviors and numbing of responsiveness.*
- *Flashbacks to a traumatic event, such as nightmares, and intrusive thoughts.*
- *All of the preceding following the experience of traumatic events such as exposure to violence, physical or sexual abuse, natural disasters, car accidents, dog bites, and unexpected personal tragedies.*

General Considerations

Factors that predispose individuals to the development of posttraumatic stress disorder (PTSD) include proxim-

ity to the traumatic event or loss, a history of exposure to trauma, preexisting depression or anxiety disorder, and lack of an adequate support system. PTSD can develop in response to natural disasters, terrorism, motor vehicle accidents, and significant personal injury in addition to physical, sexual, and emotional abuse. Long-overdue attention is now being paid to the substantial effects of family and community violence on the psychological development of children and adolescents. Abused children are most likely to develop PTSD and to suffer wide-ranging symptoms and impaired functioning. Heightened concern about terrorism in the United States has created increased awareness of PTSD and community-based interventions to decrease the risk of PTSD. Studies after the terrorist attacks of September 11, 2001, and Oklahoma City reported up to 40% of children and adolescents experienced PTSD symptoms.

As many as 25% of young people exposed to violence develop symptoms of posttraumatic stress disorder. Factors that predispose to development of PTSD when a person is exposed to a traumatic event include a history of exposure to trauma, preexisting depression or anxiety disorder, and lack of an adequate support system.

Clinical Findings

Children who have been traumatized show persistent evidence of fear and anxiety and are hypervigilant to the possibility of repetition. They may regress developmentally and experience fears of strangers, of the dark, and of being alone, and avoid reminders of the traumatic event. Children also frequently reexperience elements of the events in dreams and flashbacks. In their symbolic play, one can often notice a monotonous repetition of some aspect of the traumatic event. Children with a history of traumatic experiences or neglect in infancy and early childhood are likely to show signs of reactive attachment disorder and have difficulty forming relationships with caregivers.

Treatment

The cornerstone of treatment for PTSD is education of the child and family regarding the nature of the disorder so that the child's emotional reactions and regressive behavior are not mistakenly viewed as crazy or manipulative. Support, reassurance, and repeated explanations and understanding are needed. It is critical that the child be living in a safe environment, and if caregivers have been abusive, concerns must be reported to social services. Interventions to maintain safety of the child are imperative. Individual and family psychotherapy are central features of treatment interventions. Specific fears usually wane with time, and behavioral desensitization may help. A supportive relationship with a caregiving adult is essential.

For children with more severe and persistent symptoms, assessment for treatment with medication is indicated. Sertraline has approval for the treatment of PTSD in adults. Target symptoms (eg, anxiety, depression, nightmares, aggression) should be clearly identified and appropriate medications trials initiated with close monitoring. Some of the medications used to treat children with PTSD include clonidine or guanfacine (Tenex), mood stabilizers, and antidepressants and neuroleptics. Children who have lived for an extended time in abusive environments or who have been exposed to multiple traumas are more likely to require treatment with medications. Occupational therapy for sensory integration can also be effective in decreasing reactivity to stimuli and helping the child and caregivers develop and implement self-soothing skills. Individuals who have suffered single-episode traumas usually benefit significantly from psychotherapy and may require limited treatment with medication to address symptoms of anxiety, nightmares, and sleep disturbance. Psychotherapy that includes eye movement desensitization and reprocessing (EMDR) may also be useful.

Prognosis

At 4- to 5-year follow-up investigations, many children who have been through a traumatic life experience continue to have vivid and frightening memories and dreams and a pessimistic view of the future. The effects of traumatic experiences can be far-reaching. The ability of caregivers to provide a safe, supportive, stable, empathic environment enhances the prognosis for individuals with PTSD. Timely access to therapy and use of therapy over time to work through symptoms also enhance prognosis. Evidence is growing to support a connection between victimization in childhood and unstable personality and mood disorders in later life.

SOMATIFORM DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A symptom suggesting physical dysfunction.
- No physical disorder accounting for the symptom.
- Symptoms causing distress, dysfunction, or both.
- Symptoms not voluntarily created or maintained, as in malingering.

Clinical Findings

Somatiform disorders are defined by the presence of physical illness or disability for which no organic cause can be identified, although neither the patient nor the caregiver is consciously fabricating the symptoms. The category includes body dysmorphic disorder, conversion disorder, hypochondriasis, somatization disorder, and somatoform pain disorder (Table 6–18).

Conversion symptoms most often occur in school-age children and adolescents. The exact incidence is unclear, but in pediatric practice they are probably seen more often as transient symptoms than as chronic disorders requiring help from mental health practitioners. A conversion symptom is thought to be an expression of underlying psychological conflict. The specific symptom may be symbolically determined by the underlying conflict. Furthermore, the symptom may resolve the dilemma created by the underlying wish or fear (eg, a seemingly paralyzed child need not fear expressing his underlying rage or aggressive retaliatory impulses). Although children can present with a variety of symptoms, the most common include neurologic and gastrointestinal (GI) complaints. Children with conversion disorder may be surprisingly unconcerned about the substantial disability deriving from their symptoms. Symptoms include unusual sensory phenomena, paralysis, vomiting, abdominal pain, intractable headaches, and movement or seizure-like disorders.

Table 6–18. Somatiform disorders in children and adolescents.

Disorder	Major Clinical Manifestations
Body dysmorphic disorder	Preoccupation with an imagined defect in personal appearance
Conversion disorder	Symptom onset follows psychologically stressful event; symptoms express unconscious feelings and result in secondary gain
Hypochondriasis	Preoccupation with worry that physical symptoms manifest unrecognized and threatening condition; medical assurance does not provide relief from worry
Somatization disorder	Long-standing preoccupation with multiple somatic symptoms
Somatoform pain disorder	Preoccupation with pain that results in distress or impairment beyond what would be expected from physical findings

In the classic case of conversion disorder, the child's symptoms and examination findings are not consistent with the clinical manifestations of any organic disease process. The physical symptoms often begin within the context of a family experiencing stress, such as serious illness, a death, or family discord. On closer examination, the child's symptoms are often found to resemble symptoms present in other family members. Children with conversion disorder may have some secondary gain associated with their symptoms. A number of reports have pointed to the increased association of conversion disorder with sexual overstimulation or sexual abuse. As with other emotional and behavioral problems, health care providers should always screen for physical and sexual abuse.

Differential Diagnosis

It is sometimes not possible to rule out medical disease as a source of the symptoms. Medical follow-up is required to monitor for changes in symptoms and response to recommended interventions.

Somatic symptoms are often associated with anxiety and depressive disorders (see Table 6–15). Occasionally, psychotic children have somatic preoccupations and even somatic delusions.

Treatment & Prognosis

In most cases, conversion symptoms resolve quickly when the child and family are reassured that the symp-

tom is a way of reacting to stress. The child is encouraged to continue with normal daily activities, knowing that the symptom will abate when the stress is resolved.

Treatment of conversion disorders includes acknowledging the symptom rather than telling the child that the symptom is not medically justified and responding with noninvasive interventions such as physical therapy while continuing to encourage normalization of the symptoms. If the symptom does not resolve with reassurance, further investigation by a mental health professional is indicated. Comorbid diagnoses such as depression and anxiety disorders should be addressed, and treatment with psychopharmacologic agents may be helpful.

ELIMINATION DISORDERS

1. Enuresis

It is important for the primary care provider to carefully assess the developmental age of the child, the situation in which enuresis is occurring, and to screen for medical concerns before deciding that the enuresis or encopresis is attributable to a behavioral or emotional disorder. It is not uncommon for parents to have unrealistic expectations about toilet training for young children. In many cases of enuresis, the child is simply not developmentally ready or sometimes is unable to remain dry at night. Most children with enuresis are able to remain dry by age 9.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Urinary incontinence in a child age 5 years (or developmental equivalent) or older.
- No medication or general medical condition causing the urinary incontinence.

General Considerations

Enuresis is the passage of urine into bedclothes or undergarments, whether involuntary or intentional. At least 90% of enuretic children have primary nocturnal enuresis—that is, they wet only at night during sleep and have never had a sustained period of dryness. Diurnal enuresis (daytime wetting) is much less common, as is secondary enuresis, which develops after a child has had a sustained period of bladder control. The latter two varieties are much more commonly associated with emotional stress, anxiety, and psychiatric disorders. Primary nocturnal enuresis is most often a parasomnia, a deep-sleep (stage 3 or stage 4) event. Etiologically, it is generally viewed as a developmental disorder or maturational lag that children will outgrow. Only infrequently is it associated with a serious psychopathologic disorder.

Clinical Findings

Primary nocturnal enuresis is common (Table 6–19). The incidence is three times higher in boys than in girls. Most children with enuresis become continent by adolescence or earlier. The family history in such cases frequently reveals other members, especially fathers, who have had prolonged nighttime bed-wetting problems. Although the cause of primary nocturnal enuresis is not established, it appears to be related to maturational delay of sleep and arousal mechanisms or to delay in development of increased bladder capacity.

Daytime wetting most often occurs in timid and shy children or in children with ADHD. It occurs with about equal frequency in boys and girls, and 60–80% of daytime wetters also wet at night. Secondary enuresis typically follows a stressful event, such as the birth of a sibling, a loss, or discord within the family. The symptom can be seen as the result of regression in response

Table 6–19. Incidence of enuresis in children.

Age (years)	Primary Nocturnal Enuresis (%)	Occasional Daytime Enuresis (%) ^a
5	15	8
7–8	7	—
10	3–5	—
12	2–3	1
14	1	—

^aDiurnal (daytime) enuresis tends to resolve by developmental age 6 years, with a slight recurrence around age 12 years in early adolescence.

to stress or as a more symbolic expression of the child's feelings.

Differential Diagnosis

The differential diagnosis includes urinary tract infections, neurologic diseases, seizure disorders, diabetes mellitus, and structural abnormalities of the urinary tract. Urinalysis and urine culture and observing the child's urinary stream can rule out the majority of organic causes of enuresis.

Complications

The most common complication of enuresis is low self-esteem in response to criticism from caregivers and embarrassment if peers are aware of the problem. Older children with enuresis may be reluctant to attend sleepovers and be self-conscious with peers.

Treatment

Treatment should emphasize that the symptom of nocturnal enuresis is a developmental lag and often will be outgrown even without treatment. Even with these interventions, many children will have difficulty remaining dry. If the child chooses to pursue treatment, a program of bladder exercises can be prescribed: fluids should be limited after dinner; the child should attempt to hold urine as long as possible during the day and then start and stop the stream at the toilet bowl; the child is instructed to practice getting up from bed and going to the bathroom at bedtime before sleep. These procedures are helpful in perhaps 30–40% of children with nighttime wetting. Another option is a "potty pager." This is a beeper-like object that attaches to the child's underwear and vibrates when the child is wet in an attempt to rouse the child into a wakeful state and increase awareness of the need to urinate.

Desmopressin acetate (DDAVP), administered intranasally at bedtime, can result in complete remission of nocturnal enuresis in 50% of children as long as they continue the treatment. DDAVP is expensive, but can be useful until the child develops the ability to hold urine through the night or awaken to use the bathroom. For others, a trial of the TCA imipramine is worthwhile, at dosages of 25–50 mg at bedtime for children under age 12 years and 50–75 mg for older children. Because many patients relapse once the drug is stopped, its primary use is for camp attendance or overnight visits. Mental health treatment is more often needed for children with daytime wetting or secondary enuresis. The focus is on the verbal expression of feelings that may be associated with perpetuation of the

symptom and behavioral interventions to work toward dryness and cope with episodes of wetting.

2. Encopresis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Fecal incontinence in a child age 4 years (or developmental equivalent) or older.*
- *Not due to medication or medical disorder.*

General Considerations

Functional encopresis is defined as the repeated passage of feces in inappropriate places by a child of at least the developmental equivalent of age 4 years. It may be either involuntary or intentional, although most often it is involuntary. It affects approximately 1–1.5% of school-age children; boys four times more often than girls. Functional fecal incontinence is rare in adolescence.

Clinical Findings

Functional encopresis can be divided into four types: retentive, continuous, discontinuous, and toilet phobia.

A. RETENTIVE ENCOPRESIS

In retentive encopresis, also called psychogenic megacolon, the child withholds bowel movements, leading to the development of constipation, fecal impaction, and the seepage of soft or liquid feces around the margins of the impaction into the underclothing. Marked constipation and painful defecation often contribute to a vicious cycle of withholding, thus creating larger impaction and further seepage. These children often have a history of crossing their legs to resist the urge to defecate and of infrequent bowel movements large enough to stop up the toilet, and they are found on examination to have large fecal masses in their rectal vaults. The soiling that occurs distresses most of these children.

B. CONTINUOUS ENCOPRESIS

Children with continuous encopresis have never gained primary control of bowel function. The bowel movement is usually randomly deposited in underclothing without regard to social norms. Typically, the family structure does not encourage organization and skill training, and for that reason the child has never had adequate bowel training. These children and their parents

are more apt to be socially or intellectually disadvantaged.

C. DISCONTINUOUS ENCOCPRESIS

Children with discontinuous encopresis have a history of normal bowel control for an extended period. Loss of control often occurs in response to a stressful event, such as the birth of a sibling, a separation, family illness, or marital disharmony. These children may soil their pants or on occasion defecate on the floor or smear feces as an expression of anger or of a wish to be perceived as younger. They typically display relative indifference to the symptom.

D. TOILET PHOBIA

In the infrequent case of toilet phobia, a young child views the toilet as a frightening structure to be avoided. These children may view the bowel movement as an extension of themselves, which is then swept away in a frightening manner. They may think that they, too, may be swept away, down the toilet.

Differential Diagnosis

Differential diagnosis includes the medical causes of constipation and retentive encopresis. Hirschsprung disease can be ruled out with reasonable certainty by the history of passing large-caliber bowel movements in the past and by the presence of palpable stool in the rectal vault. Neurologic disorders, hypothyroidism, hypercalcemia, and diseases of smooth muscle must be considered as well. The child should be examined for anal fissures, which tend to encourage the withholding of bowel movements. In addition, fecal soiling can be a presenting symptom in childhood depression and is sometimes a concomitant finding in children with ADHD. If the child engages in fecal smearing, an underlying psychotic disorder should be considered.

Treatment

Identifying the type of encopresis is important in treatment planning. Another important variable is the child's own concern about the symptom. Encopresis in children who display denial or indifference is much harder to treat. Children with coexisting depression or ADHD need to receive treatment for those conditions before focusing treatment on soiling.

With the most common type of encopresis, the retentive type, efforts are made to soften stool so that constipation and painful defecation do not perpetuate the behavior. These children are then taught to adopt a regular schedule of sitting on the toilet after meals. A system of positive reinforcement can be added in which the child is rewarded for each day with no soiled under-

clothes. The responsibility for rinsing soiled clothing and depositing it in the appropriate receptacle rests with the child. In the case of continuous encopresis, the family is taught to train the child. For toilet phobia, a progressive series of rewarded desensitization steps is necessary. Children with discontinuous encopresis that persists over a number of weeks often need psychotherapy to help them recognize and verbally express their anger and wish to be dependent, rather than express themselves through fecal soiling.

Prognosis

Although the ultimate prognosis is excellent, parental distress and parent-child conflict may be substantial prior to the cessation of symptoms. The natural history of soiling is that it resolves by adolescence in all but the most severely disturbed teenagers.

OVERVIEW OF PEDIATRIC PSYCHOPHARMACOLOGY

Pediatric psychopharmacology has improved significantly over the past decade with increasing study of the effect of psychoactive medications on mental illness in childhood and adolescence. Although relatively few medications are approved for use in children, many of the same psychopharmacologic agents used in adults are now used in children and adolescents.

As with any medication, the risks as well as the benefits of administering psychoactive medications must be discussed with the child's parent or guardian and with the child and adolescent, as is age-appropriate. A recommendation for medication is warranted if the disorder is interfering with psychosocial development, interpersonal relationships, daily functioning, or the patient's sense of personal well-being, and if there is significant potential for benefit with the medication and relatively low risk of harm. Informed consent should be given by the parent or guardian and noted in the record. Adolescents should also provide informed consent for treatment. In some states adolescents age 15 and older must give informed consent. Informed consent includes a discussion of the diagnosis, target symptoms, possible common side effects, any side effects that should be closely monitored, potential benefits associated with the medication, and documentation of informed consent in the medical record. Psychopharmacologic agents are seldom the only treatment for a psychiatric disorder. Most often they are best used adjunctively along with other therapeutic interventions such as individual and family psychotherapy and psychosocial interventions, including assessment of school functioning and special needs.

A good rule when considering the use of psychoactive medications in children and adolescents is, first, to identify target symptoms that can be followed to evaluate the efficacy of treatment. When initiating treatment, start with low doses and increase slowly (in divided doses, if indicated) monitoring for side effects along with therapeutic effects. When drugs are discontinued, dosages should be tapered over 2–4 weeks to minimize withdrawal effects. When multiple choices exist, one should select the medication with the fewest and least ominous risks and side effects. Polypharmacy should be avoided by choosing one drug that might di-

minish most or all of the target symptoms before considering the simultaneous administration of two or more agents.

Table 6–20 presents an overview of the clinical conditions for which psychopharmacologic agents should be considered and medication categories for which studies have been completed or published case reports have suggested some therapeutic efficacy. Only the stimulants for ADHD and fluvoxamine and sertraline for OCD have FDA approval for specific use in children and adolescents.

In the text that follows, the major classes of psychopharmacologic agents with clinical indications in child and adolescent psychiatry are represented. The more commonly prescribed drugs from each class are reviewed with reference to indications, relative contraindications, initial medical screening procedures (in addition to a general pediatric examination), dosage, adverse effects, drug interactions, and medical follow-up recommendations. This is meant to be a brief reference guide, and the physician should consult a child and adolescent psychopharmacology textbook for additional information on specific medications.

Table 6–20. Clinical conditions and appropriate medications

Diagnosis	Possible Classes of Medications to Target Symptoms
ADHD	Stimulants, bupropion, α -agonists
Anorexia nervosa	SSRIs, atypical neuroleptics
Autism	SSRIs, atypical neuroleptics, clomipramine, naltrexone
Bipolar affective disorder	Mood stabilizers, neuroleptics
Bulimia nervosa	SSRIs
Major depression and dysthymic disorder	Antidepressants
Anxiety disorders	Antidepressants, benzodiazepines
Posttraumatic stress disorder	Antidepressants, α -agonists, mood stabilizers, atypical neuroleptics
Obsessive compulsive disorder	SSRIs, clomipramine
Schizophrenia and psychotic disorders	Neuroleptics
Conduct disorder and severe aggressive behavior	Mood stabilizers, neuroleptics, α -agonists, stimulants, β blockers

SSRIs = selective serotonin reuptake inhibitors.

MEDICATIONS FOR ATTENTION-DEFICIT/HYPERACTIVITY DISORDER (ADHD)

Methylphenidate (Concerta, Metadate, Methylin, Ritalin)

Dextroamphetamine (Dexedrine)

Pemoline (Cylert)

Adderall

Atomoxetine (Strattera)

A. INDICATIONS

Approximately 75% of children with ADHD experience improved attention span, decreased hyperactivity, and decreased impulsivity when given stimulant medications. Children with ADHD who do not respond favorably to one stimulant may respond well to another. Children and adolescents with ADHD without prominent hyperactivity (ADHD, predominantly inattentive type) are also likely to be responsive to stimulant medications. Atomoxetine (Strattera) and bupropion (Wellbutrin) are nonstimulant medications used to treat ADHD. Strattera has FDA approval for the treatment of ADHD and is a selective noradrenergic reuptake inhibitor. Bupropion (Wellbutrin) is primarily used as an antidepressant, and blocks both serotonin and norepinephrine reuptake.

B. CONTRAINDICATIONS

Use stimulants cautiously in individuals with a personal or family history of motor tics or Tourette syndrome, or if there is a personal or family history of substance abuse, addictive disorders, or psychotic disorders.

C. INITIAL MEDICAL SCREENING

The initial interview should include screening for personal or family history of motor tics or Tourette syndrome. The child should be observed for involuntary movements. Height, weight, pulse, and blood pressure should be recorded. Liver enzymes should be tested if pemoline is considered.

D. ADVERSE EFFECTS

Often dose-related and time-limited.

1. Common adverse effects—Anorexia, weight loss, abdominal distress, headache, insomnia, dysphoria and tearfulness, irritability, lethargy, mild tachycardia, mild elevation in blood pressure.

2. Less common effects—Interdose rebound of ADHD symptoms, emergence of motor tics or Tourette syndrome, behavioral stereotypy, tachycardia or hypertension, depression, mania, and psychotic symptoms. Reduced growth velocity occurs only during active administration. Growth rebound occurs during

periods of discontinuation. Ultimate height is not usually noticeably compromised. Treatment with stimulant medications does not predispose to future substance abuse.

E. DRUG INTERACTIONS

Additive stimulant effects are seen with sympathomimetic amines (ephedrine, pseudoephedrine).

F. MEDICAL FOLLOW-UP

Pulse, blood pressure, height, and weight should be recorded every 3–4 months and at times of dosage increases. Assess for abnormal movements such as motor tics at each visit.

G. DOSAGE

1. Methylphenidate—The usual starting dose is 5 mg once or twice a day (before school and at noon), gradually increasing to 5–10 mg/wk. Maximum daily dose should not exceed 60 mg, and a single dose should not exceed 0.7 mg/kg. Administration on weekends and during vacations is determined by the need at those times. The duration of action is approximately 3–4 hours. Several extended-release forms can prevent the need for taking medication at school.

2. Dextroamphetamine sulfate—The dosage is 2.5–10 mg twice daily, before school and at noon, with or without another dose at 4 PM. A sustained-release preparation may have clinical effects for up to 8 hours. There is also an extended-release form.

3. Pemoline—The longer half-life of pemoline allows for the administration of a single dose each morning. The usual starting dose of 37.5 mg is increased weekly by 18.75 mg until the desired clinical effect is achieved or until a maximum daily dose of 112.5 mg is reached. The onset of clinical effect may be delayed for 3–4 weeks. Liver enzymes must be monitored during treatment. Pemoline is contraindicated in individuals with hepatic disease.

Longer acting stimulants (see a psychopharmacology reference source for pharmacologic properties and dosage information): Adderall (dextroamphetamine and amphetamine)

Methylphenidate hydrochloride extended-release tablets (Concerta, Metadate)

4. Atomoxetine Hydrochloride—The starting dose for children and adolescents up to 70 kg is 0.5 mg/kg, with titration to a maximum dose of 1.2 mg/kg, in single or divided dosing.

ANTIDEPRESSANTS

1. Selective Serotonin Reuptake Inhibitors

Citalopram, escitalopram (Celexa, Lexapro)
 Fluoxetine (Prozac, Sarafem)
 Fluvoxamine (Luvox)
 Paroxetine (Paxil)
 Sertraline (Zoloft)

A. INDICATIONS

The SSRIs have become the agents of first choice for the treatment of depression and anxiety. Fluvoxamine and sertraline both have approval from the FDA for treatment of pediatric OCD. Although no other SSRIs have FDA approval for pediatric indications, some published studies support the efficacy of SSRIs for the treatment of depression, anxiety, and OCD in pediatric populations. Each SSRI has different FDA indications. However, once an indication is obtained for one SSRI, it is widely believed that other SSRIs are likely to be effective as well for the same indication. The FDA-approved indications are the following:

Major depression (> 18 years of age): fluoxetine, paroxetine, citalopram, sertraline
 Panic disorder (> 18 years): paroxetine, sertraline
 OCD (> 6 years): sertraline, fluvoxamine
 Bulimia (> 18 years): fluoxetine
 Posttraumatic stress disorder (> 18 years): sertraline
 Premenstrual dysphoric disorder (> 18 years): fluoxetine

B. CONTRAINDICATIONS

Concern about paroxetine causing a slightly increased incidence of suicidal ideation in children and adolescents in Great Britain led to a 2003 FDA statement regarding caution in prescribing this medication for children and adolescents. Caution should be used in cases of known liver disease, because all SSRIs are metabolized in the liver. Caution should be used when prescribing for an individual with a family history of bipolar disorder, or when the differential diagnosis includes bipolar disorder, because antidepressants can induce manic or hypomanic symptoms.

C. INITIAL MEDICAL SCREENING

General medical examination only.

D. ADVERSE EFFECTS

Often dose-related and time-limited: GI distress and nausea (can be minimized by taking medication with food), headache, tremulousness, decreased appetite,

weight loss, insomnia, sedation (10%), sexual dysfunction (25%). Irritability, social disinhibition, restlessness, and emotional excitability can occur in approximately 20% of children taking SSRIs.

E. DRUG INTERACTIONS

All SSRIs inhibit the efficiency of the hepatic microsomal enzyme system. The order of inhibition is: fluoxetine > fluvoxamine > paroxetine > sertraline > citalopram. This can lead to higher than expected blood levels of other drugs, including antidepressants, antiarrhythmics, antipsychotics, β -blockers, opioids, and antihistamines. Taking tryptophan while on an SSRI may result in a serotonergic syndrome of psychomotor agitation and GI distress. A potentially fatal interaction that clinically resembles neuroleptic malignant syndrome may occur when the SSRIs are administered concomitantly with the monoamine oxidase inhibitors (MAOIs). Fluoxetine has the longest half-life of the SSRIs and should not be initiated within 14 days of the discontinuation of an MAOI, or an MAOI initiated within at least 5 weeks of the discontinuation of fluoxetine.

F. DOSAGE (TABLE 6-21)

The SSRIs are usually given once a day, in the morning with breakfast. One in 10 individuals may experience sedation and prefer to take the medication at bedtime. The alternative antidepressants and fluvoxamine are usually given in twice daily dosing. Bupropion and venlafaxine are now available in a sustained- and extended-release form. Therapeutic response should be expected 4–6 weeks after a therapeutic dose has been reached. The starting dose for a child younger than 12 years old is generally half the starting dose for an adolescent.

2. Other Antidepressants

Bupropion (Wellbutrin), bupropion SR (sustained release)
 Venlafaxine (Effexor), venlafaxine XR (extended release)
 Mirtazapine (Remeron)
 Nefazodone (Serzone)

Bupropion

A. INDICATIONS

Bupropion is an antidepressant that inhibits reuptake of primarily serotonin, but also norepinephrine and dopamine. It is approved for treatment of major depression in adults, but is receiving favorable attention for its therapeutic effects with major depressive disorder in adolescents and with ADHD in children and adoles-

Table 6–21. Medications used to treat depression in adolescents

Generic	Trade Name	Adolescent Starting Dose	Target Dose (Average Effective Dose)	Maximum Dose
SSRIs				
Citalopram	Celexa	20 mg qAM	20 mg qAM	40–60 mg qAM
Escitalopram	Lexapro	10 mg	10 mg	30 mg
Fluoxetine	Prozac	10 mg qAM	20 mg qAM	60 mg qAM
Fluvoxamine	Luvox	50 mg qhs	100–150 mg qd	100 mg bid
Paroxetine	Paxil	10 mg qAM	20 mg qAM	60 mg qAM
Paroxetine CR	Paxil CR	25 mg	25 mg	50 mg
Sertraline	Zoloft	25 mg qAM	50 mg qAM	150 mg qAM
Alternative Antidepressants				
Bupropion	Wellbutrin	75 mg qAM	150 mg bid	200 mg bid
Bupropion SR	Wellbutrin SR	100 mg qAM	100 mg bid	150 mg bid
Mirtazapine	Remeron	7.5 mg qhs	15 mg qhs	30 mg qhs
Nefazodone	Serzone	50 mg qhs	100 mg bid	300 mg bid
Venlafaxine	Effexor	37.5 mg qAM	75 mg bid	150 mg bid
Venlafaxine XR	Effexor XR	37.5 mg qAM	150 mg qd	225 mg qd

qAM = every morning; qhs = every night at bedtime; qd = every day; bid = twice a day.

cents. Like the SSRIs, bupropion has very few anticholinergic or cardiotoxic effects.

B. CONTRAINDICATIONS

History of seizure disorder or bulimia nervosa.

C. INITIAL MEDICAL SCREENING AND FOLLOW-UP

General medical examination.

D. ADVERSE EFFECTS

Psychomotor activation (agitation or restlessness), headache, GI distress, nausea, anorexia with weight loss, insomnia, tremulousness, precipitation of mania, and induction of seizures with doses above 450 mg/d.

Venlafaxine

Venlafaxine is an antidepressant that primarily inhibits reuptake of serotonin and norepinephrine.

A. INDICATIONS

It is approved for the treatment of major depression in adults.

B. CONTRAINDICATIONS

Hypertension.

C. INITIAL MEDICAL SCREENING AND FOLLOW-UP

General medical examination.

D. ADVERSE EFFECTS

The most common adverse effects are nausea, nervousness, and sweating. Hypertension is likely with doses over 300 mg or over 225 mg of the extended release version. Venlafaxine must be discontinued slowly to minimize withdrawal symptoms: severe headaches, dizziness and significant flu-like symptoms. It is also available in an extended-release form.

Mirtazapine

Mirtazapine is an α_2 -antagonist that enhances central noradrenergic and serotonergic activity.

A. INDICATIONS

It is approved for the treatment of major depression in adults.

B. CONTRAINDICATIONS

Mirtazapine should not be given in combination with MAOIs. Very rare side effects are acute liver failure (1 case per 250–300,000), neutropenia, and agranulocytosis.

C. INITIAL MEDICAL SCREENING AND FOLLOW-UP

General medical examination.

D. ADVERSE EFFECTS

Dry mouth, increased appetite, constipation, weight gain.

3. Tricyclic Antidepressants

Imipramine
Desipramine (Norpramin)
Clomipramine (Anafranil)
Nortriptyline
Amitriptyline (Elavil)

With the introduction of the SSRIs and alternative antidepressants, use of the TCAs has become uncommon for the treatment of depression and anxiety disorders. The TCAs have more significant side-effect profiles, require more substantial medical monitoring, and are quite cardiotoxic in overdose. For these reasons, in general, SSRIs or alternative antidepressants should be considered before recommending a TCA.

A. INDICATIONS

TCAs have been prescribed for chronic pain syndromes, migraines, headache, depression, anxiety, enuresis, bulimia nervosa, OCD, and PTSD in children and adolescents. Imipramine and desipramine have FDA approval for the treatment of major depression in adults and enuresis for children older than 6 years of age. Some published studies have demonstrated clinical efficacy in the treatment of ADHD, panic disorder, anxiety-based school refusal, separation anxiety disorder, bulimia, night terrors, and sleepwalking. But, as yet, the FDA has not approved their use for these indications. Studies have not supported efficacy in major depression in children and adolescents. Nortriptyline has FDA approval for the treatment of major depression in adults. Clomipramine has FDA approval for the treatment of depression and OCD in adults and may be helpful for obsessive symptoms in autism.

B. CONTRAINDICATIONS

Known cardiac disease or arrhythmia, undiagnosed syncope, known seizure disorder, family history of sudden cardiac death or cardiomyopathy, known electrolyte abnormality (with bingeing and purging).

C. INITIAL MEDICAL SCREENING

The family history should be examined for sudden cardiac death; the patient's history for cardiac disease, arrhythmias, syncope, seizure disorder, or congenital hearing loss (associated with prolonged QT interval). Other screening procedures include serum electrolytes and blood urea nitrogen (BUN) in patients who have eating disorders, cardiac examination, and a baseline electrocardiogram (ECG).

D. MEDICAL FOLLOW-UP

Measure pulse and blood pressure (monitor for tachycardia and orthostatic hypotension) with each dosage

increase, and obtain an ECG to monitor for arteriovenous block with each dosage increase; after reaching steady state, record pulse, blood pressure, and ECG every 3–4 months.

E. ADVERSE EFFECTS

1. Cardiotoxic effects—The cardiotoxic effects of TCAs appear to be more common in children and adolescents than in adults. In addition to anticholinergic effects, TCAs have quinidine-like effects that result in slowing of cardiac conduction. Increased plasma levels appear to be weakly associated with an increased risk of cardiac conduction abnormalities. Steady-state plasma levels of desipramine or of desipramine plus imipramine should therefore not exceed 300 ng/mL. In addition, each dosage increase above 3 mg/kg/d must be carefully monitored with pulse, blood pressure, and repeated ECGs to monitor for arteriovenous block. Upper limits for cardiovascular parameters when administering TCAs to children and adolescents are listed in Table 6–22.

2. Anticholinergic effects—Tachycardia, dry mouth, stuffy nose, blurred vision, constipation, sweating, vasomotor instability, withdrawal syndrome (GI distress and psychomotor activation).

3. Other effects—Orthostatic hypotension and dizziness, lowered seizure threshold, increased appetite and weight gain, sedation, irritability and psychomotor agitation, rash (often associated with yellow dye No. 5), headache, abdominal complaints, sleep disturbance and nightmares, mania.

F. DRUG INTERACTIONS

TCAs may potentiate the effects of CNS depressants and stimulants; barbiturates and cigarette smoking may decrease plasma levels; phenothiazines, methylphenidate, and oral contraceptives may increase plasma levels; SSRIs given in combination with TCAs will result in higher TCA blood levels due to inhibition of the

Table 6–22. Upper limits of cardiovascular parameters with tricyclic antidepressants.

Heart rate	130/min
Systolic blood pressure	130 mm Hg
Diastolic blood pressure	85 mm Hg
PR interval	0.2 s
QRS interval	0.12 s, or no more than 30% over baseline
QT corrected	0.45 s

TCA metabolism by liver enzymes (eg, cytochrome p450 isoenzyme).

G. DOSAGE

Refer to a pediatric psychopharmacology text for dosages. Daily dosage requirements vary considerably with different clinical disorders.

MOOD STABILIZERS

Lithium carbonate (Eskalith, Eskalith CR, Lithobid, Lithotabs)

Valproic acid (Depakote, Depakote ER)

Carbamazepine (Tegretol)

Olanzapine (Zyprexa, atypical neuroleptic)

Lithium, valproic acid, and olanzapine (neuroleptic) are FDA approved for the treatment of bipolar disorder. Carbamazepine and oxycarbamazepine, although not FDA approved for treatment of bipolar disorder, may also be effective and carry less risk of weight gain. Lamotrigine (Lamictal) was recently approved for the treatment of bipolar depression in adults. Other antiepileptic medications, such as gabapentin and topiramate, have also been used with varying efficacy. Medications that are effective as mood stabilizers may be helpful also in the treatment of severe aggressive symptoms.

Lithium

A. INDICATIONS

Lithium remains a frontline drug in the treatment of bipolar disorder and has been shown to have an augmenting effect when combined with SSRIs for treatment-resistant depression and OCD.

B. CONTRAINDICATIONS

Lithium is contraindicated in patients with known renal, thyroid, or cardiac disease; those at high risk for dehydration and electrolyte imbalance (eg, vomiting and purging); and those who may become pregnant (teratogenic effects).

C. INITIAL MEDICAL SCREENING

General medical screening with pulse, blood pressure, height, and weight; complete blood cell count (CBC); serum electrolytes, BUN, and creatinine; and thyroid function tests including thyroid-stimulating hormone levels.

D. DOSAGE

For children the starting dose is usually 150 mg once or twice a day, with titration in 150–300-mg increments. (Dose may vary with the brand of lithium used, consult a psychopharmacology textbook for medication specific

information.) Oral doses of lithium should be titrated to maintain therapeutic blood levels of 0.8–1.2 mEq/L. The drug is generally given in two doses. Blood samples should be drawn 12 hours after the last dose.

E. ADVERSE EFFECTS

1. Lithium toxicity—Lithium has a narrow therapeutic index. Blood levels required for therapeutic effect are close to those associated with toxic symptoms. Mild toxicity may be indicated by increased tremor, GI distress, neuromuscular irritability, and altered mental status (confusion), and can occur when blood levels exceed 1.5 mEq/L. Moderate to severe symptoms of lithium toxicity are associated with blood levels above 2 mEq/L. Acute renal failure can occur at levels over 2.5–3 mEq/L.

2. Side effects—Lithium side effects include intention tremor, GI distress (including nausea and vomiting and sometimes diarrhea), hypothyroidism, polyuria and polydipsia, drowsiness, malaise, weight gain, acne, and granulocytosis.

F. DRUG INTERACTIONS

Excessive salt intake and salt restriction should be avoided. Thiazide diuretics and nonsteroidal anti-inflammatory agents (except aspirin and acetaminophen) can lead to increased lithium levels. Ibuprofen should be avoided by individuals on lithium due to combined renal toxicity. Precautions against dehydration are required in hot weather and during vigorous exercise.

G. MEDICAL FOLLOW-UP

Serum lithium levels should be measured 5–7 days following a change in dosage and then quarterly at steady state; serum creatinine and thyroid-stimulating hormone concentrations should be determined every 3–4 months.

Valproic Acid

A. INDICATIONS

Valproate has FDA approval for the treatment of bipolar disorder in adults. Its efficacy in acute mania equals that of lithium, but it is generally better tolerated. Valproate is more effective than lithium in patients with rapid-cycling bipolar disorder (more than four cycles per year) and in patients with mixed states (coexisting symptoms of depression and mania). Valproate may be more effective than lithium in adolescents with bipolar disorder because they often have rapid cycling and mixed states.

B. CONTRAINDICATIONS

Liver dysfunction.

C. INITIAL MEDICAL SCREENING

CBC and LFTs.

D. DOSAGE

Usually starts at 15 mg/kg/d and is increased in increments of 5 to 10 mg/kg/d every 1–2 weeks to a range of 500–1500 mg/d in two or three divided doses. Trough levels in the range of 80–120 mg/mL are thought to be therapeutic.

E. ADVERSE EFFECTS

Between 10% and 20% of patients experience sedation or anorexia, especially early in treatment or if the dose is increased too rapidly. GI upset occurs in 25% of patients and, when severe, can usually be treated with cimetidine. Increased appetite and weight gain can be troublesome for children and adolescents. Blurred vision, headache, hair loss, and tremor occur occasionally. Slight elevations in aminotransferases are frequent. Severe idiosyncratic hepatitis, pancreatitis, thrombocytopenia, and agranulocytosis occur only rarely.

F. MEDICAL FOLLOW-UP

LFTs should be checked monthly for 3–4 months; subsequently, LFTs, a CBC, and trough valproate levels should be obtained every 3–4 months.

Carbamazepine**A. INDICATIONS**

Similar to lithium and valproate, carbamazepine may be effective for treating bipolar disorder or for the target symptoms of mood instability, irritability, or behavioral dyscontrol. Some data suggest that it is more effective than valproate for the depressive phases of a bipolar disorder. This may relate to its similarities with the TCAs. A new form of carbamazepine—oxycarbamazepine (Trileptal)—is also being used for pediatric mood disorders; however, without established efficacy. Reportedly, it does not have the worrisome side effects of bone marrow suppression and liver enzyme induction. Blood levels cannot be monitored, and the dose range is similar to that with carbamazepine.

B. CONTRAINDICATIONS

History of previous bone marrow depression or history of adverse hematologic reaction to another drug; history of sensitivity to a TCA.

C. INITIAL MEDICAL SCREENING

Obtain a CBC with platelets, reticulocytes, serum iron, and BUN; LFTs; urinalysis.

D. DOSAGE

Usually start at 10–20 mg/kg/d, in two divided doses, in children younger than age 6 years; 100 mg twice daily in children ages 6–12 years; and 200 mg twice daily in children over age 12 years. Doses may be increased weekly until there is effective symptom control. Total daily doses should not exceed 35 mg/kg/d in children younger than age 6 years; 1000 mg/d in children ages 6–15 years; and 1200 mg/d in adolescents older than age 15 years. Plasma levels in the range of 4–12 mg/mL are thought to be therapeutic.

E. ADVERSE EFFECTS

Nausea, dizziness, sedation, headache, dry mouth, diplopia, and constipation reflect the drug's mild anticholinergic properties. Rashes are more common with carbamazepine than with other mood stabilizers. Aplastic anemia and agranulocytosis are rare. Leukopenia and thrombocytopenia are more common and, if present, should be monitored closely for evidence of bone marrow depression. These effects usually occur early and transiently and then spontaneously revert toward normal. Liver enzyme induction may significantly change the efficacy of medications given concurrently.

F. MEDICAL FOLLOW-UP

Conservative management suggests that hematologic, hepatic, and renal parameters should be followed at least every 3 months for the first year. White blood cell counts below 3000/mL and absolute neutrophil counts below 1000/mL call for discontinuation of the drug and referral for hematology consultation.

Gabapentin

Like valproate and carbamazepine, gabapentin is an anticonvulsant that has been used as a mood stabilizer in some adult populations. It may be used along with either valproate or carbamazepine in individuals with treatment-resistant disorders. The usual adult dose range for seizure disorders is 900–1800 mg/d in three divided doses and may need to be adjusted downward in individuals with renal impairment. Although its use among adolescents and even children is increasing, it is not approved for this indication, and reports of its efficacy remain largely anecdotal. Some reports suggest it may worsen behavioral parameters in children with underlying ADHD.

NEUROLEPTICS**1. Atypical (Newer) Neuroleptics**

Aripiprazole (Abilify)

Clozapine (Clozaril)

Olanzapine (Zyprexa)
 Risperidone (Risperdal)
 Quetiapine (Seroquel)
 Ziprasidone (Geodon)

2. Conventional Neuroleptics

Chlorpromazine
 Thioridazine
 Haloperidol
 Thiothixene
 Molindone
 Trifluoperazine
 Perphenazine

The neuroleptics, also known as antipsychotics, are indicated for psychotic symptoms in patients with schizophrenia. They are also used for acute mania and as adjuncts to antidepressants in the treatment of psychotic depression (with delusions or hallucinations). The neuroleptics may be used cautiously in refractory PTSD, in refractory OCD, and in individuals with markedly aggressive behavioral problems unresponsive to other interventions. They may also be useful for the body image distortion associated with anorexia nervosa.

The “atypical neuroleptics” differ from conventional neuroleptics in their receptor specificity and effect on serotonin receptors. Conventional neuroleptics are associated with a higher incidence of movement disorders and extrapyramidal symptoms (EPS) due to their wider effect on dopamine receptors. The introduction of the atypical neuroleptics has significantly changed neuroleptic prescribing patterns. The atypical neuroleptics have a better side effect profile for most individuals and comparable efficacy for the treatment of psychotic symptoms and aggression. Atypical neuroleptics have a decreased incidence of EPS and tardive dyskinesias (TD). Significant side effects can include substantial weight gain and sedation. Because of their increased use over conventional neuroleptics, this section will focus primarily on the atypical neuroleptics.

Aripiprazole (Abilify)

Aripiprazole is the newest atypical neuroleptic and is indicated for the treatment of schizophrenia. It is a partial dopamine blocker and a serotonin agonist. Side effects include nausea and vomiting and fatigue. It is not associated with weight gain. Doses over 30 mg are more likely to be associated with EPS. The dose range is 10 mg–30 mg, and pills can be split.

Olanzapine (Zyprexa)

The FDA has approved this agent for the treatment of schizophrenia and bipolar disorder in adults. Olanzapine has greater affinity for type-2 serotonin receptors than dopamine-2 receptors and also has an effect on muscarinic, histaminic, and α -adrenergic receptors. As with the other atypical neuroleptics, it may be more helpful for treating the negative symptoms of schizophrenia (flat affect, isolation and withdrawal, apathy) than conventional neuroleptics. Anecdotal and case report data support its utility in child and adolescent psychotic disorders. The adult dose range of 5–15 mg/d administered in a single, bedtime dose is probably applicable to adolescents as well. Weight gain can be a significant side effect. The starting dose for children is usually 1.25 mg.

Quetiapine (Seroquel)

Quetiapine is an antagonist at multiple receptor sites, including serotonin (5-HT_{1A}, 5-HT₂), dopamine (D1, D2), histamine, and adrenergic receptors. Quetiapine is given in 25- to 50-mg increments up to 800 mg for the treatment of psychotic symptoms. It is thought to be a “weight-neutral” medication, and the primary side effect is sedation.

Risperidone (Risperdal)

Risperidone blocks type-2 dopamine receptors (similar to haloperidol) and type-2 serotonin receptors. Adult schizophrenic patients given 2–8 mg/d of risperidone had better symptom relief and fewer side effects than those treated with conventional neuroleptics. Anecdotal reports suggest that similar results may be obtained in adolescents with schizophrenia. Risperidone has also demonstrated good clinical efficacy in the treatment of Tourette syndrome. The initial dose is 1–2 mg/d in two divided doses. Side effects include weight gain and sedation.

Ziprasidone (Geodon)

Ziprasidone has affinity for multiple serotonin receptors (5-HT₂, 5-HT_{1A}, 5-HT_{1D}, and 5-HT_{2C}) and dopamine-2 receptors, and it moderately inhibits norepinephrine and 5-HT reuptake. It also has moderate affinity for H₁ and α_1 receptors. Ziprasidone has a greater effect on cardiac QT intervals and requires a baseline ECG and ECG monitoring when a dose of 80 mg is reached and with each dose change above 80 mg to monitor for QT prolongation. Ziprasidone is reported to cause minimal weight gain. The initial dose of ziprasidone is 20 mg, with dose changes 20-mg increments to a total daily dose of 140 mg for the treat-

ment of psychotic symptoms in adults. There are no studies of ziprasidone in children and adolescents at this time.

Clozapine (Clozaril)

Clozapine is usually reserved for individuals with treatment who have not responded to multiple other neuroleptics due to the side effect of agranulocytosis. Clozapine blocks type-2 dopamine receptors weakly and is virtually free of EPS, apparently including TD. It was very effective in about 40% of adult patients with chronic schizophrenia who did not respond to conventional neuroleptics.

Non-dose-related agranulocytosis occurs in 0.5–2% of subjects. Some case reports note benefit from clozapine in child and adolescent schizophrenic patients who were resistant to other treatment. Contraindications are concurrent treatment with carbamazepine and any history of leukopenia. Initial medical screening should include CBC and LFTs. The daily dose is 200–600 mg in two divided doses. Because of the risk of neutropenia, patients taking clozapine must be registered with the Clozapine Registry and a white blood cell count must be obtained biweekly before a 2-week supply of the drug is dispensed. If the white count falls below 3000/mL, clozapine is usually discontinued. Other side effects include sedation, weight gain, and increased salivation. The incidence of seizures increases with doses above 600 mg/d.

3. General Neuroleptic Information

The following adverse effects of neuroleptics apply to both typical and atypical neuroleptics, but are thought to have a significantly lower incidence with the atypical neuroleptics.

A. INITIAL MEDICAL SCREENING

One should observe and examine for abnormal movements and establish baseline values for CBC and LFTs. An ECG should be taken if there is a history of cardiac disease or arrhythmia, and to establish a baseline QT interval (cardiac repolarization) prior to initiation of the neuroleptics that have a greater effect on QT (eg, ziprasidone and thioridazine). Neuroleptics can cause QT prolongation leading to ventricular arrhythmias, such as torsades de pointes. Medications that affect the cytochrome p450 isoenzyme pathway (including SSRIs) may increase the neuroleptic plasma concentration and increase risk of QTc prolongation.

B. ADVERSE EFFECTS

The most troublesome adverse effects of the atypical neuroleptics are cognitive slowing, sedation, orthostasis, and weight gain. The conventional neuroleptics have

increased incidence of EPS and TD. Sedation, cognitive slowing, and EPS all tend to be dose-related. Because of the risk of side effects, neuroleptic medications should be used with caution and monitored regularly. The risk-benefit ratio of the medication for the identified target symptom should be carefully considered and reviewed with the parent or guardian.

1. Extrapyramidal side effects—EPS and acute dystonic reactions are tonic muscle spasms, often of the tongue, jaw, or neck. EPS symptoms can be mildly uncomfortable or may result in such dramatically distressing symptoms as oculogyric crisis, torticollis, and even opisthotonos. The onset usually occurs within days after a dosage change and may occur in up to 25% of children treated with conventional neuroleptics. Acute neuroleptic-induced dystonias are quickly relieved by anticholinergics such as benztropine (Cogentin) and diphenhydramine.

2. Tardive dyskinesias—TDs are involuntary movement disorders that are often irreversible and may appear after long-term use of neuroleptic medications. Choreoathetoid movements of the tongue and mouth are most common, but the extremities and trunk may also be involved. The risk of TD is small in patients on atypical neuroleptics, and those on conventional neuroleptics for less than 6 months. There is no universally effective treatment.

3. Pseudoparkinsonism—Pseudoparkinsonism is usually manifested 1–4 weeks after the start of treatment. It presents as muscle stiffness, cogwheel rigidity, mask-like facial expression, bradykinesia, drooling, and occasionally pill-rolling tremor. Anticholinergic medications or dosage reductions are helpful.

4. Akathisia—Akathisia is usually manifested after 1–6 weeks of treatment. It presents as a unpleasant feeling of driven motor restlessness that ranges from vague muscular discomfort to a markedly dysphoric agitation with frantic pacing. Anticholinergic agents or β -blockers are sometimes helpful.

5. Neuroleptic malignant syndrome—Neuroleptic malignant syndrome (NMS) is a very rare medical emergency associated primarily with the conventional neuroleptics, although it has been reported also with atypical neuroleptics. It is manifested by severe muscular rigidity, altered sensorium, hyperpyrexia, autonomic lability, and myoglobinemia. NMS can present without muscle rigidity with atypical neuroleptics and should be considered in the differential diagnosis of any patient on neuroleptics who presents with high fever and altered mental status. Mortality as high as 30% has been reported. Treatment includes immediate medical assessment, withdrawal of the neuroleptic, and may require transfer to an ICU.

6. Withdrawal dyskinesias—Withdrawal dyskinesias are reversible movement disorders that appear following withdrawal of neuroleptic medications. Dyskinetic movements develop within 1–4 weeks after withdrawal of the drug and may persist for months.

7. Other adverse effects—These include cardiac arrhythmias, irregular menses, gynecomastia and galactorrhoea due to increased prolactin, sexual dysfunction, photosensitivity, rashes, lowered seizure threshold, hepatic dysfunction, and blood dyscrasias.

C. DRUG INTERACTIONS

Potential of CNS depressant effects or the anticholinergic effects of other drugs may occur, as well as increased plasma levels of antidepressants.

D. MEDICAL FOLLOW-UP

One should examine the patient at least every 3 months for signs of the side effects listed. An Abnormal Involuntary Movement Scale (AIMS) can be used to monitor for TD for patients taking neuroleptics.

ADRENERGIC AGONISTS

Clonidine and Guanfacine (Tenex)

A. INDICATIONS

Clonidine is a nonselective α -adrenergic agonist that is clinically useful in decreasing states of hyperarousal seen in children and adolescents with PTSD and ADHD. Guanfacine is a selective agonist for α_2 -adrenergic receptors with advantages over the nonselective agonist clonidine. Guanfacine is less sedating and less hypotensive and has a longer half-life, allowing for twice-daily dosing. Case reports find guanfacine effective in ADHD and Tourette syndrome with comorbid ADHD. Bedtime doses of adrenergic agonists can be helpful for the delayed onset of sleep and nightmares that can occur with PTSD, for the difficulty settling for sleep seen in ADHD, or for ameliorating the side effects of stimulant medications. They are also effective in the treatment of tics in Tourette syndrome.

B. CONTRAINDICATIONS

Adrenergic agonists are contraindicated for patients with known renal or cardiovascular disease and for those with a family or personal history of depression.

C. INITIAL MEDICAL SCREENING

The pulse and blood pressure should be recorded prior to starting an adrenergic agonist.

D. DOSAGE

Initial dosage of clonidine is usually 0.025–0.05 mg at bedtime. The dosage can be increased after 3–5 days by

giving 0.05 mg also in the morning. Further dosage increases are made by adding 0.05 mg first in the morning, then at noon, and then in the evening every 3–5 days to a maximum total daily dose of 0.3 mg in three or four divided doses per day. The half-life of clonidine is in the range of 3–4 hours. Although a clinical response generally becomes apparent by about 4 weeks, treatment effects may increase over 2–3 months. Therapeutic doses of methylphenidate can frequently be decreased by 30–50% when used in conjunction with clonidine. Transdermal administration of clonidine using a skin patch can be quite effective but may result in skin irritation in 40% of patients. Patches are generally changed every 5 days.

The starting dosage of guanfacine is usually 0.5–1 mg once a day, increasing as clinically indicated after 3–5 days to 2–4 mg/d in two or three divided doses per day. Adverse effects include transient headaches and stomachaches in 25% of patients. Sedation and hypertension are mild. For medical follow-up, pulse and blood pressure should be checked every 1–2 weeks for 2 months and then at 3-month intervals.

E. ADVERSE EFFECTS

Sedation can be prominent. Side effects include fatigability, dizziness associated with hypotension, increased appetite and weight gain, headache, sleep disturbance, GI distress, skin irritation with transdermal clonidine administration, and rebound hypertension with abrupt withdrawal. Bradycardia can occasionally be marked.

F. DRUG INTERACTIONS

Increased sedation with CNS depressants; possible increased anticholinergic toxicity. Several case reports have mentioned cardiac toxicity with clonidine when combined with methylphenidate, although other medications and clinical factors were present in each case.

G. MEDICAL FOLLOW-UP

Pulse and blood pressure should be recorded every 2 weeks for 2 months and then every 3 months. The discontinuation of clonidine or guanfacine should occur gradually, with step-wise dosage decreases every 3–5 days to avoid rebound hypertension. Blood pressure should be monitored during withdrawal.

Child Abuse & Neglect

Andrew P. Sirotnak, MD, & Richard D. Krugman, MD

The problem of child abuse and neglect, barely recognized as a significant problem in the early editions of this textbook, has grown to a problem of such serious proportions that in 1990 the US Advisory Board on Child Abuse and Neglect called the present state of the nation's ability to protect children a "national emergency." Over a decade later, the emergency is still with us. What Dr. Henry Kempe and his colleagues first called battered child syndrome was thought to affect 749 children in the United States in 1960. The best data now available suggest that 1–1.5% of American children are abused or neglected annually. In 2002 an estimated 3 million children were reported to child protective service agencies as alleged victims of child abuse and neglect, which translates to an approximate national maltreatment rate of 37 victims per 1000 children. Just under one million of these cases were substantiated by child protective services in 2001, yielding an abuse substantiation rate of 12.3 per 1000 American children. At least 2000 children are victims of fatal child abuse each year. This dramatic increase in cases has resulted from increased recognition of the problem by professionals, partly in response to statutory reporting mandates; a broadening of the definitions of abuse and neglect from the original battered child concept; and changes in the demography and social structure of families and neighborhoods over the past several decades. Substance abuse, poverty and economic strains, parental capacity and skills, and domestic violence are cited as the most common presenting problems in abusive families.

Abuse and neglect of children are best considered in an ecologic perspective, which recognizes the individual, family, social, and psychological influences that come together to contribute to the problem. For most pediatric health care professionals, however, their involvement will be limited to individual cases. This chapter focuses on the knowledge necessary for the recognition, intervention, and follow-up of the more common forms of child maltreatment and highlights the role of pediatric professionals in prevention.

FORMS OF CHILD MALTREATMENT

Child maltreatment may occur either within or outside the family. The proportion of intrafamilial to extrafamilial cases varies with the type of abuse as well as the

gender and age of child. Each of the following conditions may exist as separate or concurrent diagnoses.

Physical Abuse

Physical abuse of children is most often inflicted by a caregiver or family member but occasionally by a stranger. The most common manifestations include bruises, burns, fractures, head trauma, and abdominal injuries. A small but significant number of unexpected pediatric deaths, particularly in infants and very young children (eg, sudden infant death syndrome), are related to physical abuse.

Sexual Abuse

Sexual abuse is defined as the engaging of dependent, developmentally immature children in sexual activities that they do not fully comprehend and to which they cannot give consent or activities that violate the laws and taboos of a society. It includes all forms of incest, sexual assault or rape, and pedophilia. This includes fondling, oral–genital–anal contact, all forms of intercourse or penetration, exhibitionism, voyeurism, exploitation or prostitution, and the involvement of children in the production of pornography.

Emotional Abuse

Emotional or psychological abuse has been defined as the rejection, ignoring, criticizing, isolation, or terrorizing of children, all of which have the effect of eroding their self-esteem. The most common form is verbal abuse or denigration. Children who witness domestic violence should be considered emotionally abused.

Physical Neglect

Physical neglect is the failure to provide the necessary food, clothing, and shelter and a safe environment in which children can grow and develop. Although often associated with poverty or ignorance, physical neglect involves a more serious problem than just lack of resources. There is often a component of emotional neglect and either a failure or an inability, intentionally or otherwise, to recognize and respond to the needs of the child.

Emotional Neglect

The most common feature of emotional neglect is the absence of normal parent–child attachment and a subsequent inability to recognize and respond to an infant’s or child’s needs. A common manifestation of emotional neglect in infancy is nutritional (nonorganic) failure to thrive.

Medical Care Neglect

Medical care neglect is failure to provide the needed treatment to infants or children with life-threatening illness or other serious or chronic medical conditions.

Munchausen Syndrome by Proxy

Munchausen syndrome by proxy is a relatively unusual disorder in which a caregiver, usually the mother, either simulates or creates the symptoms or signs of illness in a child. The child can present with a long list of medical problems or often bizarre recurrent complaints. Fatal cases have been reported.

RECOGNITION OF ABUSE & NEGLECT

The most common features suggesting a diagnosis of child abuse are summarized in Tables 7–1 and 7–2. Obvious signs of injury, sexual abuse, or neglect may be present. Classic radiographic and laboratory findings are discussed later in this chapter. Psychosocial factors may indicate risk for or confirm child maltreatment.

Recognition of any form of abuse and neglect of children can occur only if child abuse is entertained in the differential diagnosis of the child’s presenting medical condition. The approach to the family should be supportive, nonaccusatory, and empathetic. The individual who brings the child in for care may not have any involvement in the abuse. Approximately one third

Table 7–1. Common historical features in child abuse cases.

Discrepant, evolving, or absent history
Delay in seeking care
Event or behavior by child that triggers a loss of control of caregiver
History of abuse in the caregiver’s childhood
Inappropriate affect of the caregiver
Pattern of increasing severity or number of injuries if no intervention
Social or physical isolation of the child or the caregiver
Stress or crisis in the family or the caregiver
Unrealistic expectations of caregiver for the child

Table 7–2. Presentations of sexual abuse.

General or direct statements about sexual abuse
Sexualized play or behavior in developmentally immature children
Sexual abuse of other children by the victim
Behavioral changes
Sleep disturbances (eg, nightmares and night terrors)
Appetite disturbances (eg, anorexia, bulimia)
Depression, social withdrawal, anxiety
Aggression, temper tantrums, impulsiveness
Neurotic or conduct disorders, phobias or avoidant behaviors
Guilt, low self-esteem, mistrust, feelings of helplessness
Hysterical or conversion reactions
Suicidal, runaway threats or behavior
Excessive masturbation
Medical conditions
Recurrent abdominal pain or frequent somatic complaints
Genital, anal, or urethral trauma
Recurrent complaints of genital or anal pain, discharge, bleeding
Enuresis or encopresis
Sexually transmitted diseases
Pregnancy
Promiscuity or prostitution, sexual dysfunction, fear of intimacy
School problems or truancy
Substance abuse

of child abuse incidents occur in extrafamilial settings. Nevertheless, the assumption that the caregiver is “nice,” combined with the failure to consider the possibility of abuse, can be costly and even fatal. Raising the possibility that a child has been abused is not the same as accusing the caregiver of being the abuser. The health professional who is examining the child can explain to the family that several possibilities might explain the child’s injuries or abuse-related symptoms. If the family or presenting caregiver is not involved in the child’s maltreatment, they may actually welcome the necessary report and investigation.

History

A. PHYSICAL ABUSE

The medical diagnosis of physical abuse is based on the presence of a discrepant history, in which the history offered by the caregiver is not consistent with the clinical findings. The discrepancy may exist because the history is absent, partial, changing over time, or simply illogical or improbable. The presence of a discrepant history should prompt a request for consultation with a multidisciplinary child protection team or a report to

the child protective services agency. This agency is mandated by state law to investigate reports of suspected child abuse and neglect. Investigation by social services and possibly law enforcement officers, as well as a home visit, may be required to sort out the circumstances of the child's injuries. Other common historical features in child abuse cases are listed in Table 7-1.

B. SEXUAL ABUSE

Sexual abuse may come to the clinician's attention in different ways: (1) The child may be brought in for routine care or for an acute problem, and sexual abuse may be suspected by the medical professional as a result of the history or the physical examination. (2) The parent or caregiver, suspecting that the child may have been sexually abused, may bring the child to the health care provider and request an examination to "rule in or rule out" abuse. (3) The child may be referred by child protective services or the police for an evidentiary examination following either disclosure of sexual abuse by the child or an allegation of abuse by a parent or third party. Table 7-2 lists the presentations of child sexual abuse. It should be emphasized that with the exception of acute trauma, certain sexually transmitted infections (STIs), or forensic laboratory evidence, none of these presentations is specific. The presentations listed should arouse suspicion of the possibility of sexual abuse and lead the practitioner to ask the appropriate questions—again, in a compassionate and nonaccusatory manner. The American Academy of Pediatrics has published guidelines for the evaluation of child sexual abuse as well as other guidelines relating to child maltreatment.

C. EMOTIONAL ABUSE

Emotional abuse may cause nonspecific symptoms in children. Loss of self-esteem or self-confidence, sleep disturbances, somatic symptoms (eg, headaches, stomachaches), hypervigilance, or avoidant or phobic behaviors (eg, school refusal, running away) may be presenting complaints. These complaints may also be seen in children who experience domestic violence. Emotional abuse can occur in the home or day care, school, sports team, or other settings.

D. NEGLECT

Even though in 2002 there were three times as many reports of neglect of children as of physical abuse, neglect is not easily documented on history. Physical neglect—which must be differentiated from the deprivations of poverty—will be present even after adequate social services have been provided to families in need. Emotionally neglectful parents appear to have an inability to recognize the physical or emotional states of their children. For example, an emotionally neglectful parent may ignore an infant's cry if the cry is perceived

incorrectly as an expression of anger. This misinterpretation leads to inadequate nutrition and failure to thrive. The clinician must evaluate the psychosocial history and family dynamics when neglect is a consideration, and a careful social services investigation may be required.

E. FAILURE TO THRIVE

The history offered in cases of failure to thrive is often at odds with the physical findings. Infants who have experienced a significant deceleration in growth are probably not receiving adequate amounts or appropriate types of food despite the dietary history provided. Medical conditions causing poor growth in infancy and early childhood can be ruled out with a detailed history and minimal laboratory tests. A psychosocial history may reveal maternal depression, family chaos or dysfunction, or other previously unknown social risk factors (eg, substance abuse, violence, poverty, psychiatric illness). Placement of the child with another caregiver or hospitalization of the severely malnourished patient is usually followed by a dramatic weight gain.

Physical Findings

A. PHYSICAL ABUSE

The findings on examination of physically abused children may include abrasions, alopecia, bites, bruises, burns, dental trauma, fractures, lacerations, ligature marks, or scars. Injuries may be in multiple stages of healing. Bruises in physically abused children are sometimes patterned (eg, belt marks, looped cord marks, grab or pinch marks) and are typically found over the soft tissue areas of the body. Toddlers or older children typically sustain accidental bruises over bony prominences such as shins and elbows. Any bruise in an infant not developmentally mobile should be viewed with concern. (Other child abuse emergencies are listed in Table 7-3). Lacerations of the frenulum or tongue and bruising of the lips may be associated with force feeding. Pathognomonic burn patterns include stocking or glove distribution; immersion burns of the buttocks, sometimes with a "doughnut hole" area of sparing; and branding burns such as with cigarettes or hot objects (eg, grill, curling iron, or lighter). The absence of splash marks or a pattern consistent with spillage may be helpful in differentiating accidental from nonaccidental scald burns.

Head and abdominal trauma may present with signs and symptoms consistent with those injuries. Inflicted head trauma (eg, shaken baby syndrome) and abdominal injuries may have no visible findings on examination. The finding of retinal hemorrhages in an infant without an appropriate medical condition (eg, leukemia, congenital infection, clotting disorder) should

Table 7–3. Potential child abuse medical emergencies.

Any infant with bruises (especially head, facial, or abdominal), burns, or fractures
Any infant or child under age 2 years with a history of suspected “shaken baby” head trauma or other inflicted head injury
Any child who has sustained suspicious or known inflicted abdominal trauma
Any child with burns in stocking or glove distribution or in other unusual patterns, burns to the genitalia, and any unexplained burn injury
Any child with disclosure or sign of sexual assault within 48–72 hours after alleged event if the possibility of acute injury is present or if forensic evidence exists

arouse concern about possible inflicted head trauma. Retinal hemorrhages are not commonly seen after cardiopulmonary resuscitation in either infants or children.

B. SEXUAL ABUSE

The genital and anal findings of sexually abused children, as well as the normal developmental changes and variations in prepubertal female hymens, have been described in journal articles and visual diagnosis guides. The majority of victims of sexual abuse exhibit no physical findings. The reasons for this include delay in disclosure by the child, abuse that may cause no physical trauma (eg, fondling, oral–genital contact, exploitation by pornographic photography), or rapid healing of minor injuries such as labial, hymenal, or anal abrasions, contusions, or lacerations. Nonspecific abnormalities of the genital and rectal regions such as erythema, rashes, and irritation may not suggest sexual abuse in the absence of a corroborating history, disclosure, or behavioral changes. Finally, some medical conditions may be misdiagnosed as sexual abuse (eg, lichen sclerosis, dermatitis, labial adhesions, congenital urethral or vulvar disorders, Crohn disease, and accidental straddle injuries to the labia) and can be ruled out by careful history and examination.

Certain STIs should strongly suggest sexual abuse. *Neisseria gonorrhoeae* infection or syphilis beyond the perinatal period are diagnostic of sexual abuse. *Chlamydia trachomatis*, herpes simplex virus, trichomoniasis, and human papillomavirus (HPV) are all sexually transmitted, although the course of these perinatally acquired infections may be protracted. In the case of HPV, an initial appearance of venereal warts beyond the toddler age should raise concerns about sexual abuse. Finally, sexual abuse must be considered with

the diagnosis of human immunodeficiency virus (HIV) infection when other modes of transmission (eg, transfusion, perinatal acquisition) have been ruled out. The Centers for Disease Control and Prevention and sexual abuse atlases list guidelines for the screening of STIs in sexually abused children and adolescents.

C. NEGLECT AND NONORGANIC FAILURE TO THRIVE

Infants and children with nonorganic failure to thrive have a relative absence of subcutaneous fat in the cheeks, buttocks, and extremities. Other conditions associated with poor nutrient and vitamin intake may be present. If the condition has persisted for some time, these patients may also appear and act depressed. Older children who have been chronically emotionally neglected may also have short stature (ie, deprivation dwarfism). The head circumference is usually normal in cases of nonorganic failure to thrive. Microcephaly may signify a prenatal condition, congenital disease, or chronic nutritional deprivation and increases the likelihood of more serious and possibly permanent developmental delay.

D. MUNCHAUSEN SYNDROME BY PROXY

Children with Munchausen syndrome by proxy may present with the signs and symptoms of whatever illness is factitiously produced or simulated. They may be actually ill or reported to be ill and have a normal clinical appearance. Among the most common reported presentations are recurrent apnea, dehydration from induced vomiting or diarrhea, sepsis when contaminants are injected into a child, change in mental status, fever, gastrointestinal bleeding, and seizures.

Radiologic & Laboratory Findings

A. PHYSICAL ABUSE

Certain radiologic findings are strong indicators of physical abuse. Examples are metaphyseal “corner” or “bucket handle” fractures of the long bones in infants, spiral fracture of the extremities in nonambulatory infants, rib fractures, spinous process fractures, and fractures in multiple stages of healing. Skeletal surveys in children age 3 years or younger should be performed when a suspicious fracture is diagnosed. Computed tomography or magnetic resonance imaging findings of subdural hemorrhage in infants—in the absence of a clear accidental history—are highly correlated with abusive head trauma, especially after the advent of infant seat restraint laws that have reduced the incidence of head trauma in infants. Abdominal CT is the preferred test in suspected abdominal trauma. Any infant or very young child with suspected abuse-related head or abdominal trauma should be evaluated immediately by an emergency physician or trauma surgeon.

Coagulation studies and a complete blood count with platelets are useful in children who present with multiple or severe bruising in different stages of healing. Coagulopathy conditions may confuse the diagnostic picture but can be excluded with a careful history, examination, laboratory screens, and hematologic consultation if necessary.

The differential diagnosis of all forms of physical abuse can be considered in the context of a detailed trauma history, family medical history, radiographic findings, and laboratory testing. The diagnosis of osteogenesis imperfecta or other collagen disorders, for example, may be considered in the child with skin and joint findings or multiple fractures with or without the classic radiographic presentation and is best made in consultation with a geneticist, an orthopedic surgeon, and a radiologist. Trauma—accidental or inflicted—leads the differential diagnosis list for subdural hematomas. Coagulopathy, disorders of copper metabolism, amino acid or organic acid metabolism (eg, Menkes syndrome, glutaric acidemia type 1), chronic or previous central nervous system infection, birth trauma, or congenital central nervous system malformation (eg, arteriovenous malformations, cerebrospinal fluid collections) may need to be ruled out in some cases. It should be recognized, however, that children with these rare disorders can also be abuse victims.

B. SEXUAL ABUSE

The forensic evaluation of sexually abused children should be performed in a setting that prevents further emotional distress. If the history indicates that the child may have had contact with the ejaculate of a perpetrator within 72 hours, an examination looking for semen or its markers (eg, acid phosphatase) should be performed according to established protocols. More important, if there is a history of possible sexual abuse within the past 48–72 hours, and the child reports a physical complaint or a sign is observed (eg, genital or anal bleeding or discharge), the child should be examined for signs of trauma. The most experienced examiner (pediatrician, nurse examiner, child advocacy center) is preferable. The laboratory and serologic evaluation of STIs should be guided by the type of contact reported and the epidemiology of these infections in the community.

C. NEGLECT AND GROWTH FAILURE

Children with failure to thrive or malnutrition may not require an extensive work-up. Complete blood count, urinalysis, electrolyte panel, and liver function tests are sufficient screening. Newborn screening should be documented as normal. Other tests should be guided by any clinical history that points to a previously undiagnosed condition (eg, thyroid, metabolic studies). A

skeletal survey may be helpful if concurrent physical abuse is suspected. The best screening method, however, is placement in a setting in which the child can be fed and monitored. Hospital or foster care placement may be required. Weight gain may not occur for several days to a week in severe cases.

Any child with recurrent polymicrobial sepsis (especially in children with indwelling catheters), recurrent apnea, chronic dehydration of unknown cause, or other highly unusual, unexplained laboratory findings should raise the suspicion of Munchausen syndrome by proxy.

MANAGEMENT & REPORTING OF CHILD ABUSE & NEGLECT

Physical abuse injuries, STIs, and medical sequelae of neglect should be treated immediately. Children with failure to thrive related to emotional and physical neglect need to be placed in a setting in which they can be fed and cared for. Likewise, the child in danger of recurrent abuse or neglect needs to be placed in a safe environment.

In the United States, clinicians and many other professionals who come in contact with or care for children are mandated reporters. If abuse or neglect is suspected, a report must be made to the local or state agency designated to investigate such matters. In most cases, this will be the child protective services agency. Law enforcement agencies may also receive such reports. The purpose of the report is to permit professionals to gather the information needed to determine whether the child's environment (eg, home, school, day care setting, foster home) is safe. Many hospitals and communities make child protection teams or consultants available when there are questions about the diagnosis and management in a child abuse case. A listing of pediatric consultants in child abuse is available from the American Academy of Pediatrics.

Except in extreme cases, the reporting of emotional abuse is not likely to generate a response from child protection agencies. This should not deter reporting, especially if the concern is in the context of domestic violence or other forms of abuse or neglect. Practitioners can encourage parents to get involved with parent effectiveness training programs (eg, Parents as First Teachers or Parents Anonymous) or to seek mental health consultation. Support for the child may also include mental health counseling or age-appropriate peer activities in school or the community.

PREVENTION OF CHILD ABUSE & NEGLECT

Physical abuse is preventable in many cases. Extensive experience and evaluation of high-risk families has

shown that the provision of home visitor services to families at risk can prevent abuse and neglect of children. These services can be provided by public health nurses or trained paraprofessionals, although more data are available describing public health nurse intervention. This makes it as easy for the family to pick up the telephone and ask for help before they abuse a child as it is for a neighbor or physician to report an episode of abuse after it has occurred. Parent education and anticipatory guidance may also be helpful, particularly with respect to handling situations that stress parents (eg, colic, crying, behaviors, toilet training), age-appropriate discipline, and general developmental issues. Prevention of abusive injuries perpetrated by nonparent caregivers (eg, babysitters, nannies, unrelated adults in the home) may be addressed by education and counseling of mothers about safe child care arrangements.

The prevention of sexual abuse is more difficult. Most efforts in this area involve teaching children to protect themselves and their “private parts” from harm or interference. These programs are useful but are in general not as efficacious as they are necessary. The age of toilet training is a good anticipatory guidance time to encourage parents to consider this discussion. The most rational approach is to place the burden of responsibility of prevention on the adults who supervise the child and the medical providers rather than on the children themselves.

Efforts to prevent emotional abuse of children have been undertaken through extensive media campaigns. No data are available to assess the effectiveness of this approach.

Ambulatory & Community Pediatrics

8

Robert M. Brayden, MD, Matthew F. Daley, MD, & Jeffrey M. Brown, MD, MPH

Pediatric outpatient services provide a child or adolescent with comprehensive longitudinal care and emphasize preventive health care. This chapter discusses common elements of ambulatory visits and offers guidance in the conduct of the health supervision visit, visits for acute and chronic disease management, and consultations. Special attention is paid to the pediatric history and physical examination, normal developmental stages, office telephone management, and community pediatrics.

The development of a physician–patient–parent relationship is of crucial importance if the patient or parent is to effectively confide his or her concerns. The relationship develops over time and with increasing numbers of visits. It is facilitated by the continuity of clinicians and other pediatric staff members. The trust that supports this relationship comes as a result of several experiences in the context of the office visit. Perhaps the greatest factor to facilitate the relationship is for patients or parents to experience advice as valid and effective. Skills such as choosing vocabulary that communicates understanding and competence, commitment of time and attention to the concern, and respect for areas that the patient or parent does not wish to address (assuming the lack of abuse or neglect concerns) are important. Parents and patients often seek evidence that their concerns will be managed confidentially and that the clinician both understands and sympathizes with those concerns. The effective physician–patient–parent relationship is one of the true joys of ambulatory pediatrics.

■ PEDIATRIC HISTORY

Pediatrics is unique in that patients seldom provide their own history. Instead, the parent usually describes the child's complaints and behavior to the physician. As with any history, this information may be detailed and accurate or vague and unreliable. A vague exposition of complaints offered by a parent may be a statement of the parent's own concerns. For example, in-

stead of reporting that a child has had a warm, red, tender, swollen knee for 2 days, the parent may say that the child no longer wants to play on the soccer team.

Parents may or may not be able to distinguish whether symptoms are caused by organic illness or a psychological concern. It is often helpful to ask specifically what problems the parents wish to address in order to determine what really prompted the office visit. Some visits are occasioned by problems at school, such as low grades or troublesome peer relationships. Understanding the family and its hopes for and concerns about the child can help in the process of distinguishing organic illness from emotional or behavioral conditions, thus minimizing unnecessary testing and intervention.

Although the parents' concerns need to be understood, it is essential also to obtain as much of the history as possible directly from the patient. Direct histories not only provide firsthand information but also give the child a degree of control over a potentially threatening situation and may reveal important information about the family.

Obtaining a comprehensive pediatric history is time-consuming. Many offices provide questionnaires for parents to complete before the clinician sees the child. Data from questionnaires can make an outpatient visit more productive, allowing the physician to address problems in detail while more quickly reviewing areas that are not of concern. Questionnaires may be more productive than face-to-face interviews in revealing sensitive parts of the history. However, failure to review and assimilate this information prior to the interview may cause a parent or patient to feel that the time and effort have been wasted.

Elements of the history that will be useful over time should be readily accessible in the medical record. Such information can be accumulated on a summary sheet, as illustrated in Figure 8–1. Demographic data; a problem list; information about chronic medications, allergies, and previous hospitalizations; and the names of other physicians providing care for the patient are commonly included. Documentation of immunizations, including all data required by the National

Table 8-1. Components of the pediatric historical database.^a

1. Demographic data	Patient's name and nickname, date of birth, social security number, sex, race, parents' names (first and last), siblings' names, and payment mechanism.
2. Problem list	Major or significant problems, including dates of onset and resolution.
3. Allergies	"Triggering allergen," nature of the reaction, treatment needed, and date allergy diagnosed.
4. Chronic medications	Name, concentration, dose, and frequency of chronically used medications.
5. Birth history	Maternal health during pregnancy, medications, street drugs used, complications of pregnancy; duration and ease of labor; form of delivery; analgesics and anesthetics used; need for monitoring; and labor complications. Infant's birth weight, gestational age, Apgar scores, and problems in the neonatal period.
6. Screening procedures	Results of newborn screening, vision and hearing screening, any health screen, or screening laboratory tests. (Developmental screening results are maintained in the development section; see item 14, below.)
7. Immunizations	Date of each immunization administered, vaccine manufacturer and lot number, and name and title of the person administering the vaccine; previous reaction and contraindication to immunization (eg, immunodeficiency or an evolving neurologic problem).
8. Reasons for visit	The patient's or parents' concerns, stated in their own words, serve as the focus for the visit.
9. Present illness	A concise chronologic summary of the problems necessitating a visit, including the duration, progression, exacerbating factors, ameliorating interventions, and associations.
10. Medical history	A statement regarding the child's functionality and general well-being, including a summary record of significant illnesses, injuries, hospitalizations, and procedures.
11. Diet	Eating patterns, likes and dislikes, use of vitamins, and relative amounts of carbohydrates, fat, and protein in the diet.
12. Family history	Information about the illnesses of relatives, preferably in the form of a family tree.
13. Social history	Family constellation, relationships, parents' educational background, religious preference, and the role of the child in the family; socioeconomic profile of the family to identify resources available to the child, access to services that may be needed, and anticipated stressors.
14. Development	(1) Attainment of developmental milestones (including developmental testing results); (2) social habits and milestones (toilet habits, play, major activities, sleep patterns, discipline, peer relationships); (3) school progress and documentation of specific achievements and grades.
15. Sexual history	Family's sexual attitudes, sex education, sexual development and activity, sexually transmitted diseases, and birth control measures.
16. Review of systems (ROS)	This area tends to be overlooked because of the work required to obtain a complete ROS and integrate data into the patient's problems list and care plan. A focused ROS is essential if any problem is to be addressed adequately.

^aThe components of this table should be included in a child's medical record and structured to allow easy review and modification. The practice name and address should appear on all pages.

what is occurring and what is expected. A gentle, friendly manner and a quiet voice help establish a setting that yields a nonthreatening physical examination. The order in which the child's organ systems are examined should take into consideration the need for a quiet child, the extent of trust established, and the possibility of an emotional response. Painful or unpleasant procedures should be deferred until the end of the examina-

tion. Whether or not the physician can establish rapport with the child, the process should proceed efficiently and systematically.

Because young children may fear the examination and become fussy, simple inspection is very important. For example, during an acute-care visit for fever, the examiner should observe the child's work of breathing prior to beginning the examination. During a health

supervision visit, observation will provide the examiner with an opportunity to assess parent–child interactions.

Clothing should be removed slowly and gently to avoid threatening the child. A parent or the child himself or herself is usually the best person to do this. Modesty should always be respected, and gown or drapes should be provided. Examinations of adolescents should be chaperoned whenever a pelvic examination or a stressful or painful procedure is performed.

Examination tables are convenient, but a parent’s lap is a safe haven for a young child. For most purposes, an adequate examination can be conducted on a “table” formed by the parent’s and examiner’s legs as they sit facing each other.

The nature of the physical examination changes as the child develops. Although a thorough physical examination is important at every age, at some ages the examination tends to focus on specific issues and concerns. At any age, an astute clinician can detect signs of important clinical conditions in an asymptomatic child. In infancy, for example, physical examination can reveal the presence of craniosynostosis, congenital heart disease, or congenital hip dysplasia. Similarly, examination of a toddler may reveal pallor (from iron deficiency anemia) or strabismus. The routine examination of an adolescent may reveal scoliosis or acanthosis nigricans (a finding associated with insulin resistance).

HEALTH SUPERVISION VISITS

One of several timetables for health supervision visits is illustrated in Figure 8–2. (*Note:* A PDF printable format of this figure is available at aap.org.) The federal Maternal and Child Health Bureau has developed comprehensive health supervision guidelines through their Bright Futures program (brightfutures.org). In areas where evidence-based information is lacking, expert opinion has been used as the basis for these plans. For example, immunizations are proven to be effective and necessary (Centers for Disease Control and Prevention, www.cdc.gov/nip), whereas there is disagreement about whether screening for certain metabolic diseases is universally warranted. Practitioners should remember that guidelines are not meant to be rigid; services should be individualized according to the child’s needs.

During health supervision visits, the practitioner should review child development and acute and chronic problems, conduct a complete physical examination, order appropriate screening tests, and anticipate future developments. New historical information should be elicited through an interval history. Development should be assessed by parental report and clinician ob-

serva-tion at each visit. Developmental surveillance is facilitated further through the systematic use of parent-directed questionnaires or screening tests. Growth is carefully recorded, and the growth chart is brought up to date (see Chapter 2). Vision and hearing should be assessed subjectively at each visit, with objective assessments at intervals beginning after the child is old enough to cooperate with the screening test. A variety of laboratory screening tests may also be part of the visit.

A major portion of the health supervision visit is anticipatory guidance. This portion of the visit enables the health care provider to address behavioral, developmental, injury prevention, nutritional issues, school problems, and other age-appropriate issues that will arise before the next well child care visit.

American Academy of Pediatrics Committee on Practice and Ambulatory Medicine: Recommendations for Preventive Pediatric Health Care. *Pediatrics* 2000;105:645.

DEVELOPMENTAL & BEHAVIORAL ASSESSMENT

At each visit, the parent should be interviewed about aspects of the child’s development and behavior. Questionnaires or formal screening tests help to document development objectively. Useful tests include the Denver II, the Parents’ Evaluations of Developmental Status (PEDS), the Denver Articulation Screening Examination, and the Early Language Milestone Scale. School-age children’s cognitive functions can be assessed through academic achievement and any educational testing that may have been performed. Emotional well-being can be screened by interview and observation. Practices may decide to use screening tools for adolescent depression.

Observation of parent–child interactions (eg, feeding, compliance tasks) may provide the clinician with information to help shape behavioral counseling. Observing the child’s temperament and gathering history about the family’s disciplinary techniques are other important considerations before providing guidance.

The pediatrician must be familiar with normal development in order to provide effective patient assessment and counsel. The following sections summarize some important motor, language, and emotional milestones of child development.

Newborns & Infants

Infancy is commonly a period of concern about growth and behavioral and developmental issues, particularly for the first-time parent. Normal motor and language development, feeding, sleep, elimination, and self-stim-

Recommendations for Preventive Pediatric Health Care (RE9939)

Committee on Practice and Ambulatory Medicine

Each child and family is unique; therefore, these **Recommendations for Preventive Pediatric Health Care** are designed for the care of children who are receiving competent parenting, have no manifestations of any important health problems, and are growing and developing in satisfactory fashion. **Additional visits may become necessary** if circumstances suggest variations from normal.

These guidelines represent a consensus by the Committee on Practice and Ambulatory Medicine in consultation with national committees and sections of the American Academy of Pediatrics. The Committee emphasizes the great importance of **continuity of care** in comprehensive health supervision and the need to avoid **fragmentation of care**.

- A prenatal visit is recommended for parents who are at high risk, for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breastfeeding and planned method of feeding per AAP statement "The Prenatal Visit" (1996).
- Every infant should have a newborn evaluation after birth. Breastfeeding should be encouraged and instruction and support offered. Every breastfeeding infant should have an evaluation 48-72 hours after discharge from the hospital to include weight, formal breastfeeding evaluation, encouragement, and instruction as recommended in the AAP statement "Breastfeeding and the Use of Human Milk" (1997).
- For newborns discharged in less than 48 hours after delivery per AAP statement "Hospital Stay for Healthy Term Newborns" (1995).
- Developmental, psychosocial, and chronic disease issues for children and adolescents may require frequent counseling and treatment visits separate from preventive care visits.
- If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested age, the schedule should be brought up to date at the earliest possible time.
- If the patient is uncooperative, rescreen within 6 months.
- All newborns should be screened per the AAP Task Force on Newborn and Infant Hearing statement, "Newborn and Infant Hearing Loss: Detection and Intervention" (1999).
- By history and appropriate physical examination; if suspicious, by specific objective devel-

- opmental testing. Parenting skills should be fostered at every visit.
- At each visit, a complete physical examination is essential, with infant totally unclothed, older child undressed and suitably draped.
- These may be modified, depending upon entry point into schedule and individual need.
- Metabolic screening (eg, thyroid, hemoglobinopathies, PKU, galactosemia) should be done according to state law.
- Schedule(s) per the Committee on Infectious Diseases, published annually in the January edition of *Pediatrics*. Every visit should be an opportunity to update and complete a child's immunizations.
- See AAP *Pediatric Nutrition Handbook* (1998) for a discussion of universal and selective screening options. Consider earlier screening for high-risk infants (eg, premature infants and low birth weight infants). See also "Recommendations to Prevent and Control Iron Deficiency in the United States", *MMWR*, 1998;47 (RR-3):1-29.
- All menstruating adolescents should be screened annually.
- Conduct dipstick urinalysis for leukocytes annually for sexually active male and female adolescents.
- For children at risk of lead exposure consult the AAP statement "Screening for Elevated Blood Levels" (1998). Additionally, screening should be done in accordance with state law where applicable.
- TB testing per recommendations of the Committee on Infectious Diseases, published in the current edition of *Red Book: Report of the Committee on Infectious Diseases*. Testing

- should be done upon recognition of high-risk factors.
- Cholesterol screening for high-risk patients per AAP statement "Cholesterol in Childhood" (1998). If family history cannot be ascertained and other risk factors are present, screening should be at the discretion of the physician.
- All sexually active patients should be screened for sexually transmitted diseases (STDs).
- All sexually active females should have a pelvic examination. A pelvic examination and routine pap smear should be offered as part of preventive health maintenance between the ages of 18 and 21 years.
- Age-appropriate discussion and counseling should be an integral part of each visit for care per the AAP *Guidelines for Health Supervision III* (1996).
- Refer to the AAP injury prevention program (TIIPP[®]) as described in *A Guide to Safety Counseling in Office Practice* (1994).
- Violence prevention and management for all patients per AAP Statement "The Role of the Pediatrician in Youth Violence Prevention in Clinical Practice and at the Community Level" (1999).
- Parents and caregivers should be advised to place healthy infants on their backs when putting them to sleep. Side positioning is a reasonable alternative but carries a slightly higher risk of SIDS. Consult the AAP statement "Changing Concepts of Sudden Infant Death Syndrome: Implications for Infant Sleeping Environment and Sleep Position" (2000).
- Age-appropriate nutrition counseling should be an integral part of each visit per the AAP

Key: • = to be performed
 * = to be performed for patients at risk
 S = subjective, by history
 O = objective, by a standard testing method
 ← → = the range during which a service may be provided, with the dot indicating the preferred age.

NB: Special chemical, immunologic, and endocrine testing is usually carried out upon specific indications. Testing other than newborn (eg, newborn errors of metabolism, sickle disease, etc) is discretionary with the physician.
 The recommendations in this statement do not indicate an exclusive course of treatment or standard of medical care. Variations, taking into account individual circumstances, may be appropriate. No part of this statement may be reproduced in any form or by any means without prior written permission from the American Academy of Pediatrics except for one copy for personal use. etc) is discretionary with the physician.

Figure 8-2. Recommendations for preventive health care.

ulating behaviors (thumb sucking, rocking, head banging) are frequently of concern. More complete information about developmental milestones and behavioral concerns of infancy is found in Chapter 2.

Attachment is the process by which an infant develops a relationship with a caregiver. Attachment has both biologic and experiential roots and serves as the basis for additional interpersonal interactions. It develops over months to years and shifts in focus as the child develops. Initially the child seeks proximity to the attachment figure but then gradually moves away in distance to meet exploratory needs.

The Second Year

Using the first year as a template for secure relationships, normal toddlers have an expanding set of relationships with other individuals. The toddler learns a broad set of general and specific behavioral expectations. The child may be dependent on the caregiving figure(s) and at other times may stubbornly wish to be independent. However, children begin to understand parental expectations and what is not permitted.

Children begin to understand feelings of others and develop empathy. They take pleasure in their achievements and express distress when they have misbehaved. Spoken language normally expands rapidly, as do gross motor skills.

Preschool Years: Ages 2–4 Years

Gross motor development during the preschool years results in children running, jumping, and climbing. Children learn to balance on one foot and hop. Vocabulary continues to expand rapidly with the mastery of hundreds of words. Language development proceeds with multiword sentences, the use of pronouns, and the gradual improvement in articulation skills. Children normally master the concept of numbers 1, 2, and 3 by 3½ years. Four-year-old children should know basic colors and clearly articulate most words.

The social and emotional development of preschool children is characterized by the transition from parallel to group play and the development of magical thinking. Parallel play is the observation of the play of others and initiation of similar activities individually. By age 4 years, most children will begin to prefer the social aspects of group play.

Toileting skills usually are mastered during these years. Toilet training requires a variety of developmental skills. Expressive and receptive language skills are needed to express and respond to questions about the need to use the toilet. Gross motor skills are needed to get to the bathroom and to control urination and defe-

cation. Fine motor skills are needed to dress and undress and to wash the hands.

Early School Years: Ages 5–7 Years

Separation–individuation is a theme of the early school years. The child is ready to relate to peers in a more interactive manner than he or she did during preschool years. Sensorimotor abilities are maturing and facilitate pencil-and-paper tasks and participation in sports activities.

The first-grader is generally able to recognize numbers, letters, and words; read and write; and understand the concept of conservation of length and mass. Magical thinking tends to decrease during this time.

Middle Childhood Years: Ages 8–11 Years

Academic skills become more sophisticated. Not only can a child add and subtract multiple-digit numbers, but he or she has a growing ability to perform multiplication and division. The child should also be able to provide effective verbal descriptions. For example, in response to the question “What is an orange?” the child may reply, “A sweet-tasting fruit.” Children develop an awareness of month, day, and year. Peers, organized clubs, and sports are important activities for preadolescent children.

Adolescence

The behavioral and developmental stages of adolescence are outlined in Chapter 3. Familiarity with the child and family over several years makes the pediatrician an excellent professional to screen for the many concerns in this age group.

<http://paediatrics.aappublications.org>

Levine MD et al (eds): *Developmental-Behavioral Pediatrics*, 3rd ed. WB Saunders, 1999.

GROWTH PARAMETERS

Pediatric growth charts are based on a broad sampling of the US population, with representation of young infants, breastfed infants, and certain ethnic minorities. The 2- to 18-year growth charts include a chart of body mass index (BMI) for age. The BMI is calculated as the weight (in kilograms) divided by the squared height (in meters). The BMI is useful for determining obesity (BMI ≥ 95th percentile for age) and underweight status (BMI ≤ 5th percentile for age). The BMI is highly correlated with secondary complications of obesity.

Height, weight, and head circumference are carefully measured and plotted at each visit during the first 3 years (see growth charts in Chapter 2). For children older than 3 years, height and weight should be measured at each well-child examination. To ensure accurate weight measurements for longitudinal comparisons, infants should be undressed completely, and young children should be wearing underpants only. Recumbent length is plotted on the chart for birth to 3 years (see Figures 2-1 and 2-2). When the child is old enough to be measured upright, height should be plotted on the charts for ages 2-18 years (see Figures 2-3 and 2-4). If circumferential head growth has been steady for the first 2 years, routine measurements may be suspended. However, if a central nervous system problem exists or develops, or if the child has growth deficiency, this measurement continues to be useful. Tracking the growth velocity for each of these parameters allows early recognition of deviations from normal.

Kuczumarski RJ et al: *CDC Growth Charts: United States. Advance Data from Vital and Health Statistics*, no. 314. National Center for Health Statistics, 2000.

www.cdc.gov/growthcharts/default.htm

BLOOD PRESSURE

Blood pressure screening at well-child visits should start at age 3 years. If the child has a renal or cardiovascular abnormality, a blood pressure reading should be obtained at each visit regardless of age. Accurate determination of blood pressure requires proper equipment (stethoscope, manometer and inflation cuff, or an automated system) and a cooperative, seated subject. Although automated blood pressure instruments are widely available and easy to use, blood pressure readings from these devices are typically 5 mm Hg higher for diastolic and 10 mm Hg higher for systolic blood pressure compared with auscultatory techniques. Therefore, the diagnosis of hypertension should not be made on the basis of automated readings alone. Additionally, blood pressure varies somewhat by the height and weight of the individual. Consequently, hypertension is diagnosed as a systolic or diastolic blood pressure greater than the 95th percentile based on the age and height (or weight) percentile of the patient.

The width of the inflatable portion of the cuff should be 40-50% of the circumference of the limb. Obese children thus need a larger cuff size to avoid a falsely elevated blood pressure reading. Cuffs that are too narrow will overestimate and those that are too wide will underestimate the true blood pressure. Blood pressure norms are provided in Chapter 19.

VISION & HEARING

Examination of the eyes and an assessment of vision should be performed at every health supervision visit. Parents should be queried about any concerns regarding vision, eye alignment, or any other eye problems. For example, parental observation of photophobia or excessive tearing may be suggestive of glaucoma.

For children from birth to 3 years of age, the eyes and eyelids should be inspected, the movement and alignment of the eyes assessed, and the pupils and red reflexes examined. The red reflex, performed on each pupil individually and then on both eyes simultaneously, is used to detect eye opacities (eg, cataracts or corneal clouding) and retinal abnormalities (eg, retinal detachment or retinoblastoma). In children younger than 3 years of age or in nonverbal children of any age, vision can be assessed by testing a child's ability to fixate on and follow an object.

For children 3 years and older, in addition to the eye evaluations, formal testing of visual acuity should be done. This can be performed in the office with a variety of tests, including the tumbling E chart or picture tests such as Allen cards. Each eye is tested separately, with the nontested eye completely covered. Credit is given for any line on which the child gets more than 50% correct. Children 4 years and older who are unable to cooperate should be retested, ideally within 1 month, and those who cannot cooperate with repeated attempts should be referred to an ophthalmologist. Because visual acuity improves with age, results of the test are interpreted using the cutoff values in Table 8-2; however, any two-line discrepancy between the two eyes should be referred to an ophthalmologist. Throughout childhood and adolescence, the clinician should screen for undetected strabismus (ocular misalignment) and decreased visual acuity. The random dot E test is recommended for detecting strabismus. The corneal light re-

Table 8-2. Age-appropriate visual acuity.^a

Age (years)	Minimal Acceptable Acuity
3-5	20/40
6 and older	20/30

^aRefer to an ophthalmologist if minimal acuity is not met at a given age or if there is a difference in scores of two or more lines between the eyes.

flex test, the cover test, and visual acuity tests are described further in Chapter 15.

Hearing loss, if undetected, can lead to substantial impairments in speech, language, and cognitive development. Because significant bilateral hearing loss is one of the more common major anomalies found at birth, and early detection and intervention of hearing loss leads to better outcomes for children, universal hearing screening of all infants is required in many parts of the United States. Hearing in infants is assessed using either auditory brainstem responses or evoked otoacoustic emissions. Because universal newborn hearing screening will inevitably be associated with some false-positive test results, confirmatory audiology testing is required for all abnormal tests.

In infants and toddlers, hearing can be assessed by asking the parent to provide examples of sounds to which the baby has responded and by using simple techniques such as shaking rattles or snapping the fingers. Pure tone audiometry in the office is feasible beginning at age 3 years. Any evidence of hearing loss should be substantiated by repeated testing, and if still abnormal, a referral for formal hearing testing should be made. A number of inherited or acquired conditions increase the risk of hearing loss. Children with any risk factors for hearing loss should be closely followed and periodically screened. Additional details are provided in Chapter 17.

LABORATORY SCREENING

Newborn Screening

Newborn screening involves population-wide testing for metabolic and genetic diseases. Blood samples are collected by heelstick from newborns before hospital discharge, and results are usually available within 1 week. States vary in the types of diseases for which they screen, and many states repeat blood testing between 7 and 14 days of life. Repeat testing is necessary to detect such diseases as phenylketonuria (PKU), which may not be discovered if the first newborn blood screen is performed before 24 hours of life.

All state newborn screening programs include tests for PKU and congenital hypothyroidism. If undiag-

nosed, both diseases result in severe mental retardation. Early treatment maintains cognitive function in the normal range. Also, most states test for galactosemia and sickle cell disease. Additional diseases screened for in some state programs include congenital adrenal hyperplasia, homocystinuria, maple syrup urine disease, biotinidase deficiency, tyrosinemia, other metabolic conditions, cystic fibrosis, and toxoplasmosis. After newborn screening is performed, several additional steps are necessary. Infants with a positive screen result should receive close follow-up, with additional confirmatory studies performed. Screening tests are usually accurate, but the sensitivity and specificity of a particular screening test must be carefully considered. If the screening test result is reported as positive, a confirmatory test must be performed. If symptoms of a disease are present despite a negative screening test, the infant should be tested further. Once a diagnosis is confirmed, the infant will need further evaluation and treatment.

Advances in science and technology, such as the Human Genome Project (<http://www.nhgri.nih.gov>), have created the potential to test for myriad additional inherited diseases. Any such screening should directly benefit the infant, because not all conditions are worth looking for in current newborn screening programs. To justify testing the entire population for a condition, that condition would have to be a serious and prevalent health problem; early detection and treatment of the disease must improve patient outcomes; and testing would have to be simple, safe, and affordable.

Lead Screening

The developing infant and child are at risk of lead poisoning because of their propensity to place objects in the mouth and their efficient absorption of the metal. High blood levels ($> 70 \mu\text{g/dL}$) can cause severe health problems such as seizures and coma. Blood lead levels as low as $10 \mu\text{g/dL}$ may cause behavioral problems and learning disabilities, and these effects persist into later life. Blood lead levels below $10 \mu\text{g/dL}$ have been correlated with lower intelligence quotients. The primary source of lead exposure in this country remains lead-based paint, even though most of its uses have been banned since 1977. Typically, children are exposed through chronic ingestion of dust that is contaminated with lead. Environmental controls such as the elimination of leaded gasoline and paints as well as public service educational efforts are thought to be the main reason blood lead levels have declined nationally from a mean of $16 \mu\text{g/dL}$ in 1976 to $2 \mu\text{g/dL}$ in 2001. However, considerable variation in lead levels exists in different regions of the United States, and a majority of children at risk of lead toxicity are not currently screened. To eliminate childhood lead poisoning by 2010 (a na-

tional health objective—<http://www.healthypeople.gov>), health care providers need to be vigilant about this environmental health threat.

State public health authorities set policies on childhood lead screening. The Centers for Disease Control and Prevention (www.cdc.gov) recommends universal lead screening for communities with a high percentage of old housing (> 27% of houses built before 1950) or a high percentage of children with elevated blood lead levels (> 12% of children with levels above 10 µg/dL). Communities with inadequate data regarding local blood lead levels should also undergo universal screening. Medicaid requires that all children (ages 1–5 years) be screened twice, once at 1 year of age and a second screen at 2 years of age. In communities with newer housing and a lower percentage of children with elevated lead levels, blood lead screening is recommended only for targeted groups of children. In these areas, caregivers of children between ages 6 months and 6 years may be interviewed by questionnaire about environmental risk factors for lead exposure (Table 8–3), although the data to support the use of this screening are inconclusive. If risk factors are present, a blood lead level should be obtained.

A venous blood sample is preferred over a capillary specimen. An elevated capillary (fingerstick) blood sample should always be confirmed by a venous sample. No action is required for blood lead levels below 10 µg/dL. The cognitive development of children with confirmed

blood levels over 14 µg/dL should be evaluated and attempts made to identify the environmental source. Iron deficiency should be treated if present. Chelation of lead should be considered for levels above 25 µg/dL, is always indicated for levels over 44 µg/dL, and is urgently required for levels of 70 µg/dL or more. All families should receive education to decrease the risk of lead exposure. With any elevated lead level (> 10 µg/dL) rescreening should be performed at recommended intervals.

Iron Deficiency

Iron deficiency is the most common nutritional deficiency in the United States. Severe iron deficiency causes anemia, behavioral problems, and cognitive effects, but recent evidence suggests that even iron deficiency without anemia may cause behavioral and cognitive difficulties. Furthermore, the developmental effects of iron deficiency may be present after 10 years, even if iron deficiency is corrected in infancy. Risk factors for iron deficiency include preterm or low-birth-weight births, multiple pregnancy, iron deficiency in the mother, use of nonfortified formula or cow's milk before age 12 months, and an infant diet that is low in iron-containing foods. Infants and toddlers consuming greater than 24 oz of cow's milk per day are at risk, as are children with chronic illness, restricted diet, or extensive blood loss.

Primary prevention of iron deficiency should be achieved through dietary means, including feeding infants iron-containing cereals by age 6 months, avoiding low-iron formula during infancy, and limiting cow's milk to 24 oz/d in children age 1–5 years. Selective early screening for iron deficiency should be considered with the presence of any of the preceding risk factors. A screening hemoglobin or hematocrit should be obtained for high-risk children between ages 9–12 months and again at 15–18 months, and it should be considered annually through age 5 years. Premature and low-birth-weight infants may need testing before 6 months of age. Universal anemia screening at 9 and 15 months of age is appropriate for children in communities or patient populations in which anemia is found in 5% or more of those tested. Biochemical tests of iron deficiency focusing on ferritin, transferrin saturation, and erythrocyte protoporphyrin may be useful because they are sensitive measures of iron status. Lead poisoning can cause iron deficiency anemia and should be explored as a cause for at-risk infants and children. A screening hematocrit is recommended for pregnant teenagers.

Hypercholesterolemia & Hyperlipidemia

The benefits of screening and treatment for hypercholesterolemia and hyperlipidemia in children are not

Table 8–3. Elements of a lead risk questionnaire.

Recommended questions

1. Does your child live in or regularly visit a house built before 1950? This could include a day care center, pre-school, the home of a baby-sitter or relative, and so on.
2. Does your child live in or regularly visit a house built before 1978 with recent, ongoing, or planned renovation or remodeling?
3. Does your child have a sister or brother, housemate, or playmate being followed for lead poisoning?

Questions that may be considered by region or locality

1. Does your child live with an adult whose job (eg, at a brass/copper foundry, firing range, automotive or boat repair shop, or furniture refinishing shop) or hobby (eg, electronics, fishing, stained-glass-making, pottery-making) involves exposure to lead?
2. Does your child live near a work or industrial site (eg, smelter, battery recycling plant) that involves the use of lead?
3. Does your child use pottery or ingest medications that are suspected of having a high lead content?
4. Does your child have exposure to burning lead-painted wood?

fully known. However, the American Academy of Pediatrics (www.aap.org) and the American Heart Association (www.americanheart.org) recommend obtaining a total cholesterol measurement in children older than 2 years who have a parent with elevated cholesterol (above 240 mg/dL). If there is a family history of cardiovascular disease before age 55 years, a complete lipoprotein analysis (fasting cholesterol, high-density lipoproteins, low-density lipoproteins, triglycerides) is recommended. For all children, a prudent diet is advised (see Nutrition Counseling section).

Tuberculosis

In 2002, 15,075 cases of tuberculosis were reported in the United States, with 946 of these cases occurring in children younger than age 15 years. Well-child care should include assessment of the risk of tuberculosis, and tuberculosis screening should be based on high-risk status. High risk is defined as contact with a person with known or suspected tuberculosis; having symptoms or radiographic findings suggesting tuberculosis; birth, residence, or travel to a region with high tuberculosis prevalence (Asia, Middle East, Africa, Latin America); contact with a person with AIDS or HIV; contact with a prisoner, migrant farm worker, illicit drug user, or a person who is or has been recently homeless. The Mantoux test (5 tuberculin units of purified protein derivative) is the only recommended screening test. It can be done as early as 3 months of age and should be repeated annually if the risk persists. The tine test should not be used. Previous vaccination with bacille Calmette-Guérin (BCG) is not a contraindication to tuberculosis skin testing.

Screening of Adolescent Patients

Screening adolescents for blood cholesterol, tuberculosis, and HIV should be offered based on high-risk criteria outlined in this chapter and in Chapter 37. Females with heavy menses, weight loss, poor nutrition, or athletic activity should have a screening hematocrit. During routine visits, adolescents should be questioned sensitively about sexually transmitted infection (STI) risk factors (eg, multiple partners; early onset of sexual activity, including child sexual abuse) and STI symptoms (eg, genital discharge, infectious lesions, pelvic pain). A dipstick urinalysis for leukocytes is generally recommended for sexually active adolescents. Teenage girls who are sexually active and all girls regardless of sexual experience age 18 years and older should have a pelvic examination with Papanicolaou (Pap) smear. A Pap smear should be performed at least every 3 years thereafter and more frequently in patients with STI risk factors. Because females with STIs are often not sympto-

matic, gonococcal and chlamydial cultures and screening tests for syphilis and trichomoniasis are appropriate at the time of each pelvic examination.

ANTICIPATORY GUIDANCE

A major portion of the health supervision visit is anticipatory guidance. This time enables the clinician to direct the parent's or the older child's attention to issues that may arise in the future. Guidance must be appropriate to age and should focus on, but not be limited to, concerns expressed by the parent or patient. Anticipatory guidance should focus on issues in depth rather than run through a number of issues superficially. A combination of oral and printed presentations may be used. Handouts are an important supplement to anticipatory guidance. A routine schedule for preventive handouts is shown in Table 8–4. Areas of concern include diet, injury prevention, developmental and behavioral issues, and health promotion. Injury prevention is discussed in the next section; other topics are found in other chapters of this book.

Injury Prevention

Injuries are the leading cause of death in children and adolescents after the first year of life (Figure 8–3). For young people age 15–24 years, injuries are responsible for more than 50% of all deaths. Each year, 16 million visits to emergency departments are occasioned by injuries to children and adolescents, and more than 500,000 of these patients are hospitalized. In the case of physical injury to a young child, the physician must recognize that some injuries may be intentional or the result of parental neglect (see Chapter 7).

Table 8–4. Preventive handouts for health supervision visits.

Age	Suggested Topics
2 weeks	Sleep problems: Prevention
2 months	Passive smoking
4 months	Weaning problems: Prevention
6 months	Teething
12 months	Temper tantrums
18 months	Toilet training basics
2 years	Time-out technique
3 years	Spoiled children: Prevention
4 years	Sex education for preschoolers
5 years	Television: Reducing the negative impact
6 years	School work: Preventing problems
8 years	Siblings' arguments and quarrels
10 years	R-rated movies
12 years	Adolescents: Dealing with normal rebellion

Adapted and reproduced, with permission, from *Contemporary Pediatrics*. These and other topics relevant to preventive health services can be purchased in the *Pediatric Advisor*, a computerized patient handout program. Information about the *Pediatric Advisor* is available by calling Clinical Reference Systems at 1-800-237-8401. The author has a financial interest in this product.

Injury prevention counseling should be part of each health supervision visit and can be reinforced at episodic visits. Counseling should focus on problems that are frequent and age-appropriate. Passive strategies of prevention should be emphasized, because these are more effective than active strategies; for example, encouraging the use of childproof cupboard latches to prevent poisoning will be more effective than instructing parents to watch their children closely.

Informational handouts about home safety, such as The Injury Prevention Program (TIPP; available from the American Academy of Pediatrics), can be provided in the waiting room. Advice can then be tailored to the specific needs of each family, with reinforcement from age-specific TIPP handouts.

The pediatrician's influence can extend beyond the office to advocate for safer communities. For example, a community program in Seattle, Washington, to promote the use of bicycle helmets has increased helmet use from 2% to nearly 40%. The primary care provider is in an ideal position to identify high-risk situations and intervene before injury occurs. If a teenager has emotional problems (eg, depression) and a history of driving violations, for example, the clinician should recommend interventions that could prevent a motor vehicle accident.

A. MOTOR VEHICLE INJURIES

The primary cause of death of children in the United States is motor vehicle injuries. In 1998, about 57% of

children 15 years old or younger killed in motor vehicle accidents were unrestrained. Car safety seats for children are required in this country, and their proper use could reduce vehicle-associated fatalities and hospitalizations by at least 50%. The type of safety seat to be used depends on the child's weight and age: rear-facing infant seat for a child under 20 lb and 1 year of age; forward-facing car seat for a child 20–40 lb and older than 1 year; a belt-positioning booster seat for a child who has outgrown the safety seat. When children have grown enough to properly fit the vehicle seat belts (usually when 4 feet tall), they should use a combination lap/shoulder belt. A rear-facing car seat should never be used in a seat with a passenger air bag. A car seat should never be used if the child has outgrown the seat—for example, ears above the back of the seat or shoulders above the seat strap slots.

Up-to-date information on car seats can be found at www.aap.org/family/carseatguide.htm.

When a child is a passenger in a car crash, the case fatality rate is 1%; for children hit by cars, the risk of fatality increases threefold. Pedestrian safety skills should be taught to children early in childhood; however, parental supervision of children near roadways continues to be required for many years. A final motor vehicle risk for health involves the use of portable electronic devices. Using a cellular telephone while driving is associated with a fourfold increase in motor vehicle accidents. Parents and teenage drivers should avoid this risk.

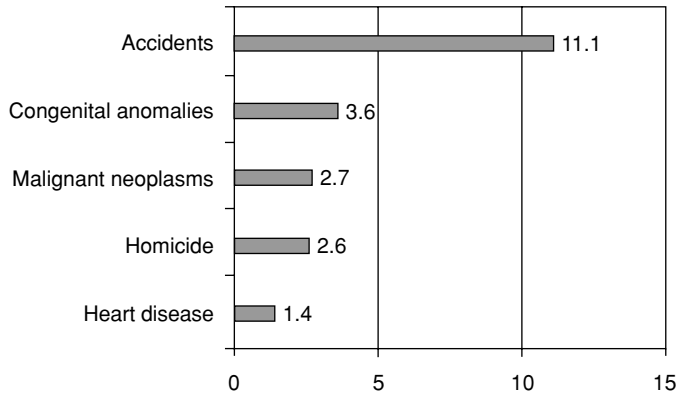

B. BICYCLE INJURIES

In 2001, over 400,000 Americans sustained a bicycle injury, and two thirds of these injuries involved children or adolescents. Head trauma accounts for three fourths of all bicycle-related fatalities. More than 85% of brain injuries can be prevented through the use of bicycle helmets, and the rate of fatality to bicyclists is dropping. Therefore, bike riders should wear a helmet every time they ride. Unfortunately, 25% or less of children wear a bike helmet when riding.

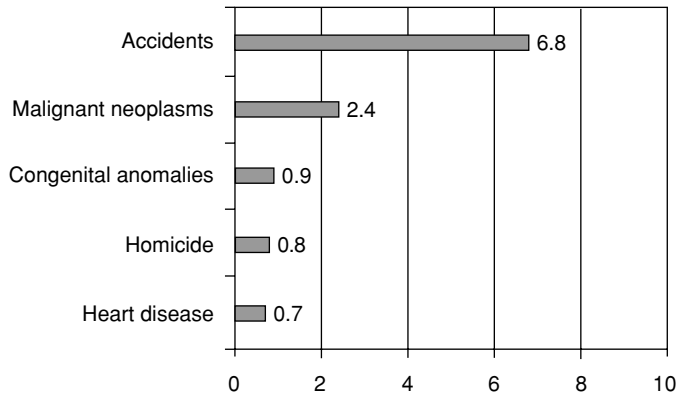

C. FIREARM INJURIES AND VIOLENCE PREVENTION

The United States has a higher rate of firearm-related death than any other industrialized country. Injuries from firearms are more frequent for young people age 15–24 years than for any other age group, and black males are especially vulnerable. Some gun deaths may be accidental, but most are the result of homicide or suicide. A gun in the home doubles the likelihood of a lethal suicide attempt. Although handguns are often kept in homes for protection, a gun is more likely to kill a family member or a friend than an intruder. The most effective way to prevent firearm injuries is to remove guns from the home and community. Families

Children 1–4 years

Children 5–14 years

Young adults 15–24 years

Figure 8–3. Leading causes of death in children at 1–4 years, at 5–14 years, and at 15–24 years (the 1999 rate per 100,000 population). (National Center for Health Statistics. Used with permission.)

who keep firearms at home should lock them in a cabinet or drawer and store ammunition in a separate locked location.

A nonviolent environment should be provided to all children. Secure parent–infant attachments, social and conflict-resolution skills, and the avoidance of violence (on television or actual) all have a role in promoting nonviolence.

D. DROWNING AND NEAR DROWNING

Drowning is the second leading cause of injury-related death in children, and those age 1–3 years have the highest rate of drowning. For every death by drowning, six children are hospitalized for near drowning, and up to 10% of survivors experience severe brain damage. Children younger than age 1 year are most likely to drown in the bathtub. Buckets filled with water also present a risk of drowning to the older infant or toddler. For children age 1–4 years, drowning or near drowning occurs most often in home swimming pools; and for school-age children and teens, drowning occurs most often in large bodies of water (eg, swimming pools or open water). After the age of 5 years, the risk of drowning in a swimming pool is much greater for black males than white males. School-age children should be taught to swim, and recreational swimming should always be supervised. Home pools must be fenced securely, and parents should know how to perform cardiopulmonary resuscitation.

E. FIRE AND BURN INJURIES

Fires and burns are the leading cause of injury-related deaths in the home. Categories of burn injury include smoke inhalation; flame contact; scalding; and electrical, chemical, and ultraviolet burns. Scalding is the most common type of burn in children. Most scalds involve foods and beverages, but nearly one fourth of scalds are with tap water, and for that reason it is recommended that hot water heaters be set to less than 54°C (130°F). The greatest number of fire-related deaths result from smoke inhalation. Smoke detectors can prevent 85% of the injuries and deaths caused by fires in the home. Families should practice emergency evacuation from the home.

Sunburn is a common thermal injury, perhaps because symptoms of excessive sun exposure do not begin until after the skin has been damaged. Sunburn and excessive sun exposure are associated with skin cancers. Prevention of sunburn is best achieved by sun avoidance, particularly during the midday hours of 10 AM, to 3 PM. Sunscreen using a sun protection factor (SPF) of 15 or greater extends the duration of time that a child can spend in the sun without sunburn. Hats, sunglasses, and special precautions for fair-skinned individuals and infants are also important aspects of safe sun

exposure. The safety of sunscreen is not established for infants younger than 6 months; thus sun avoidance, appropriate clothing, and hats are recommended for this age group.

NUTRITION COUNSELING

Screening for nutritional problems and guidance for age-appropriate dietary choices should be part of every health supervision visit. Undernutrition, overnutrition, and eating disorders can be detected early by the careful analysis of food choices and eating behaviors, particularly when interpreted in the context of the child's growth pattern. Clinicians should assess the structure of meals (ie, does the family eat three regular meals interspersed with healthy snacks), the type and amounts of food provided, and the degree to which the child grazes or watches television while eating. Iron-fortified formula or breast milk should be used for the first year of life, after which whole cow's milk can be given. Because of continued rapid growth and high energy needs, children should continue to drink whole milk until age 2 years. Baby foods are generally introduced around ages 4–6 months.

For children 2 years old and older, a prudent diet consists of diverse food sources, encourages high-fiber foods (eg, fruits, vegetables, grain products), and limits sodium and fat intake. Foods to be avoided or limited include processed foods, soft drinks, and candy. For additional information on nutritional guidelines, see Chapter 10; for eating disorders, see Chapter 5; for obesity, see Chapter 3.

IMMUNIZATIONS

A child's immunization status should be assessed at every clinic visit. Even though parents may keep an im-

munization record, it is critical that providers also keep an accurate record of a child's immunizations. This information may be written in a prominent location in the chart or kept in a specialized computer database, called an immunization registry.

Despite high overall national immunization coverage levels, areas of underimmunization continue to exist in the United States. Therefore, it is important that clinicians screen records and administer required immunizations at all types of visits, and administer all needed vaccinations simultaneously. Additionally, clinicians should operate reminder/recall systems, in which parents of underimmunized children are prompted by mail or telephone to visit the clinic for immunization. The assessment of clinic-wide immunization levels and feedback of these data to providers has also been shown to increase immunization rates. Finally, clinicians should emphasize to parents the importance of timely immunization.

Immunization schedules and other details of specific vaccines are presented in Chapter 9. A wealth of information for parents and providers about immunizations is also available at the National Immunization Program's website (<http://www.cdc.gov/nip>).

■ OTHER TYPES OF GENERAL PEDIATRIC SERVICES

ACUTE-CARE VISITS

Acute-care visits account for 30% or more of the general pediatrician's office visits. These visits must be conducted in an efficient, structured way. Office personnel should determine the reason for the visit, obtain a brief synopsis of the child's symptoms, carefully document vital signs, and list known drug allergies. The physician should document the events related to the presenting problem and note them with the results of the physical examination. The record should include supporting laboratory data and a diagnosis. Treatments and follow-up instructions must be recorded, including when to return to the office if the problem is not ameliorated. Immunization status should be screened and appropriate vaccinations given. As time allows, age-appropriate health maintenance screenings and anticipatory guid-

ance should be provided. Careful documentation of these visits is important for medicolegal reasons.

PRENATAL VISITS

Ideally, a couple's first trip to a physician's office should take place before the birth of the baby. A prenatal visit goes a long way toward establishing trust and enables the physician to learn about a family's expectations, concerns, and fears regarding the anticipated birth. If the infant develops a problem during the newborn period, the physician who has already met the family is in a better position to maintain rapport and communication with the new parents. If possible, both parents should be present for this visit.

A prenatal visit provides an easy way to acquaint parents with how the practice is conducted, its hours of operation, after-hours coverage, appointment scheduling, and billing. Parents want to know whom they will speak to when they call the office, when they may bring in children for acute-care visits, and how their concerns will be managed.

SPORTS PHYSICALS

The purpose of the preparticipation health evaluation is to determine whether a child can safely participate in organized sports activity. Attention should be directed toward those parts of the body that are most vulnerable to the stresses of sports. The history and physical examination should focus on the following systems: cardiovascular (stenotic lesions, hypertension, surgery), respiratory (asthma), vision, genitourinary (absence or loss of function of one testicle), gastrointestinal (hepatosplenomegaly, hernia), skin (infection), musculoskeletal (inflammation, dysfunction), and neurologic (concussions, uncontrolled seizures). The sports physical should include counseling about medication usage (eg, diuretic, steroid, and β -blocker abuse, changes in insulin requirements), protective equipment, proper supervision and instruction, injury management, and the emotional aspects of competition and teamwork. The physician should suggest sports that will be compatible with the child's size, strength, endurance, agility, and chronic illness history. The potential for mild menstrual irregularities should be explained to the adolescent female athlete. The athlete with moderate to severe menstrual irregularities should be referred for endocrinologic evaluation. Anticipatory guidance should address nutritional needs to maintain growth, cessation of activity when pain occurs, and fluid and electrolyte availability to avoid dehydration. (See Chapter 24 for a more detailed discussion of sports medicine.)

CHRONIC DISEASE FOLLOW-UP

Chronic disease is defined as illness that has been present for more than 3 months. When both the history from the parent and the physical examination are used to define chronic disease, 25% of children and 35% of adolescents will meet the definition of chronic illness. The most common chronic illnesses in pediatric practice include asthma, otitis media with effusion, skin disorders, and allergic diseases.

The goal of chronic disease management is to optimize quality of life. The child and family’s emotional responses to chronic illness should be addressed, and referrals to counselors should be offered if needed. Specialty referrals need to be monitored and results recorded in the chart in an organized manner. Chronic

problems often mean chronic use of medications and the need to monitor their use. Notes should be made in the chart whenever a prescription is refilled. A medication summary page in the chart allows easy access to the drug history and is a convenient place to make notes such as when the anticonvulsant level was last checked and what it was at that time (Figure 8–4). Children with medical appliances such as gastrostomy tubes and indwelling intravenous and bladder catheters need advice on their management. Nutritional intake is often complicated and must be closely and carefully monitored.

COUNSELING

Topics amenable to office counseling include behavioral issues such as negativism and noncompliance, temper tantrums, oppositional behavior, and biting; childhood fears and feeding disorders; school problems; family upheavals such as separation, divorce, or remarriage; attention-deficit/hyperactivity disorder; and deaths of family members or close friends. Forty-five minutes is usually enough time for the therapeutic process to evolve, and this time should be protected from interruption. The young child is usually interviewed with the parent; school-age children and adolescents benefit from time alone with the physician. After assessing the situation in one or two sessions, the primary care physician must decide whether the child's and family's needs are within his or her area of expertise or whether referral to another professional such as a psychologist or an education specialist would be appropriate. The pediatrician should know the warning signs for childhood depression and bipolar disorder and have a low threshold for referral of these concerns to the appropriate mental health professional.

CONSULTATIONS^a

Referring Source

Physicians, other professionals, and parents may initiate consultations with a general pediatrician. The general pediatrician may be called on to evaluate many different types of problems both in the hospital and in the ambulatory setting. Parents sometimes desire a second opinion regarding a specific concern while maintaining a relationship with another clinician for their child's primary care. Subspecialists, family physicians, or professionals such as school officials, psychologists, or social workers may also seek second opinions. Finally, an insurance company physician or administrator may want a second opinion before authorizing a set of services.

Consultations usually require one or two 45- to 60-minute appointments. When the patient is referred to a pediatric consultant, the number of visits and the extent of service should be specified. A screening questionnaire, completed in advance by a parent, should delineate the patient's physical, behavioral, and developmental (or school) problems and serve as an initial database.

The types of consultations the general pediatrician may be asked to do include an evaluation only, an evaluation and interpretation, or an evaluation and treatment of an isolated problem. The type of consultation

being requested should be clearly determined at the time of referral of the patient. This understanding should be clarified with the patient's insurance company so that appropriate authorization and reimbursement for the visit can occur.

Communication with the Referring Source

Communication is the key to a satisfactory referral process. The pediatric consultant frequently sends the referral source a brief note acknowledging the referral and requesting additional information. The final consultation report should be sent promptly, with content appropriate for the referring source. School officials usually want to know only whether the patient is physically healthy or, if not, what their responsibility is. A referring physician expects a full report. Recommendations should be specific (eg, drugs, dosages, other forms of therapy, duration of therapy, specific laboratory tests). A copy of or reference to a recent review article on the subject will also be appreciated.

A medical evaluation should contain a factual summary of the history, physical examination, and laboratory and radiologic findings. Families are grateful if a copy is sent to them for their information and records. At the end of the consultation, the parents should be told when the patient should see the primary physician—usually in 1–2 weeks. Positive comments about the referring physician's competence and judgment serve to support the primary physician–patient relationship. The parents must feel confident that the primary physician can provide the necessary follow-up care. If the referring physician had tentatively made the correct diagnosis prior to referral, the consultant's corroboration should be made clear to the parents and included in the consultation report.

TELEPHONE TRIAGE AND ADVICE^b

Providing appropriate, efficient, and timely clinical advice over the telephone is a critical element of patient care for all primary care providers. In fact, an estimated 20–30% of all clinical care delivered by general pediatric offices is provided by telephone. Telephone calls to and from patients occur both during regular office hours and after the office has closed (termed after-hours), and the personnel and systems in place to handle office-hours versus before- and after-hours calls may differ. In either circumstance, several principles are important: (1) advice is given only by clinicians or other staff with formal medical education (eg, nurse, medical assistant), (2) staff is given additional training in pro-

^aContributed by Barton D. Schmitt, MD.

^bContributed by Barton D. Schmitt, MD.

viding telephone care, (3) documentation is made of all pertinent information from calls, (4) standardized protocols covering the most common pediatric symptoms are used, and (5) a physician is always available to handle urgent or difficult calls.

During routine office hours, approximately 20–25% of all telephone calls made to pediatric offices are regarding clinical matters. Many of these calls, however, are routine in nature, and an experienced nurse within the office can screen calls and provide appropriate advice by telephone. Calls from inexperienced or anxious parents about simple concerns should be answered with understanding and respect. Certain types of calls received during office hours should be promptly transferred to a physician: (1) true emergencies, (2) calls regarding hospitalized patients, (3) calls from other medical professionals, and (4) calls from parents who demand to speak with a physician. Nurses should also seek help from a clinician whenever they are uncertain about how to handle a particular call. When in doubt about the diagnosis or necessary treatment, nurses giving telephone advice should err on the side of having the patient seen in the office.

Several different options are available for handling after-hours pediatric telephone care. Clinicians may choose to take all calls from their patients, may rely on “advice” nurses without specific pediatric protocols or training, or may use a system specifically designed for pediatric telephone care, called a pediatric after-hours call center. Pediatric call centers, although not available in all communities and potentially more expensive than other options for after-hours care, have certain benefits. Calls are managed using standardized protocols, the call centers are typically staffed by nurses with abundant pediatric experience, the calls are well-documented, and call centers often perform ongoing quality assurance. Extensive research on pediatric call centers has revealed a high degree of appropriate referrals to emergency departments, and a high level of parent satisfaction with the process.

In general, after-hours pediatric telephone calls tend to be more serious than calls made during regular office hours. Deciding which patients need to be seen, and how urgently, are the most important aspects of these after-hours telephone “encounters.” Several factors influence this final patient disposition: (1) the age of the patient, (2) the duration and type of symptom, (3) the presence of any underlying chronic condition, (4) whether the child appears “very sick” to the caller, and (5) the anxiety level of the caller. Once all the pertinent medical information is gathered, a decision is made about whether the child should be seen immediately (by ambulance versus car), seen in the office later (today versus tomorrow), or whether the illness can be safely cared for at home. At

the end of the call, it should be confirmed that parents understand and feel comfortable with the plan for their child.

COMMUNITY PEDIATRICS

Community pediatrics is by definition “a concern for all children in the community, especially children who do not get adequate medical care.” Pediatricians have historically been very involved in supporting and developing services for vulnerable children in their communities. As a group, pediatricians recognize that communities are integral determinants of a child’s health and that the synthesis of public health and personal health principles and practices is important in the practice of community pediatrics. As well, pediatricians have a long commitment to work with other professionals in the community and advocate for the needs of all children.

Pediatricians in practice are frequently instrumental in referring children and families to valuable services and resources. For example, uninsured children can be enrolled in either their state Medicaid program or State Children’s Health Insurance Program (SCHIP). Children with special health care needs may be eligible for services typically funded through state health departments and through programs such as those provided based on the Individuals with Disabilities Education Act (IDEA). A variety of community-based immunization programs can provide access to needed immunization for eligible children. Food and nutrition programs such as the federally funded Women, Infant and Children (WIC) program provide sources of free food for eligible families. Finally, subsidized preschool and child care services such as the federally funded Head Start program provide needed preschool programs. Pediatricians are in a unique position to make referrals to these important services from the ambulatory and hospital-based practice settings.

COMMON GENERAL PEDIATRIC ISSUES

FEVER

Definition and Measurement

Fever is one of the most common reasons for pediatric office visits, emergency department encounters, and after-hours telephone calls. Several different definitions of fever exist, but most experts define fever as a rectal temperature of 38°C or above. Temperature in pediatric patients can be measured in a variety of manners: rectal (using a mercury or digital thermometer), oral (mercury, digital), axillary (mercury, digital, or liquid crystal strip), forehead (liquid crystal strip), or tympanic (using a device that measures thermal infrared energy from the tympanic membrane). Tympanic measurement of temperature, because it is quick, not particularly uncomfortable, and requires little patient cooperation, is rapidly becoming the norm in many settings. However, several cautions apply to the use of this technique: tympanic temperatures have been shown to be less accurate in infants younger than 3 months old and are subject to false readings if the instrument is not positioned properly or the external ear canal is occluded by wax.

Causes of Fever

Fever occurs when there is a rise in the hypothalamic set-point in response to endogenously produced pyrogens. A tremendously broad range of conditions cause fever, including infections, malignancies, autoimmune diseases, metabolic diseases, chronic inflammatory conditions, medications (including immunizations), central nervous system abnormalities, and exposure to excessive environmental heat. In most settings, however, the majority of fevers in pediatric patients are caused by self-limiting viral infections. Teething does not cause fever over 38.4°C.

Evaluation

A. GENERAL CONSIDERATIONS

When evaluating a child with fever, one should elicit from the parents information about the duration of fever, the maximum height of fever documented at home, all associated symptoms, any chronic medical conditions, any medications taken, medication allergies, fluid intake, urine output, exposures and travel, and any additional features of the illness that concern the parents (Table 8–5). In the office, a temperature,

Table 8–5. Guidelines for evaluating children with fever.

A. See immediately if:

- (1) The child is less than 3 months old.
- (2) The fever is over 40.6°C.
- (3) The child is crying inconsolably or whimpering.
- (4) The child is crying when moved or even touched.
- (5) The child is difficult to awaken.
- (6) The child's neck is stiff.
- (7) Purple spots or dots are present on the skin.
- (8) The child's breathing is difficult, and not better after the nasal passages are cleared.
- (9) The child is drooling saliva and is unable to swallow anything.
- (10) A convulsion has occurred.
- (11) The child acts or looks "very sick."

B. See within 24 hours if:

- (1) The child is 3–6 months old (unless fever occurs within 48 hours after a diphtheria-tetanus-pertussis vaccination and the infant has no other serious symptoms).
- (2) The fever exceeds 40°C (especially if the child is under age 3 years).
- (3) Burning or pain occurs with urination.
- (4) The fever has been present for more than 24 hours without an obvious cause or identified site of infection.
- (5) The fever has subsided for more than 24 hours and then returned.
- (6) The fever has been present for more than 72 hours.

heart rate, respiratory rate, and blood pressure should be documented, as well as an oxygen saturation if the child has any increased work of breathing. A complete physical examination, including a neurologic exam, should then be performed, with particular attention paid to the child's degree of toxicity and hydration status. A well-appearing, well-hydrated child with evidence of a routine viral infection can be safely sent home with symptomatic treatment and careful return precautions. Depending on the age of the patient, presence of underlying conditions, type of infection, and the provider's assessment of toxicity and hydration, many focal bacterial infections can also be treated as outpatients, with appropriate oral antibiotics as discussed in Chapter 38.

B. FEVER WITHOUT A FOCUS OF INFECTION

Children who present with fever but without any symptoms or signs of a focal infection are often a diagnostic and management challenge. Literally hundreds of articles have been published in the medical literature

about the proper evaluation and treatment of infants and young children with fever. When assessing a child with fever but no apparent source of infection on examination, the provider needs to carefully consider the likelihood of a serious but "hidden" or occult bacterial infection. With the widespread use of effective vaccines against *Haemophilus influenzae* type b and *Streptococcus pneumoniae*, two of the most common causes of invasive bacterial infections in unimmunized children, the incidence of occult bacterial infections appears to be declining. However, vaccines are not 100% effective, and other organisms cause serious occult infections in children; therefore, febrile children will always demand careful evaluation and observation. Appropriate choices for empiric antibiotic therapy of children with fever without focus are discussed in Chapter 35.

Febrile infants 28 days old or younger, because of their likelihood of serious disease including sepsis, should always be treated conservatively. Hospitalization and parenteral antibiotics should be strongly considered in all circumstances. An initial diagnostic evaluation should include complete blood count; blood culture; urinalysis; urine culture; Gram stain, protein, and glucose tests of cerebrospinal fluid (CSF); and CSF culture. Consideration should also be given to the possibility of a perinatal herpes simplex virus infection (neonatal herpes is described in more detail in Chapter 36). A chest radiograph should be obtained for any infant with increased work of breathing.

Infants age 29–90 days are at risk of a variety of invasive bacterial infections, including perinatally acquired organisms (eg, group B streptococci) or infections acquired in the household (eg, pneumococci or meningococci). Febrile infants without a focus of infection can be divided into those who appear toxic versus nontoxic, and those at low risk versus higher risk of invasive bacterial disease. As with febrile neonates, toxic children in this age group should be admitted to the hospital for parental antibiotics and close observation. In nontoxic infants, low risk has been defined as previously healthy; no focal infection on examination; white blood cell (WBC) count between 5000 and 15000/mm³; band cells < 1500/mm³; normal urinalysis; and, when diarrhea is present, < 5 WBCs/hpf. Nontoxic low-risk infants in this age group are typically treated as outpatients with close follow-up. Longstanding practice guidelines, published by Baraff and colleagues in 1993, recommend that nontoxic but high-risk infants be admitted, undergo lumbar puncture, and receive parental antibiotics. Other experts have more recently suggested that in certain circumstances these infants can be safely treated as outpatients.

In an era of increasing immunization coverage against the most commonly invasive pneumococcal serotypes, it is difficult to estimate the risk of occult

bacteremia in febrile 3–36-month-olds with no focus of infection. Nevertheless, for children 3–36 months old with temperatures $\geq 39^{\circ}\text{C}$, urine cultures should be considered in all male children younger than 6 months of age and in all females younger than 2 years of age. Chest radiographs should be performed in any child with increased work of breathing and should also be considered in children with high ($\geq 20,000/\text{mm}^3$) WBC counts but no respiratory symptoms. Depending on the child's appearance, underlying medical condition, and the height of fever, blood cultures should also be obtained. Empiric antibiotic therapy may be considered, particularly for children with temperature $\geq 39^{\circ}\text{C}$ and WBC count $\geq 15,000/\text{mm}^3$. However, in previously healthy, well-appearing, fully immunized children with reassuring laboratory studies, observation without antibiotics is safe and appropriate in many circumstances.

Treatment of Fever

Fever phobia is a term that describes parents' anxious response to the fevers that all children experience. In a recent study, 91% of caregivers thought that a fever could cause harmful effects. Seven percent of parents thought that if they did not treat the fever, it would keep going higher. Parents need to be reassured that fevers $< 41.7^{\circ}\text{C}$ cause no brain damage. Parents need to be counseled that, although fevers can occasionally ($\approx 4\%$) cause seizures, in which case their child needs to be seen, febrile seizures are generally harmless and also cause no brain damage.

Several safe and effective medications are available for the treatment of fever. Acetaminophen is indicated for children older than 2 months of age for fevers $\geq 39^{\circ}\text{C}$ or if the child is uncomfortable. Acetaminophen is given in a dosage of 15 mg/kg of body weight per dose and can be given every 4–6 hours. The other widely used antipyretic in the United States is ibuprofen. Ibuprofen is given in a dosage of 10 mg/kg of body weight per dose and can be given every 6–8 hours. Ibuprofen and acetaminophen are similar in safety and their ability to reduce fever; however, ibuprofen is longer lasting. Aspirin should not be used for treating fever in any child or adolescent, because of its association with the development of Reye syndrome (particularly during infections with varicella and influenza).

GROWTH DEFICIENCY

Growth deficiency—formerly termed failure to thrive—is deceleration of growth velocity resulting in crossing two major percentile lines on the growth chart. The diagnosis is warranted also if a child younger than age 6 months has not grown for 2 consecutive months or if a child older than age 6 months has not grown for 3 consecutive months. Growth deficiency occurs in about 8% of children.

Patterns of growth deficiency suggest, but are not specific for, different causes. In type I growth deficiency, the head circumference is preserved and the weight is depressed more than the height. This most common type results from inadequate caloric intake, excessive loss of calories, excessive intake of calories, or inability to use calories peripherally. Most such cases result from inadequate delivery of calories. This may be the result of poverty, lack of caregiver understanding, poor caregiver–child interaction, abnormal feeding patterns, or a combination of factors. Type II growth deficiency, which is associated with genetically determined short stature, endocrinopathies, constitutional growth delay, heart or renal disease, or various forms of skeletal dysplasias, is characterized by normal head circumference and proportionate diminution of height and weight. In type III growth deficiency, all three parameters of growth—head circumference, weight, and height—are lower than normal. This pattern is associated with central nervous system abnormalities, chromosomal defects, and in utero or perinatal insults.

Clinical Findings

A. INITIAL EVALUATION

The history and physical examination will identify the cause of growth reduction in the vast majority of cases (Table 8–6). The physical examination should focus on signs of organic disease or evidence of abuse or neglect: dysmorphic features, skin lesions, neck masses, adventitious breath sounds, heart murmurs, abdominal masses, and neuromuscular tone and strength. Throughout the evaluation, the physician should observe the caregiver–child interaction and the level of family functioning. Developmental screening and laboratory screening tests (complete blood count, blood urea nitrogen, creatinine, electrolytes, urinalysis, and urine culture) complete the initial office evaluation.

Table 8–6. Components of initial evaluation.

Birth history: Newborn screening result. Rule out intrauterine growth retardation, anoxia, congenital infections.
Feeding and nutrition: Difficulty sucking, chewing, swallowing. Feeding patterns. Intake of formula, milk, juice, solids.
Stooling and voiding of urine: Diarrhea, constipation, vomiting, poor urine stream.
Growth pattern: Several points on the growth chart are crucial.
Recurrent infections.
Hospitalizations.
HIV risk factors.
Developmental history.
Social and family factors: Family composition, financial status, supports, stresses. Heritable diseases, heights and weights of relatives.
Review of systems.

B. FURTHER EVALUATION

A prospective 3-day diet record should be a standard part of the evaluation. This is useful in assessing undernutrition even when organic disease is present. The diet history is evaluated by a pediatric dietitian for calories, protein, and micronutrients as well as for the pattern of eating. Additional laboratory tests should be ordered based on the history and physical examination. For example, stool collection for fat determination is indicated if a history of diarrhea suggests malabsorption. Moderate or high amounts of proteinuria should prompt work-up for nephrotic syndrome. Vomiting should suggest a gastrointestinal, metabolic, neurologic, infectious, or renal cause. The tempo of evaluation should be based on the severity of symptoms and the magnitude of growth failure.

Treatment

A successful treatment plan addresses the child's diet and eating patterns, the child's development, caregiver skills, and any organic disease. High-calorie diets and frequent monitoring (every 1 or 2 weeks initially) are essential. Acceptable weight gain varies by age (Table 8–7).

The child with growth deficiency may also be developmentally delayed because of living in an environment that fails to promote development or from the effect on the brain of nutrient deprivation. Restoring nutrition does not fully reverse the deficit but does reduce the long-term consequences.

Education in nutrition, child development, and behavioral management as well as psychosocial support of the primary caregiver is essential. If family dysfunction

Table 8-7. Acceptable weight gain by age.

Age (months)	Weight Gain (g/d)
Birth to 3	20-30
3-6	15-20
6-9	10-15
9-12	6-11
12-18	5-8
18-24	3-7

is mild, behavior modification and counseling will be useful. Day care may benefit the child by providing a structured environment for all activities, including eating. If family dysfunction is severe, the local department of social services can help provide structure and

assistance to the family. Rarely, the child may need to be temporarily or permanently removed from the home. Hospitalization is reserved for management of dehydration, for cases in which home therapy has failed to result in expected growth, for children who show evidence of abuse or willful neglect, for management of an illness that compromises a child's ability to eat, or for care pending foster home placement.

Weston JA: Growth deficiency. In Berman S (ed): *Pediatric Decision Making*, 4th ed. Mosby-Year Book, 2003.

Immunization is used either to prevent primary infection or to prevent the secondary consequences of an infection. Any assessment of the benefits of a proposed immunization program must take into account the likelihood of occurrence of infection in a defined population or specific individual, the consequence of infection, and the likelihood that the vaccination will prevent that infection. The anticipated benefit of immunization must be weighed against the risk to the individual of adverse consequences. The physician must present this information to the parents so they can give informed consent to immunization. The immunization recommendations outlined in this chapter are current but will change as technology evolves and our understanding of the epidemiology of vaccine-preventable diseases changes. The most useful sources for current information about immunization are the following:

1. *Morbidity and Mortality Weekly Report*. Published weekly by the Centers for Disease Control and Prevention (CDC), Atlanta, GA 30333. Available at <http://www.cdc.gov/mmwr>.
2. *The Red Book: Report of the Committee on Infectious Diseases*. Published at 2- to 3-year intervals by the American Academy of Pediatrics (AAP). The 2003 *Red Book* is available from the AAP. Updates are published in the journal *Pediatrics* and can be accessed at <http://www.aap.org/>.
3. CDC: National Immunization Program Information Hotline. Provides services to consumers and health care professionals regarding new vaccines, new schedules, and safety issues. 1-800-232-2522 (Spanish 1-800-232-0233). Operates from 8:00 AM to 11:00 PM Monday through Friday. Printed information can be obtained at <http://cdc.gov/nip/>.
4. CDC: Advisory Committee on Immunization Practice. Available at <http://www.cdc.gov/nip/ACIP>.

STANDARDS FOR PEDIATRIC IMMUNIZATION PRACTICES

An estimated 11,000 children are born each day in the United States, each requiring 15–19 doses of vaccine by age 18 months to be protected against 12 childhood

diseases. Although 97–98% of these children are vaccinated by or shortly after school entry, about a quarter of the 2-year-olds in this country are not fully immunized. Low immunization coverage has been attributed to difficulties in reaching the urban poor and racial and ethnic minorities, and an increasingly mobile society. However, deficiencies in the health care delivery system are also a contributor, as is limited use of recall systems. Some parents seeking immunization for their children face significant barriers; not all providers take advantage of opportunities to administer vaccines, and inadequate or absent third-party payment for immunizations further reduces coverage. The AAP recommends the following specific proven practices to improve this coverage: (1) sending caretakers reminder and recall notices, (2) using prompts during all visits, (3) periodic measurement of immunization rates, and (4) having standing orders for vaccines.

The National Childhood Vaccine Injury Act of 1986 requires that for each vaccine covered under the Vaccine Injury Compensation Program (VICP) caretakers should be advised about the risks and benefits of vaccination, in a standard manner, using the Vaccine Information Statements (VIS). In addition the CDC and AAP have the requirements and recommendations summarized later on. Each time a VICP covered vaccine is administered the current version of VIS must be provided to the nonminor patient or legal caretaker. Documentation is required in the medical record, including the vaccine manufacturer, lot number, and its date of administration and expiration. The name and address of the person administering the vaccine, VIS version and date, and site and route of administration should also be recorded.

The use of disposable syringes and needles or some other form of single-dose delivery of vaccine is preferred to minimize the opportunity for contamination. A 70% solution of alcohol is appropriate for disinfection of the stopper of the vaccine container and of the skin at the injection site. A 5% topical emulsion of lidocaine–prilocaine (EMLA) cream applied to the site of vaccination for 30–60 minutes prior to the injection minimizes the pain, especially when multiple vaccines are administered.

The manufacturer's recommendations for route and site of administration of injectable vaccines are critical

for safety and efficacy. All vaccines containing an adjuvant must be administered intramuscularly to avoid granuloma formation or necrosis. Such injections should be given at a 90-degree angle into the anterolateral thigh (not intragluteally) in infants (< age 18 months) and may be given in the deltoid or triceps in older children. A 22-gauge needle $\frac{7}{8}$ –1 $\frac{1}{4}$ inches long is recommended for children, but a 25-gauge $\frac{7}{8}$ –1 inch needle may be sufficient for young infants. Aspiration prior to intramuscular injection is suggested by many experts. Vaccines may be administered intramuscularly, subcutaneously, or intradermally. Subcutaneous injections should be administered at a 45-degree angle on the volar surface of the forearm using a 25-gauge $\frac{7}{8}$ -inch needle. Intradermal injections should be administered with the bevel facing upward using a $\frac{3}{8}$ - to $\frac{5}{8}$ -inch 25- to 27-gauge needle. A 25-gauge $\frac{3}{8}$ - to $\frac{5}{8}$ -inch needle is recommended. A separate syringe and needle should be used for each vaccine.

It is safe to administer many combinations of vaccines simultaneously without increasing the risk of adverse effects or compromising response. Up to seven injections may be necessary at the 12- to 15-month visit. (See the following individual preparations for further discussion.) Inactivated vaccines (with the exception of cholera and yellow fever) can be given simultaneously or at any time after a different vaccine. Parenteral live-virus vaccines, if not administered on the same day, should be given at least 30 days apart (eg, measles, mumps, rubella [MMR] and varicella [VAR]). Lapses in the immunization schedule do not call for reinstitution of the series. Extra doses of hepatitis B (HepB), *Haemophilus influenzae* type B (Hib), MMR, or VAR are not harmful, but repetitive exposure to tetanus vaccine beyond the recommended intervals can result in hypersensitivity reactions and should be avoided. If an immunoglobulin (Ig) or blood product has been administered, live-virus vaccination should be delayed 3–10 months, depending on the product, to avoid interference with the immune response (eg, 3 months for tetanus Ig, hepatitis A Ig, and hepatitis B Ig, 5–6 months for measles Ig or cytomegalovirus Ig (CMV Ig), 9 months for respiratory syncytial virus immunoglobulin, and 11 months for IgIV for Kawasaki disease).

With the large number of vaccine preparations available, interchangeability of vaccines is an issue. All brands of Hib conjugate, hepatitis B, and hepatitis A vaccines are interchangeable. For vaccines containing acellular pertussis antigens, it is recommended that the same brand be used, but when the brand is unknown or the same brand is unavailable, any DTaP (diphtheria, tetanus toxoids, and acellular pertussis vaccine) should be used to continue vaccination. Longer than recommended intervals between vaccinations does not reduce

final antibody titers, and thus lapsed schedules do not require restarting the series.

THE COMPOSITION OF IMMUNIZING AGENTS

ACTIVE IMMUNIZATION

The immune response to immunization varies. A small proportion of children receiving certain antigens simply do not mount a response capable of conferring protection. For this reason, every vaccine has a definable failure rate.

The immunogen is suspended or dissolved in sterile water or saline, or in more complex media such as tissue culture medium, which may contain constituents from the biologic system used to produce the immunogen. Most vaccines contain preservatives and trace amounts of antibiotics such as neomycin to prevent bacterial overgrowth. Some vaccines contain adjuvants such as aluminum hydroxide and aluminum phosphate that also help to retain the immunogen at the site of inoculation for a prolonged time, thus increasing antigenic stimulation. The theoretical cumulative toxicity of mercury in thimerosal-containing vaccines has led to the development of thimerosal-free vaccines. All vaccines routinely administered to children are now free of thimerosal.

Although the prospect is unlikely, vaccine administration could have unforeseen adverse consequences. Thus vaccines should be administered where there is ready access to emergency resuscitative equipment and drugs (eg, epinephrine, antihistamines).

PASSIVE IMMUNIZATION

Immune globulin (Ig) is derived from pooled donations of large numbers of individuals (more than 1000 per lot). Ig is prepared by alcohol fractionation, is sterile, and will not transmit any infectious agents (including hepatitis B and C viruses and HIV). Ig is a 16.5% solution consisting primarily of IgG with very small amounts of IgA and IgM.

ROUTINE CHILDHOOD & ADOLESCENT IMMUNIZATIONS

Table 9–1 sets forth a schedule of routine immunizations for normal infants and children. Table 9–2 presents recommended schedules for children who did not start vaccination at the recommended time during the first year of life. Variations from these schedules may be necessitated by epidemiologic or individual clinical circumstances. Recommendations for minimum ages and intervals between doses are shown in Table 9–2.

To complete the 2004 schedule, 19 separate injections may be required from birth to age 6 years. Combination vaccines represent a solution to the problem of large numbers of injections during any single clinic visit. Currently available combination vaccines include MMR and various combinations of Hib, HepB, and diphtheria, tetanus, and pertussis vaccines, and more recently a DTaP–HBV–IPV/Hib combination vaccine.

Combination vaccines incorporating hepatitis A, meningococcal, pneumococcal, and varicella vaccines are being developed, and a pentavalent vaccine combining MMR, HepB, and IPV will soon be available. Separate vaccines should not be combined into one syringe by the provider, unless approved by the FDA, because this could decrease the efficacy of each component vaccine.

Safe Handling of Vaccines

The numerous vaccines and other immunologic substances, such as antibody preparations and immunoglobulins for routine use by the practitioner, vary in the storage temperatures required. Vaccines that require routine freezing are VAR and oral poliovirus (OPV). Yellow fever vaccine may also be stored frozen. Product package inserts should be consulted for detailed information on vaccine storage conditions and shelf life.

SAFETY OF IMMUNIZATION

VACCINE FACTORS

The safety standards for all vaccines licensed for use in the United States are established by the Food and Drug Administration (FDA) and involve regular examination of manufacturing techniques as well as production lots of vaccine. No incidents of bacterial or viral contamination of vaccines at the factory level have been reported in the United States for decades.

HOST FACTORS

The contraindications and precautions relating to immunization presented in Table 9–3 reflect the current recommendations of the Advisory Committee on Immunization Practices and the Committee of Infectious Diseases of the AAP.

Healthy Children

Minor acute illnesses, with or without low-grade fever, are not contraindications (see Table 9–3) to vaccination, because there is no evidence that vaccination under these conditions increases the rate of adverse effects or decreases efficacy. A moderate to severe febrile illness may be a reason to postpone vaccination. Routine physical examination and temperature assessment are not necessary before vaccinating healthy infants and children.

Children with Chronic Illnesses

Most chronic diseases are not contraindications to vaccination; in fact, children with chronic diseases may be at greater risk of complications from vaccine-preventable diseases such as influenza and pneumococcal

infections. Premature infants are a good example. They should be immunized according to their chronologic, not gestational, age. Vaccine doses should not be reduced for preterm or low-birth-weight infants. The one exception to this rule may be children with progressive central nervous system (CNS) disorders. Vaccination may be deferred or avoided entirely for such children, whereas children with static CNS diseases are candidates for vaccination.

Immunodeficient Children

Congenitally immunodeficient children should not be immunized with live-virus or live-bacteria vaccines. Depending on the nature of the immunodeficiency, other vaccines are safe, but may fail to evoke an immune response. Children with cancer and children receiving high-dose corticosteroids or other immunosuppressive agents should not be vaccinated with live-virus or live-bacteria vaccines. This contraindication does not apply if the malignancy is in remission and chemotherapy has not been administered for at least 90 days. Live-virus vaccines may also be administered to previously healthy children receiving low to moderate doses of corticosteroids (defined as up to 2 mg/kg/d of prednisone or prednisone-equivalent, with a 20 mg/d maximum) for less than 14 days; children receiving low to moderate doses of alternate-day corticosteroids; children being maintained on physiologic corticosteroid therapy without other immunodeficiency; and children using only topical, inhaled, or intraarticular corticosteroids.

Contraindication of live-pathogen vaccine also applies to children with HIV infection, with the proviso that MMR is recommended at 12 months of age (after 6 months during an epidemic). The booster dose may be given as early as 1 month later, but doses given before 1 year of age should not be considered part of a complete series. VAR vaccination is recommended for CDC class N1 or A1 ($CD4 \geq 25\%$). Severely immunocompromised children with HIV infection should not receive the measles or VAR vaccines. OPV is contraindicated and is no longer recommended in the United States. The ACIP recommends routine vaccination for all children with an all inactivated poliovirus vaccine (IPV) vaccination schedule. Thus immunodeficient children should no longer be exposed to oral poliovaccine through household contacts. MMR and VAR are not contraindicated in household contacts of immunocompromised children.

Allergic or Hypersensitive Children

Hypersensitivity reactions are rare following vaccination, occurring in 1.53 cases/million doses. They are generally attributable to a trace component of the vac-

cine rather than to the antigen itself. MMR, IPV, and VAR contain microgram quantities of neomycin, and IPV also contains trace amounts of streptomycin and polymyxin B. Children with known anaphylactic responses to these antibiotics should not be given these vaccines. Trace quantities of egg antigens may be present in influenza, and yellow fever vaccines and MMR. Children who have had anaphylactic reactions to eggs should not be given these vaccines; children with less serious reactions to eggs may generally be safely immunized. If doubt exists about the nature of a child's egg sensitivity, a skin testing procedure is outlined in the *Red Book*. Some vaccines (MMR, VAR, and yellow fever) contain gelatin, a substance to which persons with known food allergy may develop an anaphylactic reaction. Skin testing before vaccination may be an option in such cases.

Special Circumstances

Detailed recommendations for preterm low-birth-weight babies; pediatric transplant recipients; Alaskan Natives/American Indians; children in residential institutions or military communities; or are refugees, new immigrants, or travelers are available in the *AAP Red Book*.

American Academy of Pediatrics: 2003 *Red Book: Report of the Committee on Infectious Diseases*, 26th ed. American Academy of Pediatrics, 2003.

Bohlke K et al: Vaccine Safety Datalink Team: Risk of anaphylaxis after vaccination of children and adolescents. *Pediatrics* 2003;112:815 [PMID: 14523172].

DIPHTHERIA

The risk for exposure to toxigenic strains of *Clostridium diphtheriae* in the United States is low (2 cases in 2002); however, diphtheria remains endemic in many countries. Diphtheria toxoid is prepared by the formaldehyde inactivation of diphtheria toxin. The protective efficacy of diphtheria toxoid has never been measured on a mass scale, but is estimated to be greater than 85%.

Preparations Available

1. Diphtheria toxoid is used only when tetanus toxoid and pertussis vaccine are both contraindicated.
2. Diphtheria-tetanus vaccine (DT) (pediatric) is used when pertussis vaccine is contraindicated. DT contains more diphtheria toxoid per dose than preparations used for adults and should not

Table 9-1. Recommended childhood and adolescent immunization schedule^{a,j}: United States, January–June 2004.

Vaccine	Range of recommended ages			catch-up vaccination					Preadolescent assessment

----- Vaccines below this line are for selected populations -----												
Hepatitis A ^h									Hepatitis A			
Influenza ⁱ				Influenza (yearly)								

^aIndicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2003, for children through age 18 years. Any dose not given at the recommended age should be given at any subsequent visit when indicated and feasible.  Indicates age groups that warrant special effort to administer those vaccines not given previously. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance on how to obtain and complete a VAERS form is available at <http://www.vaers.org> or by telephone, 800-822-7967.

^b**Hepatitis B vaccine (HepB).** All infants should receive the first dose of HepB vaccine soon after birth and before hospital discharge; the first dose also may be given by age 2 months if the infant's mother is HBsAg-negative. Only monovalent HepB vaccine can be used for the birth dose. Monovalent or combination vaccine containing HepB may be used to complete the series; 4 doses of vaccine may be administered when a birth dose is given. The second dose should be given at least 4 weeks after the first dose except for combination vaccines, which cannot be administered before age 6 weeks. The third dose should be given at

least 16 weeks after the first dose and at least 8 weeks after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before age 24 weeks. *Infants born to HBsAg-positive mothers* should receive HepB vaccine and 0.5 mL hepatitis B immune globulin (HBIG) within 12 hours of birth at separate sites. The second dose is recommended at age 1–2 months. The last dose in the vaccination series should not be administered before age 24 weeks. These infants should be tested for HBsAg and anti-HBs at age 9–15 months. *Infants born to mothers whose HBsAg status is unknown* should receive the first dose of the HepB vaccine series within 12 hours of birth. Maternal blood should be drawn as soon as possible to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 week). The second dose is recommended at age 1–2 months. The last dose in the vaccination series should not be administered before age 24 weeks.

^c**Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).** The fourth dose of DTaP may be administered at age 12 mo provided 6 mo have elapsed since the third dose and the child is unlikely to return at age 15–18 mo. The final dose in the series should be given at age ≥4 y. **Tetanus and diphtheria toxoids (Td)** is recommended at age 11–12 y if at least 5 y have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Subsequent routine Td boosters are recommended every 10 y.

^d**Haemophilus influenzae type b (Hib) conjugate vaccine.** Three Hib conjugate vaccines are licensed for infant use. If PRP-OMP (PedvaxHIB or ComVax [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. DTaP/Hib combination products should not be used for primary vaccination in infants at ages 2, 4, or 6 mo but can be used as boosters after any Hib vaccine. The final dose in the series should be given at age ≥ 12 mo.

^e**Measles, mumps, and rubella vaccine (MMR).** The second dose of MMR is recommended routinely at age 4–6 y but may be administered during any visit provided that at least 4 weeks have elapsed since the first dose and that both doses are administered beginning at or after age 12 months. Those who have not received the second dose previously should complete the schedule by the visit at age 11–12 years.

^f**Varicella vaccine (VAR).** Varicella vaccine is recommended at any visit at or after age 12 months for susceptible children (i.e., those who lack a reliable history of chickenpox). Susceptible persons aged ≥ 13 years should receive 2 doses given at least 4 weeks apart.

^g**Pneumococcal vaccine.** The heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all children aged 2–23 mo and for certain children aged 24–59 mo. The final dose in the series should be given at age ≥ 12 mo. **Pneumococcal polysaccharide vaccine (PPV)** is recommended in addition to PCV for certain high-risk groups. See *MMWR* 2000;49(No. RR-9):1–35.

^h**Hepatitis A vaccine.** Hepatitis A vaccine is recommended for children and adolescents in selected states and regions, and for certain high-risk groups. Consult local public health authority and *MMWR* 1999;48(No. RR-12):1–37. Children and adolescents in these states, regions, and high-risk groups who have not been

vaccinated against hepatitis A can begin the hepatitis A vaccination series during any visit. The two doses in the series should be administered at least 6 months apart.

ⁱ**Influenza vaccine.** Influenza vaccine is recommended annually for children aged ≥ 6 months with certain risk factors (including but not limited to asthma, cardiac disease, sickle cell disease, HIV, and diabetes), and household members of persons in groups at high risk (see *MMWR* 2003;52[No. RR-8]:1–36), and can be administered to all others wishing to obtain immunity. In addition, healthy children aged 6–23 mo are encouraged to receive influenza vaccine if feasible because children in this age group are at substantially increased risk for influenza-related hospitalizations. For healthy persons aged 5–49 y, the intranasally administered live-attenuated influenza vaccine (LAIV) is an acceptable alternative to the intramuscular trivalent inactivated influenza vaccine (TIV). See *MMWR* 2003;52(No. RR-13):1–8. Children receiving TIV should be administered a dosage appropriate for their age (0.25 mL if 6–35 mo or 0.5 mL if ≥ 3 y). Children aged ≤ 8 y who are receiving influenza vaccine for the first time should receive 2 doses (separated by at least 4 weeks for TIV and at least 6 weeks for LAIV).

^jAdditional information about vaccines, including precautions and contraindications for vaccination and vaccine shortages, is available at <http://www.cdc.gov/nip> or from the National Immunization information hotline, telephone 800-232-2522 (English) or 800-232-0233 (Spanish). Approved by the **Advisory Committee on Immunization Practices** (<http://www.cdc.gov/nip/acip>), the **American Academy of Pediatrics** (<http://www.aap.org>), and the **American Academy of Family Physicians** (<http://www.aafp.org>). Reproduced, with permission, from recommended adulthood and adolescent immunization schedule—United States, January–June 2004. *MMWR* 2004;53; Q1–4 [PMID 14733209].

be used in adults because of potentially severe local adverse reactions.

3. Tetanus–diphtheria vaccine (Td) (adult) is for use in persons age 7 years or older. It is less likely to produce local reactions while still eliciting a good immunogenic response in this population.
4. Diphtheria–tetanus–pertussis vaccine (DTP) was the standard immunizing agent for healthy children prior to availability of DTaP but may still be used when DTaP is unavailable. DTP is no longer manufactured in the United States.
5. Diphtheria–tetanus–acellular pertussis vaccine (DTaP) contains an amount of diphtheria toxins similar to DTP and is recommended as the standard immunizing agent for healthy children.
6. Diphtheria–tetanus–acellular pertussis and *H influenzae* type b conjugate vaccine (DTaP–Hib) is licensed only for the fourth dose in the DTP–Hib series (age 15–18 months). Earlier use may result in suboptimal response to the Hib component.

7. Diphtheria–tetanus–acellular pertussis–hepatitis B–inactivated poliovirus (DTaP–HepB–IPV) is licensed for use in infants ages 2, 4, and 6 months.

Dosage & Schedule of Administration

The preceding preparations are given intramuscularly in a dose of 0.5 mL. The use of jet injection may be associated with more local reactions. See Table 9–1 for the routine schedule and Table 9–2 for immunization of children not appropriately immunized during the first year of life.

Adverse Effects

No significant adverse reactions have been associated with diphtheria toxoid alone.

Antibody Preparations

Equine diphtheria antitoxin is available for the treatment of diphtheria. Dosage depends on the size and lo-

Table 9–2. Catch-up immunization schedule for children and adolescents who start late or who are >1 month behind.

Catch-up schedule for children aged 4 months–6 years				
Dose 1 (minimum age)	Minimum interval between doses			
	Dose 1 to dose 2	Dose 2 to dose 3	Dose 3 to dose 4	Dose 4 to dose 5
DTaP (6 wk)	4 wk	4 wk	6 mo	6 mo ^a
IPV (6 wk)	4 wk	4 wk	4 wk ^b	
HepB ^c (birth)	4 wk	8 wk (and 16 wk after 1st dose)		
MMR (12 mo)	4 wk ^d			
VAR (12 mo)				
Hib ^e (6 wk)	4 wk: if 1st dose given at age <12 mo 8 wk (as final dose): if 1st dose given at age 12–14 mo No further doses needed: if 1st dose given at age ≥15 mo	4 wk ^f : if current age <12 mo 8 wk (as final dose) ^f : if current age ≥12 mo and 2nd dose given at age <15 mo No further doses needed: if previous dose given at age ≥15 mo	8 wk (as final dose): this dose only necessary for children aged 12 mo–5 y who received 3 doses before age 12 mo	
PCV ^g (6 wk)	4 wk: if 1st dose given at age <12 mo and current age <24 mo 8 wk (as final dose): if 1st dose given at age ≥12 mo or current age 24–59 mo No further doses needed: for healthy children if 1st dose given at age ≥24 mo	4 wk: if current age <12 mo 8 wk (as final dose): if current age ≥12 mo No further doses needed: for healthy children if previous dose given at age ≥24 mo	8 wk (as final dose): this dose only necessary for children aged 12 mo–5 y who received 3 doses before age 12 mo	

Catch-up schedule for children aged 7–18 years		
Minimal interval between doses		
Dose 1 to dose 2	Dose 2 to dose 3	Dose 3 to booster dose
Td: 4 wk	Td: 6 mo	Td ^h : 6 mo: if 1st dose given at age <12 mo and current age <11 y 5 y: if 1st dose given at age ≥12 mo and 3rd dose given at age <7 y and current age ≥11 y 10 y: if 3rd dose given at age ≥7 y
IPV ⁱ : 4wk	IPV ⁱ : 4wk	IPV ^{b,i}
HepB: 4 wk	HepB: 8 wk (and 16 wk after 1st dose)	
MMR: 4 wk		
VAR ⁱ : 4 wk		

Note: A vaccine series does not require restarting, regardless of the time that has elapsed between doses.
^a**Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP):** The fifth dose is not necessary if the fourth dose was given after the fourth birthday.
^b**Inactivated polio vaccine (IPV):** For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if third dose was given at age ≥4 years. If both OPV and IPV were given as part of a series, a total of 4 doses should be given, regardless of the child’s current age.

cation of the diphtheritic membrane and an estimate of the patient's level of intoxication. Before using this preparation, the presence or absence of equine serum sensitivity must be determined using a scratch test of a 1:1000 dilution. If the test is positive, desensitization must be undertaken. If negative, the doses shown in Table 9-4 are suggested.

As of January 1997, diphtheria antitoxin is no longer commercially available in the United States but may be obtained from the CDC.

TETANUS

When anaerobic *Clostridium tetani* colonizes devitalized tissue, the exotoxin tetanospasmin is disseminated to inhibitory motor neurons, resulting in tetanus. Tetanus primarily occurs in unvaccinated or inadequately vaccinated persons. Despite the existence of a safe and effective vaccine, 22 cases of tetanus were reported in the United States in 2002. Tetanus-prone wounds include (1) puncture wounds, including those acquired due to body piercing, tattooing, and intravenous drug abuse; (2) animal bites; (3) lacerations or abrasions; and (4) wounds resulting from nonsterile delivery and umbilical cord care (neonatal tetanus). Intravenous drug abusers are an increasing proportion of tetanus patients in the United States, accounting for up to 20–40% of cases in some states.

Tetanus toxoid is prepared by inactivating the toxin with formaldehyde. The protective efficacy of tetanus toxoid has never been measured in any large study, but it is believed to be high.

Preparations Available

1. Tetanus toxoid (fluid) is used rarely—only when rapid immunization is desirable.
2. Tetanus toxoid adsorbed on aluminum phosphate is the standard single-antigen booster toxoid.
3. Tetanus–diphtheria vaccines (pediatric DT and adult Td) are the standard dual-antigen booster toxoids and are more often used for prophylaxis in routine wound management over the single-antigen preparation.
4. DTaP with or without Hib (discussed in the section on Hib).
5. DTaP–Hep B–IPV.

Dosage & Schedule of Administration

The preceding preparations are administered intramuscularly in a dose of 0.5 mL. See Table 9-1 for the routine schedule and Table 9-2 for vaccination of children not appropriately immunized during the first year of life. A booster dose of Td should be scheduled at age 11–12 years or at age 14–16 years and every 10 years thereafter to protect against tetanus and diphtheria.

Table 9-5 summarizes recommendations for the use of tetanus prophylaxis in routine wound management. Patients with non-tetanus-prone wounds should be boosted if more than 10 years have elapsed since their last immunization; those with tetanus-prone wounds should receive a booster if more than 5 years have elapsed.

⁴Hepatitis B vaccine (HepB): All children and adolescents who have not been vaccinated against hepatitis B should begin the hepatitis B vaccination series during any visit. Providers should make special efforts to immunize children who were born in, or whose parents were born in, areas of the world where hepatitis B virus infection is moderately or highly endemic.

⁵Measles, mumps, and rubella vaccine (MMR): The second dose of MMR is recommended routinely at age 4–6 years, but may be given earlier if desired.

⁶Haemophilus influenzae type b (Hib) conjugate vaccine: Vaccine generally is not recommended for children aged ≥ 5 years.

⁷Hib: If current age is <12 months and the first 2 doses were PRP-OMP (PedvaxHIB[®] or ComVax[®] [Merck]), the third (and final) dose should be given at age 12–15 months and at least 8 weeks after the second dose.

⁸Pneumococcal conjugate vaccine (PCV): Vaccine generally is not recommended for children age ≥ 5 years.

⁹Tetanus and diphtheria toxoids (Td): For children aged 7–10 years, the interval between the third and booster dose is determined by the age when the first dose was given. For adolescents aged 11–18 years, the interval is determined by the age when the third dose was given.

¹⁰IPV: Vaccine generally is not recommended for persons aged ≥ 18 years.

¹¹Varicella vaccine (VAR): Give 2-dose series to all susceptible adolescents aged ≥ 13 years.

Reporting adverse reactions. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance on completing a VAERS form is available at <http://www.vaers.org> or at telephone, 800-822-7967. **Disease reporting.** Suspected cases of vaccine-preventable diseases should be reported to state or local health departments. Additional information about vaccines, including precautions and contraindications for vaccination and vaccine shortages, is available at <http://www.cdc.gov/nip> or at the National Immunization information hotline, telephone 800-232-2552 (English) or 800-232-0233 (Spanish).

Reproduced, with permission, from Recommended childhood and adolescent immunization schedule United States, January–June 2004. MMWR 2004;53; Q1–4 [PMID 14733209].

Table 9–3. Guide to contraindications and precautions^a to commonly used vaccines.

Vaccine	True contraindications and precautions ^a	Untrue (vaccines can be administered)
General for all vaccines, including diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP); pediatric diphtheria-tetanus toxoid (DT); adult tetanus-diphtheria toxoid (Td); inactivated poliovirus vaccine (IPV); measles-mumps-rubella vaccine (MMR); <i>Haemophilus influenzae</i> type b vaccine (Hib); hepatitis A vaccine; hepatitis B vaccine; varicella vaccine; pneumococcal conjugate vaccine (PCV); influenza vaccine; and pneumococcal polysaccharide vaccine (PPV)	<p>Contraindications Serious allergic reaction (eg, anaphylaxis) after a previous vaccine dose Serious allergic reaction (eg, anaphylaxis) to a vaccine component</p> <p>Precautions Moderate or severe acute illness with or without fever</p>	Mild acute illness with or without fever Mild to moderate local reaction (ie, swelling, redness, soreness); low-grade or moderate fever after previous dose Lack of previous physical examination in well-appearing person Current antimicrobial therapy Convalescent phase of illness Premature birth (hepatitis B vaccine is an exception in certain circumstances) ^b Recent exposure to an infectious disease History of penicillin allergy, other nonvaccine allergies, relatives with allergies, receiving allergen extract immunotherapy
DTaP	<p>Contraindications Severe allergic reaction after a previous dose or to a vaccine component Encephalopathy (eg, coma, decreased level of consciousness; prolonged seizures) within 7 days of administration of previous dose of DTP or DTaP Progressive neurologic disorder, including infantile spasms, uncontrolled epilepsy, progressive encephalopathy: defer DTaP until neurologic status clarified and stabilized.</p> <p>Precautions Fever of >40.5°C ≤48 h after vaccination with a previous dose of DTP or DTaP Collapse or shock-like state (ie, hypotonic hyporesponsive episode) ≤48 h after receiving a previous dose of DTP/DTaP Seizure ≤3 d of receiving a previous dose of DTP/DTaP^c Persistent, inconsolable crying lasting ≥3 h ≤48 hours after receiving a previous dose of DTP/DTaP Moderate or severe acute illness with or without fever</p>	Temperature of <40.5°C, fussiness or mild drowsiness after a previous dose of diphtheria toxoid-tetanus toxoid-pertussis vaccine (DTP)/DTaP Family history of seizures ^c Family history of sudden infant death syndrome Family history of an adverse event after DTP or DTaP administration Stable neurologic conditions (eg, cerebral palsy, well-controlled convulsions, developmental delay)

Influenza	<p>Contraindication Severe allergic reaction to previous dose or vaccine component, including egg protein</p> <p>Precautions Moderate or severe acute illness with or without fever</p>	Nonsevere (eg, contact) allergy to latex or thimerosal Concurrent administration of coumadin or aminophylline
PPV	<p>Contraindication Severe allergic reaction after a previous dose or to a vaccine component</p> <p>Precaution Moderate or severe acute illness with or without fever</p>	—

^aEvents or conditions listed as precautions should be reviewed carefully. Benefits and risks of administering a specific vaccine to a person under these circumstances should be considered. If the risk from the vaccine is believed to outweigh the benefit, the vaccine should not be administered. If the benefit of vaccination is believed to outweigh the risk, the vaccine should be administered. Whether and when to administer DTaP to children with proven or suspected underlying neurologic disorders should be decided on a case-by-case basis.

^bHepatitis B vaccination should be deferred for infants weighing < 2000 g if the mother is documented to be hepatitis B surface antigen (HbsAg)-negative at the time of the infant's birth. Vaccination can commence at chronological age 1 month. For infants born to HbsAg-positive women, hepatitis B immunoglobulin and hepatitis B vaccine should be administered at or soon after birth regardless of weight. See text for details.

^cAcetaminophen or other appropriate antipyretic can be administered to children with a personal or family history of seizures at the time of DTaP vaccination and every 4–6 h for 24 h thereafter to reduce the possibility of postvaccination fever (**Source:** American Academy of Pediatrics. Active immunization. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2000).

^dMMR and varicella vaccines can be administered on the same day. If not administered on the same day, these vaccines should be separated by ≥ 28 d.

^eSubstantially immunosuppressive steroid dose is considered to be ≥ 2 wk of daily receipt of 20 mg or 2 mg/kg body weight of prednisone or equivalent.

^fMeasles vaccination can suppress tuberculin reactivity temporarily. Measles-containing vaccine can be administered on the same day as tuberculin skin testing. If testing cannot be performed until after the day of MMR vaccination, the test should be postponed for ≥ 4 weeks after the vaccination. If an urgent need exists to do skin test, do so with the understanding that reactivity might be reduced by the vaccine.

^gSee text for details.

^hIf a vaccinee experiences a presumed vaccine-related rash 7–25 d after vaccination, avoid direct contact with immunocompromised persons for the duration of the rash.

Reproduced, with permission, from MMWR Recomm Rep 2002;51(RR-2)1–35 [PMID 11848294].

Table 9-4. Suggested dosing for equine diphtheria antitoxin.^a

Site	Duration of Lesion	Toxic (?)	Dose (units)
Pharyngeal or laryngeal	≤ 48 h	NA	20,000–40,000

^aNA = Not applicable.

Adverse Effects

Significant reactions to tetanus toxoid, historically an extremely safe preparation, are very unusual. Anaphylaxis, Guillain-Barré syndrome, and brachial neuritis related to tetanus toxoid are extremely rare.

Antibody Preparations

Tetanus immune globulin (TIG) (human) is indicated in the management of tetanus-prone wounds in individuals who have had an uncertain number or fewer than three tetanus immunizations with tetanus toxoid, as described earlier. Persons fully immunized with at least three doses do not require TIG, regardless of the nature of their wounds (see Table 9-5). The dose is

300–600 units (one or two vials) intramuscularly. Part of the dose may be infiltrated locally.

Tetanus Surveillance—United States, 1998–2000. *MMWR* 2003;52 (SS-3):1 [PMID: 12825541].

PERTUSSIS

Pertussis is increasingly recognized as a disease affecting older children and adults, including fully vaccinated persons with waning immunity. Maintaining vaccination in young infants will protect against severe disease in this age group, but because booster vaccination is not approved for children over age 7 years, a reservoir of disease among those with waning immunity is a continuing problem.

Pertussis vaccines currently used in the United States for initial immunization contain purified components of pertussis antigens. The DTaP preparations have a protective efficacy of about 70–90% after three doses, depending on the source. Further epidemiologic evidence of the efficacy of pertussis vaccine is provided by the observation of a large increase in pertussis cases in Great Britain and Japan after those countries reduced or abandoned use of the vaccine.

Preparations Available

1. DTaP
2. DTaP–Hib
3. DTaP–HepB–IPV

Dosage & Schedule of Administration

Each of the available preparations is administered in a dose of 0.5 mL intramuscularly. See Table 9–1 for the routine schedule and Table 9–2 for vaccination of those children not appropriately immunized during the first year of life.

Adverse Effects

A large number of adverse reactions have been attributed to pertussis vaccine. These can be divided into three categories: local reactions, mild to moderate systemic reactions (that occur in up to half of children), and severe systemic reactions. The estimated rates of these reactions within the first 48 hours after vaccination are shown in the following discussion. The only absolute contraindications to the further use of pertussis vaccine are an anaphylactic reaction to the vaccine or a severe acute neurologic illness within 7 days after vaccination (see Table 9–3). Precaution is urged for the following associations: a convulsion within 3 days (1:1750); persistent, severe, inconsolable screaming or crying for over 3 hours (1:100); a hypotonic–hyporesponsive episode within 48 hours (1:1750); and an unexplained temperature rise to 40.5°C within 48 hours (1:330).

Controversy continues regarding the causation of serious neurologic illness by pertussis vaccine. The only large-scale case-controlled study with enough statistical power to examine this issue—the British National Childhood Encephalopathy Study (NCES)—has minimized any potential relationship.

It was calculated that although the attributable risk for serious acute neurologic injury ranges from less than 1:1,000,000 to 1:140,000, the risk for permanent brain damage is even lower, if indeed there is any risk. This reassessment, along with new studies, has led the AAP, the Canadian National Advisory Committee, and the British Pediatric Association to conclude that pertussis vaccine has not been proven to cause brain damage and to reaffirm the safety and effectiveness of routine pertussis vaccine in immunization programs for infants and children.

The 1991 National Academy of Sciences Institute of Medicine report concluded that the vaccine was causally related to only four adverse effects: acute encephalopathy, the range of excess risk being nil to 10.5 per million immunizations; shock (and an unusual shock-like state), 3.5–291 cases per 100,000 immunizations; anaphylaxis, 2 cases per 100,000 injections of DTP; and protracted, inconsolable crying, 0.1–6% of recipients. Thus, although epidemiologic evidence may be consistent with a causal relationship, pertussis toxin has no proven role in severe neurologic reactions to DTP.

DIPHTHERIA–TETANUS–PERTUSSIS VACCINE

DTP has been used for the vaccination of healthy infants against diphtheria, tetanus, and pertussis for more than 40 years. It has the combined clinical efficacy of the three single-dose preparations, and the efficacy of pertussis vaccine may even be enhanced by the adjuvant effect of the diphtheria and tetanus toxoids. DTP is no longer manufactured in the United States.

As of 1999, DTaP is the recommended vaccination against diphtheria, tetanus, and pertussis for all doses in the routine vaccination series (the DTaP–Hib combination vaccine can only be used as the fourth dose).

Two basic types of acellular (DTaP) vaccines have been studied. The T-type vaccines are produced by extraction and purification of *B pertussis* cultures. In contrast, the B-type vaccines contain combinations of pertussis toxin (PT), filamentous hemagglutinin (FHA), pertactin (Prn), and fimbriae (Fim). It has been hypothesized that immunity against PT alone may be sufficient to protect against pertussis, but this view has been challenged, and it has been claimed that antibodies against FHA, Prn, and Fim may be required for optimal protection.

Efficacy trials of various acellular pertussis vaccines in Sweden, Germany, Italy, and Senegal have established a 2- to 10-fold lower frequency of minor adverse events and reduced rates of more serious events (hypotonic–hyporesponsive episodes, persistent crying, temperatures higher than 40°C, and seizures) compared with the whole-cell vaccine, good immunogenicity, and a protective efficacy ranging from 59% to 89%. Tripedia (Aventis Pasteur, Inc) is licensed for use as the complete five-dose series. Infanrix (GlaxoSmithKline) and DAPTACEL (Aventis Pasteur) are approved for use for the first four doses of the five-dose series. Licensure of other DTaP vaccines as a five-dose series is anticipated. For children with adverse reactions in the precaution category to DTP, DTaP may be substituted. In those with a true contraindication, neither vaccine should be used. Studies are underway to evaluate the efficacy and safety of acellular vaccines containing reduced quantities of pertussis antigens for use as boosters in adolescents.

Preparations Available

1. DTaP (Tripedia [Aventis Pasteur]) contains diphtheria toxoid, tetanus toxoid, PT, and FHA.
2. DTaP (Infanrix [GlaxoSmithKline]) contains diphtheria toxoid, tetanus toxoid, PT, FHA, and Prn.
3. DTaP (DAPTACEL) contains PT, FHA, pertactin, and fimbriae types 2 and 3.

4. DTaP–Hib (TriHIBit [Aventis Pasteur]) has been licensed for use as the fourth dose (booster) in the DPT immunization series.
5. DTaP–Hep B–IPV (Pediarix) contains PT, FHA, and pertactin and is licensed for the first three doses beginning at 2 months of age.

Dosage & Schedule of Administration

DTaP is administered in a dose of 0.5 mL intramuscularly. See Table 9–1 for the routine schedule and Table 9–2 for the procedure in children not immunized during the first year. The ACIP/AAP and AAFP recommend a series of five vaccinations before age 7 years (at 2, 4, 6, and 15–18 months and at 4–6 years). Whenever feasible, the same brand of DTaP should be used for all doses.

Adverse Effects

Local reactions, fever, and other mild systemic effects occur with one fourth to two thirds the frequency noted following whole-cell DTP vaccination. Moderate to severe systemic effects, including fever of 40.5°C, persistent inconsolable crying lasting 3 hours or more, and hypotonic–hyporesponsive episodes, are less frequent than with whole-cell DTP. These are without sequelae. Severe neurologic effects have not been temporally associated with DTaP vaccinations in use in the United States. Data are limited regarding differences in reactivity among currently licensed acellular pertussis vaccines. With all currently licensed DTaP vaccines, reports of the frequency and magnitude of substantial local reactions at injection sites have increased with increasing dose number (including swelling of the thigh or entire upper arm after receipt of fourth and fifth doses).

POLIOMYELITIS

Vaccines directed against poliovirus infections have eliminated the naturally occurring disease in developed countries. In the United States, the number of reported cases of paralytic poliomyelitis has fallen from more

than 18,000 in 1954 to 0–10 per year currently. As of November 2003, 556 polio cases were reported worldwide since the beginning of the year, from the Indian subcontinent (India, Pakistan, and Afghanistan), the Middle East (Lebanon and Egypt), and west Africa (Burkina Faso, Nigeria, Chad, Togo, Niger, and Ghana). The World Health Organization (WHO) has reset the target of 2008 for global eradication of poliomyelitis. The injectable poliovirus vaccine of enhanced potency (IPV-E), which has a higher content of antigens than the old IPV, is the only vaccine against poliomyelitis available in the United States.

IPV is incapable of causing poliomyelitis by virtue of being inactivated, whereas OPV can do so rarely. The rate of this in the United States was 1 case of paralytic disease per 760,000 first doses of OPV distributed. Ninety-three percent of recipient cases and 76% of all vaccine-associated paralytic poliomyelitis (VAPP) occurred after administration of the first or second dose of OPV. The risk of paralysis in the immunodeficient recipient may be as much as 6800 times that in normal subjects. However, IPV cannot protect against intestinal infection with wild virus, as OPV does. IPV cannot produce so-called secondary vaccination of close contacts when vaccine-strain virus is shed into the environment. IPV, however, produces a much higher serologic response than OPV, a higher booster response at lower prevaccination levels, and an equivalent mucosal response. IPV has the practical advantage of not requiring freezing for storage, as OPV does. On the basis of these data, the ACIP recommends that all children in the United States receive an all-IPV schedule (four doses of IPV). However, the mass administration of OPV requires no needles and syringes.

Completely immunized adult visitors to areas of continuing wild-type poliovirus circulation should receive a booster dose of IPV-E. Unimmunized or incompletely immunized adults and children should have received two (preferably three) doses of the vaccine prior to travel to these and other areas with circulation of wild-type or vaccine-type virus.

Preparations Available

1. Inactivated IPV-E (IPOL) [Aventis Pasteur] contains antigens of types 1, 2, and 3 poliovirus.
2. DTaP–HepB–IPV (PEDIARIX), [GlaxoSmithKline Biologicals] contains diphtheria and tetanus toxoids and acellular pertussis adsorbed (DTaP), hepatitis B (HepB), and inactivated poliovirus vaccine (IPV-E)

Dosage & Schedule of Administration

IPV-E is administered in a dose of 0.5 mL subcutaneously. The DTaP–HepB–IPV combination vaccine

can be used in the primary series at 2, 4, and 6 months and can be used to complete the primary series. It can be administered with Hib and pneumococcal conjugate (PCV) vaccines at separate sites, but is not approved for the fourth dose of IPV or fourth and fifth doses of DTaP.

Adverse Effects

IPV has essentially no adverse effects associated with it other than possible rare hypersensitivity reactions to trace quantities of antibiotics. The DTaP–HepB–IPV combination has similar rates of local and systemic adverse responses to three doses administered separately except for fever, which is higher in the combination vaccinated children.

MEASLES

In the 20 years after the 1963 introduction of measles vaccination in the United States, the annual number of reported cases decreased from 500,000 to fewer than 1500. However, between 1989 and 1991 there was a resurgence of measles, with 55,622 cases reported. The major reasons for the increase in cases and the resulting deaths were failure to provide vaccine to preschool children aged 15 months or older, the presence in the community of susceptible children younger than age 15 months, and the growing number of appropriately vaccinated but nonimmune individuals (primary vaccine failures: 2–10%) in schools and colleges. These reasons have led to recommendations for a two-dose vaccination schedule at 12–15 months and at 4–6 years of age.

Given the efficacy rate of the current vaccine (> 95%), the elimination of indigenous measles from the Americas is an attainable public health goal. Only 116 measles cases (1 death) were reported in the United States during 2001. It is believed there is no endemic circulation of measles in the Americas. In 2002 only Venezuela and Columbia had indigenous transmission.

Recently reports in the medical and lay press have suggested a possible association between MMR vaccination, autism, and gastrointestinal inflammation. This association, has been refuted because of the limited number of patients studied, methods of case and control selection, and means of determining developmental regression. Several large epidemiologic studies subsequently found no association between MMR vaccination and either autism or bowel inflammation. Also, no evidence has been found to support the separate administration of measles, mumps, and rubella vaccines (as opposed to the MMR combination). However, the influence of the lay press is most profound in the United Kingdom, where low vaccination rates with measles vaccine has led to a resurgence of measles, with a distinct possibility that it will become an endemic disease in the United Kingdom.

Preparations Available

The Moraten strain is a live attenuated vaccine derived from the Edmonston B strain after multiple passages in chick embryo tissue culture. The Moraten strain is available as a monovalent vaccine or in combination with rubella vaccine (MR) or in the MMR combination.

Dosage & Schedule of Administration

A. ROUTINE VACCINATION

Measles vaccine should be given as MMR at 12–15 months and again at 4–6 years of age. A dose of 0.5 mL, whether alone or in combination, should at least be given subcutaneously. The second dose of MMR is recommended at school entry to help prevent school-based measles outbreaks. Children not reimmunized at school entry should receive their second MMR by 11–12 years of age. If an infant receives the vaccine before 12 months of age, two doses are required to complete the series, the first after at least 12 months of age and the second at least 1 month later. Ig interferes with the immune response to the attenuated vaccine strains of MMR. Therefore, MMR immunization after Ig administration should be deferred by 3 to 11 months, depending on the type of Ig product received. Consult the American Academy of Pediatrics' 2003 *Red Book* for specific recommendations.

B. VACCINATION OF TRAVELERS

People traveling abroad should be immune to measles. In high-risk areas, age at primary vaccination should be as soon as possible after the first birthday (ie, at 12 months). However, younger infants 6–11 months of age traveling to high-risk areas should receive the monovalent vaccine followed by two doses at 12–15 months given at least 4 weeks apart, and should complete the series at 4–6 years.

C. REVACCINATION UNDER OTHER CIRCUMSTANCES

Persons entering college and other institutions for education beyond high school, medical personnel beginning employment, and persons traveling abroad should have documentation of immunity to measles, defined as receipt of two doses of measles vaccine after their first birthday, birth before 1957, or a documented measles history or immunity.

D. OUTBREAK CONTROL

A community outbreak is defined as a single documented case of measles. Control depends on immediate protection of all susceptible persons (defined as persons who have no documented immunity to measles in the affected community. In the case of unvaccinated individuals, the following recommendations hold: (1) age 6–11 months, monovalent measles vaccine (or MMR) if cases are occurring in children younger than age 1 year, followed by two doses of MMR at age 12–15 months and again at age 4–6 years; and (2) age 12 months or older, MMR followed by revaccination at 4–6 years. A child with an unclear or unknown vaccination history should be reimmunized with MMR. Anyone with a known exposure who is not certain of receiving two doses of MMR should receive an additional dose. Unimmunized persons who are not immunized within 72 hours of exposure should be excluded from contact with potentially infected persons until at least 2 weeks after the onset of rash of the last case of measles.

Measles vaccination is contraindicated in pregnant women, women intending to become pregnant within the next 28 days, immunocompromised persons (except those with asymptomatic HIV or those with HIV infection who are not severely immunocompromised), and persons with anaphylactic egg or neomycin allergy. It is also contraindicated in children receiving high-dose steroid therapy (greater than or equal to 2 mg/kg/d, or 20 mg/day total, for longer than 14 days) with the exception of those receiving physiologic replacement doses. In these patients, an interval of 1 month between cessation of steroid therapy and vaccination is sufficient. Leukemic patients who have been in remission and off chemotherapy for at least

3 months can receive MMR safely. Children with minor acute illnesses (including febrile illnesses), nonanaphylactic egg allergy, or a history of tuberculosis should be immunized. Monovalent measles or MMR may be safely administered simultaneously with other routine pediatric immunizations.

Adverse Effects

Between 5% and 15% of vaccinees become febrile to 39.5°C or higher about 6–12 days following vaccination, lasting approximately 1–2 days, and 5% may develop a transient morbilliform rash. Transient thrombocytopenia occurs in 1:25,000 to 1:100,000 persons. Encephalitis and other CNS conditions such as aseptic meningitis and Guillain-Barré syndrome are reported to occur at a frequency of 1 case per 3 million doses in the United States. This rate is lower than the rate of these conditions in the general unvaccinated population, implying that the relationship between them and measles vaccination may not be causal. MMR vaccination is associated with an increased risk of febrile seizures 8 to 14 days after vaccination, but no subsequent long-term complications have been seen. A recent study found an increase in female mortality in Guinea Bissau after receiving the high titered measles vaccine at less than 6 months of age.

Antibody Preparations

If a child is seen within 72 hours after exposure, vaccination is the preferred method of protection. If vaccine is contraindicated, Ig, given intramuscularly at a dose of 0.25 mL/kg (0.5 mL/kg in immunocompromised patients; maximum dose in either circumstance is 15 mL), is effective in preventing or modifying measles if it is given within 6 days after exposure. Measles vaccine should be given 5 months later to children receiving the 0.25 mg/kg dose and 6 months later for the higher dose. For children receiving regular IgIV, a dose of 100–400 mg/kg should be adequate for measles prophylaxis for exposures occurring within 3 weeks of the last dose.

MUMPS

Mumps vaccine has dramatically reduced this infection and its complications in the United States, from 185,691 cases in 1967 to 226 cases in 2001. Most reported cases of mumps are in children age 5–14 years.

Preparations Available

The Jeryl Lynn Strain is the only mumps vaccine available in the United States. It is prepared from virus isolated from a child and passaged in embryonated eggs and in chick embryo tissue culture. The vaccine is available as a monovalent vaccine and, in its preferred form, in the MMR combination.

Dosage & Schedule of Administration

Mumps vaccine is given to children in the combination vaccine MMR at age 12–15 months and again at age 4–6 years. Despite the greater than 95% efficacy of the mumps vaccine, outbreaks have been reported in highly vaccinated populations. Most cases were attributed to primary vaccine failure. It is hoped that the two-dose schedule (with the second dose given before school entry) will prevent school-based outbreaks. As monovalent vaccine, it is safe and effective if given after the first birthday. The dose of either monovalent or MMR vaccine is 0.5 mL subcutaneously. Use of the monovalent vaccine is limited to susceptible individuals with proven immunity to the other constituents of MMR. Revaccination with mumps vaccine or any of the vaccines in MMR is not harmful; therefore, anyone with an unclear vaccination history should be immunized with MMR. The same recommendations and contraindications apply to mumps vaccine as to measles vaccine, except as relates to travel. Because maternal antibody to mumps is present in most infants, and the disease is not severe in infancy, infants younger than 12 months of age traveling to endemic countries need not routinely be given mumps vaccine (see previous discussion).

Adverse Effects

Reactions after mumps vaccination are rare and include parotitis, low-grade fever, and orchitis. In 1989, a nationwide surveillance of neurologic complications after a mumps vaccine was conducted in Japan. At least 311 cases of mild aseptic meningitis (96 had vaccine-type mumps virus in the cerebrospinal fluid) occurred among 630,157 recipients. There were no sequelae. Aseptic meningitis may be more common than was previously suspected (1–4 cases per 10,000 vaccinations). This rate was also found in Brazil but not in Germany, where different vaccine strains were used.

RUBELLA

The use of rubella vaccine represents an important deviation from the public health philosophy underlying the other vaccines discussed in this chapter. It is not intended to protect individuals from rubella infection but rather to prevent the serious consequences of rubella infection during pregnancy: miscarriage, fetal demise, and congenital rubella syndrome (CRS). CRS is a group of birth defects including deafness, cataracts, heart defects, and mental retardation. In the United States, the approach has been to vaccinate young children. The intent is to reduce transmission to susceptible women of childbearing age via a herd immunity effect. Immunity lasts for at least 15 years. Other countries, notably the United Kingdom, vaccinate pubertal girls (age 11–14 years). The relative efficacy of these two strategies in the prevention of CRS is unclear.

With the use of rubella vaccines since 1970, rubella incidence rates have declined more than 99%. Twenty-three cases were reported during 2001 in the United States. However, approximately 10% of young adults are now susceptible to rubella. Outbreaks of rubella continue to occur in the United States, despite widespread use of MMR, but the epidemiology of rubella transmission has changed in the past decade. Currently most cases of rubella are seen in foreign-born adults, and outbreaks have occurred in poultry and meat processing plants that employ many foreign-born workers. Similarly, 92% of infants with CRS during 1997–1999 were born to foreign-born mothers.

Preparations Available

The RA 27/3 strain is the only vaccine available in the United States. It is grown in human diploid cells. The RA 27/3 strain is available as a monovalent vaccine, in combined preparations with measles vaccine, or in measles and mumps vaccines. In most circumstances, MMR vaccination is the recommended means of immunizing against rubella.

Dosage & Schedule of Administration

Either the monovalent or combined form should be administered subcutaneously in a dose of 0.5 mL. Current practice is to administer MMR vaccine at age 12–15 months and again at 4–6 years. A person can be considered immune only with documentation of either serologic immunity to rubella or vaccination with at least one dose of rubella vaccine after age 1 year, or if born before 1957. A clinical diagnosis of rubella is unacceptable. Susceptible pubertal girls and postpubertal women identified by premarital or prenatal screening should also be immunized. Whenever rubella vaccination is offered to a woman of childbearing age, pregnancy should be ruled out and the woman advised to prevent conception for 3 months following vaccination. If a pregnant woman is vaccinated or becomes pregnant within 3 weeks of vaccination, she should be counseled regarding the risk to her fetus. It has been estimated that the risk of serious malformations attributable to giving the RA 27/3 vaccine to pregnant women is from zero to 1.6%. This is much less than the 20–85% risk of CRS after maternal infection in the first trimester of pregnancy. All susceptible adults in institutional settings (including colleges), day care center personnel, military personnel, and hospital and health care personnel should be immunized.

Adverse Effects

In children, adverse effects from rubella vaccination are very unusual. Between 5% and 15% of children develop rash, fever, or lymphadenopathy 5–12 days after vaccination. Rash also occurs alone or as a mild rubella illness in 2–4% of adults. Arthralgia and arthritis occur in 10–25% of adult vaccinees, as opposed to only 0–2% of 6- to 16-year-old vaccinees. Chronic arthritis may be causally related to RA 27/3 vaccinations and occurs more often in women age 45 or older, starting 10–11 days after the vaccination and lasting for up to a year. Rare complications include peripheral neuritis and neuropathy, transverse myelitis, and diffuse myelitis.

HAEMOPHILUS INFLUENZAE TYPE B INFECTION

The first vaccine licensed against *Haemophilus influenzae* type b in the United States, composed of the capsular polysaccharide of *H influenzae* type b polyribosyl ribitol phosphate (PRP), was moderately effective in preventing *H influenzae* type b disease in children older than 18 months of age. Conjugation of the PRP with protein carriers confers T-cell–dependent characteristics on the vaccine and enhances the immunologic response to PRP in infancy. Since 1993, the incidence of *H influenzae* type b invasive disease in children younger than age 5 years has declined 99% in the United States.

Three conjugate vaccines are currently available in the United States (Table 9–6). Studies in infants ages 2–6 months demonstrated the immunogenicity of each of these vaccines except DTaP-Hib, which is approved only for the fourth (booster) dose. A geometric mean titer (GMT) of 1 mcg/mL of antipolysaccharide antibody 3 weeks postvaccination has correlated with long-term protection from invasive disease. After three doses at ages 2, 4, and 6 months, each of the three vaccines (see Table 9–6) produces protective levels of antibody. Regardless of the vaccine used in the primary series, booster vaccination of children older than age 12 months with any licensed vaccine elicits an adequate response. Furthermore, each vaccine is immunogenic as a single dose given after age 15 months. Limited information on interchangeability of different *H influenzae* type b vaccines suggests that any combination of the *H influenzae* type b conjugate vaccines will provide adequate protection.

If PRP-OMP is administered as only part of a primary series, the recommended number of doses to complete the series is determined by the other Hib conjugate vaccine.

Table 9-6. *Haemophilus influenzae* type b conjugate vaccines for children.

Vaccine	Trade Name and Manufacturer	Polysaccharide	Linkage	Protein Carrier
HbOC	HibTITER (Wyeth-Lederle-Praxis)	Small	None	CRM ¹⁹⁷ mutant <i>Corynebacterium diphtheriae</i> toxin protein
PRP-OMP	PedvaxHIB (Merck & Co.)	Medium	Thioether	<i>Neisseria meningitidis</i> outer membrane protein complex
PRP-T	ACTHIB (Aventis Pasteur)	Large	Six-carbon	Tetanus toxoid
PRP-T DTaP	TriHIBit (Aventis Pasteur)	Large	Six-carbon	See above for PRP-T
PRP-OMP- Hepatitis B	Comvax (Merck & Co.)	Medium	Thioether	See above for PRP-OMP

Because of the differences in the immunogenic response and the different regimens used in these trials, the recommendations for use of HbOC, PRP-T, and PRP-OMP differ and are summarized in Table 9-7. Regardless of the regimen implemented, it is crucial to complete the series, because cases of invasive *H influenzae* type b disease have been described in partially vaccinated children. Given the increased risk of disease in early infancy among Native American and Alaskan Native children, the use of PRP-OMP for the first dose in the series is recommended because high antibody responses occur after the first dose in this vaccine.

The FDA has licensed PRP-OMP-HepB (Comvax) for use in infants as young as 6 weeks of age. Antibody

responses are comparable to those for HbOC and DTP or PRP-OMP and HepB administered separately. In addition, PRP-T-DTaP (TriHIBit) has been licensed for use as a booster. Use in the primary series may result in insufficient titers to Hib. If the exact conjugate vaccine previously administered is unknown, it is recommended that at least three doses of conjugate vaccine be administered to children between ages 2 and 6 months. Unvaccinated or partially vaccinated children younger than age 2 years who experience invasive *H influenzae* type b disease should receive a complete series of vaccinations. Children older than age 2 years mount an adequate immune response to invasive *H influenzae* type b disease and do not require further vaccinations. Unim-

Table 9-7. Schedule for *Haemophilus influenzae* type b conjugate vaccine administration.

Vaccine	Age at First Vaccination	Primary Series (Same Vaccine If Possible)	Booster (Any Conjugate Vaccine)
HbOC or PRP-T ^a	2-6 mo	Three doses 2 mo apart	12-15 mo
	7-11 mo	Two doses 2 mo apart	12-19 mo
	12-14 mo	One dose	2 mo later
	15-59 mo	One dose	...
PRP-OMP ^b	2-6 mo	Two doses 2 mo apart	12-15 mo
	7-11 mo	Two doses 2 mo apart	12-18 mo
	12-14 mo	One dose	2 mo later
	15-59 mo	One dose	...

^aA booster dose of DTP or DTaP should be administered at 4-6 y of age, before kindergarten or elementary school. This booster is not necessary if the fourth vaccinating dose was administered after the fourth birthday. DTaP-Hib (TriHIBit) is only approved for the fourth (booster) dose.

^bComvax may be administered by the same schedule for primary immunization as PRP-OMP. It should only be used in infants of hepatitis B-negative mothers. If the series is started late, three doses should be given if started in infants (≤ 10 mo), two doses if started at 11-14 mo, and one dose if started at age 15-71 mo. However, three doses of hepatitis B vaccine are required regardless of age of starting immunization.

munized children age 5 years or older with a chronic illness known to be associated with invasive *H influenzae* type b disease, such as sickle cell anemia and asplenia, should be given a single dose of any of the licensed conjugate vaccines.

Preparations Available

See Table 9–6.

Dosage & Schedule of Administration

The dose for all preparations is 0.5 mL, given intramuscularly.

Adverse Effects

Fewer than 5% of those immunized develop systemic reactions (including fever) to the vaccine. About 25% of recipients develop mild transient local reactions. Adverse effects following the second dose of PRP-OMP are more frequent than following the first dose and more frequent following the third dose of HbOC than following the first two doses.

PNEUMOCOCCAL INFECTIONS

Streptococcus pneumoniae is the most common cause of invasive bacterial infection in children, with most invasive disease occurring in children younger than age 2 years. Prior to the year 2000, the available pneumococcal polysaccharide vaccine had an overall efficacy of 57%, was not effective in children younger than 2 years, and therefore was only indicated for certain high-risk children age 2 years or older. However, the seven most common serotypes of pneumococcus that cause invasive disease in children in the United States have now been linked to a nontoxic but immunogenic variant of diphtheria toxin. In the largest efficacy and safety trial, the heptavalent pneumococcal conjugate vaccine (PCV7) was 97.4% effective at preventing invasive disease by vaccine serotypes. Additionally, the reduction in total invasive pneumococcal infections in children who had received one or more vaccine doses, regardless of pneumococcal serotype, was 89.1%. PCV7 was much less effective in preventing acute otitis media. Although the vaccine's effect on invasive disease in American Indian children was difficult to demonstrate, PCV7 has been shown to reduce the incidence of invasive disease and carriage of antibiotic-resistant

pneumococci in day care centers. Postlicensure, its routine implementation in infancy has led not only to a remarkable 92% reduction in invasive disease in children younger than 2 years, but also a 46% reduction against vaccine type in adults and 47% effectiveness against disease in the elderly caused by the types in the vaccine.

Subsequently studies with a heptavalent pneumococcal polysaccharide-meningococcal outer membrane protein complex conjugate vaccine (PnOMPC) in Finland demonstrated an overall vaccine efficacy of 56% against acute otitis media (AOM) in children age 6–24 months, with vaccine serotype-specific efficacy ranging from 37–82%, but a trial in 383 Dutch children with recurrent AOM showed no efficacy in this population. A trial in South Africa of a nonavalent pneumococcal polysaccharide vaccine (PnCRM9) reduced invasive disease by 83% in children without HIV and 65% in those with HIV. However, it only reduced radiographic pneumonia by 20%.

Universal immunization of all infants with PCV7 is now recommended, with four doses given at 2, 4, 6, and 12–15 months of age. Children age 24 to 59 months at high risk of invasive pneumococcal disease should receive both the conjugate vaccine (PCV7) and the 23-valent polysaccharide vaccine (23PS). Although definitive data about using PCV7 and 23PS in combination are not available for invasive disease, it does reduce AOM in one study. It is also known that immunization with PCV7 induces immunologic memory that is boosted by some of the serotypes in 23PS. Additionally, 23PS provides coverage against a broader range of serotypes than does PCV7. Recommendations for using PCV7 and 23PS in high-risk children age 24–59 months are found in Table 9–8. Children at high risk of invasive pneumococcal disease include those with chronic cardiovascular, pulmonary (cystic fibrosis but not asthma), or liver diseases, and those with anatomic and functional asplenia (including sickle cell disease), nephrotic syndrome, chronic renal failure, diabetes mellitus, cerebrospinal fluid leak, or immunosuppression (including those with HIV infection, complement deficiencies, malignancies, prolonged use of steroids, and organ transplants). Penicillin prophylaxis of patients with sickle cell disease should be continued regardless of vaccination with PCV7 or 23PS. Insufficient data are available to provide definitive recommendations for pneumococcal vaccination for immunocompromised children 5 years and older. Providers can consider giving one dose each of PCV7 and 23PS, separated by 6 to 8 weeks, to older children at risk of invasive pneumococcal disease. An additional 23PS booster should be given 3–5 years later. Additionally, because otherwise healthy Alaskan Natives and American Indians are at moderately increased risk of invasive pneu-

Table 9–8. Recommended pneumococcal (PCV7 and 23PS) immunization of children at high risk of invasive pneumococcal disease.

Age	Previous Doses	PCV7	23PS
2–6 mo	None	3 doses, 6–8 wk apart 1 booster dose at 12–15 mo	1 dose at 24 mo ^a 2nd dose 3–5 y after the first dose of 23PS
7–11 mo	None	2 doses, 6–8 wk apart 1 booster dose at 12–15 mo	1 dose at 24 mo ^a 2nd dose 3–5 y after the first dose of 23PS
12–23 mo	None	2 doses, 6–8 wk apart	1 dose at 24 mo ^a 2nd dose 3–5 y after the first dose of 23PS
24–59 mo	4 doses of PCV7	None	1 dose, 6–8 wk after last dose of PCV7 2nd dose 3–5 y after the first dose of 23PS
24–59 mo	1–3 doses of PCV7	1 dose, 6–8 wk after the last dose of PCV7	1 dose, 6–8 wk after last dose of PCV7 2nd dose 3–5 y after the first dose of 23PS
24–59 mo	1 dose of 23PS	2 doses, 6–8 wk apart, starting 6–8 wk after 23PS dose	1 dose 3–5 y after the first dose of 23PS
24–59 mo	None	2 doses, 6–8 wk apart	1 dose, 6–8 wk after last dose of PCV7 2nd dose 3–5 y after the first dose of 23PS

^aThe dose of 23PS should be given at least 8 weeks after the last dose of PCV7.

Modified, with permission, from American Academy of Pediatrics. Pneumococcal infections. In Pickering LK (ed): *Red Book 2003 Report of the Committee on Infectious Diseases*, 20th ed. American Academy of Pediatrics, 2003, p 498.

mococcal disease, they also may benefit from receiving both PCV7 and 23PS.

Preparations Available

Pneumococcal conjugate vaccine (Prevnar) is composed of seven purified capsular polysaccharides, each coupled to a nontoxic modified diphtheria toxin. Serotypes included in the vaccine and potentially cross-reacting serotypes accounted for 86% of bacteremia, 83% of meningitis, and 65% of AOM cases caused by pneumococcus during the period 1978–1994. The vaccine is licensed for use in children age 6 weeks to 9 years.

The 23-valent polysaccharide vaccine (Pneumovax) is only for use in persons 2 years and older. It contains 25 µg of each purified capsular polysaccharide antigen of 23 serotypes of *S pneumoniae*. These 23 types cause 88% of cases of pneumococcal bacteremia and meningitis in adults and nearly 100% of those in children in the United States. Cross-reactive antibody responses may protect against an additional 8% of bacteremic serotypes in adults.

Dosage & Schedule of Administration

PCV7 is given as a 0.5-mL intramuscular dose. The first dose can be given as early as 6 weeks of life, with a recommended vaccination schedule of 2, 4, 6, and

12–15 months. Children who receive their first dose of PCV7 at 7–11 months of age should receive two doses separated by 6–8 weeks, followed by a booster dose at 12–15 months. Children who receive their first dose of PCV7 at 12–23 months require two doses total, separated by 6–8 weeks. PCV7 may be given concurrently with the other routinely recommended childhood immunizations.

Children older than 23 months at high risk of invasive pneumococcal disease should receive both PCV7 and 23PS, as outlined in Table 9–8. PCV7 and 23PS should not be given simultaneously, and when both are indicated, they should be given 6–8 weeks apart. The dose of 23PS is 0.5 mL, given intramuscularly. If splenectomy or immunosuppression can be anticipated, vaccination should be done at least 2 weeks beforehand. Revaccination with 23PS may be considered after 3–5 years in children at high risk of fatal pneumococcal infection.

Adverse Effects

The most common adverse effects associated with PCV7 administration are fever, induration, and tenderness at the site of the injection. When it is given simultaneously with DTaP, no increase in febrile seizures has been seen when compared with administration of DTaP alone. Vaccination with PCV7 is contraindi-

cated for individuals with a known hypersensitivity to any component of the vaccine.

With 23PS, 50% of all vaccine recipients develop pain and redness at the injection site. Fewer than 1% develop systemic side effects such as fever and myalgia. Anaphylaxis is rare. The vaccine is contraindicated during pregnancy.

HEPATITIS A

In 2001, approximately 11,000 cases of hepatitis A infection were reported in the United States. This represents a substantial decline from the 32,000 cases reported in 1995, the year hepatitis A vaccine (HepA) was first licensed. However, because the incidence of hepatitis A infection varies from year to year and from region to region in the United States, continued surveillance will be needed to determine if the decline in

disease will be sustained, and if the decline is the result of HepA vaccination strategies.

Children are known to be an important source of transmission of hepatitis A through a community. Approximately one third of all reported cases occur in children younger than 15 years of age. Additionally, the likelihood of being symptomatic from infection varies inversely with age, with approximately 70% of children younger than 6 years of age being asymptomatic when infected. The predominance of a fecal-oral route of transmission, the less than vigilant hand-washing among young children, and their preponderance of asymptomatic infections all combine to create a potent mechanism for spread of hepatitis A infection.

National hepatitis A vaccination recommendations were revised in 1999, with increased emphasis on childhood immunization as a means of hepatitis A control. Routine vaccination of children 2 years and older is recommended for areas with greater than twice the national average of hepatitis A infection (primarily the western United States), and vaccination should be considered in areas with disease rates exceeding (but less than twice) the national average. Although the long-term effect of this strategy is unknown, one community with recurrent hepatitis A epidemics documented a 94% reduction in infections after instituting routine childhood vaccination, and disease incidence declined in both children and adults.

In addition to the routine immunization of children in areas of increased disease incidence, HepA is indicated for the following groups: (1) international travelers (except to Canada, Western Europe, Japan, Australia, and New Zealand), (2) children with chronic hepatitis B or hepatitis C infections or other chronic liver disease, (3) children with clotting factor disorders, (4) homosexual or bisexual males, (5) persons with an occupational exposure to hepatitis A, and (6) illegal drug users.

Vaccine efficacy is 94–100% at protecting against clinical hepatitis A. HepA is not approved for use in children younger than 2 years old.

Preparations Available

Two inactivated hepatitis A vaccines are currently available for children: Havrix (GlaxoSmithKline) and Vaqta (Merck). Havrix contains a preservative (2-phenoxyethanol), but Vaqta does not. A combination vaccine against hepatitis A and hepatitis B (Twinrix, GlaxoSmithKline) is also available, but is only licensed in the United States for persons 18 years and older.

Dosage & Schedule of Administration

Havrix is available in two formulations. For individuals between the ages of 2 and 18 years, 720 ELU (ELISA

units) is administered in two doses of 0.5 mL, separated by 6–12 months. For persons older than 18 years, a higher dose (1440 ELU) is recommended, also in two doses.

Vaqta also has two formulations. For persons 2–17 years of age, two doses of 25 ELU (0.5 mL) are given, separated by 6–18 months. Individuals older than 17 years old are given 50 ELU (1.0 mL) in a two-dose schedule.

Both vaccines should be stored and shipped at 2–8°C and should not be frozen. HepA is given intramuscularly, and may be given simultaneously with other vaccines, including hepatitis B vaccine.

Adverse Effects

Adverse reactions are mild and consist of pain and induration at the injection site, feeding problems, and headache. The vaccine should not be administered to children with hypersensitivity to 2-phenoxyethanol (in the case of Havrix) or alum (for both preparations).

Antibody Preparations

For children younger than age 2 years at increased risk of hepatitis A infection (eg, those traveling to endemic areas or those with clotting factor disorders), Ig should be used as preexposure prophylaxis. The recommended dosages are 0.02 mL/kg in a single intramuscular dose if the duration of exposure is likely to be less than 3 months and 0.06 mL/kg if exposure is likely to be more than 3 months. For long-term prophylaxis of persons not eligible for vaccination, prophylactic doses can be repeated every 5 months.

Postexposure prophylaxis with Ig should be given to previously unvaccinated persons exposed within the prior 2 weeks to hepatitis A. Postexposure Ig is recommended for household or sexual contacts of persons with serologically confirmed hepatitis A, and for day care staff and attendees in outbreak situations. Individuals given one dose of HepA at least 1 month before exposure do not need Ig. When indicated, a single intramuscular dose of Ig (0.02 mL/kg) should be given as soon as possible, but not more than 2 weeks after the last exposure. If HepA is also indicated, it may be given simultaneously with Ig, but at a different anatomic injection site.

HEPATITIS B

Hepatitis B vaccine (HepB), when given with hepatitis B immune globulin (HBIG), is 95% effective in preventing vertical (perinatal) transmission of hepatitis B virus. HepB alone is 90–95% effective in preventing horizontal hepatitis B transmission in susceptible children and adults. Between 1982 and 2002 an estimated 40 million children and 30 million adults in the United States received hepatitis B vaccine. The use of HepB is also increasing internationally, with 126 (66%) of 191 World Health Organization member countries reporting childhood HepB vaccination programs.

All pregnant women should be routinely screened for hepatitis B surface antigen (HBsAg). Women with positive reactions are highly likely to transmit the infection to their offspring. Infants born to HBsAg-positive mothers should receive both HepB and HBIG immediately after birth. Infants for whom the maternal HBsAg status is unknown should receive HepB (but not HBIG) within 12 hours of birth, and the mother's HBsAg status (and thus the newborn's need for HBIG) should be determined as soon as possible.

Universal HepB immunization of low-risk newborns (those with HBsAg-negative mothers) was temporarily halted in July of 1999 because of concerns about the amount of thimerosal (a mercury-containing preservative) that infants were receiving through vaccination. Once a thimerosal-free vaccine became available, the AAP and ACIP recommended reinstating HepB vaccination of all infants at birth, using only thimerosal-free vaccine. Despite the updated recommendations, some institutions have been slow to restart their newborn HepB programs, thereby missing an important opportunity to interrupt hepatitis B transmission.

Routine immunization with HepB is recommended for all infants and all previously unvaccinated children 0–18 years of age. A two-dose schedule (as opposed to the standard pediatric three doses) is available for adolescents (see following discussion). Since initiating universal recommendations, the percentage of children age 19–35 months receiving three doses of HepB increased from less than 10% in 1991 to 90% in 2002.

In addition to the universal immunization of children, older persons in several risk categories have been identified as target populations for preexposure vaccination. Those that are relevant to physicians caring for children include residents and staff in institutions for the developmentally delayed, residents and staff of hemodialysis units, recipients of clotting factor concentrates, homosexually active males, users of illicit injectable drugs, household contacts of chronic hepatitis B carriers, incarcerated juveniles, long-term international travelers to endemic areas, and all health care

personnel. Screening for markers of past infection before HepB immunization is generally not indicated for children and adolescents, but may be considered for high-risk individuals. Because vaccines consist of a purified inactive subunit of the virus and are not infectious, they are not contraindicated in immunosuppressed individuals or in pregnant women.

HepB is immunogenic in infants, children, and young adults. The protective efficacy of HepB correlates well with antibody levels, and virtually all persons with levels of 10 mIU/mL or more are protected in clinical trials.

Preparations Available

1. HepB (Recombivax HB, Merck) contains recombinant hepatitis B vaccine only.
2. HepB (Engerix-B, GlaxoSmithKline) contains recombinant hepatitis B vaccine only.
3. HepB-Hib (Comvax, Merck) contains Recombivax HB and *Haemophilus influenzae* type b (PRP-OMP) vaccine.
4. DTaP-IPV-HepB (Pediarix, GlaxoSmithKline) contains diphtheria and tetanus toxoids and acellular pertussis (DTaP), inactivated poliovirus (IPV), and Engerix-B vaccines.
5. HepB-HepA (Twinrix, GlaxoSmithKline) contains Engerix-B and hepatitis A vaccines; only approved for persons 18 years of age or older.

Only the single-antigen vaccines (Recombivax HB, Engerix-B) can be given between birth and 6 weeks of

age. Any single or combination vaccine (except Twinrix) may be used to complete the hepatitis B vaccination series. All pediatric formulations contain trace to no thimerosal.

Dosage & Schedule of Administration

HepB is administered as part of the primary childhood immunization schedule for infants and children, as outlined in Table 9–9. The preferred initial dose is during the postpartum period. For children younger than 11 years of age, three intramuscular doses of HepB are needed. Adolescents age 11–15 years have two options: the standard pediatric three-dose schedule or two doses of adult Recombivax HB (1.0-mL dose), with the second dose administered 4–6 months after the first dose. Simultaneous administration with other vaccines at different sites is safe and effective. HepB should be given intramuscularly in either the anterolateral thigh or deltoid, depending on the age and size of the patient. Administration intradermally or in the buttocks results in poor immune responses in some individuals.

A. NEONATAL

Infants of HBsAg-positive mothers should be cleansed of blood in the delivery room. Both HepB (see Table 9–9) and HBIG (0.5 mL intramuscularly) should be administered simultaneously at different sites within 12 hours of birth. The vaccine should be repeated at 1 month and 6 months. After completion of the HepB series, at 9 to 15 months of age, immunized infants should be tested for anti-HBs. If the anti-HBs assay is positive, vaccination has been effective. If the result is

Table 9–9. Hepatitis B vaccine schedule and dosage.

	Recombivax HB	Engerix-B	Dose Schedule and Ages
Infants of HBsAg-negative mothers ^a	0.5 mL	0.5 mL	0–2 d, 1–2 mo, and 6–18 mo
Infants of HBsAg-positive mothers ^b (HBIG 0.5 mL should also be given)	0.5 mL	0.5 mL	Day 0, 1 mo, and 6 mo
Children and adolescents < 20 y old	0.5 mL ^c	0.5 mL	Day 0, 1 mo, and 4 mo
Immunosuppressed persons and dialysis patients	1.0 mL ^d	2.0 mL ^e	

^aInfants of mothers with unknown HBsAg status should be tested at delivery. The infant should receive hepatitis B vaccine within 12 hours of birth. Preterm and low-birth-weight infants of HBsAg-negative mothers should receive the first vaccine dose at 30 days of chronologic age if medically stable, or at discharge if before 30 days of age.

^bPreterm and low-birth-weight infants of HBsAg-positive mothers should receive Hepatitis B vaccine and HBIG within 12 hours of birth regardless of birthweight and gestational age; these infants should receive 4 vaccine doses total.

^cA 2-dose schedule (1.0 mL at 0 months and 4–6 months) is also available for adolescents age 11–15 years.

^dSpecial formulation containing 40 micrograms/mL.

^eTwo doses of 1.0 mL at one site in a four-dose schedule at Day 0 and at 1, 2, and 6 months.

HBsAg: hepatitis B surface antigen; HBIG: hepatitis B immune globulin.

Modified from MMWR Vol 40, No RR13;001

negative, HBsAg should be tested for; if that test result is positive, immunization has failed and the infant is a chronic carrier. If both HBsAg and anti-HBs are negative, the series should be repeated at 0, 1, and 6 months, followed by repeat anti-HBs testing 1 month after the third dose.

For infants born to mothers of unknown HBsAg status, the same schedule should be followed, except that HBIg should be withheld until the HBsAg status of the mother is known. If the mother is HBsAg-positive, HBIg should be initiated as soon as possible but no later than 7 days after birth.

For infants born to HBsAg-negative mothers, the first dose should be administered in the newborn period, or, if this is not possible, at least before age 2 months. The doses and the schedule for routine vaccination of these infants are set forth in Table 9–9. For preterm infants with birth weights of less than 2 kg born to HBsAg-negative mothers, initiation of HepB should be delayed until 30 days of chronologic age if the infant is medically stable or prior to hospital discharge if discharged before 30 days of age.

If maternal screening is not possible, the infant should receive the first dose of HepB within 12 hours after birth, the second at age 1–2 months, and the third at 6 months. There should be at least 1 month between first and second doses. The third dose should be administered at least 4 months after the first dose and at least 2 months after the second dose, but not before the child is 6 months old.

B. OLDER CHILDREN AND ADOLESCENTS

All children should receive HepB as part of the routine schedule. The universal immunization of all adolescents is recommended, on either a two- or three-dose schedule. (See Table 9–9 for dosages and schedules.)

C. IMMUNOSUPPRESSED PERSONS AND DIALYSIS PATIENTS

Hemodialysis patients and other immunocompromised persons should be vaccinated with larger doses or an increased number of doses (or both) (see Table 9–9).

D. LAPSED HEPATITIS B IMMUNIZATION

The HepB series can be completed regardless of the interval from the last vaccine dose. There is no need to start the series over or to test routinely for anti-HBs in healthy children unless the child's mother is HBsAg-positive.

E. POSTEXPOSURE PROPHYLAXIS

Postexposure prophylaxis is indicated for unvaccinated persons with perinatal, sexual, household, percutaneous, or permucosal exposure to hepatitis B. When prophylaxis is indicated, unvaccinated individuals

should receive HBIg (0.06 mL/kg) and the first dose of HepB at a separate anatomic site. For sexual contact or household blood exposure with an acute case of hepatitis B, HBIg and HepB should be given. Sexual and household contacts of someone with chronic infection should receive immunization (but not HBIg). For individuals with percutaneous or permucosal exposure to blood, HepB should be given, and HBIg considered depending on the HBsAg status of the person who was the source of the blood and on the vaccination response status of the exposed person. All previously vaccinated persons exposed to hepatitis B should be retested for anti-HBs. If levels are adequate (≥ 10 mIU/mL), no treatment is necessary. If levels are inadequate and the exposure was to HBsAg-positive blood, HBIg and vaccination are required.

Adverse Effects

The overall rate of adverse effects is low and minor, and effects include fever (1–6%) and pain at the injection site (3–29%). There is no evidence of an association between vaccination and sudden infant death syndrome, multiple sclerosis, autoimmune disease, or chronic fatigue syndrome.

Antibody Preparations

HBIg is prepared from HIV-negative and hepatitis C virus-negative donors with high titers of hepatitis B surface antibody. The process used to prepare this product inactivates or eliminates HIV and hepatitis C virus. The use of HBIg is described earlier in this section.

VARICELLA

Prior to the availability of vaccine, about 4 million cases of varicella-zoster virus (VZV) infection occurred annually in the United States, mostly in children younger than 10 years. This resulted in 11,000 hospitalizations and 100 deaths per year due to severe complications such as secondary bacterial infections, pneumonia, encephalitis, hepatitis, and Reye syndrome. A live attenuated (VAR) vaccine was developed in Japan in the

1970s and licensed in the United States by the FDA in 1995 for children older than 12 months. As of 2002, approximately 81% of children age 19–35 months in the United States have received one dose of VAR. In three communities participating in an active disease surveillance program, reported VZV cases declined from 71% to 84% from 1995 to 2000. VZV disease declined by a similar amount in all age groups, including infants and susceptible adults, suggesting that disease transmission has been reduced even among the unvaccinated.

In seven postlicensure studies, vaccine effectiveness ranged from 95% to 100% in preventing moderate and severe disease, and 71% to 100% in preventing any disease among vaccinees. However, a more recent investigation of a VZV outbreak at a day care center revealed vaccine effectiveness of 86% against serious disease and 44% against any disease. Preliminary data suggest that vaccine effectiveness may be somewhat diminished when (1) vaccine is given nonsimultaneously but within 28 days of MMR vaccination or (2) oral steroids have been used in the preceding 3 months. The administration of vaccine at younger than 15 months of age has been suggested as a potential risk factor for diminished protection, but this has not been confirmed. Some concern has also arisen that vaccine-induced immunity may wane over time, although no evidence supports this contention to date. The necessity for and cost-effectiveness of changing to a two-dose schedule for children has not been determined.

In February 1999, the ACIP expanded its recommendations for VZV vaccine to promote wider usage. It is predicted that with 97% coverage rates, transmission of VZV could be ended in 30 years. Updated recommendations include (1) establishing child care and school entry requirements, (2) use of the vaccine following exposure and for outbreak control, (3) use for some children with HIV infection, and (4) use in adults and adolescents at risk for exposure.

Proof of immunity to VZV is recommended as a requirement for day care and school entry, and is now required in 38 states; vaccination, physician diagnosis of VZV infection, and serologic documentation of protective antibody meet this requirement.

Data from US and Japanese studies suggest that vaccine is effective in preventing or modifying VZV severity in susceptible individuals if used within 3–5 days of exposure, and this is now recommended by the ACIP and the AAP. A study in the United States suggests that the efficacy of postexposure vaccination is 95% for prevention of any disease and 100% for prevention of moderate or severe disease. There is no evidence that postexposure prophylaxis will increase the risk for vaccine-related adverse events or interfere with development of immunity. In addition to routine childhood

immunization, susceptible groups targeted for immunization include: (1) adults or adolescents older than 13 years residing in households with susceptible children; (2) those who work as teachers of young children or as day care workers; (3) persons living or working in environments that facilitate transmission (eg, colleges, correctional facilities); (4) international travelers; and (5) nonpregnant women of childbearing age.

Preparations Available

A cell-free preparation of OKA strain VZV is produced and marketed in the United States (Merck). Each dose of VAR contains not less than 1350 plaque-forming units of VZV and trace amounts of neomycin and gelatin. Storage in a freezer at a temperature of -15°C or colder provides a shelf life of 15 months. VAR may be stored for 72 hours at refrigerator temperature in its lyophilized state, VAR must be administered within 30 minutes after thawing and reconstitution.

Dosage & Schedule of Administration

One dose (0.5 mL) of VAR is recommended for immunization for all healthy children age 12 months to 12 years who lack a history of VZV infection. Children 13 years or older require two doses of VAR 1 month apart. Asymptomatic or mildly symptomatic HIV-infected children (CDC class N1 or A1) should receive two doses of vaccine (with a 3-month interval between doses). VAR may be given simultaneously with MMR at separate sites. If not given simultaneously, the interval between administration of VAR and MMR must be greater than 28 days. Simultaneous VAR administration does not appear to affect the immune response to other childhood vaccines. VAR should be delayed 5 months after intravenous immunoglobulin infusion.

Adverse Events

Since the approval of VAR in 1995, more than 30,000,000 doses have been distributed in the United States. The most commonly recognized adverse reactions, occurring in approximately 20% of vaccinees, are minor injection site reactions. Additionally, 3–5% of patients will develop a localized rash, and an additional 3–5% will develop a sparse generalized varicelliform rash. These rashes typically consist of two to five lesions and may appear 5–26 days after immunization. In most cases in which rash occurred within the first 2 weeks after immunization, polymerase chain reaction (PCR) analysis of these lesions has demonstrated the presence of wild-type rather than vaccine-strain virus, suggesting natural infection sometime immediately prior to vaccination. Transmission of vaccine virus from healthy pa-

tients to healthy recipients is very rare; has never occurred in the absence of a rash in the index case; and has only resulted in mild disease. One case involved transmission from a vaccinee to a susceptible pregnant female. The pregnancy was terminated, but PCR analysis of the fetus showed no evidence of VZV infection. Based on data from the Vaccine Adverse Event Reporting System (VAERS), rates of serious adverse events following VAR are not increased compared with rates expected after natural infection or the background rates of similar events in the community. Herpes zoster infection has occurred following VAR administration in immunocompetent and immunocompromised persons within 25–722 days after immunization. Many of these cases were due to presumably unappreciated latent wild-type virus. Furthermore, based on preliminary data, the age-specific risk of herpes zoster infection seems to be lower in immunocompetent children following VAR immunization than after natural infection.

Contraindications

Table 9–3 lists contraindications to VZV immunization, such as known hypersensitivity or allergy to any VAR component, including neomycin. VAR is also contraindicated in children who have cellular immunodeficiencies, including those with leukemia, lymphoma, other malignancies affecting the bone marrow or lymphatic systems, and congenital T-cell abnormalities (although vaccine administration to children with acute lymphocytic leukemia is under investigation). The exception to this rule is the recommendation that VAR be administered to HIV-infected children in CDC immunologic class I (CD4+ T-lymphocyte count of 25% or more) because the vaccine is safe and immunogenic in this group. Children receiving immunosuppressive therapy, including high-dose steroids, should not receive VAR. Household contacts of immunodeficient patients should be immunized. VAR should not be given to pregnant women; however, the presence of a pregnant mother in the household is not a contraindication to immunization of a child within that household.

Antibody Preparations

Varicella-zoster immune globulin (VZIG) is prepared from plasma harvested from persons known to have high titers of anti-VZV antibody. It is indicated for high-risk susceptible persons who are exposed to VZV, for example, immunocompromised individuals without a history of chickenpox, susceptible pregnant women, newborns whose mothers develop varicella 5 days prior to delivery or within 48 hours after delivery, hospitalized premature infants 28 weeks or more gestation

(whose mother lacks history of chickenpox or is seronegative), and hospitalized premature infants less than 28 weeks gestation (regardless of maternal history or serostatus). Exposure is defined as a household contact or playmate contact (over 1 h/d), hospital contact (in the same or contiguous room or ward), intimate contact with a person with zoster deemed contagious, or a newborn contact. Susceptibility is defined as the absence of anti-VZV antibody by an appropriate test. VZIG should be given as soon as possible after exposure, but should be administered within 96 hours. Newborns should be given one vial (125 U) intramuscularly. The dose for all others is 125 U/10 kg body weight intramuscularly (maximum dose, 625 U). VZIG should be readministered following reexposure of susceptible persons if more than 3 weeks has elapsed since a prior dose of VZIG.

INFLUENZA

Influenza occurs each winter and early spring, often associated with significant morbidity and mortality rates in certain high-risk persons. Up to 36,000 deaths per year in the United States are attributable to influenza, and global epidemics (pandemics) can occur. Children at high risk of influenza-related complications include those with hemoglobinopathies and those with chronic cardiac, pulmonary (including asthma), metabolic, renal, and immunosuppressive diseases. Children and adolescents receiving long-term aspirin therapy are also at risk of substantial morbidity from influenza-related Reye syndrome. Additionally, healthy children younger than 2 years of age are at increased risk of hospitalization during influenza season.

Annual influenza vaccination is indicated for all children older than 6 months of age who have a chronic health condition that places them at higher risk of complications from influenza infection. Members (including other children) of households with persons in high-risk groups should also be immunized. The vaccine may be administered to healthy children older than age 6 months, and the inactivated vaccine is now routinely recommended for all children ages 6–23 months.

Physicians should identify high-risk children in their practices and encourage parents to seek influenza vaccination for them each fall. In pandemic years, it may be important to advocate vaccination in all children regardless of their usual state of health. Influenza vaccination has a 65–80% efficacy in protecting against disease. In high-risk groups, it may be even more effective in preventing lower respiratory disease or other secondary complications, thereby decreasing hospitalizations and deaths. Each year, recommendations are formulated in the spring and summer regarding the constituents of influenza vaccine for the coming season. These recommendations are based on the results of surveillance in Asia and the southern hemisphere during the spring and summer. The vaccine each year is a trivalent inactivated vaccine containing antigens from two strains of influenza A and one strain of influenza B, chosen as those likely to circulate in the United States during the upcoming winter.

To eliminate the need for injections, and potentially to enhance mucosal and systemic immune response to vaccination, a live attenuated intranasal vaccine has been developed. This vaccine is trivalent (containing two type A strains and one type B strain), cold-adapted, and temperature-sensitive. These viruses replicate poorly in the lower respiratory tract but well in the nasal mucosa (thereby producing immunity). The vaccine is effective in preventing influenza in healthy children. However, because of questions regarding its possible association with pneumonia and asthma in vaccines aged 12–60 months, it is currently licensed only for otherwise healthy children and adults age 5–49 years of age.

Preparations Available

The inactivated influenza vaccine virus is grown in eggs, formalin-inactivated, and contains trace quantities of thimerosal as a preservative. These whole-virus preparations may be further treated with detergents to produce split (subvirion) or purified surface antigen vaccines. Only split-virus or purified surface antigen preparations should be used for children age 12 years and younger. Several manufacturers produce similar vaccines each year. Fluzone split-virus (Aventis Pasteur) is approved for children 6 months and older; Fluvirin (Evans Vaccines) is approved only for children 4 years and older.

The intranasal trivalent live attenuated influenza virus vaccine (Flumist, Medimmune) is also produced in a trivalent formulation using identical virus strains to the killed vaccine. It is also made in eggs and comes in a single-use prefilled sprayer. It should be stored at -15°C in a frost-free freezer. It may be thawed and stored in a $4\text{--}8^{\circ}\text{C}$ refrigerator for less than 24 hours prior to use. It should not be refrozen after thawing.

Dosage & Schedule of Administration

A. INACTIVATED INFLUENZA VIRUS VACCINE

Because influenza can circulate yearly from November through early March in the United States, the key time to initiate vaccination is between October and early November of each year. However, providers should continue vaccinating individuals as long as vaccine is available and there is still influenza activity in the community. Children younger than age 6 months should not be immunized. Two doses are recommended for children younger than age 9 years who are receiving influenza vaccine for the first time; subsequent seasons require single doses. Older children receiving vaccine for the first time require only a single dose. The dose for children ages 6–35 months is 0.25 mL, given intramuscularly; for older children, 0.5 mL, given intramuscularly. The recommended site of vaccination is the anterolateral aspect of the thigh for younger children and the deltoid for older children. Because this vaccine is inactivated, pregnancy is not a contraindication to its use. The vaccine is recommended for women in the second or third trimester of pregnancy (or those who will enter the second or third trimester) during the influenza season. Influenza vaccine has been shown in some but not all studies to transiently increase HIV replication. Nevertheless, the CDC currently recommends influenza vaccination for all HIV-infected persons. Simultaneous administration with other routine vaccinations is acceptable.

B. LIVE ATTENUATED INFLUENZA VIRUS VACCINE

This vaccine is supplied in a prefilled single-use sprayer containing 0.5 mL of the vaccine, approximately half of which is sprayed into each nostril. A dose divider clip is provided to assist in dividing the dose. If the patient sneezes during administration, the dose should not be repeated. It can be administered to children with minor illnesses, but should not be given if significant nasal congestion is present. Because it is a live vaccine it should be administered 48 hours after cessation of therapy in children receiving antiinfluenza antivirals, and antivirals should not be given for 2 weeks after vaccination.

Adverse Effects

A. INACTIVATED VACCINE

The killed vaccine is safe. A small proportion of children will experience some systemic toxicity, consisting of fever, malaise, and myalgias. These symptoms generally begin 6–12 hours after vaccination and may last 24–48 hours. Cases of Guillain-Barré syndrome followed the swine influenza vaccination program in 1976–1977, but careful study by the Institute of Medi-

cine showed no association with that vaccine in children and young adults—nor in any age with vaccines given in subsequent years. For patients with anaphylactic egg allergies in whom influenza vaccination is indicated, a protocol for influenza vaccination is referenced in later discussion.

B. LIVE VACCINE

In 20 studies of the vaccine where 28,000 doses were administered to more than 20,000 children, signs and symptoms reported more in vaccinees than placebo recipients were runny nose and nasal congestion (20–75%), headache (2–46%), fevers (0–26%), myalgias (0–21.5%), vomiting (3–13%), and abdominal pain (2%). These were reported more frequently with the first dose and were all self-limited. However, in a study of the vaccine in children age 1–17 years of age, significant increases in asthma or reactive airway disease occurred in the subset age 11–59 months. Hence, it is not recommended in high-risk patients or in children younger than 5 years of age.

Chemoprophylaxis and Treatment

In the United States four influenza antiviral agents are available: amantadine, rimantidine, zanamivir, and oseltamivir. The prophylactic and therapeutic uses of these drugs are discussed in Chapter 36. Chemoprophylaxis is not a substitute for vaccination, and chemoprophylaxis does not interfere with vaccine immunogenicity.

VACCINATIONS FOR SPECIAL SITUATIONS

RABIES

Human rabies infection is almost universally fatal, even with aggressive treatment. Fortunately, the incidence of human rabies in the United States is very low, with fewer than three cases per year in the 1990s. Of the 36 human cases with rabies reported in the United States from 1980 to 1996, bat exposure was suspected in 21 cases. However, there was a definite history of bite in only one or two of these cases. Although dogs represent the most important vector for human rabies worldwide, in the United States, because of widespread vaccination of dogs and cats, bats are the most important cause of human rabies. Rabies is also common in skunks, raccoons, and foxes; it is uncommon in rodents.

Human rabies is preventable with appropriate and timely postexposure prophylaxis. Postexposure care consists of local wound care, passive immunization, and active immunization. Immediately after an animal bite, all wounds should be flushed and aggressively cleaned with soap and water. If possible, the wound should not be sutured. Passive immunization after high-risk exposure consists of the injection of rabies immune globulin near the wound, as described later. Active immunization is accomplished by completing a schedule of immunization with one of the three rabies vaccines available in the United States. It is important to keep in mind that bites from bats are often unrecognized; prophylaxis should be given if a bat is found indoors even if there is no history of contact, especially if found in the same room with a sleeping or unattended child or with an intoxicated or otherwise incapacitated individual.

Local public health officials should be consulted before postexposure rabies prophylaxis is started to avoid unnecessary vaccination and to assist in the proper handling of the animal (if confinement or testing of the animal is appropriate). To facilitate consultation, the physician should know the species of animal, its availability for testing or confinement, the nature of the attack (provoked or unprovoked), and the nature of the exposure (bite, scratch, lick, aerosol of saliva). Preexposure prophylaxis is indicated for veterinarians, animal handlers, and any persons whose work or home environment potentially places them in close contact with

animal species in which rabies is endemic—bats, skunks, raccoons, and foxes. Rabies immunization should also be considered for children traveling to countries where rabies is endemic; this is particularly important for travelers who will not have prompt access to medical care should an exposure occur.

Preparations Available

Rabies vaccines stimulate immunity after 7–10 days, and the immunity persists for 2 years or more postvaccination. Three preparations are available:

1. Human diploid cell vaccine (HDCV) is grown in human cell culture (Imovax, Aventis Pasteur).
2. Rabies vaccine adsorbed (RVA) is prepared in fetal rhesus lung cell culture (BioPort Corporation).
3. Purified chick embryo cell vaccine (PCEC) is grown in chick embryo cells (RabAvert, Chiron).

Dosage & Schedule of Administration

The three rabies vaccines available in the United States are equally safe and efficacious for both preexposure and postexposure prophylaxis. For all three vaccines, 1.0 mL is given intramuscularly in the deltoid (for adults and older children) or anterolateral thigh (for infants and young children). The volume of the dose is not reduced for children. Vaccine should not be given in the gluteal region. In some parts of the world, because of limited resources, a smaller dose of vaccine is given intradermally; this is not recommended in the United States.

A. PRIMARY PREEXPOSURE VACCINATION

Preexposure rabies immunization should be considered for individuals at high risk for exposure to rabies, for example, veterinarians, animal handlers, spelunkers, and people moving to or extensively traveling in areas with endemic rabies. Three intramuscular injections in the deltoid area of 1 mL of any vaccine are given on days 0, 7, and 21 or 28.

B. POSTEXPOSURE PROPHYLAXIS

Postexposure prophylaxis is a medical urgency, but there is time for consultation with local or state public health officials. The incubation period for rabies virus is usually several weeks but up to one year.

1. In unvaccinated individuals—As soon as possible after exposure (and up to 7 days after the first dose of vaccine), human rabies immune globulin (RIG) should be administered (recommended dose 20 IU/kg). The full dose of RIG should be infiltrated near the wound, if anatomically possible, with the remainder infiltrated in-

tramuscularly at a site distant from vaccine administration. The first dose of rabies vaccine should be administered as soon as possible. Vaccine and RIG should never be mixed in the same syringe or given at the same anatomic site. Postexposure failures occurred only when some deviation from the approved protocol occurred (eg, less than usual amount of RIG, no RIG at wound site, no cleansing of wound, vaccination in the gluteal area). Four subsequent doses of rabies vaccine should be given on days 3, 7, 14, and 28. The WHO recommends an additional dose on day 90, but the ACIP does not concur.

2. In previously vaccinated individuals—RIG is not necessary, and only two doses of vaccine on days 0 and 3, are needed.

C. BOOSTER VACCINATION

Previously vaccinated individuals with potential continued exposure to rabies should have a serum sample tested for rabies antibody every 2 years. If the titer is less than 1:5 for complete neutralization by the rapid fluorescent focus inhibition test, a booster dose of rabies vaccine should be administered.

Adverse Effects

The rabies vaccines are relatively free of side effects. Approximately 15–25% of adults experience pain, swelling, or erythema at the injection site; 10–20% may have mild systemic reactions such as headache, nausea, muscle aches, and dizziness. Three cases of Guillain-Barré syndrome have been described; all three patients recovered fully. Children complain of side effects less frequently. An immune complex-like reaction occurs in about 6% of persons 2–21 days after receiving booster doses of HDCV. Travelers to countries where rabies is endemic may need immediate postexposure prophylaxis and may have to use locally available vaccines and antisera. In many developing countries, the only vaccines readily available may be nerve tissue vaccines (NTV) derived from the brains of adult animals or suckling mice, and the antirabies sera may be of equine origin. Although adverse reactions to antisera are uncommon and typically mild, the NTV may induce neuroparalytic reactions in 1:2000 to 1:8000 vaccinees; this is a significant risk and may justify preexposure vaccination prior to travel.

Antibody Preparations

RIG is prepared from the plasma of human volunteers hyperimmunized with rabies vaccine. The recommended dose is 20 IU/kg body weight. The rabies-neutralizing antibody content is 150 IU/mL, supplied in 2-mL or 10-mL vials. It is very safe.

TYPHOID FEVER

Typhoid vaccines have shown variable efficacy in field trials, typically producing protection in the 50–80% range. Two vaccines are currently available in the United States: a parenteral vaccine derived from a virulence (Vi) antigen capsular polysaccharide (ViCPS); and a live attenuated oral vaccine (Ty21a). Moderate protection against invasive *Salmonella typhi*, the causative bacterium of typhoid fever, has been demonstrated for 2–5 years following vaccination.

Routine typhoid vaccination is recommended only for children who reside in households with a documented typhoid carrier or who are going to live or travel extensively in an endemic area. The oral vaccine is most commonly used because of its ease of administration. However, noncompliance with oral vaccine dosing instructions occurs frequently, and correct usage should be stressed or the parenteral ViCPS vaccine used. Travelers should be advised, however, that because none of the vaccines offer total protection, careful selection of food and drink is imperative.

Preparations Available

1. Parenteral ViCPS (Typhim Vi, Aventis Pasteur) is for intramuscular use.
2. Oral live attenuated Ty21a vaccine (Vivotif Berna Vaccine, Swiss Serum and Vaccine Institute) is supplied as enteric-coated capsules.

Dosage & Schedule of Administration

ViCPS is administered as a single intramuscular dose (0.5 mL), with boosters needed every 2 years if exposure continues. It is approved for children 2 years and older.

The dose of the oral preparation is one capsule every 2 days for a total of four capsules, taken 1 hour before meals. The capsules should be taken with cool liquids, and should be kept refrigerated. A full course of four capsules is recommended every 5 years if exposure continues. This vaccine is not approved for children younger than age 6 years, and capsules should not be

dispensed from a package that has been opened beforehand. The antimalarial drugs mefloquine and chloroquine can be given simultaneously with oral typhoid vaccine; however, the antimalarial proguanil, as well as antimicrobials, should not be given simultaneously with Ty21a.

Adverse Reactions

The oral and parenteral typhoid vaccines may produce mild adverse reactions such as abdominal complaints (for oral) and injection site swelling or redness (for parenteral). As with all live attenuated vaccines, Ty21a should not be given to immunocompromised patients.

MENINGOCOCCAL DISEASE

Infection with *Neisseria meningitidis* causes significant morbidity and mortality, with 120,000 cases worldwide per year, including 2400–3000 cases in the United States. Meningococcal disease has a 10% case-fatality rate in the United States, and up to 19% of survivors are left with serious disabilities, such as neurologic impairment, loss of limb function, or hearing loss. Infants younger than 1 year of age have the highest rate of disease, but college freshmen, particularly those living in dormitories, have a higher incidence than the general US population. Five serogroups of meningococcus (A, B, C, W-135, and Y) cause the vast majority of disease.

In prior years, meningococcal disease in the United States was caused primarily by serogroup B and C strains (45% each), with the remainder of cases due to W-135 and Y serogroups (10%). Now disease due to serogroup B is decreasing, and disease due to Y is increasing (up to 43% in some areas). The majority of disease in developing countries is caused by serogroups A and C.

A polysaccharide-based vaccine against serogroups A, C, Y, and W-135 is available in the United States. The vaccine has 85–100% efficacy in older children and adults against groups A and C disease. The vaccine is not recommended for routine immunization because it is relatively ineffective in children younger than 2 years; it is unable to protect against serogroup B disease; and the immunity it confers appears to be short-lived, and its repeated use may actually decrease antibody response. However, functionally or anatomically

asplenic children should be vaccinated, as well as those with terminal complement or properdin deficiencies. Meningococcal vaccine provides some protection for travelers to countries with epidemic or endemic disease (primarily sub-Saharan Africa). The vaccine is also recommended in outbreaks caused by vaccine-preventable serogroups. Because of a moderately increased risk (three- to fourfold) of meningococcal disease in college freshmen, the ACIP and AAP recommend that care providers discuss meningococcal vaccination with incoming and current freshmen, and administer vaccine to those who request it.

Because of the severe disease caused by the meningococcus and the limitations of the currently licensed vaccine, intensive effort is going into the development of new meningococcal vaccines. However, a number of barriers still exist. Because of the global variation in the incidence of different meningococcal serogroups, a vaccine designed for use in the United States and western Europe may provide little benefit to the developing world. The bacterial capsule proteins of serogroup B, which causes a substantial proportion of disease in the United States, particularly in infants younger than 1 year old, are poorly immunogenic in humans. Antibodies to serogroup B capsular proteins cross-react with human embryonal neural tissue, and therefore serogroup B vaccines carry a theoretical risk of producing autoimmunity. Finally, the relatively low incidence of meningococcal disease makes studying vaccine efficacy difficult and costly.

Despite these challenges, there are a number of promising meningococcal vaccine developments. Serogroup A and C polysaccharide have been linked to protein carriers and found to be immunogenic in infants. In 1999, the United Kingdom began routine childhood immunization with a conjugate meningococcal serogroup C vaccine. Early results have shown an 80% reduction in serogroup C disease in targeted age groups.

The only vaccine currently available in the United States is the quadrivalent A, C, W-135, and Y vaccine (Menomune, Aventis Pasteur). Each dose contains 50 µg of the four purified capsular polysaccharides. It is approved for children 2 years of age and older.

Dosage & Schedule of Administration

Quadrivalent meningococcal vaccine is given as a single 0.5-mL subcutaneous injection. It can be given simultaneously with other vaccines. It should be given to high-risk individuals and to those affected by vaccine-preventable outbreaks. Because reimmunization of young children produces serogroup A but not serogroup C antibodies, reimmunization is only recommended when there is continued risk of serogroup A infection.

Adverse Effects

With more than 6 million doses of vaccine distributed, few serious adverse events have been reported. A recent national review of meningococcal vaccine safety found that fever, injection site hypersensitivity, and allergic reactions were the most common associated events.

Until better vaccines are available, chemoprophylaxis with rifampin, ceftriaxone, or ciprofloxacin (adults) should be used to prevent meningococcal disease in exposed individuals (see Chapter 38).

CHOLERA

Cholera causes significant morbidity and mortality worldwide. It may present only as travelers diarrhea. For travelers, the risk of developing cholera per month of stay in a developing country is low, ranging from 0.001% to approximately 0.01%. No cholera vaccines are available in the United States. Because the causative bacterium *Vibrio cholerae* is not invasive, and because secretory IgA (sIgA) is crucial, newer vaccines available in other countries are administered orally. Two oral vaccines (one consisting solely of live attenuated bacteria and the other in combination with the B subunit of cholera toxin) are safe and immunogenic. Cholera vaccination is no longer required for international travel or for entry into any countries.

TUBERCULOSIS

In 2000, 22 states in the United States had tuberculosis incidence rates of less than 3.5 cases/100,000 popula-

tion, setting the stage for possible elimination of the disease in these areas. However, of the 11,795 cases reported to the CDC in 2002, nearly 40% of new cases of TB occur in persons born in other countries. Bacille Calmette-Guérin vaccine (BCG) consists of live attenuated *Mycobacterium bovis*. BCG is not currently indicated for mass use in the United States, chiefly because of doubts about its efficacy. BCG is the most widely used vaccine in the world and has been administered to over 2.5 billion people (71% of infants worldwide are vaccinated) with a low incidence of serious complications. It is inexpensive, can be given any time after birth, sensitizes the vaccinated individual for 5–50 years, and stimulates both B-cell and T-cell immune responses. BCG is useful in two circumstances in the United States: (1) in tuberculin-negative infants or older children residing in households with untreated or poorly treated individuals with active infection with isoniazid- and rifampin-resistant *Mycobacterium tuberculosis* and (2) in infants or children found to live under constant exposure without the possibility of removal from continuous exposure or access to prophylaxis and treatment. BCG reduces the risk of tuberculous meningitis and disseminated TB in pediatric populations by 50–100%. BCG appears to have had little epidemiologic effect on TB, despite a reported efficacy of 50% in a meta-analysis of 26 vaccine trials, with the greatest protection against pulmonary disease. The two currently licensed BCG vaccines in the United States are produced by Connaught Laboratories and Organon Teknika Corporation. They are given intradermally in a dose of 0.05 mL for newborns and 0.1 mL for all other children. Mantoux testing is advised 2–3 months later, and revaccination is advised if the Mantoux test is negative. Adverse effects occur in 1–10% of healthy individuals, including local ulceration, regional lymph node enlargement, and lupus vulgaris. The vaccine is contraindicated in pregnant women and in immunocompromised individuals, including those with HIV infection, because it has caused disseminated or fatal infection.

Factors associated with increased probability that a positive TB skin test (TST) is due to *M tuberculosis* infection include (1) larger reactions, (2) contact with an individual known to be infected, (3) family history of TB, (4) longer interval between BCG administration and skin testing, and (5) country of origin with increased incidence of endemic TB. The details and cutoff observations for TB skin testing are described in Chapter 38. To ensure that those infected with TB are evaluated, a 5-mm or greater cutoff for a positive Mantoux test is used in immunocompromised children. In immunocompetent persons, the cutoff is 10 mm or above, whereas it is 15 mm or above when no risk factors are present in the absence of clinical disease (eg,

screening). Recently, a case-control study from New York identified that contact with an adult with active TB, foreign birth, foreign travel, or a relative with a positive TST predicted latent TB (with use of the TST). This may justify routinely testing children with these risk factors as well. In 2001 a new test (Quantiferon-TB) that measures the release of interferon- γ in whole blood in response to stimulation with purified protein derivative (PPD) was approved by the FDA. This test is not recommended for persons with symptoms of active TB who are at increased risk for progression to active TB, but may be used instead of TST in those at increased or low risk for latent TB infection, including as a screening of recent immigrants. BCG almost invariably causes its recipients to be tuberculin-positive (5–7 mm), but the reaction often becomes negative after 3–5 years. However, a positive Mantoux test in a child with a history of BCG vaccination who is being investigated for TB as a case contact should be interpreted as indicating infection with *M tuberculosis*.

YELLOW FEVER

Immunization against yellow fever is indicated for children as young as age 4 months traveling to endemic areas or to countries that require it for entry, but otherwise immunization should be delayed until age 9 months or older. Public health authorities maintain updated information on these requirements and must be consulted. Yellow fever vaccine is a live vaccine made from the 17D yellow fever attenuated virus strain grown in chick embryos. It is contraindicated in infants younger than age 4 months due to an increased susceptibility to vaccine-associated encephalitis, in pregnant women, in persons with anaphylactic egg allergy, and in immunocompromised individuals. It can only be administered at licensed yellow fever vaccination locations (usually public health departments). A single subcutaneous injection of 0.5 mL of reconstituted vaccine is

administered. The International Health Regulations require revaccination at 10-year intervals, but immunity may be lifelong. Adverse reactions are generally mild—consisting of fever, mild headache, and myalgia 5–10 days after vaccination occurring in less than 25% of vaccinees. The risk for vaccine-associated encephalitis within 30 days following vaccination has been estimated to be less than 1/8,000,000 persons. Recently, a new serious adverse reaction syndrome was described. This yellow fever vaccine-associated viscerotropic disease consists of severe multiple organ system failure and death within 1–2 two weeks postvaccination, especially in older adults. These reports have caused a reevaluation of the vaccine's use. Health care providers should be careful to administer yellow fever vaccine only to persons truly at risk for exposure to yellow fever. There is no contraindication to giving other live-virus vaccines simultaneously with yellow fever vaccine or at intervals of a day to a month.

ANTHRAX

Anthrax is an acute infectious disease caused by the spore-forming bacteria *Bacillus anthracis*. Although it occurs most frequently as a disease of cattle, goats, and sheep, humans may become infected through contact with, ingestion of, or inhalation of spores from infected animals or their products. The spore is durable and can be delivered as an aerosol, with an incubation of 2–30 days. Inhalation causes the most serious form of human anthrax, making it an attractive agent for potential use by bioterrorists (see Chapter 11). In December 2001, the US Department of Health and Human Services obtained a limited supply of anthrax vaccine for potential preexposure civilian vaccination. The only available anthrax vaccine in the United States is an inactivated, noninfectious, cell-free anthrax vaccine (BioPort Corporation). It is prepared from a toxigenic, nonencapsulated strain and is aluminum hydroxide-adsorbed. Routine preexposure vaccination with anthrax vaccine adsorbed (AVA) is indicated for persons at risk for repeated exposure to *B anthracis* spores, such as laboratory personnel handling environmental specimens for bioterrorism level B and C laboratories, workers making repeated entries into known *B anthracis* spore-contaminated areas after a terrorist attack, and workers in other

settings in which repeated exposure to aerosolized *B anthracis* spores might occur. For military personnel, and for other selected populations for which a calculable risk can be assessed, preexposure vaccination has been used.

The recommended vaccination schedule is subcutaneous injections at 0, 2, and 4 weeks; then at 6 months, 12 months, and 18 months. Postexposure vaccination consists of three injections: as soon as possible after exposure and again at 2 and 4 weeks after exposure in combination with antimicrobial chemoprophylaxis for 60 days. The duration of protection in humans is unknown; however, annual booster injections are recommended to maintain immunity. The vaccine has not been evaluated for safety and efficacy in children younger than age 18 years or in adults older than age 60 years.

Adverse Events

No studies have definitively documented occurrence of chronic diseases (eg, cancer or infertility) following anthrax vaccination. Although controversial, analysis of VAERS data documents no pattern of serious adverse events clearly associated with the vaccine, except mild injection site reactions.

SMALLPOX (VARIOLA)

Smallpox is a highly contagious infection caused by the variola virus. In 1972, routine smallpox immunization was discontinued in the United States, and in 1980 the World Health Organization declared smallpox to be eradicated worldwide. In recent years, concern that smallpox virus stocks may be in the hands of bioterrorists and potentially released within a nonimmune population has incited a debate about whether a large-scale smallpox immunization should be resumed. A smallpox immunization plan has been implemented in the United States to develop smallpox response teams throughout the nation. The only smallpox vaccine licensed in the United States is a lyophilized, live vaccinia virus preparation. Vaccinia is related to variola and is highly effective in preventing smallpox. Vaccine is administered using a bifurcated needle to deliver vaccine into the epidermis. Vaccine “take” is determined by the development of a papule progressing to vesicle to pustule to scab that heals after 14–21 days. Fever is common after primary immunization and less common

after reimmunization. Severe complications of immunization include death, postvaccinal encephalitis, progressive vaccinia, myocarditis, eczema vaccinatum, and accidental inoculation to other body sites. Transmission of vaccine virus from a recently immunized individual to a susceptible contact can occur. Smallpox vaccine is not recommended for people younger than 18 years of age. The US government has contracted for development of 200 million doses of tissue culture-derived vaccinia vaccine and has encouraged development of safer effective smallpox vaccines. Vaccinia immune globulin (VIG) is recommended only for the treatment of complications of vaccination and not for prophylaxis or treatment.

PASSIVE PROPHYLAXIS

Intramuscular Immune Globulin

Ig may prevent or modify infection with hepatitis A virus if administered in a dose of 0.02 mL/kg within 14 days after exposure. Measles infection may be prevented or modified in a susceptible person if Ig is given in a dose of 0.25 mL/kg within 6 days after exposure. Special forms of Ig include TIg, HBIG, RIg, VIg, and VZIG. These are obtained from donors known to have high titers of antibody against the organism in question. Their use has been described earlier in this chapter. Palivizumab is a humanized monoclonal antibody against respiratory syncytial virus (RSV) and is used to prevent RSV in high-risk populations with monthly doses during RSV season.

Ig must be given intramuscularly. The dose varies depending on the clinical indication. Adverse reactions include pain at the injection site, headache, chills, dyspnea, nausea, and anaphylaxis, although all but the first are rare.

Intravenous Immune Globulin

The primary indications for IVIg are for replacement therapy in antibody-deficient individuals, for the treat-

ment of Kawasaki disease, idiopathic thrombocytopenic purpura, Guillain-Barré syndrome, and other autoimmune diseases, and chronic B-cell lymphocytic leukemia. IVIg may be beneficial in some children with HIV infection, toxic shock syndrome, and for anemia caused by parvovirus B19. Specific antibody-enriched IVIg preparations have also been developed for the prevention and treatment of the following viral infections: cytomegalovirus immune globulin (CMVIG) for prevention and treatment of CMV disease and respiratory syncytial virus immune globulin (RSVIG) for prevention of RSV illness in high-risk children. Prophylaxis to prevent RSV in infants and children at increased risk for severe disease is available in either an intravenous (RSV-IVIg) or intramuscular (Palivizumab) preparation. Both products should be considered for (1) infants and children younger than age 2 years with chronic lung disease who have required medical therapy (supplemental oxygen, bronchodilator, diuretic, or corticosteroid therapy) for their disease within 6 months before the anticipated RSV season, (2) infants born between 33 and 35 weeks (32 weeks 1 day and 35 weeks 0 days) gestation or earlier without chronic lung disease with two or more risk factors (child care attendance, school-age siblings, exposure to environmental air pollution, congenital airway abnormalities, or severe neuromuscular disease) up to age 6 months, (3) infants born at 29–32 weeks up to 6 months of age, and (4) up to age 12 months for infants born at 28 weeks or earlier.

Palivizumab is approved for use in children who are 24 months old or younger with hemodynamically significant cyanotic or acyanotic congenital heart disease. Those most likely to benefit from prophylaxis are infants (< 1 year of age) who are receiving medication to control congestive heart disease, with moderate to severe pulmonary hypertension and cyanotic heart disease. An increased number of cyanotic events occurred following RSV-IVIg administration in these infants. RSV prophylaxis should be initiated at the onset of the RSV season and continued until the end of the season, regardless of breakthrough RSV illness during that RSV season.

RSV-IVIg (RespiGam [MedImmune]) is derived from human donors screened for high levels of RSV-neutralizing activity. It is administered intravenously in a dose of 750 mg/kg once a month during the RSV season. RSV intramuscular monoclonal antibody, palivizumab (Synagis [MedImmune]), is a humanized monoclonal antibody directed against the F glycoprotein of RSV, a surface protein that is highly conserved among RSV isolates. It is administered in a dose of 15 mg/kg once a month and is packaged in 50- and 100-mg vials.

Although palivizumab has greater ease of administration and fewer adverse effects, some considerations

may favor the use of RSV-IVIg. Specifically, RSV-IVIg provides protection from other non-RSV respiratory infections, including influenza and acute and recurrent otitis media. In contrast, palivizumab avoids the risk of transmission of human pathogens, because it is a pure preparation of RSV antibody. Palivizumab does not interfere with response to routine childhood vaccinations; infants receiving RSV-IVIg should have MMR and VAR deferred for 9 months after their last dose.

IVIg must only be administered intravenously. Adverse reactions include headache, flushing, diaphoresis, hypotension, fever, nausea, vomiting, and anaphylaxis. Since November 1997, a shortage of IVIg has existed in the United States. Distribution and production factors have contributed to the shortage, but increased off-label use of the product is also a factor. Despite FDA, National Institutes of Health, and CDC guidelines, over 50% of IVIg is issued for unapproved purposes.

Antitoxins & Antivenins

Igs of animal origin are available for use in certain situations. These include botulinum antitoxin, tetanus antitoxin, diphtheria antitoxin, and snake and spider antivenins. A variety of adverse reactions, including acute febrile responses, anaphylaxis, and serum sickness, may develop after use of these products. A schedule for hypersensitivity testing and desensitization for antisera of equine origin can be found in the *Red Book*.

LEGAL ISSUES IN IMMUNIZATION

The National Childhood Vaccine Injury Act of 1986 established two programs: the National Vaccine Program (NVP) and the National Vaccine Injury Com-

pensation Program (NVICP). The purpose was to provide no-fault compensation for persons found to have been injured by certain vaccines. Under the terms of the act, liability claims against those who administer or manufacture vaccines must go before a federal compensation board before a civil suit may be filed. Compensation may be sought for certain events following certain immunizations within specified time intervals. The compensation system is funded by a continuing surcharge levied against the manufacturers for each dose sold of the specified vaccines.

Physicians administering the specified vaccines are also obliged by the act to report any of the specified reactions to the VAERS (call 1-800-822-7967 for forms). Compensation forms from the NVICP may be obtained by calling 1-800-338-2382. The act provides no penalty for failure to report.

Recognizing the need to improve its capability to study vaccine safety, the CDC participated in pilot studies using large linked databases of computerized vaccination and medical records. The Vaccine Safety Datalink Project (which is a network of several health maintenance organizations' computerized information on immunization, medical outcomes, and potential confounders) was initiated in 1989 and has served as a useful tool to accumulate and analyze data as new vaccines are introduced.

Vaccine information materials are available from the CDC to meet the requirements of the act. Separate short (1500- to 2000-word) forms are used for DTaP, MMR, and poliovirus vaccines. Patients or parents are legally required to sign these forms if the vaccine is purchased on a federal contract. Informed consent is also needed for physicians who wish to be covered fully by the vaccine compensation program. Current recommendations of the AAP and CDC for VCIP were discussed at the start of this chapter and should be followed.

■ NUTRITIONAL REQUIREMENTS

NUTRITION & GROWTH

The nutrient requirements of children are influenced by their growth rate and body composition and the composition of new growth. These factors vary with age and are especially important during early postnatal life. Growth rates are higher in early infancy than at any other time, including the adolescent growth spurt (Table 10–1). Growth rates decline rapidly starting in the second month of postnatal life (proportionately later in the premature infant). Because of their more rapid growth rate in early infancy, nutrient requirements are slightly higher in males than in females.

Nutrient requirements also depend on body composition. In the adult, the brain, which accounts for only 2% of body weight, contributes 19% to the total basal energy expenditure. In contrast, in a full-term neonate, the brain accounts for 10% of body weight and for 44% of total energy needs under basal conditions. Thus, in the young infant, total basal energy expenditure and the energy requirement of the brain are relatively high.

Composition of new tissue is a third factor influencing nutrient requirements. For example, fat accounts for about 40% of weight gain between birth and 4 months but for only 3% between 24 and 36 months. The corresponding figures for protein are 11% and 21%; for water, 45% and 68%. The high rate of fat deposition in early infancy has implications not only for energy requirements but also for the optimal composition of infant feedings.

Because of the high nutrient requirements for growth and the body composition, the young infant is especially vulnerable to undernutrition. Slowed physical growth rate is an early and prominent sign of undernutrition in the young infant. The limited fat stores of the very young infant mean that energy reserves are unusually restricted. The relatively large size and continued growth of the brain render the central nervous system

(CNS) especially vulnerable to the effects of malnutrition in early postnatal life.

ENERGY

The major determinants of energy expenditure are basal metabolism, metabolic response to food, physical activity, and growth. The efficiency of energy use may be a significant factor, and thermoregulation may contribute in extremes of ambient temperature if the body is inadequately clothed. Because adequate data on requirements for physical activity in infants and children are unavailable and because individual growth requirements vary, recommendations have been based on calculations of actual intakes by healthy subjects. The recent trend toward lower figures for infants reflects a move away from hypercaloric and possibly inappropriate feeding practices that were in vogue in past decades. Suggested guidelines for energy intake of infants and young children are given in Table 10–2. Also included in this table are calculated energy intakes of infants who are exclusively breast-fed, which have been verified recently in a number of centers. Growth velocity of breast-fed infants during the first 3 months typically equals or exceeds the 50th percentile for the National Center for Health Statistics (NCHS) grids. The recommended dietary allowances (RDAs) of the Food and Nutrition Board, National Academy of Sciences, and National Research Council (10th edition) are not synonymous with requirements. The RDAs do not take into account the rapid changes in requirements that occur during infancy, especially the first 6 months, RDAs should therefore be used cautiously for calculating energy requirements of infants.

After the first 4 years, energy requirements expressed on a body weight basis decline progressively. The estimated daily energy requirement is about 40 kcal/kg/d at the end of adolescence. Approximate daily energy requirements can be calculated by adding 100 kcal per year to the base of 1000 kcal per day at age 1 year. Appetite and growth are reliable indices of caloric needs in most healthy children, but intake also depends to some

Table 10-1. Changes in growth rate, energy required for growth, and body composition in infants and young children.

Age (months)	Growth Rate (g/d)			Energy Requirements for Growth (kcal/kg/d)	Body Composition		
	Male	Both	Female		Water	Protein	Fat
0-0.25		0 ^a			75	11.5	11
0.25-1	40		35	50			
1-2	35		30	25			
2-3	28		25	16			
3-6		20		10	60	11.5	26
6-9		15					
9-12		12					
12-18		8					
18-36		6		2	61	16	21

^aBirth weight is regained by 10 d. Weight loss of more than 10% of birth weight indicates dehydration or malnutrition; this applies to both formula-fed and breast-fed infants.

Data from Fomon SJ (ed): *Infant Nutrition*, 2nd ed. WB Saunders, 1974. Used with permission.

extent on the energy density of the food offered. Individual energy requirements of normal infants and children vary considerably, and malnutrition and disease increase the variability. Premature infant energy requirements can exceed 120 kcal/kg/d, especially during illness or when catch-up growth is desired.

One method of calculating requirements for malnourished patients is to base the calculations on the ideal body weight (ie, 50th percentile weight for the patient's length age or 50th percentile weight-for-height)

rather than actual weight. Alternatively the extra daily energy requirement for catch-up growth can be calculated as:

$$\frac{5 \times \text{Weight (g) deficit below IBW}}{\text{Interval (days) for correction of deficit}}$$

where 5 kcal is the energy cost of each gram of new tissue deposited. These calculations should be adjusted according to the growth response.

Table 10-2. Recommendations for energy and protein intake.

Age	Energy (kcal/kg/d)			Protein (g/kg/d)	
	Based on Measurements of Energy Expenditure	Intake from Human Milk	Guidelines for Average Requirements	Intake from Human Milk	Guidelines for Average Requirements
10 days to 1 month	—	105	120	2.05	2.5
1-2 months	110	110	115	1.75	2.25
2-3 months	95	105	105	1.36	2.25
3-4 months	95	75-85	95	1.20	2.0
4-6 months	95	75-85	95	1.05	1.7
6-12 months	85	70	90	—	1.5
1-2 years	85	—	90	—	1.2
2-3 years	85	—	90	—	1.1
3-5 years	—	—	90	—	1.1

PROTEIN

Only amino acids and ammonium compounds are usable as sources of nitrogen in humans. Amino acids are provided through the digestion of dietary protein. Nitrogen is absorbed from the intestine as amino acids and short peptides. Absorption of nitrogen is more efficient from synthetic diets that contain peptides in addition to amino acids. Some intact proteins are absorbed in early postnatal life, a process that may be important in the development of protein tolerance or allergy.

The liver plays a central role in amino acid metabolism, including regulation of the absorbed amino acids. Excess amino acids, including essential amino acids, are degraded in the liver, except for the branched-chain amino acids, which pass into the systemic circulation and are taken up primarily by muscle. Insulin stimulates this uptake and suppresses muscle protein catabolism. Protein turnover rates far exceed intake, indicating a reuse of amino acids. However, some of these amino acids released from protein turnover are degraded. After removal of the amino group, the keto acids are either used directly for energy or converted to carbohydrate and fat. Nitrogen is excreted primarily via the kidney as urea.

Because there are no major stores of body protein, a regular dietary supply of protein is essential. In infants and children, optimal growth depends on an adequate dietary protein supply. Relatively subtle effects of protein deficiency are now recognized, especially those affecting tissues with rapid protein turnover rates, such as the immune system and the GI mucosa.

Relative to body weight, rates of protein synthesis and turnover and accretion of body protein are exceptionally high in the infant, especially the premature infant. Eighty percent of the dietary protein requirement of a premature infant is used for growth, compared with only 20% in a 1-year-old child. Protein requirements per unit of body weight decline rapidly during infancy as growth velocity decreases. The recommendations in Table 10-2 are derived chiefly from the Joint FAO/WHO/UNO Expert Committee and are similar to the RDAs. They deliver a protein intake above the quantity provided in breast milk. The protein intake required to achieve protein deposition equivalent to the in utero rate in very low birth weight infants is 3.7–4.0 g/kg/day simultaneous with adequate energy intake. Protein requirements increase in the presence of skin or gut losses, burns, trauma, and infection. Requirements also increase during times of catch-up growth accompanying recovery from malnutrition (ap-

proximately 0.2 g of protein per gram of new tissue deposited). Young infants experiencing rapid recovery may need as much as 1–2 g/kg/d of extra protein. By age 1 year, the extra protein requirement is unlikely to be more than 0.5 g/kg/d. Inadequate protein intake may occur in breast-fed infants fed low-protein supplements (eg, fruit juices), in infants with protein malabsorption (cystic fibrosis), or in infants fed low-protein weaning food (eg, cassava) as the dietary staple.

The quality of protein depends on its amino acid composition. Infants require 43% of protein as essential amino acids, and children require 36%. Adults cannot synthesize eight essential amino acids: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Histidine may be added to this list. Cysteine and tyrosine are considered partially essential because their rates of synthesis are limited and may be inadequate in certain circumstances. In young infants, synthetic rates for cysteine, tyrosine, and perhaps taurine are insufficient for needs. Taurine, an amino acid used to conjugate bile acids, may also be conditionally essential in infancy. Taurine supplementation may improve fat absorption in preterm infants and in infants with cystic fibrosis. Taurine supplements may also improve auditory brainstem evoked potentials in preterm infants. Lack of an essential amino acid leads to weight loss within 1–2 weeks. Wheat and rice are deficient in lysine, and legumes are deficient in methionine. Appropriate mixtures of vegetable protein are therefore necessary to achieve high protein quality.

Because the mechanisms for removal of excess nitrogen are efficient, moderate excesses of protein are not harmful and may help to ensure an adequate supply of certain micronutrients. Adverse effects of excessive protein intake may include increased calcium losses in urine and, over a life span, increased loss of renal mass. Excessive protein intake may also cause elevated blood urea nitrogen, acidosis, hyperammonemia, and, in the premature infant, failure to thrive, lethargy, and fever.

LIPIDS

Fats are the main dietary energy source for infants and account for up to 50% of the energy in human milk. Over 98% of breast milk fat is triglyceride, which has an energy density of 9 kcal/g. Fats can be stored efficiently in adipose tissue with a minimal energy cost of storage. This is especially important in the young in-

fant. Fats are required for the absorption of fat-soluble vitamins and for myelination of the CNS. Fat also provides essential fatty acids (EFAs) necessary for brain development, for phospholipids in cell membranes, and for the synthesis of prostaglandins and leukotrienes. The EFAs are polyunsaturated fatty acids, linoleic acid (18:2 ω 6) and linolenic acid (18:3 ω 3). Arachidonic acid (20:4 ω 6) is derived from dietary linoleic acid and is present primarily in membrane phospholipids. Oxygenation of arachidonic acid through the lipoxygenase pathway yields leukotrienes, and oxygenation through the cyclooxygenase pathway yields prostaglandins. Important derivatives of linolenic acid are eicosapentaenoic acid (20:5 ω 3) and docosahexaenoic acid (22:6 ω 3) found in human milk and brain lipids. Visual attention and possibly psychomotor development of formula-fed premature infants is improved in formulae supplemented with 20:5 ω 3, which is not derived readily from 18:3 ω 3.

Clinical features of EFA ω 6 deficiency include growth failure, erythematous and scaly dermatitis, capillary fragility, increased fragility of erythrocytes, thrombocytopenia, poor wound healing, and susceptibility to infection. The clinical features of deficiency of ω 3 fatty acids are less well defined, but dermatitis and neurologic abnormalities including blurred vision, peripheral neuropathy, and weakness have been reported. Marine oil-supplemented formula improves visual acuity of preterm infants through age 4 months by improving docosahexaenoic acid status. Fatty fish are the best dietary source of ω 3 fatty acids. A high intake of fatty fish is associated with decreased platelet adhesiveness and decreased inflammatory response.

Up to 5–10% of fatty acids in human milk are polyunsaturated. Most of these are ω 6 series with smaller amounts of long-chain ω 3 fatty acids. About 40% of breast milk fatty acids are monounsaturates, primarily oleic acid (18:1), and up to 10% of total fatty acids are medium-chain triglycerides (MCTs) (C_8 and C_{10}) with a calorie density of 7.6 kcal/g. In general, the percentage of calories derived from fat is a little lower in infant formulas than in human milk. Infant formulas usually contain a relatively high percentage of linoleic acid but very little long-chain ω 3 fatty acid. The American Academy of Pediatrics recommends that infants receive at least 30% of calories from fat, with at least 1.7% of total calories from ω 6 fatty acids and 0.5% from ω 3 fatty acids. It is appropriate that 40–50% of energy requirements be provided as fat during the first 2 years of life. Children older than 2 years should be switched gradually to a diet containing approximately 30% of total calories from fat, with no more than 10% of calories either from saturated fats or polyunsaturated fats.

During digestion, triglycerides are hydrolyzed to monoglycerides, free fatty acids, and glycerol in the

lumen of the gut. Substantial hydrolysis of triglycerides in milk formulas occurs in the stomach by the action of lingual and gastric lipases. Pancreatic lipases and bile salt levels are relatively low in early postnatal life, but breast milk contains a bile salt-stimulated lipase that is effective in the lumen of the duodenum. Bile salts promote the formation of the colipase–lipase complex, which adheres to the triglycerides prior to hydrolysis. Bile salts also have a major role in the emulsification of fatty acids, allowing their passage through the unstirred water layer to the surface of the mucosal cell. After passage into the enterocyte, long-chain ($\geq C_{12}$) fatty acids and monoglycerides are reesterified to triglycerides and are packaged with phospholipids, cholesterol, and protein into chylomicrons, which are transported in the lymphatics to the liver and thence the circulation. At the capillary endothelial surface of adipose and muscle tissue, lipoprotein lipase (LPL) hydrolyzes triglycerides from chylomicrons, releasing free fatty acids and glycerol, which are taken up by the adjacent cells. LPL also hydrolyzes triglycerides synthesized in the liver and transported to peripheral tissues as very low density lipoproteins.

Beta-oxidation of fatty acids occurs in the mitochondria of muscle and liver. Carnitine is necessary for oxidation of the fatty acids, which must cross the mitochondrial membranes as acylcarnitine. Carnitine is synthesized in the human liver and kidney from lysine and methionine. Carnitine needs of infants are met by breast milk or formulas, and carnitine is now added routinely to soy-based formulas. In the liver, substantial quantities of fatty acids are converted to ketone bodies, which are then released into the circulation as an important fuel for the brain of the young infant.

MCTs are sufficiently soluble that micelle formation is not required for transport across the intestinal mucosa. They are transported directly to the liver via the portal circulation. MCTs are rapidly metabolized in the liver, undergoing beta-oxidation or ketogenesis. They do not require carnitine to enter the mitochondria. Ketones are formed from MCTs even when provided orally. MCTs are useful for patients with luminal phase defects, absorptive defects, and chronic inflammatory bowel disease. The potential side effects of MCT administration include diarrhea when given in large quantities; high octanoic acid levels in patients with cirrhosis; and, if they are the only source of lipids, deficiency of EFA.

CARBOHYDRATES

The energy density of carbohydrate is 4 kcal/g. Approximately 40% of caloric intake in human milk is in the form of lactose, or milk sugar. Lactose supplies 20% of the total energy in cow's milk. The percent of total energy in infant formulas from carbohydrate is similar to that of human milk.

After the first 2 years of life, 55–60% of energy requirements should be derived from carbohydrates, with no more than 10% from simple sugars. These dietary guidelines are, unfortunately, not reflected in the diets of North American children, who typically derive 25% of their energy intake from sucrose and less than 20% from complex carbohydrates.

The rate at which lactase hydrolyzes lactose to glucose and galactose in the intestinal brush border determines how quickly milk carbohydrates are absorbed. Lactase levels are highest in young infants, declining by more than 50% later in the first year. Lactase levels decline further with age depending on genetic factors. Lactose-intolerant children experience varying degrees of symptoms depending on the specific activity of their own intestinal lactase and the amount of lactose consumed. Lactase is located predominantly at the tip of the intestinal villi, where it is especially vulnerable to the effects of gastroenteritis or malnutrition. Thus, it may be helpful to avoid giving lactose-containing foods to children recovering from gastroenteritis or malnutrition, although this is not universally necessary. Galactose is preferentially converted to glycogen in the liver prior to conversion to glucose for subsequent oxidation. Infants with galactosemia, an inborn metabolic disease caused by deficient galactose-1-phosphate uridylyltransferase, require a lactose-free diet starting in the neonatal period.

Starch is broken down in the lumen of the gut into disaccharides and oligosaccharides, which are hydrolyzed into glucose by maltase, isomaltase, and glucoamylase in the brush border. Glucoamylase, which hydrolyzes oligosaccharides of 4–9 glucose units, is located predominantly at the base of the villi, where it may be protected from partial villus atrophy. Glucose polymers of this length are used extensively in infant formulas and as caloric supplements. Advantages include a relatively low osmolality and better hydrolysis by the damaged mucosa. Glucose and galactose are absorbed actively with sodium. This provides the theo-

retic basis for the composition of oral rehydration solutions in the management of diarrhea. The glucose enhances the absorption of sodium (and thus of water) and also supplies some energy.

During and immediately following a meal, plasma glucose levels are maintained by glucose absorption. If less than 10% of dietary energy is regularly provided by carbohydrate, ketosis results. Between 2–4 hours after a meal, plasma glucose depends increasingly on use of hepatic glycogen stores. These provide only 100–150 g glucose in the adult and only 6 g in the neonate. After liver glycogen is depleted, the body progressively depends on gluconeogenesis. Glucose is the principal fuel for the brain and is the main energy source for other tissues, including red and white blood cells.

Children and adolescents in North America consume large quantities of sucrose in soft drinks, candy, syrups, and sweetened breakfast cereals. A high sucrose intake may predispose a child to obesity and is a major risk factor for dental caries. Sucrase hydrolyzes sucrose to glucose and fructose in the brush border of the small intestine. Fructose is absorbed more slowly than and independently of glucose by facilitated diffusion. This characteristic can be an advantage. Neither fructose nor galactose stimulates insulin secretion. Fructose, however, is easily converted to hepatic triglycerides, which may be undesirable in malnourished patients.

Dietary fiber can be classified in two major types: nondigested carbohydrate (β 1–4 linkages) and noncarbohydrate (lignin). Insoluble fibers (cellulose, hemicellulose, and lignin) increase stool bulk and water content and decrease gut transit time. They may impair mineral absorption. Soluble fibers (pectins, mucilages, oat bran) bind bile acids and reduce lipid and cholesterol absorption. Pectins also slow gastric emptying and the rate of nutrient absorption. Fiber intakes are low in North America. Few data regarding the fiber needs of children are available. Federally recognized standards for dietary fiber intake do not yet exist. However, the American Academy of Pediatrics suggests 0.5 g dietary fiber for every kilogram of the child's weight, up to 35 g/d. The American Health Foundation recommends that children older than 2 years consume in grams per day an amount of fiber equal to 5 plus the age in years.

MAJOR MINERALS

(See Table 10–3 for recommended intakes.)

Calcium

The major dietary sources of calcium are milk and other dairy products. Although some calcium is available from legumes, broccoli, some green leafy vegetables, and fortified cereals, it is difficult to achieve an adequate calcium

Table 10-3. Summary of dietary reference intakes for selected minerals and trace elements

	0-6 mo	7-12 mo	1-3 yr	4-8 yr	9-13 yr	14-18 yr male	14-18 yr female
Calcium (mg/d)	210 ^a	270 ^a	500 ^a	800 ^a	1300 ^a	1300 ^a	1300 ^a

^aAdequate Intakes (AI). All other values represent the Recommended Dietary Allowances (RDA). Both the RDA and AI may be used as goals for individual intakes.

National Academy of Sciences, Food and Nutritional Board, Institute of Medicine: *Dietary Reference Intakes, Applications in Dietary Assessment*. National Academy Press, Washington, DC 2000: 287-289. <http://www.nap.edu>.

intake without dietary dairy products or calcium supplementation. Average calcium absorption, is 20-30%, but calcium absorption from human milk is 60%. Absorption is enhanced by lactose, glucose, and protein and is impaired by phytate, fiber, oxalate, and unabsorbed fat. Control of calcium absorption is exerted primarily by variations in serum 1,25-dihydroxycholecalciferol (calcitriol), which increases in response to increases in circulating parathyroid hormone (PTH). PTH is secreted in response to a fall in plasma ionized calcium. It also promotes the release of calcium from bone. Calcium is excreted primarily via the kidney. It is the most abundant mineral in the body, and more than 99% is in the skeleton. Many vital cellular processes depend on calcium, especially changes in cytosolic free calcium levels. Changes in these levels also occur in various pathologic states and can grossly disturb intracellular metabolism. A deficiency in dietary calcium can occur in premature infants and lactating adolescents as a result of restricted milk intake and also in patients with steatorrhea. Deficient calcium intake results in decreased bone density. Bone density increases with increasing calcium intake up to a daily intake of more than 1000 mg in adolescents. Maximizing bone density in adolescence has im-

portant implications for achieving peak bone density and minimizing postmenopausal osteoporosis.

Phosphorus

Phosphorus is abundant in meats, eggs, dairy products, grains, legumes, and nuts. Phosphorus levels are high in processed foods and very high in colas and other soft drinks. Approximately 80% of dietary phosphorus is absorbed; the kidney is responsible for homeostatic control. PTH decreases tubular reabsorption of phosphorus. More than 85% of body phosphorus is in bone. Phosphorus is also a component of many organic compounds with vital metabolic roles, including adenosine triphosphate (ATP) and 2,3-diphosphoglycerate. Many of the clinical effects of phosphorus depletion are attributable to cellular energy depletion from lack of ATP or to cellular anoxia secondary to impaired release of oxygen from hemoglobin. Other key compounds containing phosphorus include cell membrane phospholipids and nucleotides.

Nutritional phosphorus deficiency is rare but has occurred in very premature infants fed human milk, in whom it can produce osteoporosis and rickets, and in

patients with severe protein-energy malnutrition. Non-nutritional phosphorus depletion may result from chronic diarrhea, Fanconi tubulopathy, and the ingestion of phosphorus-binding antacids. Severe hypophosphatemia results from a deficiency together with an acute extracellular-to-intracellular shift in phosphorus. This shift can be triggered by glucose, by insulin, or during nutritional rehabilitation of the malnourished patient. Phosphorus deficiency affects most organ systems, including muscle (weakness progressing to rhabdomyolysis), cellular components of blood (both physiologic and functional changes), the GI system, the CNS, and bone (bone pain, osteomalacia). Respiratory insufficiency may result from weakness of the diaphragm. Phosphate depletion in the premature infant can cause hypercalcemia. Phosphorus depletion can be treated with phosphorus salts or skim milk. Phosphorus excess may cause neonatal tetany due to decreased serum calcium. Phosphorus retention in chronic renal disease leads to metabolic bone disease.

Magnesium

Two thirds of dietary magnesium is derived from vegetables, cereals, and nuts. The kidney controls magnesium homeostasis by minimizing excretion when intake is low. Magnesium is the second most abundant intracellular cation; 50% is in bone. Levels in the cytosol are 10 times that in the extracellular fluids and are especially high in mitochondria. Magnesium activates many enzymes, especially phosphorus-hydrolyzing and -transferring enzymes involved in energy metabolism. Magnesium also plays major roles in nucleic acid metabolism.

Dietary magnesium deficiency is not recognized except as a component of protein-energy malnutrition, but magnesium depletion may occur secondary to renal disease, intestinal malabsorption, or medications inducing magnesium loss from the gut or kidney. Hypomagnesemia produces neuromuscular excitability, muscle fasciculation and tremors, personality changes, neurologic abnormalities, and electrocardiographic changes (depression of ST segment and T waves). Disturbances of PTH metabolism can cause secondary hypocalcemia. Acute magnesium depletion can be treated with a 50% solution of $MgSO_4$, providing 0.3–1.0 mEq of magnesium per kilogram given intravenously over a 24-hour period. Magnesium excess can cause respiratory depression, lethargy, and coma.

Sodium

In the United States and western Europe, only 10% of sodium intake is derived from unprocessed foods; 15% is derived from salt added while cooking and 75% from

salt added to processed foods during manufacturing. The 10% derived from unprocessed foods is sufficient to meet normal requirements. Current dietary recommendations suggest that North Americans should reduce sodium intake so as to restore a normal ratio of dietary sodium to potassium. The present ratio is approximately 2:1, but in other cultures and in other mammalian species the ratio is 0.25:1. A high sodium-to-potassium ratio has been implicated in the pathogenesis of hypertension, especially if the intake of dietary calcium is low.

Excessive sweating or high sweat sodium (as in cystic fibrosis) may increase the requirement for dietary sodium. Sodium deficiency occurs most commonly as a result of diarrhea and vomiting. Anorexia, vomiting, and mental apathy may result from chronic depletion of sodium chloride. Hyponatremic and hypernatremic dehydration are discussed in Chapter 42.

Severe malnutrition and severe stress or hypermetabolism can disturb the ionic gradient across cell membranes and lead to excess intracellular sodium, which can adversely affect cellular metabolism. Sodium should be administered with great caution in these circumstances. Suggested dietary intake of sodium for infants is 50 mg/kg/d; for children older than 1 year, it is 250–500 mg/d.

Chloride

The intake and homeostasis of dietary chloride are closely linked with those of sodium. However, chloride is itself important in the physiologic mechanisms of the kidney and the gut. Active chloride transport in the ascending loop of Henle is necessary for the passive reabsorption of sodium. Deficiency of chloride leads to a decrease in the absorption of sodium in the ascending loop of Henle and an increase in the amount of sodium presented to the distal tubule. This sodium is exchanged for H^+ and K^+ , which can result in hypokalemic alkalosis.

Infants fed formulas low in chloride have experienced a nutritional deficiency of chloride. Other causes of chloride deficiency include cystic fibrosis, pyloric stenosis and other causes of vomiting, familial chloride diarrhea, chronic diuretic (furosemide) therapy, and Bartter syndrome. Chloride deficiency has been associated with failure to thrive and may especially affect head growth. Other features include anorexia, lethargy, muscle weakness, vomiting, dehydration, and hypovolemia. Laboratory features include hypochloremia, hypokalemia, metabolic alkalosis, and hyperreninemia. Suggested dietary intake of chloride for infants is 70 mg/kg/d; for children older than 1 year, it is 700 mg/d.

Potassium

Potassium is readily available in unprocessed foods, including nuts, whole grains, meats and fish, beans, bananas, and orange juice. Relatively high potassium intakes are encouraged except in the presence of renal failure. The kidneys control potassium homeostasis via the aldosterone–renin–angiotensin endocrine system. Potassium is the principal intracellular cation. The amount of total body potassium, therefore, depends on lean body mass. Potassium deficiency occurs in protein-energy malnutrition and can be a cause of sudden death from cardiac failure if not treated aggressively during the initial phase of rehabilitation. Because of loss of lean body mass, excessive potassium is excreted in the urine in any catabolic state. This too requires aggressive replenishment during recovery. During acidosis, intracellular potassium is exchanged for H^+ . Potassium is shifted into the extracellular fluid, and large amounts may be lost in the urine (eg, in diabetic ketoacidosis) despite normal or elevated plasma potassium. Other causes of potassium deficiency are diarrhea and diuretics. Potassium deficiency may produce muscle weakness, mental confusion, and sudden death from arrhythmias. Electrocardiographic findings include depression of the ST segment and low T waves. Hyperkalemia may result from renal insufficiency. Suggested dietary intake of potassium for infants is 80 mg/kg/d; for children older than 1 year, it is 800 mg/d.

TRACE ELEMENTS

Trace elements with a recognized role in human nutrition are iron, iodine, zinc, copper, selenium, manganese, molybdenum, chromium, cobalt (as a component of vitamin B_{12}), and fluoride. Dietary requirements of trace elements are summarized in Table 10–3. Iron deficiency is discussed in Chapter 27. In general, good dietary sources of trace elements include human milk, meats, shellfish, legumes, nuts, and whole-grain cereals. Fish are a good source of selenium. Absorption of iron, zinc, copper, and probably other trace elements from human milk is especially efficient; healthy full-term breast-fed infants generally do not require exogenous trace elements, including iron, until approximately 6 months. Factors affecting trace element absorption include the quantity in the diet, the simultaneous ingestion of foods promoting the formation of insoluble complexes (phytate, fiber, phosphate, oxalate), the oxidation state of the element (ascorbic acid increases iron absorption and decreases copper absorption), its chemical form in the diet (heme versus nonheme iron), competitive inhibition of mucosal absorption (interactions of iron, zinc, and copper), and host factors such as nutritional status, diarrhea, and in-

testinal function. The GI tract is the major site of homeostatic control for iron and zinc; the liver for copper; the intestinal tract and liver for manganese; and the kidneys for selenium, chromium, and iodine.

Deficiencies of iron, zinc, and possibly copper, occur in the free-living population. In certain geographic regions iodine and selenium deficiency is common because of deficiencies in soil and water. Infants exclusively fed cow's milk are at risk for iron and copper deficiency. Excessive loss and impaired absorption can cause iron, zinc, or copper deficiency. Trace element deficiencies have been associated with the use of synthetic diets and especially intravenous (IV) nutrition. Protein-energy malnutrition may be complicated by deficiencies in iron, zinc, copper, selenium, or chromium. Deficiencies in zinc, copper, iron, and molybdenum occur as a result of specific genetic diseases affecting the absorption or metabolism of these elements (see Chapter 33).

Zinc

Zinc is a component of many enzymes and plays important roles in nucleic acid metabolism, protein synthesis, and membrane structure and function. Zinc deficiency is the result of diets low in available zinc (high phytate) and synthetic diets (oral or IV) lacking adequate zinc supplements. Diseases associated with impaired absorption (regional enteritis, celiac disease, cystic fibrosis) or excessive loss (chronic diarrhea), and inborn diseases of zinc metabolism may produce a state of zinc deficiency. Although the zinc in human milk is very efficiently absorbed, the zinc concentration in breast milk steadily declines over time. After 6 months, the exclusively breast-fed infant is likely to need additional zinc from complementary foods.

Several recent large trials have shown that zinc supplementation in infants and young children is associated with a significant reduction in the incidence of pneumonia and of acute and chronic diarrhea. Improved zinc status has also been associated with improved immunocompetence. Low-birth-weight infants appear to be particularly vulnerable to zinc deficiency, and randomized trials of zinc supplementation in developing countries have shown significant improvements in growth as well as reduction in the mortality and morbidity associated with infection. Mild deficiency is associated with impaired growth and poor appetite. Severe deficiency is characterized by mood changes, irritability, and lethargy. Impairment of the immune system, especially T-cell function, has been linked to increased susceptibility to infection. The most severe deficiency state is characterized by an acrodermatitis skin rash, usually accompanied by diarrhea and alopecia. These features occur in patients with acrodermatitis en-

teropathica, an inborn error of zinc metabolism, in subjects receiving IV feeding without adequate zinc supplements, and in some breast-fed infants whose mothers have a defect in the secretion of zinc by the mammary gland. Plasma zinc collected before breakfast is below 6 $\mu\text{mol/L}$ (40 $\mu\text{g/dL}$) in patients with severe zinc deficiency and 6–9 $\mu\text{mol/L}$ (40–60 $\mu\text{g/dL}$) in patients with moderate zinc deficiency. In patients with mild zinc deficiency, plasma zinc concentration may be within the normal range (60–100 $\mu\text{g/dL}$).

Dietary zinc deficiency can be treated with 1 mg/kg/d of zinc for 3 months (eg, 4.5 mg of ZnSO_4 + 7 $\text{H}_2\text{O/kg/d}$), preferably administered separately from meals and iron supplements. Sustained clinical remission in acrodermatitis enteropathica is usually achieved with 30–50 mg Zn^{2+} per day, but larger quantities may be required.

Copper

Copper is a vital component of several oxidative enzymes: cytochrome c oxidase, the terminal oxidase in the electron transport chain; cytosolic and mitochondrial superoxide dismutase, which have key roles in the body defense against free radicals; lysyl oxidase, which is necessary for the cross-linking of elastin and collagen; and ferroxidases (including ceruloplasmin) necessary for the oxidation of ferrous storage iron to ferric iron prior to attachment to transferrin for transport to the red cell precursors in the bone marrow. Cu^{2+} is highly reactive and must be transported in the circulation bound to ceruloplasmin so that its oxidative potential can be contained.

Copper deficiency occurs in the following circumstances: in premature infants fed milk preparations low in copper; in association with prolonged feeding with unmodified cow's milk; in association with generalized malnutrition; in patients maintained on prolonged total parenteral nutrition (TPN) without copper supplementation; and in patients with intestinal malabsorption or prolonged diarrhea.

Osteoporosis is an early finding of copper deficiency. Later, enlargement of costochondral cartilages,

cupping and flaring of long-bone metaphyses, and spontaneous rib fractures may occur. The radiologic findings must be distinguished from child abuse (asymmetrical fractures), rickets, and scurvy. Neutropenia and hypochromic anemia are other early manifestations. The anemia is unresponsive to iron therapy. Very severe CNS disease is present in Menkes steely (kinky) hair syndrome, in which a profound copper deficiency state results from an X-linked defect in cellular metabolism of copper.

A low plasma copper or ceruloplasmin level helps confirm the diagnosis of copper deficiency. However, these levels are normally very low in the young infant, especially the premature infant, and are higher than adult values in later infancy and early childhood. Hence, age-matched normal data are necessary for comparison. Interleukin-1 grossly elevates both ceruloplasmin and copper levels; the levels are also high in pregnancy.

Copper deficiency can be treated with a 1% copper sulfate solution (2 mg of the salt or 500 mg of elemental copper per day for infants).

Olivares M et al: Copper homeostasis in infant nutrition: Deficit and excess. *J Pediatr Gastroenterol Nutr* 2000;31(2):102 [PMID: 10941959].

Selenium

Selenium is an essential component of glutathione peroxidase, which catalyzes the reduction of hydrogen peroxide to water in the cell cytosol by the addition of reducing equivalents derived from glutathione. Hence, selenium plays an important role in protection against free-radical injury.

Selenium deficiency is the major causal factor in Keshan disease, an often fatal cardiomyopathy primarily affecting infants, children, and young women in a large area of China where there is a severe geochemical selenium deficiency. Similar cases have been identified in the United States in patients maintained on long-term TPN without adequate selenium supplement, in whom symptoms also include skeletal muscle pain and tenderness. Macrocytosis and loss of hair pigment occur in milder selenium deficiency. Premature infants have exceptionally low serum selenium levels, which decline further without supplementation. Blood levels are especially low in premature infants with bronchopulmonary dysplasia. The minimum recommended selenium content for full-term infant formulas is 1.5 $\mu\text{g}/100$ kcal, and that for preterm infant formulas is 1.8 $\mu\text{g}/100$ kcal.

A plasma selenium level less than 0.5 $\mu\text{mol/L}$ (< 40 $\mu\text{g/L}$) suggests mild selenium deficiency. A level less than 0.12 $\mu\text{mol/L}$ (< 10 $\mu\text{g/L}$) indicates a possible severe selenium deficiency.

Iodine

Endemic goiter resulting from environmental iodine deficiency has been eradicated in North America by prophylactic measures but continues to be a health problem in many developing countries. Goiter occurs when iodine intake is less than 20 mg/d. Most persons with endemic goiter are clinically euthyroid. Maternal iodine deficiency causes endemic neonatal hypothyroidism in about 5–15% of neonates who may have goiter at birth.

Neurologic endemic cretinism, seen in most parts of the world, is characterized by severe mental retardation, deaf–mutism, spastic diplegia, and strabismus. Evidence of hypothyroidism is usually absent, and it is thought that the neurologic damage is due to a direct effect of fetal iodine deficiency or to an imbalance between thyroxine (low) and triiodothyronine (normal or elevated). Myxedematous endemic cretinism occurs in some central African countries. Signs of congenital hypothyroidism are present. Milder neurologic damage occurs in some cases of endemic neonatal goiter.

The use of iodized salt has been highly effective in preventing goiter. In areas where endemic goiter occurs, intramuscular depot injections of iodized oil have also been used for prevention.

Fluoride

When fluoride is incorporated into the hydroxyapatite matrix of dentin, it effectively reduces the incidence of dental caries. Fluoride is most effectively administered as an additive to drinking water, but in infancy and childhood, fluoride vitamin preparations serve the same purpose. Ready-made formulas contain less than 0.3 ppm of fluoride. The recognized benefits of topical fluoride supplementation in preventing caries must be weighed against the increasing incidence of fluorosis in children in the United States. Fluorosis is characterized by an increased porosity (undermineralization) of the enamel and is evident clinically as discoloration of the teeth. Recommendations for fluoride supplementation in infants have been revised (Table 10–4). The American Academy of Pediatrics Committee on Nutrition, recommends withholding fluoride supplementation until age 6 months.

VITAMINS

1. Fat-Soluble Vitamins

Because they are insoluble in water, the fat-soluble vitamins require digestion and absorption of dietary fat and a carrier system for transport in the blood. Deficiencies in these vitamins develop more slowly than deficiencies in water-soluble vitamins because the body accumulates stores of fat-soluble vitamins. Excessive intakes carry a considerable potential for toxicity (Table 10–5).

Vitamin A

Dietary sources of vitamin A include dairy products, fortified margarine, eggs, liver, meats, fish oils, and corn. The vitamin A precursor β -carotene is abundant in yellow and green vegetables. Dietary retinyl palmitate requires hydrolysis by pancreatic and intestinal hydrolases. β -Carotene is cleaved in the intestinal mucosal cells by dioxygenase to yield two molecules of retinal (retinaldehyde), which is then reduced to retinol (vitamin A alcohol). Carotene appears to have an important role in its own right as an antioxidant.

Retinol is reesterified in the intestinal mucosa and transported in chylomicrons to the liver for storage. From the liver, vitamin A is exported to the body attached to retinol-binding protein and prealbumin. Retinol-binding protein may be decreased in liver disease or in protein-energy malnutrition. Circulating retinol-binding protein may be increased in chronic renal failure.

Vitamin A has a critical role in the photochemical basis of vision. The photosensitive pigment rhodopsin is formed from retinal and a protein called opsin. Vitamin A also modifies differentiation and proliferation of epithelial cells, especially in the respiratory tract. Vitamin A is necessary for glycoprotein synthesis. Retinol

Table 10–5. Effects of vitamin toxicity.

Thiamin	(Very rare.) Anaphylaxis; respiratory depression
Riboflavin	None
Pyridoxine	Sensory neuropathy at doses > 500 mg/d
Niacin	Histamine release → cutaneous vasodilation; cardiac arrhythmias; cholestatic jaundice; gastrointestinal disturbance; hyperuricemia; glucose intolerance
Pantothenic acid	Diarrhea
Biotin	None
Folic acid	May mask B ₁₂ deficiency, hypersensitivity
Cobalamin	None
Vitamin C	Interference with copper absorption; decreased tolerance to hypoxia, increased oxalic acid excretion
Carnitine	None recognized
Vitamin A	(> 20,000 IU/d): Vomiting, increased intracranial pressure (pseudotumor cerebri); irritability; headaches; insomnia; emotional lability; dry, desquamating skin; myalgia and arthralgia; abdominal pain; hepatosplenomegaly; cortical thickening of bones of hands and feet
Vitamin D	(> 40,000 IU/d): Hypercalcemia; vomiting; constipation; nephrocalcinosis
Vitamin E	(? 25–100 mg/kg/d intravenously): Necrotizing enterocolitis and liver toxicity (but probably due to polysorbate 80 used as a solubilizer)
Vitamin K	<i>Lipid-soluble vitamin K:</i> Very low order of toxicity. <i>Water-soluble, synthetic vitamin K:</i> Vomiting, porphyrinuria; albuminuria; hemolytic anemia; hemoglobinuria; hyperbilirubinemia (do not give to neonates)

can be irreversibly oxidized to retinoic acid, which is effective in glycoprotein synthesis but is ineffective for vision.

Vitamin A deficiency occurs in premature infants, in association with IV nutrition with inadequate vitamin A supplement, and in association with protein-energy malnutrition, when the manifestations are frequently made more severe by measles. Other causes of vitamin A deficiency are dietary insufficiency and fat malabsorption.

The features of vitamin A deficiency are primarily related to the eye and vision. Night blindness progresses to xerosis (dryness of cornea and conjunctiva), xerophthalmia (extreme dryness of the conjunctiva), Bitot spots, keratomalacia (clouding and softening of the cornea), ulceration and perforation of the cornea, prolapse of the lens and iris, and eventually blindness. Vitamin A deficiency is the leading cause of blindness in children worldwide. Other features of vitamin A deficiency include follicular hyperkeratosis (dry, thickened, rough skin), pruritus, growth retardation, increased susceptibility to infection, anemia, and hepatosplenomegaly. Vitamin A treatment of children with rubeola in developing countries has been associated with reduction in morbidity and mortality from this viral infection.

Serum retinol levels below 20 µg/dL are low, and levels less than 10 µg/dL indicate deficiency. A ratio of retinol to retinol-binding protein below 0.7 is also indicative of vitamin A deficiency.

Suggested intakes of vitamin A are summarized in Table 10–6. Therapy of xerophthalmia requires 5000–10,000 international units (IU)/kg/d for 5 days orally or intramuscularly. The standard maintenance dose in fat malabsorption syndromes is 2500–5000 IU (800–1600 µg). Doses as high as 25,000–50,000 IU/d may be needed, but monitoring to avoid toxicity is essential. The effects of vitamin A toxicity are summarized in Table 10–5.

Villamor E, Fawzi WW: Vitamin A supplementation: Implications for morbidity and mortality in children. *J Infect Dis* 2000;182 (Suppl):S122 [PMID: 10944494].

Vitamin D

Vitamin D requirements are normally met primarily from cholecalciferol (vitamin D₃) produced by ultraviolet radiation of dehydrocholesterol in the skin. Similarly, ergocalciferol (vitamin D₂) is derived from UV irradiation of ergosterol in the skin. Vitamin D is transported from the skin to the liver attached to a specific carrier protein. The primary dietary source of vitamin D is fortified milk and formulas. Egg yolk and fatty fish contain some vitamin D. Vitamin D absorption depends on normal fat absorption. Absorbed vitamin D is transported to the liver in chylomicrons. Vitamins D₂ and D₃ undergo 25-hydroxylation in the liver and then 1α-hydroxylation in kidney proximal tubules to yield 1,25-dihydroxycholecalciferol (calcitriol) and calcitriol, respectively. PTH activates the 1α-hydroxylase enzyme in the kidney. 25-Hydroxycholecalciferol (calcidiol) is the major circulating form of vitamin D. Calcitriol is the biologically active form of vitamin D. Calcitriol stimulates the intestinal absorption of cal-

National Academy Press, Washington, DC 2000: 287-89. <http://www.nap.edu>.

cium and phosphate, the renal reabsorption of filtered calcium, and the mobilization of calcium and phosphorus from bone.

Vitamin D deficiency usually results from a combination of inadequate sunlight exposure and low dietary intake. An infant with light skin pigmentation requires only about 30 minutes per week of total body sun exposure or 2 hours per week of head exposure to maintain adequate vitamin D status. Adequate amounts of sun exposure for infants with more darkly pigmented skin are difficult to quantify. Furthermore, dermatolo-

gists advise caution in exposure to sun, even for young infants. Vitamin D content of human milk is low. In the United States, cow's milk and infant formulas are routinely supplemented with vitamin D. The American Academy of Pediatrics now recommends vitamin D supplementation for all breast-fed infants until they are receiving at least 500 mL/d of vitamin D in fortified formula or milk. Supplementation should be initiated during the first 2 months of life.

Vitamin D deficiency also occurs in fat malabsorption syndromes. Use of P-450-stimulating drugs may

decrease hydroxylated vitamin D, which can also be decreased by hepatic and renal disease and by inborn errors of metabolism. End-organ unresponsiveness to calcitriol may also occur.

The clinical effects of vitamin D deficiency are osteomalacia (adults) or rickets (children), in which osteoid (matrix) with reduced calcification accumulates in bone. Cartilage fails to mature and calcify. Clinical findings include craniotables, rachitic rosary, pigeon breast, bowed legs, delayed eruption of teeth and enamel defects, Harrison groove, scoliosis, kyphosis, dwarfism, painful bones, fractures, anorexia, and weakness. Radiographic findings include cupping, fraying, and flaring of metaphyses. The loss of sharp definition of bone trabeculae accounts for the general decrease in skeletal radiodensity. The diagnosis is supported by characteristic radiologic abnormalities of the skeleton, low serum phosphorus, high serum alkaline phosphatase, and high serum PTH. The diagnosis can be confirmed by a low level of serum 25-hydroxycholecalciferol.

Rickets is treated with 1600–5000 IU/d of vitamin D₃ (1 IU = 0.025 µg). If this is poorly absorbed, calcidiol, 25 µg/d (1000 IU), or calcitriol, 0.05–0.2 µg/kg/d, is given. Renal osteodystrophy is treated with calcitriol.

Suggested dietary intakes for vitamin D are summarized in Table 10–6 and toxic effects in Table 10–5.

Vitamin E

Vegetable oils are the main dietary source of vitamin E. Coconut and olive oils, however, are low in vitamin E. Some vitamin E is present in cereals, dairy products, and eggs. Vitamin activity may decrease with processing, storage, or heating. Vitamin E is a family of compounds, the tocopherols, with four major forms: alpha, gamma, beta, and delta. α -Tocopherol has the highest biologic activity. Vitamin E can donate an electron to a free-radical molecule to stop oxidation reactions. Oxidized vitamin E is then reduced by ascorbic acid or glutathione. The reduced tocopherol is able to scavenge another free radical. The nutrients that participate in antioxidant defenses include β -carotene, vitamin C, selenium, copper, manganese, and zinc. Vitamin E is located at specific sites in the cell to protect polyunsaturated fatty acids in the membrane lipids from lipid peroxidation and to protect thiol groups and nucleic

acids. Vitamin E also functions as a cell membrane stabilizer, may function in the electron transport chain, and may modulate chromosomal expression.

Vitamin E deficiency may occur in the following circumstances: prematurity; cholestatic liver disease, pancreatic insufficiency, abetalipoproteinemia, and short bowel syndrome; as an isolated inborn error of vitamin E metabolism; and perhaps as a result of increased use due to oxidant stress.

Vitamin E deficiency shortens red cell half-life and may cause hemolytic anemia. Chronic vitamin E deficiency results in a progressive neurologic disorder with loss of deep tendon reflexes, loss of coordination, vibratory and position sensation, nystagmus, weakness, scoliosis, and retinal degeneration. In premature infants, vitamin E deficiency may contribute to oxidant injury of the lung, retina, and brain (brain hemorrhage). These putative adverse effects in the premature infant require confirmation.

Vitamin E nutritional status can be partially assessed by measuring serum vitamin E (normal range for children is 3–15 mg/mL). The ratio of serum vitamin E to total serum lipid is normally more than 0.8 mg/g. Sensitivity of erythrocytes to hydrogen peroxide-induced hemolysis is also used as a test of vitamin E status.

Suggested dietary intakes of vitamin E are summarized in Table 10–6. Requirements increase if dietary polyunsaturated fatty acids increase. Between 0.4 mg and 0.5 mg of vitamin E is needed per gram of polyunsaturated fatty acids in the diet (1 IU = 1 mg of DL- α -tocopherol acetate).

Large oral doses (up to 100 IU/kg/d) of vitamin E correct the deficiency resulting from most malabsorption syndromes. For abetalipoproteinemia, 100–200 IU/kg/d of vitamin E are needed. Vitamin E therapy in ischemia-reperfusion injury and in the prevention of intracranial hemorrhage in the preterm infant remains controversial. Toxic effects of intravenously administered vitamin E are summarized in Table 10–5.

Vitamin K

Vitamin K₁ (phylloquinone) is obtained from leafy vegetables, soybean oil, fruits, seeds, and cow's milk. Vitamin K₂ (menaquinone), which has 60% of the activity of K₁, is synthesized by intestinal bacteria. K₂ may be a major source of vitamin K in infants and young children, but less is produced in the intestine of breast-fed infants.

Vitamin K is necessary for the posttranslational carboxylation of glutamic acid residues of the vitamin K-dependent coagulation proteins. Carboxylation allows these proteins to bind calcium, leading to activation of the clotting factors. Thus vitamin K is necessary for the maintenance of normal plasma levels of coagulation

factors II (prothrombin), VII, IX, and X and is also necessary for maintenance of normal levels of the anticoagulation protein C. Vitamin K deficiency occurs in newborns, especially those who are breast-fed and who do not receive vitamin K prophylaxis at delivery. The deficiency may result in hemorrhagic disease of the newborn. Later, vitamin K deficiency may result from fat malabsorption syndromes and the use of nonabsorbed antibiotics and anticoagulant drugs (eg, warfarin). Clinical features are bruising or bleeding in the GI tract, genital urinary tract, gingiva, lungs, joints, and brain. Vitamin K status can be assessed with plasma levels of protein-induced vitamin K absence or by prothrombin time.

Vitamin K requirements are summarized in Table 10–6. Newborns require prophylactic intramuscular vitamin K (0.5–1 mg). For older children with acute bleeding, 3–10 mg of vitamin K is given intramuscularly or intravenously. For chronic malabsorption syndromes, 2.5 mg twice weekly to 5 mg/d is given orally. To reverse warfarin effect, 25–50 mg of IV vitamin K is given. Toxic effects of vitamin K are summarized in Table 10–5.

2. Water-Soluble Vitamins

Deficiencies of water-soluble vitamins are uncommon in the United States because of the abundant food supply and fortification of prepared foods. Most bread and wheat products are routinely fortified with B vitamins, including the mandatory addition of folic acid to enriched grain products since January 1998. There is conclusive evidence that folic acid supplements (400 µg/d) during the periconceptional period protect against neural tube defects. Dietary intakes of folic acid from natural foods and enriched products also result in protection. Recommended intakes of folic acid during the periconceptional period may also afford protection later against neuroectodermal brain tumors in young children.

The risk of toxicity from water-soluble vitamins is not as great as that associated with fat-soluble vitamins because excesses of the former can be excreted in the urine. However, deficiencies in these vitamins develop more quickly than deficiencies in fat-soluble vitamins because of the limited stores.

Additional salient details are summarized in Tables 10–6 to 10–11. Although dietary intake of the water-soluble vitamins on a daily basis is not necessary, these

Table 10–7. Summary of biologic roles of water-soluble vitamins.

B vitamins involved in production of energy

Thiamin (B₁)

Thiamin pyrophosphate is coenzyme in oxidative decarboxylation (pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, and transketolase).

Riboflavin (B₂)

Coenzyme of several flavoproteins (eg, flavin mononucleotide [FMN] and flavin adenine dinucleotide [FAD]) involved in oxidative/electron transfer enzyme systems.

Niacin

Hydrogen-carrying coenzymes: nicotinamide-adenine dinucleotide (NAD), nicotinamide-adenine dinucleotide phosphate (NADP); decisive role in intermediary metabolism.

Pantothenic acid

Major component of coenzyme A.

Biotin

Component of several carboxylase enzymes involved in fat and carbohydrate metabolism.

Hematopoietic B vitamins

Folic acid

Tetrahydrofolate has essential role in one-carbon transfers. Essential role in purine and pyrimidine synthesis; deficiency → arrest of cell division (especially bone marrow and intestine).

Cobalamin (B₁₂)

Methyl cobalamin (cytoplasm): synthesis of methionine with simultaneous synthesis of tetrahydrofolate (reason for megaloblastic anemia in B₁₂ deficiency). Adenosyl cobalamin (mitochondria) is coenzyme for mutases and dehydratases.

Other B vitamins

Pyridoxine (B₆)

Prosthetic group of transaminases, etc, involved in amino acid interconversions; prostaglandin and heme synthesis; central nervous system function; carbohydrate metabolism; immune development.

Other water-soluble vitamins

L-Ascorbic acid (C)

Strong reducing agent—probably involved in all hydroxylations. Roles include collagen synthesis; phenylalanine → tyrosine; tryptophan → 5-hydroxytryptophan; dopamine → norepinephrine; Fe³⁺; folic acid → folinic acid; cholesterol → bile acids; leukocyte function; interferon production; carnitine synthesis. Copper metabolism; reduces oxidized vitamin E.

Carnitine

Transfer of long-chain fatty acids from cytosol to mitochondria (necessary for beta-oxidation).

Table 10–8. Major dietary sources of water-soluble vitamins.

Thiamin	Whole grains, cereals (including fortification), lean pork, legumes
Riboflavin	Dairy products, meat, poultry, wheat germ, leafy vegetables
Pyridoxine	All foods
Niacin	Meats, poultry, fish, legumes, wheat, all foods except fats, synthesized in body from tryptophan
Pantothenic acid	Ubiquitous
Biotin	Yeast, liver, kidneys, legumes, nuts, egg yolks (synthesized by intestinal bacteria)
Folic acid	Leafy vegetables (lost in cooking), fruits, whole grains, wheat germ, orange juice, beans, nuts
Cobalamin	Eggs, dairy products, liver, meats; none in plants
Vitamin C	Fresh fruits and vegetables
Carnitine	Meats, dairy products; none in plants

Table 10–9. Circumstances in which the possibility of vitamin deficiencies merit consideration.

Circumstance	Possible Deficiency
Prematurity	All vitamins
Protein-energy malnutrition	B ₁ , B ₂ , folate, A
Synthetic diets (including total parenteral nutrition)	All vitamins
Inherited disorders	Folate, B ₁₂ , D, carnitine
Vitamin–drug interactions	B ₆ , biotin, folate, B ₁₂ , carnitine, fat-soluble vitamins
Fat malabsorption syndrome	Fat-soluble vitamins
Breast-feeding	B ₁ , ^a folate, ^b B ₁₂ , ^c D, ^d K ^e
Periconceptual	Folate

^aAlcoholic or malnourished mother.
^bFolate-deficient mother.
^cVegan mother or maternal pernicious anemia.
^dInfant not exposed to sunlight and mother’s vitamin D status suboptimal.
^eMaternal status poor; neonatal prophylaxis omitted.

Table 10–10. Causes of deficiencies in water-soluble vitamins.

Thiamin	Infantile beriberi; seen in infants breast-fed by mothers with history of alcoholism or poor diet; has been described as complication of total parenteral nutrition (TPN); protein-energy malnutrition; prematurity
Riboflavin	General undernutrition; prematurity; inactivation in total parenteral nutrition solutions exposed to light
Pyridoxine	Prematurity (these infants may not convert pyridoxine to pyridoxal-5-P); B ₆ dependency syndromes; drugs (isoniazid); heat-treated formulas (historical)
Niacin	Maize or millet diets (high leucine and low tryptophan intakes); prematurity
Pantothenic acid	None
Biotin	Suppressed intestinal flora and impaired intestinal absorption
Folic acid	Prematurity; seen in term breast-fed infants whose mothers are folate-deficient and in term infants fed unsupplemented processed cow’s milk or goat’s milk; kwashiorkor; chronic overcooking; malabsorption of folate because of a congenital defect; sprue; celiac disease; drugs (phenytoin) Increased requirements: chronic hemolytic anemias, diarrhea, malignancies, hypermetabolic states, infections, extensive skin disease, cirrhosis, pregnancy
Cobalamin	Rare; seen in breast-fed infants of mothers with latent pernicious anemia or who are on an unsupplemented strict vegetarian diet; absence of luminal proteases; congenital malabsorption of B ₁₂
Vitamin C	Prematurity; maternal megadoses during pregnancy → deficiency in infants; lack of fresh fruits or vegetables; seen in infants fed formula and pasteurized cow’s milk (historical)
Carnitine	Seen in premature infants fed unsupplemented formula or fed intravenously; dialysis; inherited deficits in carnitine synthesis; organic acidemias; valproic acid

Table 10–11. Clinical features of deficiencies in water-soluble vitamins.

Thiamin	Infantile beriberi (cardiac; aphonic; pseudomeningitic)
Riboflavin	Cheilosis; angular stomatitis; glossitis; soreness and burning of lips and mouth; dermatitis of nasolabial fold and genitals; ± ocular signs (photophobia → indistinct vision)
Pyridoxine	Listlessness; irritability; seizures; gastrointestinal disturbance; anemia; cheilosis; glossitis
Niacin	Pellagra (weakness; lassitude; dermatitis of exposed areas; diarrhea; dementia)
Pantothenic acid	Weakness; gastrointestinal disturbance; burning feet.
Biotin	Scaly dermatitis; alopecia; irritability; lethargy
Folic acid	Megaloblastic anemia; neutropenia; thrombocytopenia; growth retardation; delayed maturation of central nervous system in infants; diarrhea (mucosal ulcerations); glossitis; jaundice; mild splenomegaly; neural tube defects
Cobalamin	Megaloblastic anemia; neurologic degeneration
Vitamin C	Anorexia, irritability, apathy, pallor; fever; tachycardia; diarrhea; failure to thrive; increased susceptibility to infections; hemorrhages under skin, mucous membranes, into joints and under periosteum; long-bone tenderness; costochondral beading
Carnitine	Increased serum triglycerides and free fatty acids; decreased ketones; fatty liver; hypoglycemia; progressive muscle weakness, cardiomyopathy, hypoglycemia

vitamins, with the exception of vitamin B₁₂, are not stored in the body.

Carnitine is synthesized in the liver and kidneys from lysine and methionine. In certain circumstances (see Table 10–10) synthesis is inadequate, and carnitine can then be considered a vitamin. A dietary supply of other organic compounds, such as inositol, may also be required in certain circumstances.

of neural tube defects. *Am J Clin Nutr* 2000;71(5):1308S [PMID: 10799407].

INFANT FEEDING

BREAST FEEDING

Breast feeding, one of the most important influences on children's health worldwide, provides optimal nutrition for the normal infant during the early months of life. Numerous immunologic factors in breast milk (including secretory IgA, lysozyme, lactoferrin, bifidus factor, and macrophages) provide protection against GI and upper respiratory infections. In developing countries, lack of refrigeration and contaminated water supplies make formula feeding hazardous. Allergic diseases are less common among breast-fed infants. Although formulas have improved progressively and are made to resemble breast milk as closely as possible, it is impossible to mimic the nutritional or immune composition of human milk. Additional differences of physiologic importance continue to be identified. Furthermore, the relationship developed through breast feeding can be an important part of early maternal interactions with the infant and provides a source of security and comfort to the infant.

Breast feeding has been reestablished as the predominant mode of feeding the young infant in the United States. Unfortunately, breast-feeding rates remain low among several subpopulations, including low-income, minority, and young mothers; many mothers face obstacles in maintaining lactation once they return to work. Skilled use of a breast pump, particularly an electric one, may help to maintain lactation in these circumstances.

Absolute contraindications to breast feeding are rare. They include tuberculosis (in the mother) and galactosemia (in the infant). Breast feeding is associated with maternal-to-child transmission of HIV, but the risk is influenced by duration and pattern of breast feeding and maternal factors, including immunologic status and presence of mastitis. Complete avoidance of breast feeding by HIV-infected women is presently the only mechanism to ensure prevention of maternal–infant transmission. Current recommendations are that HIV-infected mothers in developed countries refrain from breast feeding if safe alternatives are available. In developing countries, the benefits of breast feeding, especially the protection of the child against diarrheal illness and malnutrition outweigh the risk of HIV infection via breast milk.

The newborn weighing less than 1500 g and receiving human milk benefits from the addition of a human

milk fortifier designed to increase the protein, calcium, phosphorus, and micronutrient content as well as the caloric density. Breast-fed infants with cystic fibrosis can be breast-fed successfully if exogenous pancreatic enzymes are provided. If normal growth rates are not achieved in the breast-fed child with CF, energy or specific macronutrient supplements may be necessary. All infants should receive supplemental vitamins A, D, E, K, and sodium chloride based on standardized nutrition protocols for cystic fibrosis.

Ryan AS et al: Breastfeeding continues to increase into the new millennium. *Pediatrics* 2002;110(6):1103 [PMID: 12456906].

Management of Breast Feeding

In developed countries, we cannot assume that the art of breast feeding is being automatically passed from mother to daughter. Health professionals are now playing roles of greater importance in supporting and promoting breast feeding. Organizations such as the La Leche League have been effective in promoting breast feeding and providing education and support for mothers and health professionals.

Perinatal hospital routines and follow-up pediatric care have a great influence on the successful initiation of breast feeding. Breast feeding is promoted by prenatal and postpartum education, frequent mother–baby contact after delivery, one-on-one advice about breast-feeding technique, demand feeding, rooming-in, avoidance of bottle supplements, early follow-up after delivery, maternal confidence, family support, adequate maternity leave, and good advice about common problems such as sore nipples. Breast feeding is undermined by mother and baby separations, bottle-feeding babies in the nursery at night, routinely offering supplemental bottles, conflicting advice from staff, incorrect infant positioning and latch-on, scheduled feedings, lack of maternal confidence or support, delayed follow-up, early return to employment, and inaccurate advice for common breast-feeding difficulties.

It is important for mothers to know that very few women are unable to nurse their babies. The newborn is generally fed *ad libitum* every 2–3 hours, with longer intervals (4–5 hours) at night. Thus a newborn infant nurses at least eight to ten times a day, so that a generous milk supply is stimulated. This frequency is not an indication of inadequate lactation. Mothers also need reassurance about the stooling patterns of breast-fed ba-

bies. In neonates, a loose stool is often passed with each feeding; later (at age 3–4 months), there may be an interval of several days between stools. Failure to pass several stools a day in the early weeks of breast feeding suggests inadequate milk intake and supply.

Expressing milk may be indicated if the mother returns to work or if the infant is premature, cannot suck adequately, or is hospitalized. Modern electric breast pumps are very effective and can be borrowed or rented.

Technique of Breast Feeding

Breast feeding can be started after delivery as soon as both mother and baby are stable. Correct positioning and breast-feeding technique are necessary to ensure effective nipple stimulation and optimal breast emptying with minimal nipple discomfort.

If the mother wishes to nurse while sitting, the infant should be elevated to the height of the breast and turned completely to face the mother, so that their abdomens touch. The mother's arms supporting the infant should be held tightly at her side, bringing the baby's head in line with her breast. The breast should be supported by the lower fingers of her free hand, with the nipple compressed between the thumb and index fingers to make it more protractable. The infant's initial licking and mouthing of the nipple helps make it more erect. When the infant opens its mouth, the mother should rapidly insert as much nipple and areola as possible.

Some breast-fed infants fail to thrive. The most common cause of early failure to thrive is poorly managed mammary engorgement, which rapidly decreases milk supply. Unrelieved engorgement can result from inappropriately long intervals between feeding, improper infant suckling, a nondemanding infant, sore nipples, maternal or infant illness, nursing from only one breast, and latching difficulties. The mother's ignorance of technique, inappropriate feeding routines, and inadequate amounts of fluid and rest all can be factors. Some infants are too sleepy to do well on an *ad libitum* regimen and may need waking to feed at night. Primary lactation failure is rare, occurring in less than 5% of women.

A sensible guideline for duration of feeding is 5 minutes per breast at each feeding the first day, 10 minutes on each side at each feeding the second day, and approximately 15 minutes per side thereafter. A vigorous infant can obtain most of the available milk in 5–7 minutes, but additional sucking time ensures breast emptying, promotes milk production, and satisfies the infant's sucking urge. The side on which feeding is commenced should be alternated. The mother may break suction gently after nursing by inserting her finger between the baby's gums.

Follow-Up

Individualized assessment before discharge should identify the mothers and infants needing additional support. All mother–infant pairs require early follow-up. The onset of copious milk secretion between the second and fourth postpartum days is a critical time in the establishment of lactation. Failure to empty the breasts during this time can cause engorgement, which quickly leads to diminished milk production.

Common Problems

Nipple tenderness requires attention to proper positioning of the infant and correct latch-on. Ancillary measures include nursing for shorter periods, beginning feedings on the less sore side, air drying the nipples well after nursing, and use of lanolin cream. Severe nipple pain and cracking usually indicate improper infant attachment. Temporary pumping, which is well tolerated, may be needed.

Breast-feeding jaundice is exaggerated physiologic jaundice associated with inadequate intake of breast milk, infrequent stooling, and unsatisfactory weight gain (see Chapter 1). If possible, the jaundice should be managed by increasing the frequency of nursing and, if necessary, augmenting the infant's sucking with regular breast pumping. Supplemental feedings may be necessary, but care should be taken not to decrease breast milk production further.

In a small percentage of breast-fed infants, breast milk jaundice is caused by an unidentified property of the milk that inhibits conjugation of bilirubin. In severe cases, interruption of breast feeding for 24–36 hours may be necessary. The mother's breast should be emptied with an electric breast pump during this period.

The symptoms of mastitis include flu-like symptoms with breast tenderness, firmness, and erythema. Antibiotic therapy covering β -lactamase-producing organisms should be given for 10 days. Analgesics may be necessary, but breast feeding should be continued. Breast pumping may be helpful adjunctive therapy.

Neifert MR: Prevention of breastfeeding tragedies. *Pediatr Clin North Am* 2001;48(2):273 [PMID: 11339153].

Maternal Drug Use

Many factors play a role in determining the transmission of drugs in breast milk, including the route of administration, dosage, molecular weight, pH, and protein binding. In general, any drug prescribed to newborns can be consumed via breast milk without ill effect. Very few drugs are absolutely contraindicated in breast-feeding mothers; these include radioactive com-

pounds, antimetabolites, lithium, diazepam, chloramphenicol, antithyroid drugs, and tetracycline. For up-to-date information, a regional drug center should be consulted.

Maternal use of illicit or recreational drugs is a contraindication to breast feeding. Expression of milk for a feeding or two after use of a drug is not an acceptable compromise. The breast-fed infants of mothers taking methadone (but no alcohol or other drugs) as part of a treatment program have generally not experienced ill effects when the daily maternal methadone dose is under 40 mg.

Nutrient Composition

The nutrient composition of human milk is summarized and compared with that of cow's milk and formulas in Table 10–12. Outstanding characteristics include (1) relatively low but highly bioavailable protein content, which is adequate for the normal infant; (2) generous but not excessive quantity of essential fatty acids; (3) long-chain unsaturated ω 3 fatty acids, of which docosahexaenoic acid is thought to be especially important; (4) relatively low sodium and solute load; and (5) lower concentration of highly bioavailable calcium, iron, and zinc, which are adequate for the needs of normal breast-fed infants for approximately 6 months. A source of iron, from iron-fortified cereal, meat, or a supplement, should be introduced by age 6 months.

Weaning and Complementary Foods

The American Academy of Pediatrics and the World Health Organization recommend the introduction of solid foods in normal infants at about 6 months of age. Gradual introduction of a variety of foods including enriched cereals, fruits, vegetables, and meats should complement the breast milk diet. Although the order of introduction is not critical, single-ingredient complementary foods are introduced one at a time at weekly intervals before a new food is given. Fruit juice is not an essential part of an infant diet. When introduced (ideally at > 6 months and with a cup), the amount should be limited to 4 oz/d. Breast feeding should ideally con-

SPECIAL DIETARY PRODUCTS FOR INFANTS

Soy Protein Formulas

A common rationale for the use of soy protein formulas is transient lactose intolerance after acute gastroenteri-

tis. In such cases it is reasonable to recommend a soy protein formula for a period of 2–4 weeks. These formulas are also useful for infants with galactosemia and hereditary lactase deficiency. Lactose-free cow’s milk protein-based formulas are also available. Soy protein formulas are often used in cases of suspected intolerance to cow’s milk protein. Although infants with true cow’s milk protein intolerance may also be intolerant of soy protein, those with documented IgE-mediated allergy to cow’s milk protein usually do well on soy formula.

Semielemental & Elemental Formulas

Semielemental formulas include protein hydrolysate formulas. The major nitrogen source of most of these products is casein hydrolysate, supplemented with selected amino acids. These formulas contains an abundance of EFA from vegetable oil; certain brands also provide substantial amounts of MCTs. Elemental formulas are available with free amino acids and varying levels and types of fat components.

Semielemental and elemental formulas are invaluable for infants with a wide variety of malabsorption syndromes. They are also effective in infants who cannot tolerate cow’s milk and soy protein. For specific product information, consult standard pediatric reference texts, formula manufacturers, or a pediatric dietitian.

Hernell O, Lonnerdal B: Nutritional evaluation of protein hydrolysate formulas in healthy term infants: Plasma amino acids, hematology, and trace elements. *Am J Clin Nutr* 2003;78:296 [PMID: 12885712].

Formula Additives

Occasionally it may be necessary to increase the caloric density of an infant feeding to provide greater calories or restrict fluid intake. Concentrating formula to 24–26 kcal/oz is usually well tolerated, delivers an acceptable renal solute load, and increases the density of all the nutrients. Beyond this, individual nutrient additives (Table 10–13) are usually employed to achieve the desired caloric density (up to 30 kcal/oz). Adding carbohydrates (eg, glucose polymers, maltodextrin) has the following benefits: they are generally well tolerated, mix readily with the formula, and are reasonably priced. Microlipid (Mead Johnson), a safflower lipid emulsion, also mixes well but is more expensive. MCT oil doesn’t mix well and is expensive, but can be very beneficial for patients with cholestasis or malabsorptive disorders. The caloric density of breast milk can be increased by adding infant formula powder or any of the additives used with infant formula. Human milk fortifiers are generally used only for premature infants because of their specialized nutrient composition.

Special Formulas

Special formulas are those in which one component, often an amino acid, is reduced in concentration or removed for the dietary management of a specific inborn metabolic disease. Also included under this heading are formulas designed for the management of specific disease states, such as hepatic failure, pulmonary failure with chronic carbon dioxide retention, and renal failure. These condition-specific formulas were made primarily with the critically ill adult in mind and are even

Table 10–13. Common infant formula additives.

Additive	Kcal/g	Kcal/Tbsp	Kcal/mL	Comments
Dry rice cereal	3.75	15	—	Thickens formula but not breast milk
Polycose (Ross)	3.8	23	2	Glucose polymers
Moducal (Mead Johnson)	3.75	30	—	Maltodextrin
MCT oil (Mead Johnson)	8.3	116	7.7	Not a source of essential fatty acids
Microlipid (Mead Johnson)	9	68.5	4.5	Safflower oil emulsion with 0.4 g linoleic acid/mL
Vegetable oil	9	124	8.3	Does not mix well
Promod (Ross)	4.3	16.8 (3 g protein)	—	Whey protein concentrate
Casec (Mead Johnson)	3.8	16.7 (4 g protein)	—	Calcium caseinate
Duocal (SHS)	4.9	42	—	Protein-free mix of hydrolyzed corn starch (60% kcal), and fat (35% MCT)

MCT = medium-chain triglyceride.

used sparingly in those populations, thus their use in pediatrics should only be undertaken with clear indication and caution.

Complete information regarding the composition of these special formulas, the standard infant formulas, specific metabolic disease formulas, and premature infant formulas can be found in standard reference texts and in the manufacturers' literature.

PRUDENT DIET

Because of the association of diet with the development of such chronic diseases as diabetes, obesity, and cardiovascular disease, learning a healthy eating behavior at a young age is an important preventative measure.

Salient features of a prudent diet for children older than 2 years include the following:

1. Consumption of three regular meals per day, and 2 or 3 healthful snacks according to appetite, activity, and growth needs.
2. Inclusion of a variety of foods. Diet should be nutritionally complete and promote optimal growth and activity.
3. Fat less than 30% of total calories (though severe fat restriction may result in an energy deficit and growth failure). Saturated fats and polyunsaturated fats each should provide less than 10% of total calories. Monounsaturated fats should provide 10% or more of caloric intake.
4. Cholesterol intake less than 100 mg/1000 kcal/d, to a maximum of 300 mg/d.
5. Carbohydrates should provide 55–60% or more of daily caloric intake, with no more than 10% in the form of simple sugars. A high-fiber, complex carbohydrate diet is recommended.
6. Limitation of grazing behavior, eating while watching television, and the consumption of soft drinks and other high-sugar beverages.
7. Limitation of sodium intake by choosing fresh over highly processed foods.

The consumption of lean cuts of meats, poultry, and fish should be encouraged. Skim milk, soft margarine, and vegetable oils (especially olive oil) should be used. Whole-grain bread and cereals and plentiful amounts of fruits and vegetables are recommended. The consumption of processed foods, soft drinks, desserts, and candy should be limited.

A prudent diet should be only one component of counseling on lifestyles for children. Other aspects are the maintenance of a desirable body weight and body mass index (BMI), regular physical activity, avoidance of smoking, and screening for hypertension. Universal screening for total cholesterol is controversial. Current

recommendations are to routinely screen those children who have a positive family history of premature cardiovascular disease, although this approach will identify only about 50% of those with significantly elevated cholesterol levels. If the result is high (≥ 200 mg/dL), a fasting lipoprotein analysis should be obtained.

■ PEDIATRIC UNDERNUTRITION

Failure to thrive is a term used to describe infants and young children whose weight curve has fallen by two major percentile channels from a previously established rate of growth (see Chapter 8). The acute loss of weight, or failure to gain weight at the expected rate, produces a condition of reduced weight for height known as **wasting**. The reduction in height for age, as is seen with more chronic malnutrition, is termed **stunting**.

The typical pattern for mild pediatric undernutrition is decreased weight, with normal height and head circumference. In more chronic malnutrition, height and eventually head circumference growth will slow relative to the standard for age. Significant calorie deprivation produces severe wasting, called **marasmus**. Significant protein deprivation in the face of adequate energy intake, possibly with additional insults such as infection, may produce edematous malnutrition called **kwashiorkor**.

Pediatric undernutrition is usually multifactorial in origin, and successful treatment depends on accurate identification and management of those factors. The terms "organic" and "nonorganic" failure to thrive, though still used by many medical professionals, are not helpful because any systemic illness or chronic condi-

tion can cause growth impairment and yet may also be compounded by psychosocial problems.

A discussion of the multiple medical conditions that can cause pediatric undernutrition are beyond the scope of this chapter. However, the most common cause is inadequate dietary intake. Inappropriate formula mixing or a family's food beliefs may lead to hypocaloric or unbalanced dietary intakes. Highly restricted diets secondary to perceived food allergies or intolerances may result in inadequate intake of calories, protein, or specific micronutrients. Iron and zinc are micronutrients that are often marginal in many patients with undernutrition. Zinc deficiency can depress appetite and affect growth, and can easily be corrected with oral zinc supplements given over 1–2 months. Cases of severe malnutrition and kwashiorkor have occurred in infants of well-intentioned parents who substitute "health food" milk alternatives (eg, rice milk and unfortified soy milk) for infant formula.

Poor eating is often a learned behavior. Families should be counseled regarding choices of foods that are appropriate for the age and developmental level of the child. Children should have structured meal times (eg, three meals and two to three snacks during the day), ideally at the same time other family members eat. Consultation with a pediatric dietitian can be helpful for educating the families. Estimates of calorie needs should be based on the need for catch-up growth rather than on the usual RDA for age. Poor feeding may be related to family dysfunction. Children whose households are chaotic and children who are abused, neglected, or exposed to poorly controlled mental illness may be described as poor eaters, and may fail to gain. Careful assessment of the social environment of such children is critical, and disposition options may include support services, close medical follow-up visits, family counseling, and even foster placement while a parent receives therapy.

PEDIATRIC OVERWEIGHT/OBESITY **(See also Chapter 3 for specifics on adolescent obesity.)**

Background

The prevalence of childhood and adolescent obesity has increased rapidly in the United States and many other parts of the world. Currently in the United States, approximately 15% of 6- to 19-year-olds are overweight,

with even higher rates among subpopulations of minority and economically disadvantaged children. The increasing incidence of childhood obesity is related to a complex combination of genetic, environmental, psychosocial, biologic, and socioeconomic factors.

Overweight status in the pediatric population is associated with significant comorbidities, which if untreated are likely to persist into adulthood. The probability of obesity persisting into adulthood increases from 20% at 4 years to 80% by adolescence. Obesity is associated with cardiovascular and endocrine abnormalities (eg, dyslipidemia, insulin resistance and type II diabetes), orthopedic problems, pulmonary complications (eg, obstructive sleep apnea), and mental health problems.

Definitions

BMI is the standard measure of obesity in adults. Its use in children provides a consistent measure across age groups. BMI is correlated with more accurate measures of body fatness and is calculated with readily available information: weight and height ($\text{kg} \div \text{m}^2$). Routine plotting of the BMI on age- and gender-appropriate charts (<http://www.cdc.gov/growthcharts>) can identify those with excess weight gain relative to linear growth. BMI between the 85th and 95th percentile for age and sex identifies those at risk of being overweight. Overweight or obese is defined as BMI at or above 95% and is associated with increased risk of secondary complications. An upward change in BMI percentiles in any range should prompt an evaluation and possible treatment. Although the degree of change that indicates risk has not been defined, an annual increase of 3–4 BMI units is almost always an indicator of a rapid increase in body fat. For children younger than 2 years old, weight for length greater than 95th percentile indicates overweight and warrants further assessment, especially of energy intake.

Risk Factors

There are multiple risk factors for developing obesity, reflecting the complex relationships between genetic and environmental factors. Family history is a strong risk factor. If one parent is obese, the odds ratio is approximately 3 for obesity in adulthood, but if both parents are obese, the odds ratio increases to greater than 10.

Environmental risk factors offer potential areas to target for intervention. The absence of family meals, excessive consumption of sweetened beverages, large portion sizes, frequent consumption of foods prepared outside the home, excessive television viewing, and

sedentary lifestyle are all associated with a greater prevalence of obesity.

Assessment

Early recognition of high-risk patterns of weight gain or high-risk behaviors is essential, as it is likely that anticipatory guidance or intervention before weight gain becomes severe will be more successful. Routine evaluation at well-child visits should include:

1. Measurement of weight and height, calculation of BMI, and plotting all three parameters on age- and sex-appropriate growth charts (<http://www.cdc.gov/growthcharts>). Evaluate for upward crossing of BMI percentile channels.
2. History regarding diet and activity patterns (Table 10–14) Physical exam: Blood pressure, assess distribution of adiposity (central vs generalized); markers of comorbidities, such as acanthosis nigricans, hirsutism, hepatomegaly, orthopedic abnormalities; physical stigmata of genetic syndrome (eg, Prader–Willi syndrome).
3. Laboratory studies are generally reserved for children with BMI in overweight category (> 95th percentile) or those who have evidence of comorbidities; may include fasting lipid profile, insulin and glucose, liver function tests, thyroid function (if evidence of plateau in linear growth). Other studies should be guided by findings in history and physical.

Table 10–14. Suggested areas for assessment of diet and activity patterns.

Diet

- Meal and snack pattern: structured vs grazing, skipping meals
- Portion sizes: adult portions for young children?
- Frequency of meals away from home (restaurants or take out)
- Frequency/amounts of caloric beverages (soda, juice, milk)
- Frequency of eating fruits and vegetables
- Frequency of family meals?

Activity

- Time spent in sedentary activity: television, video games
 - Time spent in vigorous activity: organized sports, physical education, free play
 - Activities of daily living: walking to school, chores, yard work
-

Treatment

Therapy should be based on risk factors, including age, severity of obesity, and comorbidities, as well as family history and support. For all children with uncomplicated obesity, the primary goal is to achieve healthy eating and activity patterns, not necessarily to achieve ideal body weight. For children with a secondary complication, improvement of the complication is an important goal. For children 2–7 years old with BMI at 95% or above and without complications, the goal should generally be maintenance of baseline weight, allowing the child to “grow into” his or her height, with a gradual normalization of BMI. For children 2–7 years old with BMI at 95% or above and secondary complications, weight loss is indicated. For children older than 7 years with BMI between 85th and 95th percentile, without complications, weight maintenance is an appropriate goal. If secondary complications are present, weight loss is recommended; an appropriate goal is 1 pound weight loss/month until a BMI less than 85% is achieved. Excessive acute weight loss should be avoided, as this may contribute to nutrient deficiencies and linear growth stunting.

There are few studies of the long-term effects of weight control programs for children. Treatment focused on behavior changes in the context of the family has been associated with sustained weight loss and decreases in BMI. Clinicians should assess the family’s readiness to take action (stages-of-change model). Concurrent changes in dietary patterns and increasing physical activity are most likely to provide success. The whole family should be encouraged to adopt healthy eating patterns, with parents modeling healthy food choices, controlling foods brought into the home, and guiding appropriate portion sizes. Limiting sedentary activity has been found to be more effective than specifically promoting increased physical activity. The American Academy of Pediatrics recommends no television for children younger than 2 years old, and a maximum of 2 h/d of television and video games for older children.

Treatment may be considered at three different levels depending on the severity of the problem, the age of the child, the ability of the family to implement changes, the preferences of the parents and child, and the skills of the health care provider. (1) General: Counseling regarding problem areas identified by screening questions (see Table 10–14); emphasis on guidelines around healthy eating and physical activity patterns. This is especially appropriate for preventing further weight gain or for mildly overweight children. (2) Structured: Provide more specific and structured dietary pattern, such as meal planning, exercise prescription, behavior change goals. This may be done in the

primary care setting or, if resources are available, referred to more specialized treatment program. (3) Group treatment: Generally best for the older child or adolescent, with varying level of parental involvement depending on age of child. Several published programs are available. The Weight Information Network (WIN) is a service available through the National Institutes of Health, which disseminates information on weight control programs and is available online: (<http://www.niddk.nih.gov//NutritionDocs.html>). No single prescription is effective for all patients. The physician will do best to assess the severity of the problem, treatment needs in context of the family's preferences and abilities, and local resources, including availability of registered dietitians with expertise in pediatric weight management and behaviorists or family therapists.

Pharmacotherapy can be an adjunct to dietary, activity, and behavioral treatment, but by itself it is unlikely to result in significant or sustained weight loss. For severe obesity in adolescents, particularly with comorbidities, bariatric surgery is being performed in some centers. This is still considered experimental, and there is an urgent need for long-term outcome, safety, and efficacy data. However, there is limited evidence that in carefully selected and closely monitored patients, medications or surgery (or both) can result in significant weight loss with a reduction in comorbidities for those who are severely afflicted.

NUTRITION SUPPORT

1. Enteral

Indications

Enteral nutrition support is indicated when a patient cannot adequately meet nutritional needs by oral intake alone and has a functioning GI tract. This method of support can be used for both short- and long-term delivery of nutrition. Even when the gut cannot be used to deliver 100% of nutritional needs, some enteral feed-

ings should be attempted. Enteral nutrition, full or partial, provides multiple physiologic benefits:

1. Maintaining gut mucosal integrity
2. Preserving gut-associated lymphoid tissue
3. Stimulation of gut hormones and bile flow

Most pediatric patients requiring enteral nutrition can have their needs met with standard enteral formulations. Specialized formulas are available for patients of all ages who have conditions such as severe milk protein allergy, single- or multiple-nutrient malabsorption, renal failure, and hepatic failure. The decision to use such specialized formulas must be made in the context of the patient's condition and nutritional needs.

Access Devices

Nasogastric feeding tubes can be used for supplemental nocturnal drip or daytime bolus feedings, but generally are not used for more than 6 months. Complications such as otitis media and sinusitis may limit the duration of nasogastric tube feedings. Initiation of nasogastric feeding usually requires a brief hospital stay to ensure tolerance to feedings and to allow for parental instruction in tube placement and feeding administration.

If long-term feeding support is anticipated, a more permanent feeding device, such as a gastrostomy tube, may be considered. With either a nasogastric or a gastrostomy tube, insurance coverage is important, as many carriers do not cover the cost of formula for tube feedings. Referral to a homecare company is necessary for equipment and other services such as nursing visits and dietitian follow-up.

Table 10–15 suggests appropriate timing for initiation and advancement of drip and bolus feedings, according to a child's age. Clinical status and tolerance to feedings should ultimately guide their advancement.

Monitoring

Monitoring the adequacy of enteral feeding depends on nutritional goals. Growth should be frequently assessed, especially for young infants and malnourished children. Hydration status should be monitored carefully at the initiation of enteral feeding. Constipation and diarrhea can be problems, and attention to stool frequency, volume, and consistency can help guide management. When diarrhea occurs, factors such as infection, hypertonic enteral medications, antibiotic use, and alteration in normal gut flora should be addressed before formula changes are tried.

It is important to determine whether the feeding schedule is developmentally appropriate. This will not be possible for all patients, especially those who are crit-

Table 10–15. Guidelines for the initiation and advancement of tube feedings.

Age	Drip Feeds		Bolus Feeds	
	Initiation	Advancement	Initiation	Advancement
Preterm	1–2 mL/kg	1 mL as tolerated	5–20 mL	5–10 mL as tolerated
Birth–12 mos.	5–10 mL/h	5–10 mL q 2–8 h	10–60 mL	20–40 mL q 3–4 h
1–6 years	10–15 mL/h	10–15 mL q 2–8 h	30–90 mL	30–60 mL q feed
6–14 years	15–20 mL/h	10–20 mL q 2–8 h	60–120 mL	60–90 mL q feed
> 14 years	20–30 mL/h	20–30 mL q 2–8 h	60–120 mL	60–120 mL q feed

ically ill. However, for children who are more stable, it is recommended that tube feeding schedules mimic as closely as possible an age-appropriate feeding schedule, such as six small feedings per day for a toddler. When night drip feedings are used in conjunction with daytime feeds, it is suggested that less than 50% of goal calories be delivered at night so as to maintain a daytime sense of hunger and satiety. This will be especially important once a transition to oral intake begins. Children who are satiated by tube feedings will be less likely to take significant amounts of food by mouth, thus possibly delaying the transition from tube to oral nutrition.

2. Parenteral Nutrition

Indications

A. PERIPHERAL PARENTERAL NUTRITION

Peripheral parenteral nutrition is indicated when complete enteral feeding is not possible or desirable (eg, in the premature infant of very low birth weight during the first few days of postnatal life or in the malnourished surgical patient during the early postoperative period). Short-term partial IV feeding via a peripheral vein is a preferred alternative to dextrose and electrolyte solutions alone. Because of the osmolality of the solutions required, it is usually impossible to achieve total calorie and protein needs with parenteral nutrition via a peripheral vein.

B. TOTAL PARENTERAL NUTRITION

TPN should be provided only when clearly indicated. Apart from the expense, numerous risks are associated with this method of feeding (see Complications section). Even when TPN is indicated, every effort should be made to provide at least a minimum of nutrients enterally to help preserve the integrity of the GI mucosa and of GI function.

The primary indication for TPN is the loss of function of the GI tract that prohibits the provision of more than a small proportion of required nutrients by the enteral route. Important examples include short bowel syndrome, some congenital defects of the GI tract, and prematurity.

Catheter Selection & Position

An indwelling central venous catheter is preferred for long-term IV nutrition. For periods of up to 3–4 weeks, a percutaneous central venous catheter threaded into the superior vena cava from a peripheral vein can be used. For the infusion of dextrose concentrations higher than 12.5%, the tip of the catheter should be located in the superior vena cava. Catheter positioning in the right atrium has been associated with complications, including right atrial thrombi formation. After placement, a chest radiograph must be obtained to check this position. If the catheter is to be used for nutrition and medications, a double-lumen catheter should be used if possible.

Complications

A. MECHANICAL COMPLICATIONS

1. Related to catheter insertion or to erosion of catheter through a major blood vessel—Complications include trauma to adjacent tissues and organs, damage to the brachial plexus, hydrothorax, pneumothorax, hemothorax, and cerebrospinal fluid penetration. The catheter may slip during dressing or tubing changes, or the patient may manipulate the line.

Chaturvedi A et al: Catheter malplacement during central venous cannulation through arm veins in pediatric patients. *J Neurosurg Anesthes* 2003;15(3):170 [PMID: 12826963].

2. Clotting of the catheter—Addition of heparin (1000 U/L) to the solution is an effective means of preventing this complication. If an occluded catheter does not respond to heparin flushing, filling the catheter with recombinant tissue plasminogen activator or sterile 95% ethanol may be effective.

3. Related to composition of infusate—Calcium phosphate precipitation may occur if excess amounts of calcium or phosphorus are administered. Factors that increase the risk of calcium phosphate precipitation include increased pH and decreased concentrations of amino acids. Precipitation of medications incompatible with TPN or lipids can also cause clotting.

Freytes CO: Thromboembolic complications related to indwelling central venous catheters in children. *Curr Opin Oncol* 2003;15:289 [PMID: 12874506].

Hooke C: Recombinant tissue plasminogen activator for central venous access device occlusion. *J Pediatr Oncol Nurs* 2000;17(3):174 [PMID: 10944865].

B. SEPTIC COMPLICATIONS

Septic complications are the most common cause of nonelective catheter removal, but strict use of aseptic technique and limiting entry into the catheter can reduce the rates of line sepsis.

Fever over 38–38.5°C in a patient with a central catheter should be considered a line infection until proved otherwise. Cultures should be obtained and IV antibiotics empirically initiated. Removing the catheter may become necessary with certain infections (eg, fungal), with catheter replacement deferred until the infection is adequately treated.

Benjamin DK et al: Bacteremia, central catheters, and neonates: When to pull the line. *Pediatrics* 2001;107(6):1272 [PMID: 11389242].

C. METABOLIC COMPLICATIONS

A variety of metabolic complications associated with TPN may occur. Many of the complications are related to deficiencies or excesses of specific nutrients in administered fluids. These complications are less common as a result of experience and improvements in nutrient solutions. However, specific deficiencies still occur, especially in the premature infant. Avoidance of deficiencies and excesses and of metabolic disorders requires attention to the nutrient balance, electrolyte composition, and delivery rate of the infusate and careful monitoring, especially when the composition or delivery rate is changed.

Currently the most challenging metabolic complication is cholestasis, particularly common in premature infants of very low birth weight. The cause of cholestasis associated with TPN is unknown. Patient and med-

ical risk factors include prematurity, sepsis, hypoxia, major surgery (especially GI surgery), absence of enteral feedings, and small bowel bacterial overgrowth. Risk factors related to TPN include amino acid excess or imbalance and prolonged duration of TPN. Amino acid solutions with added cysteine decrease cholestasis. Practices that may minimize cholestasis include initiating even minimal enteral feedings as soon as feasible, avoiding sepsis by meticulous line care, avoiding overfeeding, using cysteine- and taurine-containing amino acid formulations designed for infants, preventing or treating small bowel bacterial overgrowth, protecting TPN solutions from light, and avoiding hepatotoxic medications.

NUTRIENT REQUIREMENTS & DELIVERY

Energy

When patients are fed intravenously, no fat and carbohydrate intakes are unabsorbed, and no energy is used in nutrient absorption. These factors account for at least 7% of energy in the diet of the enterally fed patient. The intravenously fed patient also expends less energy in physical activity because of the impediment to mobility. Average energy requirements are therefore at least 7% lower in children fed intravenously, and the decrease in activity probably increases this figure to a total reduction of 10–15%. Caloric guidelines for the IV feeding of infants and young children are as follows:

Age (months)	Requirements (kcal/kg/d)
0–1	100–110
2–4	90–100
5–60	70–90
> 5 years	1500 kcal for 1st 20 kg + 25 kcal for each additional kg/d

These guidelines are averages; individuals vary considerably. A multitude of factors can significantly increase the energy requirement, including exposure to a cold environment, fever, sepsis, burns, trauma, cardiac or pulmonary disease, and catch-up growth after malnutrition.

With few exceptions, such as some cases of respiratory insufficiency, at least 50–60% of energy requirements are provided as glucose. Up to 40% of calories may be provided by IV fat emulsions.

Dextrose

The energy density of IV dextrose (monohydrate) is 3.4 kcal/g. Dextrose is the main exogenous energy source provided by total IV feeding. IV dextrose suppresses gluconeogenesis and provides a substrate that can be oxidized directly, especially by the brain, red and white blood cells, and wounds. Because of the high osmolality of dextrose solutions (D₁₀W yields 505 mOsm/kg H₂O), concentrations greater than 10–12.5% cannot be delivered via a peripheral vein or improperly positioned central line.

Dosing guidelines: The standard initial quantity of dextrose administered will vary by age (Table 10–16). Tolerance to IV dextrose normally increases rapidly, due primarily to suppression of hepatic production of endogenous glucose. Dextrose can be increased by 2.5 g/kg/d; by 2.5%–5%/day; or by 2–3 mg/kg/min/d if there is no glucosuria or hyperglycemia. Standard final infusates for infants via a properly positioned central venous line usually range from 15% to 25% dextrose, though concentrations of up to 30% dextrose may be used especially at low flow rates. Tolerance to IV dextrose loads is markedly diminished in the premature neonate and in hypermetabolic states.

Problems associated with IV dextrose administration include hyperglycemia, hyperosmolality, and glucosuria

(with osmotic diuresis and dehydration). Possible causes of unexpected hyperglycemia include the following: (1) inadvertent infusion of higher glucose concentrations than ordered, (2) uneven flow rate, (3) sepsis, (4) a stress situation, and (5) pancreatitis. IV insulin reduces hyperglycemia but does not increase glucose oxidation rates; it may also decrease the oxidation of fatty acids, resulting in less energy for metabolism. Hence, insulin should be used very cautiously. A standard IV dose is 1 U/4 g of carbohydrate, but much smaller quantities may be adequate and, usually, one starts with 0.2–0.3 U/4 g of carbohydrate.

Hypoglycemia may occur after an abrupt decrease in or cessation of IV glucose. When cyclic IV nutrition is provided, the IV glucose load should be decreased steadily for 1–2 hours prior to discontinuing the infusate. If the central line must be removed, the IV dextrose should be tapered gradually over several hours.

Maximum oxidation rates for infused dextrose decrease with age. It is important to note that the ranges for dextrose administration provided in Table 10–16 are guidelines and that individual patient tolerance and clinical circumstances may warrant administration of either less or more dextrose. Quantities of exogenous dextrose in excess of maximal glucose oxidation rates are used initially to replace depleted glycogen stores; hepatic lipogenesis occurs thereafter.

Table 10–16. Pediatric macronutrient guidelines for total parenteral nutrition.

Age	Dextrose		Amino acids	Lipid
	mg/kg/min	g/kg/d	g/kg/d	g/kg/d
	50–60% kcal		10–20% kcal	30–40% kcal
Preterm	Initial 5–8	Initial 7–11	Initial 1.5–2	Initial 0.5–1
	Max 11–12.5	Max 16–18	Max 3–4	Max 2.5–3.5
Birth–12 mo.	Initial 6–8	Initial 9–11	Initial 1.5–2	Initial 1
	Max 11–15	Max 16–21.5	Max 3	Max 2.5–3.5
1–6 yr	Initial 6–7	Initial 8–10	Initial 1–1.5	Initial 1
	Max 10–12	Max 14–17	Max 2–2.5	Max 2.5–3.5
> 6 yr	Initial 5–7	Initial 8–10	Initial 1	Initial 1
	Max 9	Max 13	Max 1.5–2	Max 3
> 10 yr	Initial 4–5	Initial 5–7	Initial 1	Initial 1
	Max 6–7	Max 8–10	Max 1.5–2	Max 2–3
Adolescents	Initial 2–3	Initial 3–4	Initial 1	Initial 0.5–1
	Max 5–6	Max 7–8	Max 1.5–2	Max 2

Excess hepatic lipogenesis may lead to a fatty liver. Lipogenesis results in release of carbon dioxide, which when added to the amount of carbon dioxide produced by glucose oxidation (which is 40% greater than that produced by lipid oxidation) may elevate the PaCO₂ and aggravate respiratory insufficiency or impede weaning from a respirator.

Lipids

The energy density of lipid emulsions (20%) is 10 kcal/g of lipid or 2 kcal/mL of infusate. The lipids are derived from either soybean or safflower oil. All consist of more than 50% linoleic acid and 4–9% linolenic acid. It is recognized that this high level of linoleic acid is not ideal, except when small quantities of lipid are being given to prevent an EFA deficiency. Ultimately, improved emulsions are anticipated. Because 10% and 20% lipid emulsions contain the same concentrations of phospholipids, a 10% solution delivers more phospholipid per gram of lipid than a 20% solution. Twenty percent lipid emulsions are preferred.

The level of LPL activity is the rate-limiting factor in the metabolism and clearance of fat emulsions from the circulation. LPL activity is inhibited or decreased by malnutrition, leukotrienes, immaturity, growth hormone, hypercholesterolemia, hyperphospholipidemia, and theophylline. LPL activity is enhanced by glucose, insulin, lipid, catecholamines, and exercise. Heparin releases LPL from the endothelium into the circulation and enhances the rate of hydrolysis and clearance of triglycerides. In small premature infants, low-dose heparin infusions may increase tolerance to IV lipid emulsion.

The advantages of using fat emulsions to provide up to 40% of caloric intake include the following:

1. The high energy density allows more energy to be provided when fluid volume is restricted.
2. The low osmolality (280 mOsm/kg H₂O) is of special value when using a peripheral line.
3. EFA deficiencies can be prevented.

4. The production of CO₂ is 40% lower per unit of energy, an important consideration in cases of pulmonary insufficiency.
5. The energy cost of fat storage is negligible.
6. The risk of fatty liver is decreased because of decreased hepatic lipogenesis from dextrose.

Potential disadvantages of fat emulsions include the following:

1. Impairment of function of neutrophils, macrophages, and the reticuloendothelial system.
2. Coagulation defects, including thrombocytopenia, elevated prothrombin time, and partial thromboplastin time.
3. Decrease in pulmonary oxygen diffusion.
4. Competition by free fatty acids with bilirubin and drugs for albumin-binding sites.
5. Increase in low-density lipoprotein cholesterol.

In general, these adverse effects can be avoided by starting with modest quantities and advancing cautiously in light of results of triglyceride monitoring and clinical circumstances. In cases of severe sepsis, special caution is required to ensure that the lipid is metabolized effectively. Monitoring with long-term use is also essential.

IV lipid dosing guidelines: Check serum triglycerides before starting and after increasing the dose. Commence with 1 g/kg/d, given over 12–20 hours or 24 hours in small preterm infants. Advance by 0.6–1.0 g/kg/d, every 1–2 days, up to goal (Table 10–16).

As a general rule, do not increase the dose if the serum triglyceride level is above 250 mg/dL during infusion (150 mg/dL in neonates) or if the level is greater than 150 mg/dL 6–12 hours after cessation of the lipid infusion.

Serum triglyceride levels above 400–600 mg/dL may precipitate pancreatitis. In patients for whom normal amounts of IV lipid are contraindicated, 4–8% of calories as IV lipid should be provided (300 mg linoleic acid/100 kcal) to prevent essential fatty acid deficiency.

Table 10–17. Electrolyte requirements for parenteral nutrition.

Electrolyte	Preterm Infant	Full-Term Infant	Child	Adolescent
Sodium	2–5 mEq/kg	2–3 mEq/kg	2–3 mEq/kg	60–150 mEq/d
Chloride	2–5 mEq/kg	2–3 mEq/kg	2–3 mEq/kg	60–150 mEq/d
Potassium	2–3 mEq/kg	2–3 mEq/kg	2–3 mEq/kg	70–180 mEq/d

Neonates and malnourished pediatric patients receiving lipid-free parenteral nutrition are at high risk for EFA deficiency because of limited adipose stores.

Crook MA: Lipid clearance and total parenteral nutrition: The importance of monitoring plasma lipids. *Nutrition* 2000;16:774 [PMID: 10978859].

Nitrogen

One gram of nitrogen is yielded by 6.25 g of protein (1 g of protein contains 16% nitrogen). Caloric density of protein is equal to 4 kcal/g.

A. PROTEIN REQUIREMENTS

Protein requirements for IV feeding are the same as those for normal oral feeding (see Table 10–2).

B. PROTEIN-ENERGY INTERACTIONS

There are important interactions between protein and energy requirements. A positive nitrogen balance cannot be achieved on a hypocaloric diet, because protein will be catabolized for energy. When energy intakes are low, the administration of some amino acid does, however, lessen the severity of the negative nitrogen balance. Conversely, when nitrogen intake is low, the provision of calories improves nitrogen balance to some extent. In infants, the energy necessary to minimize nitrogen loss associated with an amino acid-free diet is approximately 70 kcal/kg/d. At this level of energy intake, positive nitrogen balance depends on the level of nitrogen intake and is independent of further increase in energy intake.

In infants receiving about 50 kcal/kg/d, increasing protein intake up to 3 g/kg/d improves the nitrogen balance. In these circumstances, therefore, a ratio of grams of nitrogen per kilocalorie as low as 1:100 can be advantageous. However, at higher levels of energy intake, ratios of 1:250 to 1:150 or more are optimal. Although these ratios provide a useful crude check, they are not usually the best means of determining protein requirements.

C. INTRAVENOUS AMINO ACID SOLUTIONS

Nitrogen requirements can be met by one of the commercially available amino acid solutions. For older children and adults, none of the standard preparations has a clear advantage over the others as a source of amino acids. For infants, however, including premature infants, accumulating evidence suggests that the use of TrophAmine (McGaw) is associated with a normal plasma amino acid profile, superior nitrogen retention, and a lower incidence of cholestasis. TrophAmine contains 60% essential amino acids, is relatively high in branched-chain amino acids, contains taurine, and is compatible with the addition of cysteine within

24–48 hours after administration. The dose of added cysteine is 40 mg/g of TrophAmine. The relatively low pH of TrophAmine is also advantageous for solubility of calcium and phosphorus.

D. DOSING GUIDELINES

Amino acids can be started at 1.0–2.0 g/kg/d in most patients (see Table 10–16). In severely malnourished infants, the initial amount should be 1.0 g/kg/d. Even in very low birth weight infants, there is evidence that higher initial amounts of amino acids are tolerated with little indication of protein “toxicity.” Larger quantities of amino acids in relation to calories can minimize the degree of negative nitrogen balance when the infusate is hypocaloric. Amino acid intake can be advanced by 0.5–1.0 g/kg/d toward the goal. Normally the final infusate will contain 2–3% amino acids, depending on the rate of infusion. Concentration should not be advanced beyond 2% in peripheral vein infusates due to osmolality.

E. MONITORING

Monitoring for tolerance of the IV amino acid solutions should include routine blood urea nitrogen. Serum alkaline phosphatase, γ -glutamyltransferase, and bilirubin should be monitored to detect the onset of cholestatic liver disease.

F. SPECIAL AMINO ACID PREPARATIONS

Some solutions are designed to provide high concentrations of branched-chain amino acids. These solutions are expensive and should not be ordered without a specific reason, which does not include their routine use in liver disease. They may be indicated in hepatic failure, especially in the presence of encephalopathy, and are also undergoing experimental use in multisystem organ failure. In this circumstance, the branched-chain amino acids are given as a source of metabolizable energy, providing up to 25% of energy intake. Solutions containing only essential amino acids may have some application in the management of acute renal failure.

G. ALBUMIN

Albumin can be added to the infusate when clinically indicated to restore blood volume or oncotic pressure. If the origin of hypoalbuminemia is considered to be primarily nutritional, however, the hypoalbuminemia should be managed by careful nutritional rehabilitation rather than by IV administration of albumin. Albumin is deficient in isoleucine and tryptophan and has too long a half-life (15–20 days) to be considered a useful nutritional source of amino acids. Potential adverse effects of IV albumin administration include loss of albumin from the circulation into interstitial fluid of the lungs and elsewhere due to increased capillary perme-

ability, coagulation defects secondary to volume expansion and dilution of clotting factors, inhibition of platelet aggregation, increases in prothrombin time and partial thromboplastin time, increased sodium intake in the albumin infusate, and increased binding to serum calcium resulting in decreased ionized calcium.

Albumin is a poor nutritional marker because of the number of nonnutritional factors that contribute to hypoalbuminemia.

Dosing Guidelines: When clinical circumstances warrant, albumin can be added to parenteral nutrition in the amount of 0.5–1.0 g/kg/d. The half-life of IV albumin in critical illness can be as short as under 12 hours. National shortages of albumin are not unusual. Thus its use must be reserved for patients with true therapeutic need who show a clinical response to the intervention.

Minerals & Electrolytes

A. CALCIUM, PHOSPHORUS, AND MAGNESIUM

Intravenously fed premature and full-term infants should be given relatively high amounts of calcium and phosphorus. Current recommendations are as follows: calcium, 500–600 mg/L; phosphorus, 400–450 mg/L; and magnesium, 50–70 mg/L. After age 1 year, the recommendations are as follows: calcium, 200–400 mg/L; phosphorus, 150–300 mg/L; and magnesium, 20–40 mg/L. The ratio of calcium to phosphorus should be 1.3:1 by weight or 1:1 by molar ratio. These recommendations are deliberately presented as milligrams per liter of infusate to avoid inadvertent administration of concentrations of calcium and phosphorus that are high enough to precipitate in the tubing. During periods of fluid restriction, care must be taken not to inadvertently increase the concentration of calcium and phosphorus in the infusate. These recommendations assume an average fluid intake of 120–150 mL/kg/d and an infusate of 25 g of amino acid per liter. With lower amino acid concentrations, the concentrations of calcium and phosphorus should be decreased.

B. ELECTROLYTES

Standard recommendations are given in Table 10–17. After chloride requirements are met, the remainder of the anion required to balance the cation should be given as acetate to avoid the possibility of acidosis resulting from excessive chloride. The required concentrations of electrolytes depend to some extent on the flow rate of the infusate and must be modified if flow rates are unusually low or high and if there are specific indications in individual patients. IV sodium should be administered sparingly in the severely malnourished patient be-

cause of impaired membrane function and high intracellular sodium levels. Conversely, generous quantities of potassium are indicated. Replacement electrolytes and fluids should be delivered via a separate infusate.

C. TRACE ELEMENTS

Recommended IV intakes of trace elements are as follows: zinc 100 µg/kg, copper 20 µg/kg, manganese 1 µg/kg, chromium 0.2 µg/kg, selenium 2 µg/kg, and iodide 1 µg/kg. Of note, IV zinc requirements may be as high as 400 µg/kg for premature infants and can be up to 250 µg/kg for infants with short bowel syndrome and significant GI losses of zinc. When IV nutrition is supplemental or limited to fewer than 2 weeks, and pre-existing nutritional deficiencies are absent, only zinc need routinely be added.

IV copper requirements are relatively low in the young infant because of the presence of hepatic copper stores. These are significant even in the 28-week fetus. Circulating levels of copper and manganese should be monitored in the presence of cholestatic liver disease. If monitoring is not feasible, temporary withdrawal of added copper and manganese is advisable. Copper and manganese are excreted primarily in the bile, but selenium, chromium, and molybdenum are excreted primarily in the urine. These trace elements, therefore, should be administered with caution in the presence of renal failure.

Although low doses of iron are routinely added in some centers to the IV infusate for infants and children, no official recommendation has been made because of the lack of adequate published data regarding compatibility. Iron added to the infusate should be in a diluted form of iron dextran in a concentration of 1 mg/L. After age 2 months, maintenance IV iron requirements for the full-term infant are approximately 100 µg/kg/d. After the first month, the premature infant requires up to 200 µg/kg/d intravenously. Although overload is unlikely to occur during short-term parenteral nutrition, a surreptitious accumulation of extra iron could occur if parenteral nutrition is prolonged. This risk is enhanced if the patient has received blood transfusions. A second concern is that the potential for free iron is increased in malnourished infants with low transferrin levels. Excess iron is thought to enhance the risk of gram-negative septicemia. Iron has powerful oxidant properties and can enhance the demand for antioxidants, especially vitamin E. None of these concerns appear to preclude the routine use of iron supplements during IV nutrition, but they do emphasize the need for a conservative attitude in determining dosage schedules.

Vitamins

Two vitamin formulations are available for use in pediatric parenteral nutrition: MVI Pediatric and MVI-

12 (AstraZeneca). MVI Pediatric contains the following: vitamin A, 0.7 mg; vitamin D, 400 IU; vitamin E, 7 mg; vitamin K, 200 µg; ascorbic acid, 80 mg; thiamin, 1.2 mg; riboflavin, 1.4 mg; niacinamide, 17 mg; pyridoxine, 1 mg; vitamin B₁₂, 1 µg; folic acid, 140 µg; pantothenate, 5 mg; and biotin, 20 µg. This formulation is suboptimal, with too little vitamin A and excessive amounts of water-soluble vitamins, but it is the best one available. Recommended dosing is as follows: 5 mL for children weighing more than 3 kg, 3.25 mL for infants 1–3 kg, and 1.5 mL for infants weighing less than 1 kg. Children older than 11 years old can receive 10 mL of the adult formulation, MVI-12, which contains the following: vitamin A, 1 mg; vitamin D, 200 IU; vitamin E, 10 mg; ascorbic acid, 100 mg; thiamin, 3 mg; riboflavin, 3.6 mg; niacinamide, 40 mg; pyridoxine, 4 mg; vitamin B₁₂, 5 µg; folic acid, 400 µg; pantothenate, 15 mg; and biotin, 60 µg. MVI-12 contains no vitamin K.

IV lipid preparations contain enough tocopherol to affect total blood tocopherol levels. The majority of tocopherol in soybean oil emulsion is α -tocopherol, which has substantially less biologic activity than the α -tocopherol present in safflower oil emulsions.

A dose of 40 IU/kg/d of vitamin D (maximum 400 IU/d) is adequate for both full-term and preterm infants.

Fluid Requirements

The initial fluid volume and subsequent increments in flow rate are determined by basic fluid requirements, the patient's clinical status, and the extent to which additional fluid administration can be tolerated and may be required to achieve adequate nutrient intake. Calculation of initial fluid volumes to be administered should be based on standard pediatric practice. Tolerance of higher flow rates must be determined on an individual basis. If replacement fluids are required for ongoing abnormal losses, these should be administered via a separate line.

Monitoring

Vital signs should be checked on each shift. With a central catheter in situ, a fever of more than 38.5°C requires that peripheral and central-line blood cultures, urine culture, complete physical examination, and examination of the IV entry point be made. Instability of vital signs, elevated white blood cell count with left shift, and glycosuria suggest sepsis. Removal of the central venous catheter should be considered if the patient is toxic or unresponsive to antibiotics.

A. PHYSICAL EXAMINATION

Monitor especially for hepatomegaly (differential diagnoses include fluid overload, congestive heart failure, steatosis, and hepatitis) and edema (differential diagnoses include fluid overload, congestive heart failure, hypoalbuminemia, and thrombosis of superior vena cava).

B. INTAKE AND OUTPUT RECORD

Calories and volume delivered should be calculated from previous day's intake and output records (that which was delivered rather than that which was ordered). The following entries should be noted on flow sheets: IV, enteral, and total fluid (mL/kg/d); dextrose (g/kg/d or mg/kg/min); protein (g/kg/d); lipids (g/kg/d); energy (kcal/kg/d); percent of energy from enteral nutrition.

C. GROWTH, URINE, AND BLOOD

Routine monitoring guidelines are given in Table 10–18. These are minimum requirements, except in the very long-term stable patient. Individual variables should be monitored more frequently as indicated, as should additional variables or clinical indications. For example, a blood ammonia analysis should be ordered for an infant with lethargy, pallor, poor growth, acidosis, azotemia, or abnormal liver test results.

Greene HL et al: Guidelines for the use of vitamins, trace elements, calcium, magnesium, and phosphorus in infants and children receiving total parenteral nutrition: Report of the Subcommittee on Pediatric Parenteral Nutrient Requirements from the Committee on Clinical Practice Issues of the American Society for Clinical Nutrition. *Am J Clin Nutr* 1988;48:1324 [PMID: 3142247].

Shulman RJ, Phillips S: Parenteral nutrition in infants and children. *J Pediatr Gastroenterol Nutr* 2003;36(5):587 [PMID: 12717082].

INTENSIVE CARE NUTRITION

Severe stress of any kind (eg, large surface area and deep burns, major trauma, major surgery, sepsis) results in common metabolic changes that require special nutritional management. First, several hormones are increased, including thyroid hormone, catecholamines, cortisol, and glucagon. These hormones, acting directly on peripheral tissues or indirectly through an increase in peripheral insulin resistance, produce a hypermetabolic state accompanied by rapid protein catabolism and hyperglycemia. These hormonal changes develop in seconds for the catecholamines, within minutes for insulin and glucagon, and within hours for thyroid and cortisol. Rapid measurements of these hormones and their metabolic effects are not available for routine clinical management, so clinicians anticipate and deal with

Table 10–18. Routine total parenteral nutrition monitoring summary.

Variables	Acute Stage	Long-Term ^b
Growth Weight Length Head circumference	Daily Weekly Weekly	Weekly
Urine Glucose (dipstick) Specific gravity Volume	With each void Void Daily	With changes in intake or status
Blood Glucose Na ⁺ , K ⁺ , Cl ⁻ , CO ₂ , blood urea nitrogen Ca ²⁺ , Mg ²⁺ , P Total protein, albumin, bilirubin, aspartate transaminase, and alkaline phosphatase Zinc and copper Triglycerides Complete blood count	4 hours after changes, ^a then daily × 2 days Daily for 2 days after changes, ^a then twice weekly Initially, then twice weekly Initially, then weekly Initially according to clinical indications Initially, 1 day after changes, ^a then weekly Initially, then twice weekly; according to clinical indications (see text)	Weekly Weekly Weekly Every other week Monthly Weekly Twice weekly

^aChanges include alterations in concentration or flow rate.

^bLong-term monitoring can be tapered to monthly or less often, depending on age, diagnosis, and clinical status of patient.

them. Early and aggressive IV and enteral nutrition are essential, with the goal of providing adequate nonprotein calories (favoring lipids over glucose) and amino acids to preserve essential protein structures. The utility of insulin infusion, including coinfusion of growth hormone and insulin-like growth factor-1 remains controversial.

Briassoulis G et al: Energy expenditure in critically ill children. *Crit Care Med* 2000;28(4):1166 [PMID: 10809300].

Provision of Nutrients in Hypermetabolic States

Enteral feeding should be continued whenever possible, so that the integrity of the enterocytes can be maintained. The increase in energy requirements varies according to the severity of hypermetabolism and its cause. Requirements are highest in burn patients, but major trauma and sepsis may increase energy requirements by 20–50% over resting energy needs. Mounting evidence suggests that increases in energy needs associated with acute stress are short-lived, and that in most cases energy needs equivalent to resting energy expendi-

ture will be adequate for the stressed patient. Ideally, energy expenditure should be measured in critically ill patients. When this is impossible, the patient should be monitored for weight gain (fluid vs tissue) and signs of overfeeding.

The muscle proteolysis and negative nitrogen balance characteristic of the hypermetabolic state cannot be counteracted totally by aggressive nutrition support, but the adverse effects can be attenuated. Negative nitrogen balance can be improved by providing 1.5–2 times the basal protein requirement for the patient’s age. Larger quantities are unlikely to improve nitrogen balance, require substantial energy expenditure for oxidation, and increase CO₂ production.

Another metabolic aberration in the stress-induced, hypermetabolic state is uncontrolled hepatic gluconeogenesis, often producing markedly elevated blood glucose concentrations. Gluconeogenesis is not switched off, as would normally be expected, by the administration of IV dextrose. In fact, dextrose administration may aggravate hyperglycemia and increase hepatic lipogenesis. In some patients (especially those who develop multisystem organ failure), only very modest quantities of dextrose (< 45% of energy requirements) are tolerated. If severe hyperglycemia and glycosuria occur, insulin therapy may be necessary. However, the effects of

insulin in hypermetabolic states are complex and not well clarified. Hypermetabolism is characterized by insulin resistance. Furthermore, insulin requires the simultaneous administration of greater than normal amounts ($\leq 25\%$ of energy needs) of amino acids to limit or partially reverse muscle catabolism and gluconeogenesis. Theoretically, insulin administration could decrease lipolysis and thus deprive the hypermetabolic patient of some of the major sources of usable endogenous fuel.

Although lipolysis is increased in hypermetabolic states, beta-oxidation of fatty acids also is increased, at least initially. IV lipids usually can be metabolized well in early stages, and up to 50% of energy may be provided as lipid. Metabolically, lipid is the preferred fuel in patients with severe sepsis. Lipid tolerance deteriorates in advanced multisystem organ failure.

The metabolic and nutritional advantages of lipid as a fuel must be balanced against potential adverse effects in the septic child (see preceding discussion of IV lipids). It is important not to administer fat emulsion in excess of quantities that can be cleared effectively from the circulation.

Much interest has focused on the potential benefits of dietary factors in conferring an advantage to the immune system, called "immunonutrition." Of the factors studied, glutamine during acute stress has garnered much attention, though clinical trials have failed to

show consistent results. Glutamine is a nonessential amino acid that is an important source of nitrogen for nucleic acid synthesis. It may become conditionally essential during acute illness and serve as a preferred energy source for certain tissues. Most glutamine supplementation studies have involved adults and have yielded conflicting results; thus its therapeutic relevance to pediatric populations is unknown. Other factors potentially useful as immune modulators include arginine, which has a central role in nitric oxide metabolism; nucleotides, which may be essential nutrients in formula-fed infants; probiotics, which may shorten the course of bacterial and viral gastroenteritis; and prebiotics, whose fermentation products (short-chain fatty acids) may be a source of nutrition for the colon. The use of these compounds in pediatric nutrition support is still experimental, and further research is needed to show clear safety and efficacy.

I. EMERGENCIES & INJURIES

F. Keith Battan, MD

ADVANCED LIFE SUPPORT FOR INFANTS & CHILDREN

A systematic approach to a seriously ill or injured child will allow rapid determination of the child's physiologic status and concurrent initiation of resuscitative measures. The goal of rapid assessment and intervention is not initially to make a specific clinical diagnosis but to correct any physiologic derangement—Is there airway obstruction or respiratory failure? Is there shock?—and then to intervene rapidly to ensure adequate oxygenation, ventilation, circulation, and thereby cerebral perfusion. Once initial resuscitative measures are begun, consideration of the cause of the arrest begins, with an emphasis on treatable, reversible causes. It is essential to determine whether any directed therapy (eg, glucose administration for hypoglycemia) is needed.

When progressive deterioration leads to bradycardia and ultimately to asystole, sufficient hypoxic and ischemic insult to the brain and other vital organs has occurred to make neurologic recovery extremely unlikely, even in the doubtful event that the child survives the arrest. Children who respond to ventilation and oxygenation alone or to less than 5 minutes of advanced life support are much more likely to survive neurologically intact. Therefore, it is essential to recognize the child who is at risk for progressing to cardiopulmonary arrest and to provide aggressive intervention before asystole occurs.

Note: Standard precautions must be maintained during resuscitation efforts.

THE ABCS OF RESUSCITATION

Severely ill children should be rapidly evaluated in a deliberate sequence of *airway* patency, *breathing* adequacy, and *circulation* integrity. Derangement at each point must be corrected before proceeding to the next function. Thus, if a child's airway is obstructed, the air-

way must be opened (eg, by head positioning and the chin lift maneuver) before breathing and then circulation are assessed.

Airway

Look, listen, and feel for upper airway patency: (1) *Look* for signs of obstruction such as inspiratory work or suprasternal retractions. A patient with significant airway obstruction will have an altered level of consciousness, such as agitation or lethargy. (2) *Listen* for adventitious breath sounds such as stridor, snoring, or gurgling. (3) *Feel* for air movement with your face near the child's mouth and nose.

The airway is managed initially by noninvasive means such as oxygen administration, chin lift, jaw thrust, suctioning, or bag–valve–mask ventilation, then by invasive maneuvers such as endotracheal intubation, laryngeal mask insertion, or, rarely, cricothyroidotomy. If neck injury is suspected, the cervical spine must be immobilized and kept from extension or flexion. (See Approach to the Pediatric Trauma Patient section.) The following discussion assumes that basic life support has been instituted.

Knowledge of pediatric anatomy is important for airway management. Infants are obligate nasal breathers; therefore, secretions or blood in the nasopharynx can cause significant distress. Children's tongues are large relative to their oral cavities, and the larynx is high and anteriorly located.

A. Place the head in the sniffing position (Figure 11–1). The neck should be slightly flexed and the head gently extended so as to bring the face forward. This position aligns the oral, pharyngeal, and tracheal planes (Figure 11–2). The head should be repositioned if airway obstruction persists after head tilt and jaw thrust. In an infant, the relatively large occiput puts the head in a sniffing position when supine; in an older child, more head extension is necessary. Avoid hyperextension of the neck, especially in infants.

B. Perform the chin lift or jaw thrust maneuver (Figure 11–3). Lift the chin upward while avoiding pressure on the submental triangle, or lift the jaw by traction upward on the angle of the jaw. Jaw thrust without head tilt should be done if cervical spine injury is possible.

Figure 11-1. Opening the airway with the head tilt/chin lift. Gently lift the chin with one hand and push down on the forehead with the other hand. (Reproduced, with permission, from *Textbook of Pediatric Life Support*. American Heart Association, 1997.)

C. Suction the mouth of secretions, blood, and foreign material.

D. Remove visible foreign bodies, using fingers or a Magill forceps—visualizing by means of a laryngoscope if necessary. Blind finger sweeps should not be done.

E. Insert an oropharyngeal or, in the conscious patient, a nasopharyngeal airway to relieve upper airway obstruction due to prolapse of the tongue into the posterior pharynx (Figures 11-4 and 11-5). This is the most common cause of airway obstruction in unconscious children. The correct size for an oropharyngeal airway is obtained by measuring from the upper central gumline to the angle of the jaw. Nasopharyngeal airways should fit snugly but not tightly within the nares and should be equal in length to the distance from the nares to the tragus.

Breathing

Assessment of respiratory status is largely accomplished by inspection. (1) *Look* for adequate and symmetrical chest rise and fall, respiratory rate, increased work of breathing (including retractions, flaring, and grunting),

accessory muscle use (eg, abdominal muscles), skin color, and tracheal deviation. Cyanosis is a late finding in children owing to their relative anemia, making pulse oximetry determination highly desirable. Again note mental status. (2) *Listen* for adventitious breath sounds such as wheezing. Auscultate for air entry, symmetry of breath sounds, and rales. (3) *Feel* for subcutaneous crepitus.

If spontaneous breathing is inadequate, initiate positive-pressure ventilation with bag-mask ventilation and 100% oxygen. If some respiratory effort is present but inadequate, coordinate bagging with the patient's efforts. Adequacy of ventilation is reflected in adequate rise and fall of the chest and auscultation of good air entry bilaterally. If the chest does not rise and fall easily with bagging, reposition the airway and repeat the maneuvers described previously in the Airway section. Perform airway foreign body extraction maneuvers if the airway remains obstructed, including visualizing the airway with a laryngoscope and using Magill forceps. The presence of asymmetrical breath sounds in a child in cardiac arrest or in severe distress suggests pneumothorax and is an indication for needle thoracostomy.

Figure 11-2. Correct positioning of the child older than 2 years of age for ventilation and tracheal intubation. **A:** With the patient on a flat surface (eg, bed or table), the oral (O), pharyngeal (P), and tracheal (T) axes pass through three divergent planes. **B:** A folded sheet or towel placed under the occiput of the head aligns the pharyngeal and tracheal axes. **C:** Extension of the atlanto-occipital joint results in alignment of the oral, pharyngeal, and tracheal axes. (Reproduced, with permission, from *Textbook of Pediatric Life Support*. American Heart Association, 1997.)

In small children, the transmission of breath sounds throughout the chest may impair the ability to auscultate the presence of a pneumothorax. Bag-mask ventilation is effective in the vast majority of cases. **Note:** Effective oxygenation and ventilation are the keys to successful resuscitation.

Using cricoid pressure (Sellick maneuver) during all positive-pressure ventilation, intubate the trachea in patients unresponsive to bag-mask ventilation, those in coma, those who require airway protection, or those who will require prolonged ventilation. Advanced airway management techniques are described in the references accompanying this section. Cricothyroidotomy is rarely necessary. (See Approach to the Pediatric Trauma Patient section.)

Circulation

The diagnosis of shock must be rapid. Diagnosis can and should be made by clinical examination. Clinical assessments A–E are often referred to as an assessment of perfusion:

A. PULSES

Check adequacy of peripheral pulses. Pulses become weak and thready only with severe hypovolemia. Compare peripheral pulses to central pulses.

B. HEART RATE

Compare with age-specific norms. Tachycardia can be a nonspecific sign of distress, whereas bradycardia for age is a prearrest sign and necessitates aggressive resuscitation.

C. EXTREMITIES

As shock progresses, extremities become cooler, from distal to proximal. For example, a child whose extremities are cool distal to the elbows and knees is in severe shock.

D. CAPILLARY REFILL TIME

This is an important indicator of perfusion. A refill time longer than 2.0 seconds is abnormal unless the child is cold.

E. MENTAL STATUS

Hypoxia, hypercapnia, or ischemia will result in altered mental status. Remember that other important treatable conditions may also result in altered mental status, such as intracranial hemorrhage, meningitis, and hypoglycemia.

F. SKIN COLOR

Compromised cardiopulmonary status can cause pallor or gray, mottled, or ashen skin colors.

Figure 11-3. Opening the airway with the jaw thrust. Lift the angles of the mandible. This moves the jaw and tongue forward and opens the airway without bending the neck. (Reproduced, with permission, from *Textbook of Pediatric Life Support*. American Heart Association, 1997.)

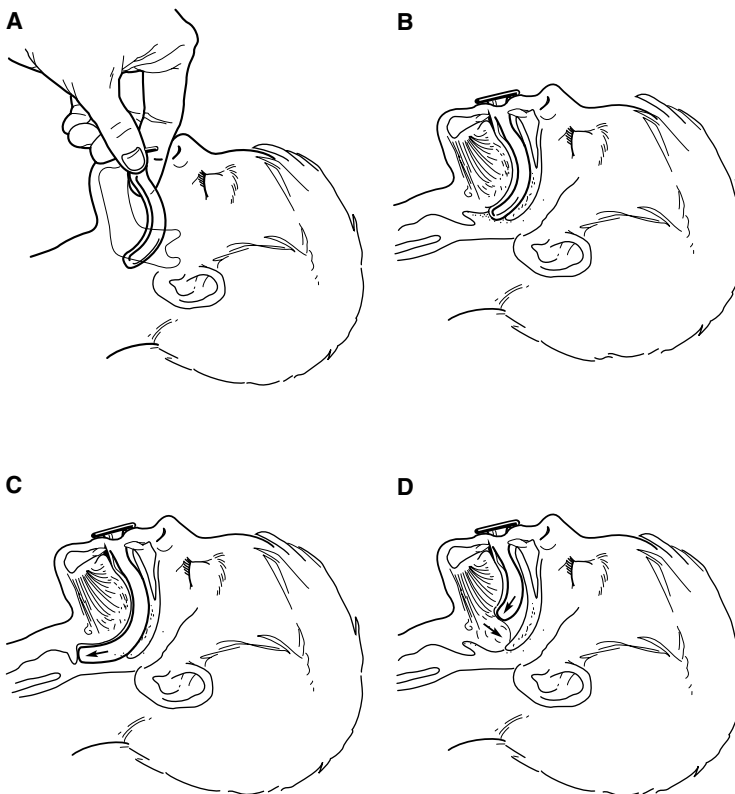

Figure 11-4. A-D: Selection of an oral airway. An airway of the proper size will relieve obstruction caused by the tongue without damaging laryngeal structures. The appropriate size can be estimated by holding the airway next to the child's face (A). The tip of the airway should end just cephalad to the angle of the mandible (dashed line), resulting in proper alignment with the glottic opening (B). If the oral airway inserted is too large, the tip will align posterior to the angle of the mandible (C) and obstruct the glottic opening by pushing the epiglottis down (arrow). If the oral airway is too small, the tip will align well above the angle of the mandible (D) and exacerbate airway obstruction by pushing the tongue into the hypopharynx (arrows). (Adapted, with permission, from Cote and Todres in *Textbook of Pediatric Life Support*. American Heart Association, 1997.)

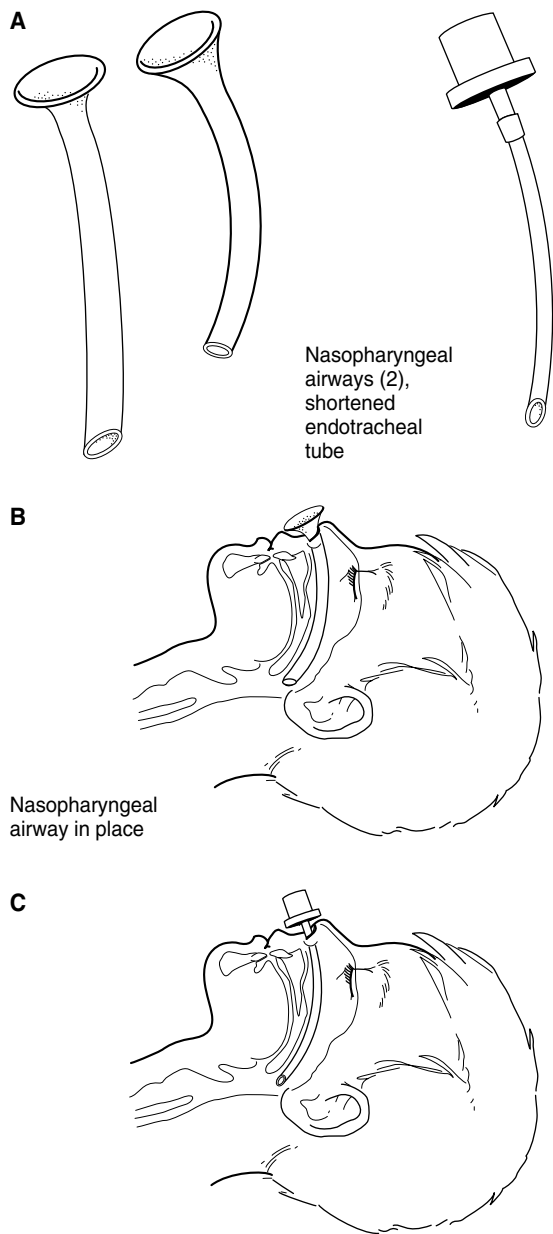

Figure 11-5. **A:** Nasopharyngeal airways. A shortened tracheal tube may be substituted (to reduce resistance). **B:** Placement of a nasopharyngeal airway. **C:** Shortened (cut) tracheal tube used as a nasopharyngeal airway. Note that the standard 15-mm adapter must be firmly reinserted into the tracheal tube. (Reproduced, with permission, from *Textbook of Pediatric Life Support*. American Heart Association, 1997.)

G. BLOOD PRESSURE

Blood pressure determination is not necessary to make the diagnosis of shock. It is important to remember that shock or inadequate perfusion of vital organs may be present before the blood pressure falls below the normal limits for age. As intravascular volume falls, peripheral vascular resistance increases so that blood pressure is maintained until there is 35–40% depletion of blood volume, followed by precipitous and often irreversible deterioration of perfusion (Figure 11-6). Shock that occurs with signs of decreased perfusion (eg, tachycardia and delayed capillary refill time) but normal blood pressure is compensated shock. When blood pressure also falls, decompensated shock is present. The appropriate-size cuff must be used to obtain an accurate blood pressure. Blood pressure determination should be done manually, because automated machines can give erroneous readings in children.

MANAGEMENT OF SHOCK

Intravenous (IV) access is essential but can be difficult to establish in children with shock. Peripheral access, especially the antecubital veins, should be attempted first, but central cannulation—depending on individual expertise—should follow quickly if peripheral access is unsuccessful. Alternatives are percutaneous cannulation

Figure 11-6. Model for cardiovascular response to hypovolemia from hemorrhage (based on normative data). (Reproduced, with permission, from *Textbook of Pediatric Life Support*. American Heart Association, 1997.)

of femoral, subclavian, or internal or external jugular veins; cutdown at antecubital, femoral, or saphenous sites; or intraosseous (IO) lines (Figure 11–7). Consider IO needle placement in any severely ill child when venous access cannot be established rapidly. Use short, wide-bore catheters to allow maximal flow rates. Two IV lines should be started in severely ill children. In newborns, the umbilical veins may be cannulated. Consider arterial access if beat-to-beat monitoring or frequent laboratory tests will be needed.

Differentiation of Shock States & Initial Therapy

Therapy for inadequate circulation is determined by the cause of circulatory failure.

A. HYPOVOLEMIC SHOCK

The most common type of shock in the pediatric population is hypovolemic. Frequent causes include dehydration, diabetes, or heat illness; hemorrhage; and burns. Initial therapy is with isotonic crystalloid solution, that is, normal saline or lactated Ringer solution. Give 20 mL/kg body weight, repeated as necessary, with frequent reassessments, until perfusion normalizes. Children tolerate large volumes of fluid replacement—the full circulating blood volume of 80 mL/kg could potentially be given safely with appropriate monitoring and reassessment. Typically, in hypovolemic shock, no more than 50 mL/kg is needed. Packed red blood cell transfusion is indicated in trauma patients not responding to two boluses of crystalloid solution. Pressors are not required in simple hypovolemic states.

B. DISTRIBUTIVE SHOCK

Distributive shock represents relative hypovolemia from increased vascular capacitance of circulating volume. Examples are sepsis, anaphylaxis, and spinal cord injury. Initial therapy is again by limited isotonic volume replacement with crystalloid, but pressors may be necessary if perfusion does not normalize after delivery of two 20 mL/kg boluses of crystalloid. Children in distributive shock must be admitted to a pediatric intensive care unit.

C. CARDIOGENIC SHOCK

Cardiogenic shock can occur as a complication of congenital heart disease, myocarditis, dysrhythmias, ingestions (eg, clonidine, cyclic antidepressants), or as a sequela of prolonged shock due to any cause. The diagnosis is suggested by any of the following signs: abnormal cardiac rhythm, distended neck veins, rales, abnormal heart sounds such as an S_3 or S_4 , friction rub, narrow pulse pressure, or hepatomegaly. Chest radiographs will show cardiomegaly and pulmonary edema—not seen in shock due to other causes. An initial bolus of crystalloid may be given, but dopamine or other pressors, and possibly agents to reduce afterload, are necessary to improve perfusion. Comprehensive cardiopulmonary monitoring is essential. Children in cardiogenic shock must be admitted to a pediatric intensive care unit.

Observation & Further Management

Reassess perfusion after each fluid bolus to determine additional fluid needs. Serial central venous pressure

Figure 11–7. IO cannulation technique. (Reproduced, with permission, from *Textbook of Pediatric Life Support*. American Heart Association, 1997.)

determinations or a chest radiograph may aid clinical assessments to help determine volume status. Place an indwelling urinary catheter to monitor urine output.

Caution must be exercised with volume replacement if intracranial pressure is potentially elevated, as in severe head injury, diabetic ketoacidosis, or meningitis. Even in such situations, however, normal intravascular volume must be restored, as reflected by adequate peripheral perfusion and mean arterial pressure, to achieve adequate cerebral perfusion pressure.

Summary of Cardiopulmonary Resuscitation

Assess the ABCs in sequential fashion and begin interventions as soon as a derangement is detected—before assessing the next system. After each intervention, it is essential that each system be reassessed to ensure improvement and to avoid failing to recognize clinical deterioration.

EMERGENCY PEDIATRIC DRUGS

Though careful attention to airway and breathing remains the mainstay of pediatric resuscitation, medications are often needed. Rapid delivery to the central circulation, which can be via peripheral IV catheter, is essential. Infuse medications close to the catheter's hub and flush in with saline to achieve the most rapid systemic effects. If no IV or IO access is achievable, some drugs may be given by endotracheal tube (Table 11–1). The use of length-based emergency measuring tapes that contain preprinted drug dosages, equipment sizes, and IV fluid amounts (Broselow tapes) or preprinted resuscitation drug charts is much more accurate than

Table 11–1. Emergency drugs that can be given by endotracheal tube.

Lidocaine
Epinephrine
Atropine
Naloxone

estimation formulas and helps minimize dosing errors. Selected emergency drugs used in pediatrics are summarized in Table 11–2.

APPROACH TO THE SERIOUSLY ILL CHILD

An unstable patient may present with a known diagnosis, such as a child known to have asthma in status asthmaticus and respiratory failure, or a child with known congenital heart disease. Often a child presents in cardiorespiratory failure of unknown cause. The initial approach is designed to rapidly identify and reverse life-threatening conditions. Children with chronic disease may present with an exacerbation in that system or secondary to a new, unrelated problem.

Preparation for Emergency Management

Resuscitation occurs simultaneously at two levels: rapid cardiopulmonary assessment, with indicated stabilizing measures, while venous access (“lifelines”) are gained and cardiopulmonary monitoring initiated. The technique of accomplishing these concurrent goals is outlined as follows:

A. If advance notice of the patient's arrival has been received, prepare a resuscitation room and summon appropriate personnel as needed, such as a neurosurgeon for an unresponsive child after severe head injury or a radiology technician for imaging studies.

B. Assign team responsibilities, including a team leader plus others designated to manage the airway, perform chest compressions, achieve access, draw blood for laboratory studies, place monitors, gather additional historical data, and provide family support.

C. Age-appropriate equipment should be made ready, including a cardiorespiratory monitor, pulse oximeter, and appropriate blood pressure cuff. Age- and weight-appropriate laryngoscope blades, endotracheal tubes, a naso- or orogastric tube, and an indwelling urinary catheter should be assembled for rapid access. Use a length-based emergency tape if available. See Table 11–3 for sizes.

Reception & Assessment

When the patient arrives, the team leader begins a rapid assessment as team members perform their preassigned tasks. If the patient is received from prehospital care providers, careful attention must be paid to their report, because they have information that they alone have observed. Interventions and medications should be ordered only by the team leader to avoid confusion, and the leader should refrain from personally perform-

Table 11–2. Emergency pediatric drugs.

Drug	Indications	Dosage and Route	Comment
Atropine	<ol style="list-style-type: none"> 1. Bradycardia, especially cardiac in origin 2. Vagally mediated bradycardia, eg, during laryngoscopy and intubation 3. Anticholinesterase poisoning 	0.01–0.02 mg/kg (minimum, 0.1 mg; maximum, 2 mg) IV, IO, ET. May repeat every 5 min.	Atropine may be useful in hemodynamically significant primary cardiac-based bradycardias. Because of paradoxical bradycardia sometimes seen in infants, a minimum dose of 0.1 mg is recommended by the American Heart Association. Epinephrine is the first-line drug in pediatrics for bradycardia caused by hypoxia or ischemia.
Bicarbonate	<ol style="list-style-type: none"> 1. Documented metabolic acidosis 2. Hyperkalemia 	1 meq/kg IV or IO; by arterial blood gas: $0.3 \times \text{kg} \times \text{base deficit}$. May repeat every 5 min.	Infuse slowly. Sodium bicarbonate will be effective only if the patient is adequately oxygenated, ventilated, and perfused. Some adverse side effects.
Calcium chloride 10%	<ol style="list-style-type: none"> 1. Documented hypocalcemia 2. Calcium channel blocker overdose 3. Hyperkalemia, hypermagnesemia 	10–30 mg/kg slowly IV, preferably centrally, or IO with caution.	Calcium is no longer indicated for asystole. Potent tissue necrosis results if infiltration occurs. Use with caution.
Epinephrine	<ol style="list-style-type: none"> 1. Bradycardia, especially hypoxic–ischemic 2. Hypotension (by infusion) 3. Asystole 4. Fine ventricular fibrillation refractory to initial defibrillation 5. Pulseless electrical activity 6. Anaphylaxis 	<p>Bradycardia and first dose in arrests: 0.01 mg/kg of 1:10,000 solution IV or IO.</p> <p>Second and subsequent doses in arrests: 0.1–0.2 mg/kg of 1:1000 solution IV or IO. Repeat every 3–5 min.</p> <p>ET: 10x intended IV dose</p> <p>SC: 0.01 mg/kg of 1:1000 solution (= 0.01 mL/kg) (anaphylactic shock). Maximum dose: 0.3–0.5 mL.</p> <p>Constant infusion by IV drip: 0.1–1 µg/kg/min.</p>	Epinephrine is the single most important drug in pediatric resuscitation. Evidence from animal studies and small series of human subjects indicates that the present recommended dose may be insufficient, and some clinicians use doses of 0.1–0.3 mg/kg IV. A randomized controlled trial has not been done.
Glucose	<ol style="list-style-type: none"> 1. Hypoglycemia 2. Altered mental status (empirical) 3. With insulin, for hyperkalemia 	0.5–1 g/kg IV or IO. May repeat as necessary.	Neonates: 1 cc/kg D ₁₀ W. Older children: 2–4 cc/kg D ₂₅ W, 6–10 cc/kg D ₁₀ W.
Naloxone	<ol style="list-style-type: none"> 1. Opioid overdose 2. Altered mental status (empirical) 	0.1 mg/kg IV, IO, or ET; maximum dose, 2 mg. May repeat as necessary.	Side effects are few. A dose of 2 mg may be given in young children. Repeat as necessary, or give as constant infusion in opioid overdoses.

ET = endotracheally, IO = intraosseously, IV = intravenously, SC = subcutaneously.

Table 11–3. Equipment sizes and estimated weight by age.

Age (years)	Weight (kg)	Endotracheal Tube Size (mm) ^a	Laryngoscope Blade (Size)	Chest Tube (Fr)	Foley (Fr)
Premature	1–2.5	2.5 uncuffed	0	8	5
Term newborn	3	3.0	0–1	10	8

ing procedures, which may distract him or her from optimal direction of the resuscitation. A complete timed record should be kept of events, including medications, interventions, and response to intervention.

A. ALL CASES

In addition to cardiac compressions and ventilation, ensure that the following are instituted:

1. 100% high-flow oxygen.
2. Monitoring, including cardiorespiratory, pulse oximetry, and end-tidal CO₂ if the patient is intubated.
3. IV (peripheral, IO, or central) access. Two lines preferred.
4. Blood drawn and sent. Bedside blood glucose determination is essential.
5. Full vital signs obtained.
6. Clothes removed.
7. Foley catheter and naso- or orogastric tube inserted.
8. Complete history.
9. Notify needed consultants.
10. Family support.
11. Consider law enforcement or security activation and emergency unit lockdown for cases possibly

involving terrorism, gang violence, or threats to staff or family.

B. AS APPROPRIATE

1. Immobilize neck.
2. Have chest radiograph taken for line and tube placement.
3. Insert central venous pressure and arterial line.

Patterson M: Resuscitation update for the pediatrician. *Pediatr Clin North Am* 1999;46:1285 [PMID: 10629685].

APPROACH TO THE PEDIATRIC TRAUMA PATIENT

Injuries, including motor vehicle crashes, falls, burns, and immersions, account for the greatest number of deaths among children older than age 1 year. All providers of pediatric care must be cognizant of this sobering statistic, become involved, and work with injury prevention specialists, prehospital providers, and emergency, critical care, and rehabilitation physicians and nurses to reduce this terrible loss.

A team approach to the severely injured child, using assigned roles as outlined in the preceding section, will

optimize outcomes. A calm atmosphere in the receiving area will contribute to thoughtful care. Conscious children are terribly frightened by serious injury; constant reassurance can help alleviate anxiety. Analgesia and sedation can and should be given to stable patients. It is unconscionable in the modern era to let children suffer pain needlessly. Treat pain expeditiously with oral or parenteral narcotics with appropriate monitoring. Parents are often anxious, angry, or guilty and require ongoing support from the services of staff, social workers or child life workers (therapists knowledgeable about child development). To provide optimal multidisciplinary care, regional pediatric trauma centers provide dedicated teams of pediatric specialists in emergency pediatrics, trauma surgery, orthopedics, neurosurgery, and critical care. Because most children with severe injuries are not seen in these centers, however, primary care providers must be able to provide initial assessment and stabilization of the child with life-threatening injuries before transport to a verified pediatric trauma center.

Mechanism of Injury

Document the time of occurrence, the type of energy transfer to the child (eg, hit by a car, rapid deceleration), secondary impacts if the child was thrown by the initial impact, appearance of the child at the scene, interventions performed, and clinical condition during transport. The report of emergency service personnel is invaluable. All information of this type must be forwarded with the patient to the referral facility if secondary transport occurs.

Trauma in children is predominantly blunt, although penetrating trauma occurs in 10% of cases. Head and abdominal injuries are particularly common and important in the pediatric age group.

Initial Assessment & Management

The vast majority of children who reach a hospital alive survive to discharge. Most deaths from trauma in children are due to head injuries. Therefore, cerebral resuscitation must be the foremost consideration when treating children with serious injuries. The ultimate measure of outcome is the child's eventual level of functioning. Strict attention to the ABCs ensures optimal oxygenation, ventilation, and perfusion, and ultimately, cerebral perfusion.

The primary and secondary survey is a method for evaluating and treating injured patients in a systematic way that provides a rapid assessment and stabilization phase, followed by a head-to-toe examination and definitive care phase.

PRIMARY SURVEY

The primary survey is designed to identify rapidly and treat immediately all physiologic derangements resulting from trauma. It is the resuscitation phase. Priorities are still airway, breathing, and circulation, but with important further considerations in the trauma setting:

- Airway*, with cervical spine control
- Breathing*
- Circulation*, with hemorrhage control
- Disability* (neurologic deficit)
- Exposure* (maintain a warm *Environment*, undress the patient completely, and *Examine*)

Evaluation and treatment of the ABCs are as discussed earlier in this chapter. Modifications in the trauma setting are added in the sections that follow.

Airway

Failure to manage the airway appropriately is the most common cause of preventable morbidity and death. Administer 100% high-flow oxygen to all patients. During assessment and management of the airway, provide cervical spine protection, initially by manual in-line immobilization, not traction. A hard cervical spine collar is then applied, and the head and body are secured to a backboard, surrounded by a lightweight means of cushioning (eg, rolled blankets) to further immobilize the head and body and allow log-rolling of the child in case of vomiting. Assess the airway for patency as before. Head positioning must avoid flexion or extension of the neck. Use jaw thrust rather than chin lift during intubation. Suction the mouth and pharynx free of blood, foreign material, or secretions, and remove loose teeth. Insert an oropharyngeal airway if upper airway noises are heard or obstruction from posterior prolapse of the tongue occurs. A child with a depressed level of consciousness or a need for prolonged ventilation, hyperventilation, or operative intervention requires endotracheal intubation after bag-mask preoxygenation. Orotracheal intubation is the route of choice and is possible without cervical spine manipulation. Nasotracheal intubation may be possible in children age 12 years or older who have spontaneous respirations—if not contraindicated by midfacial injury with the possibility of cribriform plate disruption. Rarely, if tracheal intubation cannot be accomplished—particularly in the setting of massive midfacial trauma—cricothyroidotomy may be necessary. Needle cricothyroidotomy using a large-bore catheter through the cricothyroid membrane is the procedure of choice in patients younger than age 12 years. Operative revision will be needed for formal controlled tracheostomy.

Breathing

Most ventilatory problems are resolved adequately by the airway maneuvers described earlier in this chapter and by positive-pressure ventilation. Breathing assessment is as described previously: Assess for an adequate rate and for symmetrical chest rise, increased work of breathing, color, tracheal deviation, crepitus, flail segments, deformity, or penetrating wounds. Sources of traumatic pulmonary compromise include pneumothorax, hemothorax, pulmonary contusion, flail chest, and central nervous system (CNS) depression. Asymmetrical breath sounds, particularly if tracheal deviation, cyanosis, or bradycardia is present, suggest pneumothorax, probably under tension. To evacuate the pneumothorax, insert a large-bore catheter-over-needle assembly attached to a syringe over the fourth rib in the anterior axillary line into the pleural cavity and withdraw air. If a pneumothorax or hemothorax is present, place a chest tube to water seal. Insertion should be over the rib to avoid the neurovascular bundle that runs below the rib margin. Open pneumothoraces can be treated temporarily by taping petrolatum-impregnated gauze on three sides over the wound, creating a flap valve. After airway and breathing interventions have begun, hemodynamic status may be addressed.

Circulation

Ongoing hemorrhage, external or internal, gives pediatric trauma some of its anxiety-provoking character. During the assessment of circulation, IV access should be achieved, preferably at two sites. If peripheral access is not readily available, a central line, cutdown, or IO line is established. A cardiorespiratory monitor and oximeter should be applied early in the resuscitation. Peripheral perfusion and blood pressure should be recorded at frequent intervals. Determine hematocrit, blood type and cross-match, and serum amylase. Consider blood and urine toxicologic screening.

External hemorrhage can be controlled by direct pressure. To avoid damage to adjoining nerves and vessels, avoid placing hemostats on vessels, except in the scalp.

Determination of the site of internal hemorrhage can be challenging. Sites include the chest, abdomen, retroperitoneum, pelvis, and thighs. Bleeding into the intracranial vault rarely causes shock in children except in infants. An experienced pediatric trauma surgeon and radiologic studies—principally computed tomography (CT) and ultrasound—will localize the site of internal bleeding.

Suspect cardiac tamponade after penetrating or blunt injuries to the chest if shock, pulseless electrical activity, narrowed pulse pressure, distended neck veins,

hepatomegaly, or muffled heart sounds are present. Ultrasound may be diagnostic if readily available. Diagnose and treat with pericardiocentesis and rapid volume infusion.

Treat signs of poor perfusion vigorously: A tachycardic child with a capillary refill time of 3 seconds, or other abnormalities in the perfusion examination, is in *shock* and is sustaining vital organ insults. Remember that hypotension is a late finding. Volume replacement is initially accomplished by rapid infusion of normal saline or lactated Ringer solution at 20 mL/kg of body weight, followed by 10 mL/kg of packed red blood cells if perfusion does not normalize after two crystalloid bolus infusions.

Reassessment should be done rapidly following each bolus. If clinical signs of perfusion have not normalized, repeat the bolus. Lack of response or later signs of hypovolemia suggest the need for blood transfusion and possible surgical exploration. For every milliliter of external blood loss 3 mL of crystalloid solution should be administered.

A common problem is the brain-injured child who is at risk for intracranial hypertension and who is also hypovolemic. In such cases, circulating volume must be restored to ensure adequate cerebral perfusion; therefore, fluid replacement is required until perfusion normalizes. Thereafter provide maintenance fluids with careful serial reassessments. Do not restrict fluids for children with head injuries.

Disability–Neurologic Deficit

Assess pupillary size and reaction to light and the level of consciousness. The level of consciousness can be reproducibly characterized by the AVPU system (Table 11-4). Pediatric Glasgow Coma Scale assessments should be done as part of the secondary survey (Table 11-5; see Secondary Survey section).

Exposure and Environment

Significant injuries can be missed unless the child is completely undressed and examined fully, front and back. Cutting away clothing as necessary can minimize movement. Because of their high ratio of surface area to

body mass, infants and children cool rapidly. Because hypothermia compromises outcome except with isolated head injuries, it is necessary to continuously monitor the body temperature and to use warming techniques vigorously as necessary. Hyperthermia, conversely, adversely affects outcomes in children with acute brain injuries, so maintain normal body temperatures.

Monitoring

Cardiopulmonary monitors with pulse oximetry and end-tidal CO₂ monitors should be put in place immediately. At the completion of the primary phase, additional “tubes” should be placed.

A. NASOGASTRIC OR OROGASTRIC TUBE

Children’s stomachs should be assumed to be full, and gastric distention from positive-pressure ventilation increases the chance of vomiting and aspiration.

B. URINARY CATHETER

An indwelling urinary bladder catheter should be placed to monitor urine output. Contraindications are based on the risk of urethral transection; signs include blood at the meatus or in the scrotum or a displaced prostate detected on rectal examination. Urine should be tested for blood. Urine output should exceed 1 mL/kg/h.

SECONDARY SURVEY

After the resuscitation phase, a head-to-toe examination should be performed to reveal all injuries and determine priorities for definitive care.

Skin

Search for lacerations, hematomas, swelling, and abrasions. Remove foreign material, and cleanse as necessary. Cutaneous signs may indicate underlying pathology (eg, a flank hematoma overlying a renal contusion) although surface signs may be absent even with significant internal injury. Make certain the child’s tetanus immunization status is current. Consider tetanus immune globulin for unimmunized children.

Head

Check for hemotympanum and for clear or bloody cerebrospinal fluid (CSF) leak from the nares. Battle sign (hematoma over the mastoid) and raccoon eyes are late signs of basilar skull fracture. Explore wounds, excluding foreign bodies and defects in galea or skull. CT scan of the head is an integral part of evaluation for altered level of consciousness, seizure after trauma, or focal neurologic findings (see Head Injury section). Pneumococcal vaccine is indicated for basilar skull fractures.

Spine

Cervical spine injury must be excluded in all children. This can be done without radiographs in children with normal neurologic findings on examination who are able to deny midline neck pain or midline tenderness on palpation of the neck and who have no other painful injuries that might obscure the pain of a cervical spine injury. Voluntary movement of the extremities must be observed. If radiographs are indicated, a cross-table lateral neck view is obtained initially, followed by anteroposterior and odontoid views. “Normal” studies do not exclude significant injury, which can be bony or ligamentous, or involve the spinal cord itself. Therefore, an obtunded child should be maintained in cervical spine immobilization until the child has awakened and an appropriate neurologic examination can be performed. The entire thoracolumbar spine must be palpated and areas of pain or tenderness examined by radiography.

Chest

Pneumothoraces are detected and decompressed during the primary survey. Hemothoraces can occur with rib fractures or with injury to intercostal vessels, large pulmonary vessels, or lung parenchyma. Tracheobronchial

disruption is suggested by large continued air leak despite chest tube decompression. Pulmonary contusions may require ventilatory support. Myocardial contusions and aortic injuries are unusual in children.

Abdomen

Blunt abdominal injury is common in multisystem injuries. Significant injury can exist without cutaneous signs or instability of vital signs. Tenderness, guarding, distention, lack of bowel sounds, or poor perfusion mandates immediate evaluation by a pediatric trauma surgeon. Injury to solid viscera frequently can be managed nonoperatively in stable patients; however, in the presence of intestinal perforation or hypotension, operative treatment is indicated. Serial examinations, ultrasound, and CT scan—or, in unstable patients, diagnostic peritoneal lavage—provide diagnostic help. Elevated liver function tests have good specificity but only fair sensitivity for hepatic injury. Serum amylase will rise progressively with pancreatic injury, which may not be easily visualized by initial CT.

Pelvis

Pelvic fractures are classically manifested by pain, crepitus, and abnormal motion. Pelvic fracture is a relative contraindication to urethral catheter insertion. Perform a rectal examination, noting tone, tenderness, and prostate position in boys. Stool should be tested for blood.

Genitourinary System

If urethral transection is suspected (see earlier discussion), perform a urethrogram before catheter placement. Diagnostic imaging of the child with hematuria includes CT scan, or occasionally IV urograms. Management of kidney injury is largely nonoperative except for renal pedicle injuries.

Extremities

Long bone fractures are common but rarely life-threatening. Test for pulses, perfusion, and sensation. Neurovascular compromise requires immediate orthopedic consultation. Delayed diagnosis of fracture sometimes occurs when children are comatose; reexamination is necessary to avoid overlooking previously missed fractures.

Central Nervous System

Most deaths in children with multisystem trauma are from head injuries, so optimal neurointensive care is important. Significant injuries include diffuse axonal injury; cerebral edema; subdural, subarachnoid, and epidural hematomas; parenchymal hemorrhages; and spinal cord

injury. A full sensorimotor examination should be performed. Deficits require immediate neurosurgical consultation. Extensor or flexor posturing represents intracranial hypertension, not seizure activity, until proved otherwise, and should be treated with mild hyperventilation (PaCO_2 in the mid-30s mm Hg), and adequate but not excessive volume resuscitation. If accompanied by a fixed and unreactive pupil a herniation syndrome is present, and hyperventilation should be to a PaCO_2 in the mid-20s. Diuretics, usually mannitol, should be given if perfusion is normal and signs of herniation are present. Normal peripheral perfusion must be ensured to optimize cerebral perfusion. Level of consciousness by the AVPU system (see Table 11-4) or Glasgow Coma Scale (see Table 11-5) should be assessed serially. Seizure activity warrants exclusion of significant intracranial injury. In the trauma setting, seizures are frequently treated with fosphenytoin. Acute spinal cord injury may benefit from high-dose methylprednisolone therapy. Corticosteroids are not indicated for head trauma.

HEAD INJURY

Closed head injuries range in severity from minor asymptomatic trauma without sequelae to intracranial hemorrhage leading to death. Head injury, including the shaken-baby syndrome, is common in cases of child abuse. Even following minor closed head injury, neuropsychiatric sequelae can occur.

Assessment

The considerations discussed earlier in the Approach to the Pediatric Trauma Patient section apply here as well. The history should include the time and mechanism of injury. How far did the child fall and onto what surface? Was there loss of consciousness? Does the child remember events preceding, during, and following the injury? What have been the child's levels of consciousness and activity since the injury? Has there been vomiting, headache, ataxia, seizures, or visual disturbance?

The physical examination should be complete, keeping in mind the mechanism of injury, and should include a detailed neurologic examination. Look for associated injuries such as mandibular fracture, scalp or skull injury, or cervical spine injury. CSF leak from the ears or nose or the two later-appearing signs of periorbital hematomas (raccoon eyes) and Battle sign, imply basilar skull fracture. Children with suspected basilar skull fractures should receive the pneumococcal vaccine. Obtain vital signs and assess the child's level of consciousness by the AVPU system (see Table 11-4) or Glasgow Coma Scale (see Table 11-5), noting irritability or lethargy; pupillary equality, size, and reaction to light; funduscopic examination; reflexes; body posture; and rectal tone. Always consider child abuse—the injuries observed should be consistent with the history and the child's developmental level.

Radiographic studies may be indicated. Plain films are useful only in cases of penetrating head trauma or for assessing depressed skull fractures and ruling out foreign bodies. Major morbidity does not follow from skull fracture *per se* but rather from the associated intracranial injury. The presence of a skull fracture on plain films is associated with an increased likelihood of finding a serious intracranial injury demonstrated by CT scanning. CT scan should be performed in the child with persistent vomiting or an abnormal or lateralizing neurologic examination, including an abnormal mental status that does not quickly return to normal. In infants, a normal neurologic exam does not exclude significant intracranial hemorrhage. In the setting of an appropriate mechanism, and if scalp findings such as large hematomas are found, consider performing CT.

CONCUSSION

A concussion injury is defined as a brief loss or alteration of consciousness followed by a return to normal. Brain tissue is not damaged, and there are no focal findings on detailed neurologic examination. There may be pallor, amnesia, or several episodes of vomiting. Disposition is based on the clinical course and suitability of follow-up. The patient may be discharged when neurologically normal after a period of observation. Parents should closely observe the child at home and return if the child exhibits altered level of consciousness, persistent vomiting, gait disturbances, unequal pupils, seizures, or increasing headache, or if the parents have any concerns.

CONTUSION

A bruise of the brain matter is a contusion. The child's level of consciousness decreases, and focal findings if any correspond to the area of the brain that is injured.

These patients require CT scan, a period of observation, and consideration of neurorehabilitation follow-up for posttraumatic brain injury sequelae.

DIFFUSE AXONAL INJURY

Diffuse axonal injury is a potentially severe form of traumatic brain injury characterized by coma without focal signs on neurologic examination. There may be no external signs of trauma. The initial CT scan is normal or may demonstrate only scattered small areas of cerebral contusion and areas of low density. Prolonged disability may follow diffuse axonal injury.

ACUTE INTRACRANIAL HYPERTENSION

Close observation will detect early signs and symptoms of intracranial pressure elevation. Early recognition is essential to avoid disastrous outcomes. In addition to traumatic causes, intracranial pressure elevation with or without herniation syndromes may be seen in spontaneous intracranial hemorrhage, CNS infection, hydrocephalus, ruptured arteriovenous malformation, metabolic derangement (eg, diabetic ketoacidosis), ventriculoperitoneal shunt obstruction, or tumor. Symptoms include headache, vision changes, vomiting, gait difficulties, and a progressively decreasing level of consciousness. Other signs may include stiff neck, cranial nerve palsies, and progressive hemiparesis. Cushing triad (bradycardia, hypertension, and irregular respirations) is a late and prearrest finding. Papilledema is also a late finding. Consider CT scan before lumbar puncture if there is concern about intracranial pressure elevation because of the risk of precipitating herniation. Lumbar puncture should be deferred if coma or shock is present.

Therapy for intracranial pressure elevation must be swift and aggressive. Strict attention to normal oxygenation, moderate ventilation, and adequate perfusion is paramount. Controlled rapid sequence intubation with appropriate sedation, muscle relaxation, and agents to reduce the intracranial pressure elevation that accompanies intubation is followed by mild hyperventilation (PaCO₂ lowered to 35–38 mm Hg) and avoidance of hypoperfusion and hypoxemia. Mannitol (0.5 g/kg intravenously), an osmotic diuretic, will reduce brain water, as will furosemide (0.1–0.2 mg/kg intravenously). These measures may acutely lower intracranial pressure. Fluid infusion and, ultimately, pressors should be used to maintain normal arterial blood pressure and peripheral perfusion, if necessary. Adjunctive measures include elevating the head of the bed 30 degrees, treating hyperpyrexia and pain, and maintaining the head in a midline position. Obtain immediate neurosurgical evaluation. Further details about

management of intracranial hypertension (cerebral edema) are presented in Chapter 13.

DISPOSITION FOR CHILDREN WITH CLOSED HEAD INJURY

Patients with mild head injury may be discharged with detailed written instructions—after a period of brief observation—if the examination remains normal and parental supervision and follow-up are appropriate. Children with persistent deficits require admission or prolonged observation. If the patient responds to voice commands and mental status is improving gradually over a period of several hours, observation may be done without further radiographic studies. If the mental status deteriorates, however, CT scan and neurosurgical consultations are indicated. If the CT scan is normal and the physical findings normalize, these children may also be discharged after a period of observation. Patients with severe head injury require cerebral resuscitation, evaluation by a neurosurgeon, and admission to hospital.

BURNS

Thermal injury is a major cause of accidental death and disfigurement in children. Pain, morbidity, the association with child abuse, and the preventable nature of burns constitute an area of major concern in pediatrics. Common causes include hot water or food, appliances, flames, grills, vehicle-related burns, and curling irons. Burns occur commonly in toddlers—in boys more frequently than in girls.

ELECTRICAL BURNS

Even brief contact with a high-voltage source will result in a contact burn. When an infant or toddler bites an electric cord, burns to the commissure of the lips occur

that appear gray and necrotic, with surrounding erythema. If an arc is created with passage of current through the body, the pattern of the thermal injury will depend on the path of the current; therefore, search for an exit wound and internal injuries. Extensive damage to deep tissues may occur. Current traversing the heart may cause nonperfusing arrhythmias. Neurologic effects of electrical burns can be immediate (eg, confusion, disorientation, peripheral nerve injury), delayed (eg, nerve damage in the thrombosed limb after compartment syndrome), or late (eg, impaired concentration or memory).

EVALUATION OF THE BURNED PATIENT

Classification

Burns are classified clinically according to the nature of the burn and the extent and thickness; associated injuries are ascertained in the initial evaluation.

Superficial (first-degree) burns are easily recognized and treated. They are painful, dry, red, and hypersensitive. Sunburn is a common example. Healing occurs with minimal damage to epidermis. At the other end of the spectrum are full-thickness (third-degree) burns affecting all epidermal and dermal elements, leaving avascular skin. The wound is dry, depressed, leathery in appearance, and without sensation. Unless skin grafting is provided, the scar will be hard, uneven, and fibrotic. Partial-thickness (second-degree) burns are further classified as superficial or deep, depending on appearance and healing time, with each subgroup treated differently. Superficial partial-thickness burns are red and may blister. Deep partial-thickness burns are white and dry, blanch with pressure, and the involved skin has decreased sensitivity to pain.

Management

Burn management depends on the depth and extent of thermal injury. Burn extent can be classified as major or minor. Minor burns are less than 10% of the body surface area for superficial and partial-thickness burns, or less than 2% for full-thickness burns. Partial- or full-thickness burns of the hands, feet, face, eyes, ears, and perineum are considered major.

A. SUPERFICIAL AND PARTIAL-THICKNESS BURNS

These injuries can generally be treated in the outpatient setting. It is *mandatory* that rapid and effective analgesia be provided, and redosed as indicated by the child. Oral codeine may occasionally suffice, but often parental narcotics are indicated. Superficial burns are treated with cool compresses and analgesia. Treatment of partial-thickness burns with blisters consists of antiseptic cleansing, topical antimicrobial coverage, and ob-

ervation for infection. Blisters appear early in deeper partial-thickness burns and, if open, may be debrided. Alternatively, the blister may be used as a protective flap after cleaning and dressing. After debridement, the wound should be cleansed with dilute (1–5%) povidone–iodine solution, thoroughly washed with normal saline, and covered with topical antibiotic, which does not need to be silver sulfadiazine. The wound should be protected with a bulky dressing and reexamined within 24 hours and serially thereafter. Wounds with a potential for causing loss of function or scarring—especially wounds of the hand or digits—should be referred promptly to a burn surgeon. Outpatient analgesia should be provided on discharge.

B. FULL-THICKNESS AND DEEP OR EXTENSIVE PARTIAL-THICKNESS BURNS

Major burns place particular importance on the ABCs of trauma management. Early establishment of an artificial airway is critical with oral or nasal burns because of their association with inhalation injuries and critical airway narrowing.

The trauma resuscitation protocol outlined previously, in the Primary Survey section, should be followed. There may be inhalation injury from carbon monoxide, cyanide, or other toxic products if flames were present. A nasogastric tube and bladder catheter should be placed. The secondary survey should ascertain whether any other injuries are present, including those suggestive of abuse.

Fluid administration is based on several principles. Capillary permeability is markedly increased. Fluid needs are based on examination findings, percentage of body surface area burned, depth, and age. Maintaining normal intravascular pressure and replacing fluid losses are essential. Figure 11–8 shows percentages of body surface area by body part in infants and children. The Parkland formula for fluid therapy is 4 mL/kg/% body surface area burned for the first 24 hours, with half in the first 8 hours, in addition to maintenance rates. Acutely, however, fluid resuscitation should be based on clinical assessment of volume status as described earlier.

Indications for admission include major burns as previously defined; uncertainty of follow-up; suspicion of abuse; presence of upper airway injury; explosion, inhalation, electrical, or chemical burns; burns associated with fractures; or the need for parenteral pain control. Children with chronic metabolic or connective tissue diseases and infants deserve hospitalization.

Sedation and Analgesia

What more important mission can providers have than relieving pain and anxiety in children in acute care set-

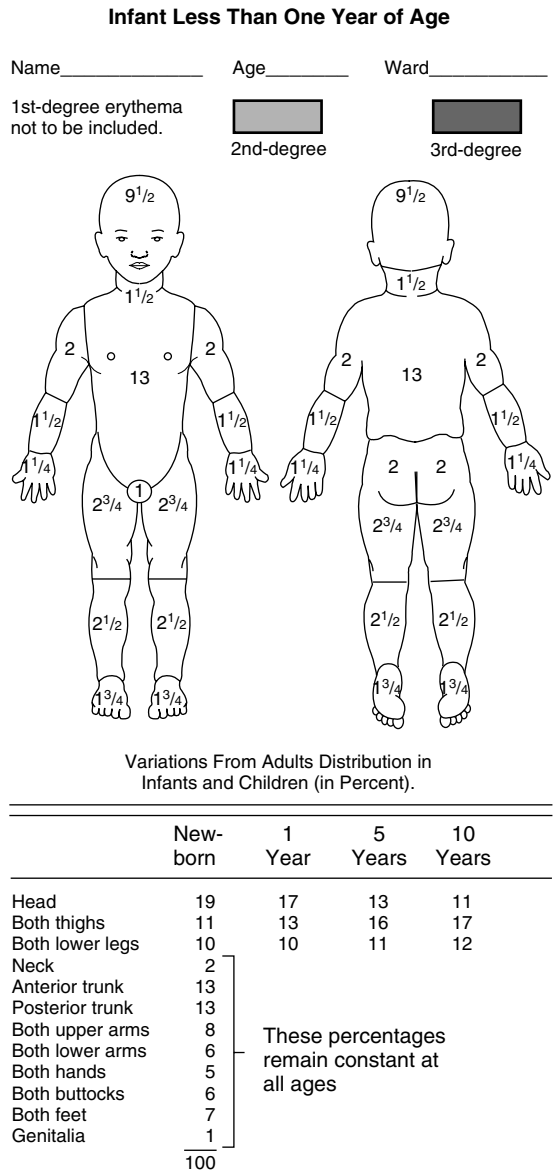

Figure 11–8. Lund and Browder modification of Borkow scale for estimating extent of burns. (The table under the illustration is after Berkow.)

tings? Consider whether the child needs relief from anxiety (sedation) or relief from pain (analgesia). Many agents also have amnestic properties. Parenteral agents can be effective and safe and produce few side effects if used judiciously.

Conditions such as fracture reduction, laceration repair, burn care, sexual assault examinations, lumbar

puncture, and diagnostic procedures such as CT and magnetic resonance imaging may all be performed more effectively and with less trauma to the child if effective sedation or analgesia is used. The clinician should decide whether procedures will require either sedation or analgesia alone, or both, and then choose agents accordingly.

Safe and effective sedation requires thorough knowledge of the selected agent and its side effects; suitable monitoring devices; resuscitative medications, equipment, and personnel; and appropriate informed consent from the parents. This process is now called procedural sedation and analgesia (PSA) and should proceed as follows:

1. Choose the right medication or combination of medications for the procedure.
2. Discuss risks and benefits of the proposed PSA and obtain verbal informed consent from the parents.
3. Ensure appropriate NPO (nothing-by-mouth) status for 4–6 hours. For certain emergency procedures, suboptimal NPO status may be allowed, with attendant risks identified.
4. Establish vascular access as required.
5. Ensure that resuscitative equipment and personnel are readily available.
6. Attach the cardiorespiratory monitor and pulse oximeter, as indicated.
7. Give the agent selected, with continuous monitoring for side effects. A dedicated observer, usually a nurse, should monitor the patient at all times. Respiratory effort, perfusion, and mental status should be assessed and documented serially.
8. Titrate the medication to achieve the desired sedation level. The ideal level is that of “conscious” or “light” sedation—that is, the patient’s sensorium is slightly dulled, but eyes are generally open and airway reflexes are preserved.
9. Continue monitoring the patient after finishing the procedure. If a painful stimulus has been eliminated (eg, fracture reduction) mental status can decrease.
10. Criteria for discharge include the child’s ability to sit unassisted, to take oral fluids, and to answer verbal commands. A PSA discharge handout should be given, with precautions for close observation and avoidance of potentially dangerous activities.

The following are some commonly used sedatives and analgesics:

1. Midazolam (Versed)—This agent has particular usefulness in pediatrics due to its safety, rapid onset,

and short half-life. Administration may be oral, rectal, intranasal, intramuscular, or IV. When given slowly intranasally, the drug’s kinetics are nearly the same as when given intravenously. Many children report a burning sensation with intranasal administration. Oral or rectal administration results in relatively delayed onset, and titration is difficult. Intramuscular injections can be combined with opioid analgesics if systemic analgesia is desired. IV administration allows optimal ability to titrate dosing to the desired sedation level. Complicated or prolonged procedures are best facilitated by IV placement to facilitate redosing, which also provides IV access if resuscitation becomes necessary. Potential side effects of midazolam include cardiorespiratory depression.

2. Barbiturates—This class of agents (eg, pentobarbital [Nembutal]) has the advantage of minimizing movement during procedures, which makes them advantageous for diagnostic studies such as CT or magnetic resonance imaging. Rectal administration of thiopental is safe and effective. Onset of action with IV administration is rapid. Potential side effects, although uncommon, include respiratory and cardiac depression and laryngospasm.

3. Narcotics—These agents (eg, morphine, meperidine, and fentanyl) have powerful analgesic and sedative effects. They can be combined with anxiolytics such as benzodiazepines. Desired and adverse effects, such as respiratory depression, are potentiated when benzodiazepines and narcotics or barbiturates are given together. Therefore, sedative doses should be reduced when sedatives and analgesics are given together.

4. Ketamine—Increasingly and now commonly used in emergency departments, this agent has the advantage of being a sympathomimetic, that is, increasing heart rate and blood pressure. It is a potent analgesic and anxiolytic and has amnesic properties. Side effects include salivation (therefore, it is usually given with glycopyrrolate as an antisalivation agent), laryngospasm (occasionally), nystagmus, emergence reactions, and vomiting. With comprehensive knowledge of this medication, its use can be a significant advantage to children.

DISORDERS DUE TO HIGH ENVIRONMENTAL TEMPERATURE

Disorders due to heat range from mild cramps to life-threatening heat stroke. Heat cramps are characterized by brief, severe cramping (not rigidity) of skeletal or abdominal muscles following exertion. Core body temperature is normal or only slightly elevated. Heat cramps may be associated with a relative sodium deficiency. Mild cases can be treated with oral salt-containing solutions; more severe cases require IV infusion of normal saline solution. Heat exhaustion is manifested by constitutional symptoms after exposure to heat and humidity. Patients continue to sweat, and core temperature is normal or only slightly increased. Patients with heat exhaustion have varying proportions of salt and water depletion. Presenting symptoms and signs include weakness, fatigue, headache, disorientation, pallor, thirst, nausea and vomiting, and occasionally muscle cramps. Shock may be present. No major CNS dysfunction should be present. Treat with IV fluids, modified by measured electrolyte levels. Both heat cramps and heat exhaustion can be avoided with acclimatization and liberal water and salt intake during exercise.

Heat stroke represents failure of thermoregulation and is life-threatening. The diagnosis is based on a rectal temperature of over 40°C with associated neurologic signs in a patient with an exposure history. Lack of sweating is not a necessary criterion. Symptoms are similar to those of heat exhaustion, but CNS dysfunction is more prominent. Patients with heat stroke are often incoherent and combative. In more severe cases, vomiting, shivering, coma, seizures, nuchal rigidity, and posturing may be present. Patients can have high, low, or normal cardiac output. Cellular hypoxia, enzyme dysfunction, and disrupted cell membranes lead to global end-organ derangements: rhabdomyolysis, myocardial necrosis, electrolyte abnormalities, acute tubular necrosis and renal failure, hepatic degeneration, adult respiratory distress syndrome, and disseminated intravascular coagulation. Consider sepsis, malignant hyperthermia, and neuroleptic malignant syndrome in the differential diagnosis.

Heat Stroke Management

1. Immediately cool the patient's body with cool water mist, ice, fans, or other cooling device.
2. If the patient is unresponsive, manage the airway, giving 100% oxygen.
3. Administer IV fluids: isotonic crystalloid for hypotension, 5% dextrose normal saline for maintenance. Consider central venous pressure determination.

4. Place monitors, check rectal temperatures continuously, and place a Foley catheter and nasogastric tube.
5. Obtain laboratory tests: complete blood count; electrolytes; glucose; creatinine; prothrombin time and partial thromboplastin time; creatine kinase; liver function tests; arterial blood gases; urinalysis; and serum calcium, magnesium, and phosphate.
6. Admit to pediatric intensive care unit.

Malignant Hyperthermia

Malignant hyperthermia is a rare but life-threatening syndrome characterized by a hypermetabolic state including high fever, diaphoresis, malaise, rhabdomyolysis, disseminated intravascular coagulation, hyperreflexia, and psychosis. It is most often associated with anesthetic agents, but can be seen in the outpatient setting in the neuroleptic-malignant syndrome. Drugs such as atropine, lidocaine, meperidine, nonsteroidal anti-inflammatory agents, tricyclic antidepressants, cocaine, and antipsychotics can induce a central hyperthermic syndrome. Treatment includes cooling, rectal acetaminophen, seizure treatment with a benzodiazepine, and, in the case of malignant hyperthermia caused by neuromuscular blockers, dantrolene sodium.

HYPOTHERMIA

Seriously ill children should have core temperature quickly determined. Hypothermia in children, defined as core body temperature less than 35°C, is frequently associated with cold water submersion accidents. Many other disorders cause incidental hypothermia, including sepsis, metabolic derangements, ingestions, CNS disorders, and endocrinopathies. Neonates, trauma victims, intoxicated patients, and the chronically disabled are particularly at risk. Mortality rates are high and are related to the underlying disorder. Conversely, mild therapeutic hypothermia following hypoxic-ischemic CNS insult and isolated traumatic brain injury may be a recommendation in the near future.

As core temperature falls, a variety of mechanisms begin to conserve and produce heat. Peripheral vasoconstriction allows optimal maintenance of core temperature. Heat production can be increased by a hypothalamic-mediated increase in muscle tone and metabolism. When shivering begins, heat production increases to two to four times basal levels.

Clinical Findings

Clinical manifestations of hypothermia depend on the severity of body temperature depression. Severe cases (\leq

28°C) mimic death: Patients are pale or cyanotic, pupils may be fixed and dilated, muscles are rigid, and there may be no palpable pulses. Heart rates as low as 4–6/min may provide adequate perfusion, because of the lowered metabolic needs in severe hypothermia. If these findings are a result of primary hypothermia and not postmortem changes, the fact of death cannot be ascertained until the patient has been rewarmed and remains unresponsive to resuscitative efforts. Children with a core temperature as low as 19°C have survived neurologically intact.

Treatment

A. GENERAL SUPPORTIVE MEASURES

Management of hypothermia is complex but largely supportive. Core body temperature must be documented by continuously monitoring with a low-reading indwelling rectal thermometer. Patients must be handled gently, because the hypothermic myocardium is exquisitely sensitive and prone to arrhythmias. Ventricular fibrillation may occur spontaneously or as a result of minor handling or invasive procedures. If asystole or ventricular fibrillation is present on the cardiac monitor, perform chest compressions and use standard pediatric advanced life support techniques and medications. Spontaneous reversion to sinus rhythm at 28–30°C may occur as rewarming proceeds.

B. REWARMING

1. Passive rewarming, such as covering with blankets, is appropriate only for mild cases (> 33°C).
2. Active rewarming is achieved by external or core rewarming techniques. External rewarming methods include warming lights, thermal mattresses or electric warming blankets, immersion in warm baths, and hot water bottles or warmed bags of IV solutions. One must be aware of the potential for core temperature depression after rewarming is begun, as warmed peripheral acidic blood is distributed to the core circulation. Core rewarming techniques are optimal and include the delivery of warmed, humidified oxygen and the use of warmed (to 40°C) fluids for IV replacement, peritoneal dialysis, bladder irrigation, and mediastinal lavage. Extracorporeal blood rewarming achieves controlled core rewarming, can stabilize volume and electrolyte disturbances, and is maximally effective (Table 11–6).

SUBMERSION INJURIES

Drowning is the second most common cause of death by unintentional injury among children. Water hazards

Table 11–6. Management of hypothermia.

General measures

- Administer warmed and humidified 100% oxygen.
- Monitor core temperature, heart and respiratory rates, and blood pressure continuously.
- Consider central venous pressure determination for severe hypothermia.

Laboratory studies

- Complete blood count and platelets
- Serum electrolytes, glucose, creatinine, amylase
- Prothrombin time, partial thromboplastin time
- Arterial blood gases
- Consider toxicology screen

Treatment

- Correct hypoxemia, hypercapnia, pH < 7.2, clotting abnormalities, and glucose and electrolyte disturbances.
- Start rewarming techniques: passive, active (core and external), depending on degree of hypothermia.
- Replace intravascular volume with warmed intravenous crystalloid infusion at 42°C.
- Treat asystole and ventricular fibrillation per PALS protocols. Cardiac massage should be continued at least until core temperature reaches 30°C, when defibrillation is more likely to be effective.

are ubiquitous and include lakes and streams; swimming pools; bathtubs; and even toilets, buckets, and washing machines. Risk factors include epilepsy, alcohol, intentional trauma, and lack of supervision. Males predominate in submersion deaths, as in most other nonintentional deaths. All pediatric care providers must make efforts to prevent these needless tragedies.

Major morbidity stems from CNS and pulmonary insult. Laryngospasm or breath-holding may lead to loss of consciousness and cardiovascular collapse before aspiration can occur (so-called dry drowning).

Anoxia from laryngospasm or aspiration leads to irreversible CNS damage after only 4–6 minutes. A child must fall through ice or directly into icy water for cerebral metabolism to be slowed sufficiently by hypothermia to provide some protection from anoxic damage.

Cardiovascular changes include myocardial depression and arrhythmias. Electrolyte alterations are generally slight. Unless hemolysis occurs, hemoglobin concentrations also change only slightly.

Assessment & Management

Depending on the duration of submersion and any protective hypothermia effects, children may appear clinically dead or completely normal. Observation over time assists with prognosis. The child who has been re-

warmed to at least 33°C and is still apneic and pulseless in the emergency department will probably not survive to discharge or will be left with severe neurologic deficits. Until a determination of brain death can be made, however, aggressive resuscitation should be continued.

One should keep in mind possible associated injuries, such as neck injury from diving into shallow water. For children who appear well initially, observation for 8–12 hours will detect late pulmonary compromise or changes in neurologic status. Respiratory distress, an abnormal chest radiograph, abnormal arterial blood gases, or hypoxemia by pulse oximetry indicates the need for treatment with supplemental oxygen, cardiopulmonary monitoring, and frequent reassessment. Serially assess the degree of respiratory distress and mental status. Signs of pulmonary infection may appear many hours after the submersion event.

Patients who are in coma and who require mechanical ventilation have a high risk of anoxic encephalopathy. The value of therapy with hyperventilation, corticosteroids, intentional hypothermia, and barbiturates remains unproved.

BITES: ANIMAL & HUMAN

Bites account for a large number of visits to the emergency department. Most fatalities are due to dog bites. However, the majority of infected bite wounds are from human and cat bites.

DOG BITES

Boys are bitten more frequently than girls, and the dog is known by the victim in most cases. Younger children have a higher incidence of head and neck wounds, whereas school-age children are bitten most often on the upper extremities.

Dog bites are treated largely the same way as other wounds: high-pressure, high-volume irrigation with normal saline, scrubbing, debridement of any devitalized tissue and removal of foreign matter, and tetanus prophylaxis. The risk of rabies from dogs is low in developed countries, but rabies prophylaxis should be considered when appropriate. Wounds should be sutured only if necessary for cosmetic reasons because closure of the wound increases the risk of infection. Prophylactic antibiotics have not been shown to decrease rates of infection in low-risk dog bite wounds not involving the hands or feet. If a bite involves a joint, periosteum, or neurovascular bundle, prompt orthopedic surgery consultation should be obtained.

Pathogens that infect dog bites include *Pasteurella multocida*, streptococci, staphylococci, and anaerobes.

Infected dog bites can be treated with penicillin for *P. multocida*, and broad-spectrum coverage can be provided by amoxicillin and clavulanic acid or cephalexin (see dose for cat bites in next section). Complications of dog bites include scarring, CNS infections, septic arthritis, osteomyelitis, endocarditis, and sepsis.

CAT BITES

Cat-inflicted wounds occur more frequently in girls, and their principal complication is infection. The infection risk is higher in cat bites than dog bites because of the puncture character of the wound produced by cat teeth. Wound management is similar to that for dog bites. Cat wounds should not be sutured except when absolutely necessary for cosmetic reasons. *P. multocida* is the most common pathogen. Cat bites create a puncture-wound inoculum, and prophylactic antibiotics (penicillin plus cephalexin, or amoxicillin and clavulanic acid) are recommended. The dose of amoxicillin trihydrate and clavulanic acid should be on the high side of recommended dosage in order to ensure adequate tissue penetration both in dog and cat bites. The dosage of the amoxicillin component should be 80 mg/kg/24 h in three divided doses. The maximum dosage is 2 g/24 h. Scratches or bites from young cats may result in cat scratch fever.

HUMAN BITES

Most human bites occur during fights. *P. multocida* is not a known pathogen in human bites—cultures most commonly grow streptococci, anaerobes, staphylococci,

PEDIATRIC EMERGENCY MEDICINE

Pediatric emergency medicine is a subspecialty with fellowship training and subboard certification that provides resuscitation and urgent care of ill or injured infants, children, and adolescents. The body of emergency research literature is substantial and growing rapidly. EMS-C (Emergency Medical Services for Children) programs exist to enhance the spectrum of care of the severely ill or injured child through, for example, community injury prevention, prehospital care by emergency medical technicians and paramedics, emergency department-based stabilization and critical care, and rehabilitation. Pediatric emergency medicine physicians are intimately involved in the care of injured patients, because trauma is the leading cause of death among children over age 1 year.

and *Eikenella corrodens*. Hand wounds and deep wounds should be treated with antibiotic coverage against *E corrodens* and gram-positive pathogens by a penicillinase-resistant penicillin. Wound management is the same as for dog bites. Only severe lacerations involving the face should be sutured. Other wounds can be managed by delayed primary closure or healing by second intention.

A major complication of human bite wounds is infection of the metacarpophalangeal joints. A hand surgeon should evaluate clenched-fist injuries from human bites. Operative debridement is followed in many cases by IV antibiotics.

Knapp JF: Updates in wound management for the pediatrician. *Pediatr Clin North Am* 1999 46(6):1201 [PMID: 10629682].

II. BIOTERRORISM

Marsha S. Anderson, MD

Bioterrorism is the intentional use of biological agents to produce disease or intoxication in a susceptible population. Biologic agents have been used frequently throughout history, the most recent instances being the United States anthrax outbreak in 2001 and the ricin contamination of the Dierksen Senate Office Building in 2004. In the anthrax outbreak inhalational and cutaneous anthrax disease resulted from exposures to anthrax spores in envelopes that traveled through the US Postal system. Over 32,000 people were treated or received antibiotic prophylaxis, 22 people contracted anthrax, and 5 died. Several cases involved postal workers, and were believed to be related to high-speed mail sorting and stamping equipment and the compressed air used to clean these machines—all of which were thought to increase aerosolization of spores in the postal facilities.

General Considerations

Bioterrorism is a concern because at least 17 nations are thought capable of producing biologic weapons. In addition, some cult groups are interested in obtaining these agents. Biologic weapons are attractive to terrorists and rogue states because they are relatively simple and cheap to manufacture, difficult to detect, and capable of inflicting mass casualties over a wide area. Moreover, most target populations are susceptible to candidate disease agents, and mass casualty and medical response systems are unprepared to deal with the effects of these agents.

Table 11–7. Potential bioterrorism agents and the diseases produced.

Agent	Disease Produced
<i>Bacillus anthracis</i>	Anthrax
Variola virus	Smallpox
<i>Yersinia pestis</i>	Plague
Botulinum toxin	Botulism
<i>Francisella tularensis</i>	Tularemia
<i>Brucella</i> species	Brucellosis
<i>Coxiella burnetti</i>	Q-fever
Filoviridae	Ebola, Marburg
Bunyaviridae	Rift Valley fever
<i>Salmonella typhi</i>	Typhoid fever

There are many potential biologic agents (Table 11–7). *Bacillus anthracis* (anthrax), variola virus (smallpox), *Yersinia pestis* (plague), and botulinum toxin (botulism) are the most likely attack agents.

Biologic agents can be delivered via aerosolization, food or water contamination, parenteral injection, or direct contact with skin. Aerosolization is thought to be the most efficient exposure method for many agents. The aim is to create an invisible cloud of infectious particles with diameters of 0.5–10 μg . At this particle size, the aerosolized infectious agents reach the alveolar spaces.

Unlike a bomb explosion or a chemical spill, a bioterrorism event is likely to be covert. A covert attack may not have an immediate effect because of the time between exposure and development of disease. Days to weeks later (depending on the agent and incubation period), patients will present to their primary care physicians or local emergency departments. Consequently, first responders to a covert biologic incident will *not* be the military or law enforcement officials. Rather, physicians, nurses, or emergency medical technicians will identify the initial cases. Only after an outbreak has been recognized will the possibility of a biologic attack be considered. For this reason, it is imperative that medical first-responders remain vigilant and report any unusual clustering of disease to their state health departments.

ANTHRAX

Anthrax is caused by the bacterium *Bacillus anthracis*, a spore-forming gram-positive rod. Anthrax occurs naturally in domesticated and wild herbivores. *B anthracis* spores, common in the soil, are ingested by grazing animals. Three proteins—protective antigen, lethal factor, and edema factor—combine to form two toxins re-

sponsible for the morbidity and mortality associated with the disease. Edema toxin (made by the linkage of protective antigen and edema factor) is an adenylate cyclase analogue that promotes generation of cyclic adenosine monophosphate and alters intercellular flux of water and ions. This is responsible for the edema characteristically seen around cutaneous lesions. Lethal toxin, produced by the interaction of protective antigen and lethal factor, is a mitogen-activated protein kinase inhibitor that influences cell signaling.

A. CUTANEOUS ANTHRAX

Ninety-five percent of naturally acquired anthrax cases are acquired by direct skin contact with infected animals, animal parts, or spores. Presumably the bacteria or spores are inoculated through wounds or small breaks in the skin. After an incubation period of 1–12 days, a small macular or papular and sometimes pruritic lesion appears at the site of inoculation. This develops into a vesicle or group of vesicles that ultimately ulcerates, enlarges, and develops a characteristic black center, or eschar. Marked edema surrounding the lesion is typical. The ulcer is depressed, painless, and may have a heaped border. Systemic symptoms such as fever, headache, and myalgias may be present. The differential diagnosis includes brown recluse spider (*Loxosceles reclusa*) bite (where these are endemic), ecthyma gangrenosum (common in neutropenic hosts), ulceroglandular tularemia, and routine wound infection (*Staphylococcus aureus*, group A *Streptococcus*). Diagnosis is made by culture and Gram stain of the vesicular fluid or a biopsy specimen. Cultures obtained prior to antibiotic treatment usually yield the diagnosis. Polymerase chain reaction (PCR) and immunohistochemical tests are available at most state health departments or through the Centers for Disease Control and Prevention (CDC). PCR can be done on formalin-fixed tissue from a biopsy specimen. All suspected anthrax cases should be immediately reported to the state health department. Although person-to-person transmission of any form of anthrax has not been reported, patients are generally placed in contact isolation because they have a draining wound.

Mortality is 10–20% without treatment. Doxycycline and ciprofloxacin are effective first-line therapy (Table 11–8). Ciprofloxacin might be preferred initially, because some investigators have reported genetically engineered *B anthracis* strains resistant to penicillin and tetracycline. Once the susceptibilities are known, therapy can be tailored (usually penicillin, ciprofloxacin, or doxycycline). Patients who are not systemically ill can be treated orally. If intravenous (IV) therapy is initiated, oral therapy can be used once the patient improves. Patients who develop cutaneous anthrax as a consequence of a bioterrorist attack may also

Table 11–8. Empiric treatment of cutaneous anthrax (without systemic involvement^a) associated with a bioterrorist attack.^b

	Initial therapy	Course
Children	Ciprofloxacin 10–15 mg/kg orally (maximum 500 mg/dose) or	60 d ^d
	Doxycycline	60 d ^d
	≤ 45 kg: 2.2 mg/kg/dose orally > 45 kg: 100 mg orally	60 d ^d
Adults ^c	Ciprofloxacin 500 mg orally or	60 d ^d
	Doxycycline 100 mg orally q12h	60 d ^d

^aCutaneous anthrax with systemic involvement, extensive edema, or lesions on the head or neck requires a multidrug regimen as in inhalational anthrax (see Table 11–9).

^bThis table is for initial therapy. Each bioterrorist episode is potentially unique, and the organisms may have unique susceptibilities. Regimens may need to be revised once the susceptibility pattern of the organism is known.

^cRecommendations for pregnant women are the same as for adults, since this is a serious and sometimes life-threatening illness. Doxycycline's adverse effects on bones and teeth is dose related.

^dAt least 60 days is recommended to treat the infection and for prophylaxis for inhalational exposures. Longer prophylaxis (up to 100 days) might be recommended if the patient is judged to be at high risk for exposure to a large number of spores. Anthrax vaccine might also be considered as part of postexposure prophylaxis (currently available under research protocol, discussion with the state health department is recommended).

be at risk for inhalational disease. For this reason, during the 2001 outbreak, the CDC recommended continuation of antibiotics for 60 days (this was later extended to a total of 100 days).

B. GASTROINTESTINAL

Gastrointestinal anthrax, which is typically acquired by the ingestion of poorly cooked contaminated meat, has an incubation period of 1–7 days. It might be acquired by swallowing aerosolized spores. The oropharyngeal form consists of fever, marked cervical adenopathy, ulcerations at the base of the tongue, dysphagia, and submental swelling. Fever, vomiting, abdominal pain, and bloody diarrhea are characteristics of the abdominal form. Massive ascites may occur. Blood culture results are often positive. Mortality is high, despite antibiotic therapy. Thus antibiotics should be instituted as soon as the diagnosis is considered. Patients should be treated with the same regimen as for inhalational anthrax (Table 11–9).

Table 11–9. Initial therapy of invasive or inhalational anthrax secondary to a bioterrorist attack.^a

Empiric therapy	
Children	Ciprofloxacin ^{b,c} 20–30 mg/kg/day, intravenously, divided in two daily doses (maximum 1 gram/day) Plus one or two additional antibiotics from this list: ^d Vancomycin Rifampin Doxycycline Penicillin ^e Imipenem Clindamycin
Adults	Ciprofloxacin ^b 400 mg intravenously every 12 hours Plus one or two additional antibiotics from this list: ^d Vancomycin Rifampin Doxycycline Penicillin ^e Imipenem Clindamycin
Pregnant Women	Same as for adults above (high mortality outweighs the risks of the antibiotics to the developing fetus).
Immunocompromised Persons	Same as for children and adults (above)

^aConsult a specialist in infectious disease as well as the state health department. Therapy may need to be modified once susceptibility results are known or in specific outbreak situations. These recommendations also apply to patient with cutaneous anthrax with signs of systemic disease or head/neck lesions, and to patients with gastrointestinal anthrax.

^bCiprofloxacin is preferred in a patient with inhalational anthrax secondary to a bioterrorist attack.

^cIf unable to give ciprofloxacin due to patient allergy or unavailability, doxycycline would be the next preferred agent. Doxycycline dose for adults and children > 45 kg is 100 mg, given intravenously every 12 hours. Doxycycline dose for children ≤ 45 kg is 2.2 mg/kg/dose, given intravenously every 12 hours.

^dDoxycycline and penicillin have in vivo activity with susceptible organisms. The rest of the list has demonstrated activity in vitro. Consider CNS penetration of antibiotics in patients with possible meningitis. Consult with an infectious disease specialist.

^e*Bacillus anthracis* may have inducible or constitutive beta lactamase production. Penicillin should not be used alone. Consult an infectious disease specialist.

C. INHALATIONAL

Inhalational anthrax, the most lethal form, occurs after the inhalation of anthrax spores. It is estimated that 8000–40,000 spores can produce lethal disease in 50% of those exposed. Onset of symptoms is typically 1–7 days after exposure, but may be as long as 60 days, depending on inoculum size, host factors, and concurrent antibiotic use (for prophylaxis or other illnesses). Patients initially develop flu-like symptoms of fever, headache, malaise, and myalgias. Vomiting and abdominal pain were observed in the 2001 inhalational anthrax outbreak. Precordial discomfort or chest pain is also common, sometimes first occurring several days after the onset of symptoms. After 2–3 days transient improvement sometimes occurs, followed by abrupt onset of respiratory deterioration, which often leads to respiratory failure, shock, and death. Aggressive antibiotic therapy as well as modern intensive care management reduced mortality from 80% to 45% in the 2001 outbreak. Inhalational anthrax is not transmitted from one person to another.

Diagnosis

The diagnosis may be difficult early in the illness (outside of a known outbreak) because the symptoms (except rhinorrhea, which is usually absent) are similar to influenza and other acute viral diseases. Almost all patients have abnormalities on either chest radiograph or CT scans. The most common abnormality is a widened mediastinum caused by mediastinitis (Figure 11–9). Pulmonary effusions are present in many patients, probably due to mechanical obstruction of lymphatic vessels (from enlarged nodes) as well as from the effects of edema toxin. Pulmonary infiltrates are seen in some patients, contradicting the classical teaching that infiltrates are not seen in inhalational anthrax.

Blood cultures obtained prior to antibiotics generally will grow *B anthracis* within 24–36 hours. Coagulation studies, blood urea nitrogen, creatinine, and liver function tests should be obtained for severely ill patients. A chest CT scan could be considered if the chest radiograph is normal. Rapid influenza tests can be performed on nasal wash specimens when influenza is in the differential diagnosis. Patients with signs or symptoms suggestive of meningitis should have a lumbar puncture. Pleural fluid may contain the organism. The state health department can arrange specific tests for anthrax, such as PCR or immunohistochemistry tests.

Treatment

Patients with possible inhalational anthrax should be started on IV antibiotics when the diagnosis is suspected. Most patients will require intensive care moni-

Figure 11–9. Chest radiograph of a patient with inhalational anthrax demonstrates the characteristic widened mediastinum and the presence of pleural effusions. (CDC, Dr PS Brachman, 1961.)

toring. The optimal antibiotic regimen for patients with inhalational anthrax is unknown. There is even less experience with pediatric patients. Table 11–9 lists recommendations for empiric therapy for invasive or inhalational anthrax prior to susceptibility results. These recommendations are for guidance until consultations with an infectious disease specialist and the state health department or CDC are available. Once the susceptibility results are known, therapy may be altered. The specific circumstances of a given bioterrorist event may prompt the CDC to issue alternative recommendations.

Combination therapy was employed during the 2001 outbreak and reduced mortality (compared with historical cases). If susceptibilities are unknown, ciprofloxacin should be used as a first-line agent with one or two other recommended drugs (see Table 11–9). Clindamycin inhibits bacterial protein synthesis and would theoretically inhibit toxin production. Strains of *B anthracis* may produce β -lactamases, so penicillin should not be used alone. If meningitis is suspected, one or two of the drugs used should be able to cross the blood–brain barrier. (If penicillin is used, be sure to use another drug that crosses the blood–brain barrier.) Once susceptibilities of the strain of *B anthracis* are known, the antibiotic regimen may be altered. Antibiotics can be changed from the IV to the oral route once

the patient is improved enough to be discharged from the hospital. Antibiotics should be continued for at least 60 days.

Steroids might be considered for meningitis, based on experience with steroids in other forms of bacterial meningitis. Steroids have been used for severe edema, particularly of the head and neck.

Postexposure Prophylaxis

A. ANTIBIOTIC PROPHYLAXIS

Once a bioterrorist attack with anthrax has been identified, the state health department and CDC will identify individuals at high risk for exposure. Possible prophylaxis regimens include oral ciprofloxacin or doxycycline. Once susceptibilities of the offending strain are known, other antibiotics might be recommended. *B anthracis* spores are hardy, and rhesus monkey studies have shown some exposed animals died even after 30 days of antibiotics. For this reason, long prophylaxis regimens are recommended. In the 2001 anthrax outbreak, high-risk individuals were asked to complete 60 days initially and then given the option to extend the prophylaxis regimen by an additional 40 days (100 days total) with or without receiving three doses of the anthrax vaccine.

B. ANTHRAX VACCINE

Currently, anthrax vaccine is not licensed for postexposure prophylaxis. Protective antigen is the immunogenic agent in a cell-free filtrate of an attenuated strain. This vaccine has been routinely given to active US military personnel and reservists to induce protective immunity *prior* to exposures. It is given subcutaneously at 0, 2 weeks, 4 weeks, 6 months, 12 months, and 18 months. After this series, annual boosters are required. Animal studies have suggested some protective efficacy of the vaccine in postexposure prophylaxis, but there are no data for humans. However, based on animal studies and human immunogenicity studies, it has been suggested that three doses of anthrax vaccine (at 0, 2, and 4 weeks postexposure) might protect against residual anthrax spores in patients receiving postexposure antibiotics. Antibiotics would be continued until about 6 weeks after the first vaccine. Use of vaccine with this approach is available under an investigational new drug protocol (contact Centers for Disease Control and Prevention, Atlanta, GA).

SMALLPOX

Smallpox is caused by the variola virus. The disease has two forms: variola major, the more severe form, with mortality rates sometimes exceeding 30% in unvaccinated persons (1% if vaccinated); and variola minor, a milder form with a mortality rate of less than 1%.

Smallpox is spread person to person by aerosol or droplet routes. There are no animal reservoirs or human “carrier states.” To eliminate smallpox as a human disease, it was essential to disrupt the human-to-human chain of transmission. The World Health Organization (WHO) began a global vaccination campaign in 1967 that eradicated smallpox by 1980. Routine vaccination in the civilian US population stopped in 1972, and the US military ceased vaccination in the late 1980s. In 1999, WHO recommended that all smallpox virus stocks be destroyed or sent for storage to two reference laboratories: CDC in Atlanta and the Institute of Virus Preparations in Moscow. The destruction of these remaining smallpox stores has been postponed, citing the need to maintain the strains for vaccine research.

There is concern that smallpox virus may exist outside the two reference laboratories. The world’s population is relatively unprotected from this virus, since no smallpox vaccine has been given worldwide for almost 20 years. Following a single vaccination, neutralizing antibody declines over a 5- to 10-year period. Few people have received more than one vaccine, except as part of travel or military requirements.

In 2002–2003 the United States began a voluntary smallpox vaccination program. The goal of the initiative was to increase the nation’s smallpox preparedness capacity by offering vaccination to public health teams and health care workers, who would be the individuals most likely to come in contact with smallpox patients in the event of an outbreak of disease. The plan called for immunization of 450,000 health care and public health workers in the first phase. By August 2003, 38,000 health care and public health workers had received the vaccine. In large part, the effort was stalled by concerns about side effects of vaccination, as well as reports of 22 cases of myocarditis and pericarditis that occurred in vaccine recipients.

Clinical Signs and Symptoms

The incubation period is 7–17 days (usually 12–14 days). Initial symptoms are similar to those of influenza: fever, headache, and myalgias. By day 4–5, a maculopapular rash develops on the face, then spreads to the extremities, and finally to the trunk. By day 6–7, the characteristic pustules form, which are quite painful and deeply embedded in the skin (Figure 11–10). The rash is most concentrated on the extremities and face, in contrast to varicella (Table 11–10). The lesions develop “in phase” (all at the same time) on a given area of the body. This also contrasts with chickenpox, in which lesions are seen in multiple phases of evolution. At the height of the illness, the patient is toxic. Death occurs from overwhelming viremia or from secondary

Figure 11–10. Typical smallpox lesions. (CDC, James Hicks, 1973.)

infections at the end of the first week or during the second week of the illness. By day 8 or 9, crusts form, and by day 12, scabs are seen. Mortality rates vary with the virulence of the strain and may approach or exceed 30%. As opposed to varicella, smallpox is a disease that affects the deep epithelial structures, including the sebaceous glands. Therefore, scarring is extensive. Smallpox lesions of the cornea can cause scarring and blindness.

Two forms of smallpox are difficult to recognize clinically: hemorrhagic smallpox and malignant smallpox. **Hemorrhagic smallpox** can occur in persons of all ages, but pregnant women are particularly vulnerable. The initial symptoms are typical of smallpox, although more severe, and are followed by a dusky erythema of the skin and the appearance of petechiae and hemorrhages of the mucosal surfaces and gastrointestinal tract. In addition hemorrhage into the skin lesions occurs. Mortality is very high, and death usually occurs within several days of the rash developing. **Malignant smallpox** also begins with the typical constitutional symptoms. Lesions develop and become confluent, but

Table 11–10. Clinical differences between chickenpox and smallpox.

	Chickenpox	Smallpox
Rash progression	Occurs in crops	Does not occur in crops
Rash distribution	Concentrated on trunk	Concentrated on face and extremities
Rash evolution	Lesions are present in multiple forms at the same time: vesicles, pustules, crusts	Lesions all look the same on a given body part—they evolve in phase.
Rash presence on palms and soles	Uncommon	Common. Extensive lesions on the palms and soles frequently seen.

never progress to the vesicular or pustular stage. Instead, they are flat and soft to the touch. The skin develops a crepe paper-like appearance, and petechiae or purpura are sometimes seen. This form of smallpox is difficult to diagnose primarily because the typical “pox” lesions are not seen. Death is common, and the few survivors often have large epidermal losses.

Smallpox is highly contagious. All patients requiring hospitalization need to be isolated in negative-pressure rooms with airborne precautions. In large outbreaks, when the number of patients exceeds isolation capacity, patients can be grouped into cohorts. In addition, a regional “smallpox” hospital or facility might need to be established.

Differential Diagnosis

The initial differential diagnosis includes influenza and other viral diseases and early anthrax (also presenting with influenza-like symptoms). Later, when the skin lesions are apparent, smallpox must be distinguished from varicella (see Table 11–10).

Diagnosis

The state health department and the CDC must be notified immediately for any case of suspected smallpox. Because smallpox is an eradicated disease, a single case constitutes a probable bioterrorist event. The reemergence of smallpox would be an international medical emergency because of its potential for spread and the vulnerability of the world’s population.

If possible, specimens from the patient should be collected by a person who has been vaccinated within the prior 3 years. In an initial case, however, this may not be possible. Personal protective equipment should be worn (gown, gloves, eye protection, and mask). To obtain vesicle or pustule fluid for viral culture, examination by electron microscopy, or PCR, the lesion will likely need to be opened with a scalpel. The material obtained should be placed in a dry vacutainer tube, the

rubber stopper replaced, and the junction of the tube and stopper sealed with adhesive tape. The whole vacutainer should then be placed in an additional waterproof, sealed container. Smallpox virus isolation and examination require BL-4 level containment facilities, to which these specimens must often be transported. Contact your state health department for specific recommendations on packaging specimens for transport. In a bioterrorist event, this specimen might be considered evidence, and chain of custody must be observed. For all these reasons, it is imperative to notify the state health department immediately if a case is suspected.

Treatment

No known therapy is effective against human smallpox. The antiviral agent cidofovir appears to prevent disease in mice and monkeys when given in the first 2 days of exposure. However, no studies have been done of its efficacy in humans with smallpox. The drug must be given intravenously and is potentially myelosuppressive and nephrotoxic.

Infection Control and Postexposure Prophylaxis

Patients who do not need hospitalization should be isolated and cared for at home to minimize spread. Those who require hospitalization should be isolated in negative-pressure rooms with aerosol precautions. Anyone entering the room should wear a gown, mask, gloves, and eye protection. All bed linens, laundry, and wastes should be bagged and autoclaved prior to being laundered or incinerated.

Smallpox vaccination administered within 2–3 days after exposure will prevent the disease in most individuals. Vaccination as late as 4–5 days after exposure may attenuate the disease and prevent death. Therefore, all close contacts of the patient must be identified, vaccinated (if within 4–5 days of exposure), and monitored for development of symptoms. If the contacts become

febrile or experience other symptoms, they should be isolated until a diagnosis is made. The Working Group for Civilian Biodefense (Johns Hopkins University) recommends vaccination of all hospital employees (unless contraindicated) at a hospital where a smallpox case is admitted. Currently, the CDC has stockpiled smallpox vaccine that could be released in the event of a smallpox outbreak. In addition to stocks of smallpox vaccine, the CDC maintains control of supplies of vaccinia immune globulin (VIG) to be used in the setting where immunocompromised persons are judged to need immunization. The following groups of patients should be given VIG if smallpox vaccination is required secondary to an exposure: (1) patients who are receiving immunosuppressive agents or radiation, (2) persons with an immunodeficiency syndrome (acquired or congenital, HIV), (3) persons with eczema or other significant exfoliative skin diseases, and (4) pregnant women. VIG should be given intramuscularly at a dose of 0.3 mL/kg in an extremity other than the one used for the smallpox vaccine at the same visit. This will not significantly affect vaccine efficacy. VIG intended for intramuscular administration *cannot* be given intravenously. In addition, VIG is indicated for some types of vaccine complications such as severe generalized vaccinia, progressive vaccinia, and eczema vaccinatum.

Potential Vaccine Complications

The strain of vaccinia used in the currently stockpiled vaccine has been associated with the lowest complication rate, but complications may still be significant. The number and severity of potential complications of smallpox vaccine are reasons (among others) why routine smallpox vaccination is not currently recommended.

- 1. Encephalopathy**—Encephalopathy is most common among children younger than 2 years of age, and 10–25 cases occur per million vaccinees.
- 2. Encephalitis**—This occurs in 2–9 vaccinees per million first-time recipients.
- 3. Autoinoculation**—Self-inoculation of the vaccinia virus from the vaccine site lesion to other sites of the body is fairly common.
- 4. Eczema vaccinatum**—Persons with active or inactive eczema or other exfoliative skin diseases may develop vaccinia lesions (sometimes extensive) at sites of current or previous eczema. This complication can be serious and even fatal.
- 5. Generalized vaccinia**—Generalized vaccinia occurs when lesions develop outside the vaccination site in otherwise healthy persons. It is seen only in first-time vaccine recipients. These lesions develop at the same

time as the primary vaccine lesion, thus distinguishing them from autoinoculation variety. They evolve in the same manner as the primary lesion.

6. Progressive vaccinia—This occurs in immunocompromised persons who receive smallpox vaccine. It has been seen in patients with humoral (agammaglobulinemia) defects, cell-mediated immunity problems, and patients receiving immunosuppressive agents. The vaccinia lesion does not heal, and the virus spreads to contiguous tissue and systemically to bones and organs. Local tissue destruction is seen. Death occurs in over one third of patients.

Patients with progressive vaccinia, eczema vaccinatum, severe generalized vaccinia, or corneal autoinoculation of vaccinia may benefit from administration of VIG. The recommended dose is 0.6 mL/kg, administered intramuscularly. Due to the large volume of this dose, it can be divided and administered over 24–36 hours. In addition, a second dose (also divided) can be administered if no improvement is noted within 48–72 hours.

A new intravenous vaccinia immune globulin (IV-VIG) is currently available from the CDC under an investigational new drug protocol for treatment of adverse events related to smallpox vaccination (CDC, 1-877-554-4652).

7. Myocarditis/pericarditis—Myocarditis or pericarditis (or both) was reported in 22 primary vaccine recipients under the pre-event voluntary health care and public health worker vaccine program. Five civilian patients had cardiac ischemic events after receiving the smallpox vaccine. Review of the data suggested a causal relationship between myocarditis/pericarditis and the vaccine. However, the rate of cardiac ischemic events in vaccine recipients was not above the expected background rate. As a precaution, the Advisory Committee on Immunization Practices (ACIP) and the CDC recommend screening and excluding persons from pre-event vaccination if there is a history of cardiac disease or any of the following risk factors: previous myocardial infarction, angina, congestive heart failure, cardiomyopathy, stroke, or transient ischemic attack. In addition, persons with three or more of the following risk factors should not receive vaccine under this program: hypertension, diabetes, hypercholesterolemia, smoking, or an immediate family member who had onset of a heart condition before age 50.

PLAGUE

Plague is caused by *Yersinia pestis*, a gram-negative bacterium. The clinical manifestations of plague caused by a bioterrorist attack would differ from bubonic plague, the type clinicians are most familiar with. A bioterrorist

attack would likely use aerosolized *Y pestis*. Inhalation of 100–500 bacilli could result in primary pneumonic plague (as opposed to “bubonic plague”). Primary pneumonic plague is rare in the United States and has been associated with cats that have acquired pneumonic plague and passed it to their owners. The incubation period for primary pneumonic plague is short: 1–6 days (usually 2–4). Symptoms include fever, malaise, shortness of breath, cough, and sometimes hemoptysis or bloody sputum. Nausea, vomiting, diarrhea, and abdominal pain are common. No buboes usually appear (as seen in bubonic plague), although occasionally cervical buboes may be seen. Chest radiograph typically shows a bilateral, lobar pneumonia. The white blood count is typically elevated with leukocytosis.

Diagnosis

No widely accessible, rapid diagnostic tests are available for plague. A presumptive diagnosis may be made from the Gram stain of sputum, lymph node aspirate (if bubo present), CSF, or stained blood smear. Gram-negative bacilli or coccobacilli, sometimes with “safety pin” bipolar staining, are characteristic. Blood culture results are usually positive. CSF and lymph node aspirate specimens, if obtained, should be cultured. The laboratory should be alerted to take appropriate precautions with the samples, and they should be informed if plague is suspected. The health department should be notified immediately for suspected plague, as pneumonic plague has the potential for rapid spread. The state health department can also facilitate further testing for plague. A direct fluorescent antibody test, as well as PCR, is available through some state health departments and the CDC.

Treatment

Primary pneumonic plague progresses rapidly. Therefore, antibiotics need to be administered immediately if the diagnosis is suspected. Mortality is quite high if antibiotic therapy is initiated later than 24 hours after symptoms start. Streptomycin has been used historically for plague and is FDA-approved for this use. However, lack of availability of this medicine, coupled with lack of familiarity with its use, has led many experts to recommend gentamicin. In addition, streptomycin must be administered intramuscularly. For patients with sepsis or shock, the intramuscular route may lead to erratic absorption. All these factors make gentamicin a reasonable choice. Doxycycline has been used in some cases with successful results. In the event that streptomycin or gentamicin cannot be given, doxycycline could be used. Ciprofloxacin has shown efficacy in animal studies, but there are no human studies of its

use in plague. Antibiotics are usually continued for 10 days or, in late responders, for several days beyond lysis of fever.

All of the medications useful for plague are potentially problematic for pregnant women. Pregnant women should not be treated with streptomycin, if avoidable, as it is associated with fetal deafness. Gentamicin is also not generally recommended in pregnancy, except for serious illness. Doxycycline has been associated with fetal bone developmental problems and maternal liver toxicity. Gentamicin is recommended as the preferred agent in pregnancy, followed by doxycycline as an alternative.

Infection Control

Primary pneumonic plague is transmitted by respiratory droplets or aerosols. A 7-day course of doxycycline is recommended for plague prophylaxis for individuals who are asymptomatic household (or close) contacts or hospital contacts. Close contacts are those who were within 6 feet of an infected person. Contacts who begin prophylaxis should also wear a surgical mask and limit unnecessary contact with others for the first 48 hours of therapy. Masks can be discontinued for asymptomatic contacts that have been on prophylaxis for more than 48 hours. Contacts who develop fever or other symptoms should be promptly evaluated, isolated, and given IV antibiotics while awaiting diagnostic evaluation. Hospital personnel attending to patients with pneumonic plague should wear gowns, gloves, masks, and eye protection.

In the event of a bioterrorist incident, postexposure prophylaxis might be recommended by the CDC or state health department to individuals known to be at high risk for an exposure. Doxycycline and ciprofloxacin would be the agents most likely recommended, because they are oral drugs and readily obtainable.

BOTULINUM TOXIN

Clostridium botulinum is a spore-forming, anaerobic bacterium that makes botulinum toxin. This is the most potent neurotoxin known. There are actually seven different botulinum toxins made by *C botulinum*, designated by the letters A through G. These act by irreversibly binding to the presynaptic cholinergic membrane and inhibiting release of acetylcholine. Botulism is classically a food-borne disease seen when humans ingest preformed toxin present in improperly canned foods. A bioterrorist release of botulinum toxin would likely be aerosolized. Inhalation of the toxin and absorption into the bloodstream carry the toxin throughout the body. The clinical syndrome seen in

these patients is very similar to food-borne botulism. The incubation period for an inhalational exposure is unknown, but is probably 12–96 hours.

Signs and Symptoms

Patients typically present with diplopia, ptosis, difficulty swallowing, and speech abnormalities (see Chapter 38). Loss of head control, symmetrical weakness, and respiratory difficulties may occur as the descending paralysis progresses. Patients may need mechanical ventilation due to loss of gag reflexes and paralysis of respiratory musculature. The toxin does not cross the blood–brain barrier, so patients have a clear sensorium. This may be difficult to establish, however, as these patients may have extreme difficulties communicating because of bulbar palsies. Patients with botulism are afebrile unless they have a secondary infection such as aspiration pneumonia. Deep tendon reflexes are often diminished or absent.

Diagnosis and Treatment (These are discussed in Chapter 38.)

Postexposure Prophylaxis

Theoretically, neutralizing antibody present prior to exposure or delivered shortly after could bind to toxins

and prevent clinical botulism. This has been demonstrated in primate studies. However, botulism antitoxins are scarce in the United States, and providing antitoxin for widespread exposures would be impossible.

Richard C. Dart, MD, PhD, & Barry H. Rumack, MD

Poisonings result from the complex interaction of the agent, the child, and the family environment. The peak incidence is at age 2 years. Most ingestions occur in children younger than age 5 years as a result of insecure storage of drugs, household chemicals, and the like. Twenty-five percent of children will have a second episode of ingestion within 1 year following the first one. Repeated poisonings may require intervention on the child's behalf. Accidental poisonings are unusual after age 5 years. Poisonings in older children and adolescents usually represent manipulative behavior, chemical or drug abuse, or genuine suicide attempts.

Watson WA et al: 2002 annual report of the American Association of Poison Control Centers Toxic Exposure Surveillance System. *Am J Emerg Med* 2003;21:353 [PMID: 14523881].

PREVENTING CHILDHOOD POISONINGS

Each year, children are accidentally poisoned by medicines, polishes, insecticides, drain cleaners, bleaches, household chemicals, and garage products. It is the responsibility of adults to make sure that children are not exposed to potentially toxic substances.

Here are some suggestions for parents:

1. Insist on packages with safety closures and learn how to use them properly.
2. Keep household cleaning supplies, medicines, garage products, and insecticides out of the reach and sight of your child. Lock them up whenever possible.
3. Never store food and cleaning products together. Store medicine and chemicals in original containers and never in food or beverage containers.
4. Avoid taking medicine in your child's presence. Children love to imitate. Never suggest that medicine is candy.
5. Read the label on all products and heed warnings and cautions. Never use medicine from an unlabeled or unreadable container. Never pour medicine in a darkened area where the label cannot be seen clearly.
6. If you are interrupted while using a product, take it with you—it takes only a few seconds for your child to get into it.
7. Know what your child can do physically. For example, if you have a crawling infant, keep household products stored above floor level, not beneath the kitchen sink.
8. Keep the phone numbers of your doctor, poison center, hospital, police department, and emergency medical system near the phone.

PHARMACOLOGIC PRINCIPLES OF TOXICOLOGY

In the evaluation of the poisoned patient, it is important to compare the anticipated pharmacologic or toxic effects with the patient's clinical presentation. If the history is that the patient ingested a tranquilizer 30 minutes ago, but the clinical examination reveals dilated pupils, tachycardia, dry mouth, absent bowel sounds, and active hallucinations—clearly anticholinergic toxicity—diagnosis and therapy should proceed accordingly.

LD₅₀

Estimates of the LD₅₀ (the amount per kilogram of body weight of a drug required to kill 50% of a group of experimental animals) or median lethal dose are of little clinical value in humans. It is usually impossible to determine with accuracy the amount swallowed or absorbed, the metabolic status of the patient, or in which patients the response to the agent will be atypical. Furthermore, these values are often not valid in humans even if the history is accurate.

Half-Life ($t_{1/2}$)

The $t_{1/2}$ of an agent must be interpreted carefully. Most published $t_{1/2}$ values are for therapeutic dosages. The $t_{1/2}$ may increase as the quantity of the ingested substance increases for many common intoxicants such as salicylates and phenytoin. One cannot rely on the published $t_{1/2}$ for salicylate (2 hours) to assume rapid elimination of the drug. In an acute salicylate overdose (150 mg/kg), the apparent $t_{1/2}$ is prolonged to 24–30 hours.

Volume of Distribution

The volume of distribution (Vd) of a drug is determined by dividing the amount of drug absorbed by the blood level. With theophylline, for example, the Vd is 0.46 L/kg body weight, or 32 L in an adult. In contrast, digoxin distributes well beyond total body water. Because the calculation produces a volume above body weight this figure is frequently referred to as an apparent volume of distribution, a designation shared by many drugs (Table 12-1).

The Vd can be useful in predicting which drugs will be removed by dialysis, extracorporeal perfusion, or exchange transfusion. When a drug is differentially concentrated in body lipids or is heavily tissue- or protein-bound and has a high volume of distribution, only a small proportion of the drug will be in the free form and thus accessible to diuresis, dialysis, or exchange transfusion. A drug that is water-soluble and has a low volume of distribution may cross the dialysis membrane well and also respond to diuresis. In general, methods of extracorporeal elimination are not effective for toxic agents with a Vd greater than 1 L/kg.

Metabolism & Excretion

The route of excretion or detoxification is important for planning treatment. Methanol, for example, is metabolized to the toxic product, formic acid. This metabolic step may be blocked by the antidote fomepizole or ethanol.

Blood Levels

Care of the poisoned patient should never be guided solely by laboratory measurements. Treatment should

be directed first by the clinical signs and symptoms, followed by more specific therapy based on laboratory determinations. Clinical information may speed the identification of a toxic agent by the laboratory.

GENERAL TREATMENT OF POISONING

The telephone is often the first contact in pediatric poisoning. Proper telephone management can reduce morbidity and prevent unwarranted or excessive treatment. The decision to refer the patient is based on the identity and dose of the ingested agent, the age of the child, the time of day, the reliability of the parent, and whether child neglect or endangerment is suspected.

Initial Telephone Contact

Basic information that should be written down at the first telephone contact includes the patient's name, age, weight, address and telephone number, the agent and amount of agent ingested, the patient's present condition, and the time elapsed since ingestion or other exposure.

Use the history to evaluate the urgency of the situation and decide whether immediate emergency transportation to a health facility is indicated. An emergency exists if the ingestant is high risk (caustic solutions, hydrogen fluoride, drugs of abuse, or medications such as a calcium channel blocker, opioid, hypoglycemic agent, antidepressant) or if the self-poisoning was intentional. If immediate danger does not exist, obtain more details about the suspected toxic agent. It may be difficult to obtain an accurate history. Obtain names of drugs or ingredients, manufacturers, prescription numbers, names and phone numbers of prescribing physician and

Table 12-1. Some examples of pK_a and Vd.

Drug	pK_a	Diuresis	Dialysis	Apparent Vd
Amobarbital	7.9	No	No	200-300% body weight
Amphetamine	9.8	No	Yes	60% body weight
Aspirin	3.5	Alkaline	Yes	15-40% body weight
Chlorpromazine	9.3	No	No	40-50 L/kg (2800-3500% body weight)
Codeine	8.2	No	No	5-10 L/kg (350-700% body weight)
Desipramine	10.2	No	No	30-40 L/kg (2100-2800% body weight)
Ethchlorvynol	8.7	No	No	5-10 L/kg (350-700% body weight)
Glutethimide	4.5	No	No	10-20 L/kg (700-1400% body weight)
Isoniazid	3.5	Alkaline	Yes	61% body weight
Methadone	8.3	No	No	5-10 L/kg (350-700% body weight)
Methicillin	2.8	No	Yes	60% body weight
Phenobarbital	7.4	Alkaline	Yes	75% body weight
Phenytoin	8.3	No	No	60-80% body weight
Tetracycline	7.7	No	No	200-300% body weight

pharmacy, and so on. Find out whether the substance was shared among several children, whether it had been recently purchased, who had last used it, how full the bottle was, and how much was spilled. If unsure of the significance of an exposure, consult with a certified Poison Control Center.

FIRST AID FOR POISONING (Advice for Parents)

Syrup of ipecac is used to induce vomiting; the activated charcoal is used to bind poisons. Use them only as instructed by your Poison Control Center or doctor. Consult your physician to decide if you should keep syrup of ipecac and activated charcoal in your home.

Inhaled Poisons

If smoke, gas, or fumes have been inhaled, immediately drag or carry the victim to fresh air. Then call 911, the Poison Control Center, or your doctor. Do not enter an area where poisonous fumes are present that have caused loss of consciousness. Too often the rescuer becomes a victim as well.

Poisons on the Skin

If the poison has been spilled on the skin or clothing, remove the clothing and flood the involved parts with water. Wash with soapy water and rinse thoroughly. Then call the Poison Control Center or your doctor.

Swallowed Poisons

If the substance swallowed is a medicine, give nothing. Milk or water should be administered immediately to any patient who has ingested a strongly acid or alkaline agent. Do not give more than 15 mL/kg (250 mL maximum in a child weighing 16 kg or more). Do not induce vomiting in patients who are comatose, convulsing, or who have lost the gag reflex. Induce emesis with ipecac or administer charcoal **only** if advised to do so by a health care professional. **Caution:** Antidote labels on products may be incorrect. Do not give salt, vinegar, or lemon juice. Call before doing anything else.

Poisons in the Eye

Rinse out the eye with plain water before the patient arrives at the emergency room. Use plain tap water—do not try to neutralize acids or bases. Pour water into the eye from a drinking glass or pitcher for 15–20 minutes or fill a basin with water and have the patient put his or her face into the water and open the eyes to dilute. Then transport the patient to the hospital.

Bring the Poison to the Hospital

Everything in the vicinity of the patient that may be a cause of poisoning should be brought to the health care facility.

OBTAINING INFORMATION ABOUT POISONS

Current data on ingredients of commercial products and medications can be obtained from a certified regional poison center. It is important to have the actual container at hand when calling. **Caution:** Antidote information on labels of commercial products or in the *Physicians' Desk Reference* may be incorrect or inappropriate.

FOLLOW-UP

In over 95% of cases of ingestion of potentially toxic substances by children, a trip to the hospital is not required. In these cases, it is important to call the parent at 1 and 4 hours after an ingestion. If the child has ingested an additional unknown agent and develops symptoms, a change in management may be needed, including transportation to the hospital. An additional call should be made 24 hours after the ingestion to begin the process of poison prevention.

PREVENTION OF POISONING

A major goal of pediatricians is to reduce the number of accidental ingestions in the high-risk age group (ie, < age 5 years). A systematic poison education effort should be part of the routine care of every patient. Parents of very young children should be encouraged to search the house and identify all hazardous substances that should be removed from the home or locked up. Pediatric or medical office staff can help families with poison prevention by telephone by asking a few simple questions about storage of hazardous substances in the home. The following is a partial list of potentially poisonous substances that must be stored safely if small children are in the home: drain-cleaning crystals or liquid, dishwasher soap and cleaning supplies, paints and paint thinners, garden spray and other insecticide materials, automobile products (antifreeze, windshield wiper fluid, gasoline), and all medications.

The section entitled Preventing Childhood Poisonings may be copied from this book and given to parents at the 6-month check-up. Although syrup of ipecac is not recommended for all poisonings, it is useful for some types, such as plant material, pills too large to be lavaged, and decontamination in rural areas where health care may be 30 minutes or more away. Rein-

forcement should occur at the 1-year check-up to make certain that adequate poison-proofing measures have been instituted and maintained.

INITIAL EMERGENCY DEPARTMENT CONTACT

Make Certain the Patient Is Breathing

As in all emergencies, the principles of treatment are attention to airway, breathing, and circulation. These are sometimes overlooked under the stressful conditions of a pediatric poisoning.

Treat Shock

Initial therapy of the hypotensive patient should consist of laying the patient flat and administering intravenous isotonic solutions. Vasopressors should be reserved for poisoned patients in shock who do not respond to these standard measures.

Treat Burns

Burns may occur following exposure to strong acid or strong alkaline agents or petroleum distillates. Burned areas should be decontaminated by flooding with sterile saline solution or water. A burn unit should be consulted if more than minimal burn damage has been sustained. Skin decontamination should be performed in a patient with cutaneous exposure. Emergency department personnel in contact with a patient who has been contaminated (with an organophosphate insecticide, for example) should themselves be decontaminated if their skin or clothing becomes contaminated.

Take a Pertinent History

The history should be taken from the parents and all individuals present at the scene. It may be crucial to determine all of the kinds of poisons in the home. These may include drugs used by family members, chemicals associated with the hobbies or occupations of family members, or the purity of the water supply. Unusual dietary or medication habits or other clues to the possible cause of poisoning should also be investigated.

DEFINITIVE THERAPY OF POISONING

Prevention of Absorption

A. EMESIS

Induced vomiting is contraindicated in patients who have ingested a minimally toxic substance (eg, most antibiotics), who are comatose or convulsing, or who have lost the gag reflex or ingested strong acids, strong bases,

some hydrocarbons, or sharp objects. The use of ipecac has decreased dramatically over the past 10 years and is reserved for those instances when medications have been taken within 30–60 minutes prior to contact.

1. Ipecac method—This may be effective if administered within an hour of ingestion. Adult dose, 30 mL; pediatric dose, 15 mL. Give orally (PO) and repeat once in 20 minutes if necessary.

2. Other emetics—The only approved oral emetic agent is syrup of ipecac. Use of sodium chloride may lead to lethal hypernatremia. Apomorphine, mustard, soap, and other emetics should not be used.

B. LAVAGE

If the patient is or is becoming unconscious, is convulsing, or has lost the gag reflex, gastric lavage following endotracheal or nasotracheal intubation should be performed rather than induction of vomiting. Lavage is rarely performed in pediatric patients. Emesis and lavage recover an average of about 30% of the stomach contents if performed soon after ingestion. Although these procedures may be helpful in reducing the amount of material available for absorption, approximately 70% of an ingested dose will remain. Additional measures such as charcoal should be instituted to prevent further absorption.

C. CHARCOAL

The dose of charcoal is 1–2 g/kg (maximum, 100 g) per dose. Repeating the dose of activated charcoal may be useful for those agents that slow passage through the gastrointestinal (GI) tract. When multiple doses of activated charcoal are given, repeated doses of sorbitol or saline cathartics must not be given. Repeated doses of cathartics may cause electrolyte imbalances and fluid loss. Charcoal dosing is repeated every 2–6 hours until charcoal is passed through the rectum.

D. CATHARSIS

Despite their widespread use, cathartics have not been shown to improve outcome. The use of cathartics should therefore be avoided.

E. WHOLE GUT LAVAGE

Whole bowel lavage uses an orally administered, non-absorbable hypertonic solution such as CoLyte or GoLYTELY. The use of this procedure in poisoned patients remains controversial. Preliminary recommendations for use of whole bowel irrigation include poisoning with sustained-release preparations, mechanical movement of items through the bowel (eg, cocaine packets, iron tablets), and poisoning with substances poorly absorbed by charcoal (eg, lithium, iron). Underlying bowel pathology and intestinal obstruction are

relative contraindications to its use. Consultation with a certified regional poison center is recommended.

Vale JA: Position statement: Gastric lavage. American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. *J Toxicol Clin Toxicol* 1997;35:711 [PMID: 9482426].

Enhancement of Excretion

Excretion of certain substances can be hastened by urinary alkalization or dialysis. It is important to make certain that the patient is not volume-depleted. Volume-depleted patients should receive a normal saline bolus of 10–20 mL/kg, followed by sufficient intravenous (IV) fluid administration to maintain urine output at 2–3 mL/kg/h.

A. URINARY ALKALINIZATION

1. Alkaline diuresis—Urinary alkalization should be chosen on the basis of the substance's pK_a , so that ionized drug will be trapped in the tubular lumen and not reabsorbed (see Table 12–1). Thus, if the pK_a is less than 7.5, urinary alkalization is appropriate; if it is over 8.0, this technique is not usually beneficial. The pK_a is sometimes included along with general drug information. Urinary alkalization is achieved with sodium bicarbonate. It is important to observe for hypokalemia, caused by the shift of potassium intracellularly. Follow serum K^+ and observe for ECG evidence of hypokalemia. If complications such as renal failure or pulmonary edema are present, hemodialysis or hemoperfusion may be required.

B. DIALYSIS

Hemodialysis (or peritoneal dialysis if hemodialysis is unavailable) is useful in the poisonings listed below. Dialysis should be considered part of supportive care if the patient satisfies any of the following criteria:

1. Clinical criteria—

a. Potentially life-threatening toxicity that is caused by a dialyzable drug and cannot be treated by conservative means.

b. Hypotension threatening renal or hepatic function that cannot be corrected by adjusting circulating volume.

c. Marked hyperosmolality or severe acid–base or electrolyte disturbances not responding to therapy.

d. Marked hypothermia or hyperthermia not responding to therapy.

2. Immediate dialysis—Immediate dialysis should be considered in ethylene glycol and methanol poisoning only if acidosis is refractory, the patient does not respond to fomepizole treatment, or blood levels of ethanol of 100 mg/dL are consistently maintained.

3. Dialysis indicated on basis of condition of patient—In general, dialyze if the patient is in a coma deeper than level 3. Peritoneal dialysis or exchange transfusion may be more useful than hemodialysis in small children—as much for ease of achieving fluid and electrolyte homeostasis as for poison removal. Other drugs not listed here may be dialyzable. Information should be verified prior to institution of dialysis.

MANAGEMENT OF SPECIFIC COMMON POISONINGS

ACETAMINOPHEN (PARACETAMOL)

Overdosage of acetaminophen is the most common pediatric poisoning and can produce severe hepatotoxicity. The incidence of hepatotoxicity in adults and adolescents has been reported to be ten times higher than in children younger than age 5 years. In the latter group, less than 0.1% develop hepatotoxicity after acetaminophen overdose. In children, toxicity most commonly results from repeated overdosage arising from confusion about the age-appropriate dose, use of multiple products that contain acetaminophen, or use of adult suppositories.

Acetaminophen is normally metabolized in the liver. A small percentage of the drug goes through a pathway leading to a toxic metabolite. Normally, this electrophilic reactant is removed harmlessly by conjugation with glutathione. In overdosage, the supply of glutathione becomes exhausted, and the metabolite may bind covalently to components of liver cells to produce necrosis. Some authors have proposed that therapeutic doses of acetaminophen may be toxic to children with depleted glutathione stores. However, there is no evidence that administration of therapeutic doses can cause toxicity, and only a few inadequate case reports have been made in this regard.

Treatment

Treatment is to administer acetylcysteine. In the United States, it may only be given PO. Consultation on difficult cases may be obtained from the Rocky Mountain Poison Center (1-800-525-6115) or any poison center. Blood levels should be obtained as soon as possible after 4 hours and plotted on Figure 12–1. The nomogram is used only for acute ingestion, not repeated supratherapeutic ingestions. If the patient has ingested acetaminophen in a liquid preparation, blood levels obtained 2 hours after ingestion will give an accurate reflection of the toxicity to be expected relative to the standard nomogram (see Figure 12–1). Acetylcysteine is administered to patients whose acetaminophen levels plot in the toxic range on the nomogram. Acetylcysteine is effective even when given more than 24 hours after ingestion although it is most effective when given within 8 hours postingestion.

The dose of acetylcysteine is 140 mg/kg PO, diluted to a 5% solution in sweet fruit juice or carbonated soft drink. The primary problems associated with administration are nausea and vomiting. After this loading dose, 70 mg/kg should be administered PO every 4 hours for 72 hours. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum bilirubin, and plasma prothrombin time should be followed daily. Significant abnormalities of liver function may not develop until up to 72 hours after ingestion. Repeated miscalculated overdoses given by parents to treat

fever are the major source of toxicity in children younger than age 10 years, and parents are often unaware of the significance of symptoms of toxicity, thus delaying its prompt recognition and therapy.

Sztajnkrzyer MJ, Bond GR: Chronic acetaminophen overdosing in children: Risk assessment and management. *Curr Opin Pediatr* 2001;13:177 [PMID: 11317062].

ALCOHOL, ETHYL (ETHANOL)

Alcoholic beverages, tinctures, cosmetics, and rubbing alcohol are common sources of poisoning in children. Concomitant exposure to other depressant drugs increases the seriousness of the intoxication. (Blood levels cited here are for adults; comparable figures for children are not available.) In most states, alcohol levels of 50–80 mg/dL are considered compatible with impaired faculties, and levels of 80–100 mg/dL are considered evidence of intoxication.

Complete absorption of alcohol requires 30 minutes to 6 hours, depending on the volume, the presence of food, and the time spent in consuming the alcohol. The rate of metabolic degradation is constant (about 20 mg/h in an adult). Absolute ethanol, 1 mL/kg, re-

Figure 12–1. Semilogarithmic plot of plasma acetaminophen levels versus time. (Modified and reproduced, with permission, from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. *Pediatrics* 1975;55:871.)

sults in a peak blood level of about 100 mg/dL in 1 hour after ingestion. Acute intoxication and chronic alcoholism increase the risk of subarachnoid hemorrhage.

Treatment

Management of hypoglycemia and acidosis is usually the only measure required. Start an IV drip of D₅W or D₁₀W if blood glucose is under 60 mg/dL. Fructose has been suggested as an accelerator of metabolism, but it may cause vomiting, intensify lactic acidosis, and decrease blood volume via osmotic diuresis. Glucagon does not correct the hypoglycemia, because hepatic glycogen stores are reduced. Death is usually caused by respiratory failure. In severe cases, cerebral edema should be treated with IV dexamethasone, 0.1 mg/kg every 4–6 hours. Dialysis is indicated in life-threatening intoxication.

Roy M et al: What are the adverse effects of ethanol used as an antidote in the treatment of suspected methanol poisoning in children? *J Toxicol Clin Toxicol* 2003;41:155 [PMID: 12733853].

AMPHETAMINES & RELATED DRUGS (METHAMPHETAMINE)

Clinical Presentation

A. ACUTE POISONING

Amphetamine and methamphetamine poisoning is common because of the widespread availability of “diet pills” and the use of “speed,” “crank,” “crystal,” and “ice” by adolescents. (Care must be taken in the interpretation of slang terms because they have multiple meanings.) A new cause of amphetamine poisoning are drugs for treating attention deficit hyperactivity disorder, such as methylphenidate. Symptoms include CNS stimulation, anxiety, hyperactivity, hyperpyrexia, hypertension, abdominal cramps, nausea and vomiting, and inability to void urine. Severe cases often include rhabdomyolysis. A toxic psychosis indistinguishable from paranoid schizophrenia may occur. Methamphetamine laboratories in homes are a potential cause of childhood exposure to a variety of hazardous and toxic substances.

B. CHRONIC POISONING

Chronic amphetamine users develop tolerance; more than 1500 mg of IV methamphetamine can be used daily. Hyperactivity, disorganization, and euphoria are followed by exhaustion, depression, and coma lasting

2–3 days. Heavy users, taking more than 100 mg/d, have restlessness, incoordination of thought, insomnia, nervousness, irritability, and visual hallucinations. Psychosis may be precipitated by the chronic administration of high doses. Depression, weakness, tremors, GI complaints, and suicidal thoughts occur frequently.

Treatment

Standard decontamination procedures should be used: gastric emptying followed by charcoal in recent ingestions; activated charcoal alone if ingestion occurred hours earlier. The treatment of choice is diazepam, titrated in small increments to effect. Very large total doses may be needed. In case of extreme agitation or hallucinations, droperidol (0.1 mg/kg/dose) or haloperidol (up to 0.1 mg/kg) parenterally has been used. When combinations of amphetamines and barbiturates (diet pills) are used, the action of the amphetamines begins first, followed by a depression caused by the barbiturates. In these cases, treatment with additional barbiturates is contraindicated because of the risk of respiratory failure.

Chronic users may be withdrawn rapidly from amphetamines. If amphetamine–barbiturate combination tablets have been used, the barbiturates must be withdrawn gradually to prevent withdrawal seizures. Psychiatric treatment should be provided.

Schwartz RH, Miller NS: MDMA (ecstasy) and the rave: A review. *Pediatrics* 1997;100:705 [PMID: 9310529].

ANESTHETICS, LOCAL

Intoxication from local anesthetics may be associated with CNS stimulation, acidosis, delirium, ataxia, shock, convulsions, and death. Methemoglobinuria has been reported following local dental analgesia. The maximum recommended dose for subcutaneous (SQ) infiltration is 4.5 mg/kg. The temptation to exceed this dose in procedures lasting a long time is great and may result in inadvertent overdosage. PO application of viscous lidocaine may produce toxicity. Hypercapnia may lower the seizure threshold to locally injected anesthetics.

Local anesthetics used in obstetrics cross the placental barrier and are not efficiently metabolized by the fetal liver. Mepivacaine, lidocaine, and bupivacaine can cause fetal bradycardia, neonatal depression, and death. Prilocaine causes methemoglobinemia, which should be treated if levels in the blood exceed 40% or if the patient is symptomatic.

Accidental injection of mepivacaine into the head of the fetus during paracervical anesthesia has caused neonatal asphyxia, cyanosis, acidosis, bradycardia, convulsions, and death.

Treatment

If the anesthetic has been ingested, mucous membranes should be cleansed carefully and activated charcoal may be administered. Oxygen administration is indicated, with assisted ventilation if necessary. Methemoglobinemia is treated with methylene blue, 1%, 0.2 mL/kg (1–2 mg/kg/dose, IV) over 5–10 minutes; this should promptly relieve the cyanosis. Acidosis may be treated with sodium bicarbonate, seizures with diazepam, bradycardia with atropine. Therapeutic levels of mepivacaine, lidocaine, and procaine are less than 5 mg/mL.

Spiller HA et al: Multi-center retrospective evaluation of oral benzocaine exposure in children. *Vet Hum Toxicol* 2000;42:228 [PMID: 10928690].

ANTIHISTAMINES

Although antihistamines typically cause CNS depression, children often react paradoxically with excitement, hallucinations, delirium, ataxia, tremors, and convulsions followed by CNS depression, respiratory failure, or cardiovascular collapse. Anticholinergic effects such as dry mouth, fixed dilated pupils, flushed face, fever, and hallucinations may be prominent.

Antihistamines are widely available in allergy, sleep, cold, and antiemetic preparations, and many are supplied in sustained-release forms, which increases the likelihood of dangerous overdoses. They are absorbed rapidly and metabolized by the liver, lungs, and kidneys. A potentially toxic dose is 10–50 mg/kg of the most commonly used antihistamines, but toxic reactions have occurred at much lower doses.

Treatment

Activated charcoal should be used to reduce drug absorption. Emetics may be ineffective if the antihistamine is structurally related to phenothiazines. Whole bowel irrigation may be useful for sustained-release preparations. Physostigmine, 0.5–2 mg IV slowly administered, dramatically reverses the central and peripheral anticholinergic effects of antihistamines, but it should be used only for diagnostic purposes. Diazepam, 0.1–0.2 mg/kg IV, can be used to control seizures. Forced diuresis is not helpful. Exchange transfusion was reported to be effective in one case.

ARSENIC

Arsenic is used in some insecticides (fruit tree or tobacco sprays), rodenticides, weed killers, and wood preservatives. It is well absorbed primarily through the GI and respiratory tracts, but skin absorption may occur. Arsenic can be found in the urine, hair, and nails by laboratory testing.

Highly toxic soluble derivatives of this compound, such as sodium arsenite, are frequently found in liquid preparations and can cause death in as many as 65% of victims. The organic arsonates found in persistent or preemergence weed killers are relatively less soluble and less toxic. Poisonings with a liquid arsenical preparation that does not contain alkyl methanearsonate compounds should be considered potentially lethal. Patients exhibiting clinical signs other than gastroenteritis should receive treatment until laboratory tests indicate that treatment is no longer necessary.

Clinical Presentation

A. ACUTE POISONING

Abdominal pain, vomiting, watery and bloody diarrhea, cardiovascular collapse, paresthesias, neck pain, and garlic odor on breath occur. Convulsions, coma, anuria, and exfoliative dermatitis are later signs. Inhalation may cause pulmonary edema. Death is the result of cardiovascular collapse.

B. CHRONIC POISONING

Anorexia, generalized weakness, giddiness, colic, abdominal pain, polyneuritis, dermatitis, nail changes, alopecia, and anemia often develop.

Treatment

In acute poisoning, empty the stomach and administer activated charcoal. Then immediately give dimercaprol (commonly known as BAL), 3–5 mg/kg intramuscularly (IM), and follow with 2 mg/kg IM every 4 hours. The dimercaprol-arsenic complex is dialyzable. A second choice is succimer. The initial dose is 10 mg/kg every 8 hours for 5 days. A third choice is penicillamine, 100 mg/kg PO to a maximum of 1 g/d in four divided doses.

Chronic arsenic intoxication should be treated with succimer or penicillamine. Collect a 24-hour baseline urine specimen and then begin chelation. If the 24-hour urine arsenic level is greater than 50 mg, continue chelation for 5 days. After 10 days, repeat the 5-day cycle once or twice depending on how soon the urine arsenic level falls below 50 mg/24 h.

Cullen MN et al: Pediatric arsenic ingestion. *Am J Emerg Med* 1995;13:432 [PMID: 7605532].

BARBITURATES

The toxic effects of barbiturates include confusion, poor coordination, coma, miotic or fixed dilated pupils, and respiratory depression. Respiratory acidosis is commonly associated with pulmonary atelectasis, and hypotension occurs frequently in severely poisoned patients. Ingestion of more than 6 mg/kg of long-acting or 3 mg/kg of short-acting barbiturates is usually toxic.

Treatment

Activated charcoal should be administered. Careful, conservative management with emphasis on maintaining a clear airway, adequate ventilation, and control of hypotension is critical. Urinary alkalinization and the use of multiple-dose charcoal may decrease the elimination half-life of phenobarbital but have not been shown to alter the clinical course. Hemodialysis is not useful in the treatment of poisoning with short-acting barbiturates. Analeptics are contraindicated.

Cote CJ et al: Adverse sedation events in pediatrics: Analysis of medications used for sedation. *Pediatrics* 2000;4:633 [PMID: 11015502].

BELLADONNA ALKALOIDS (Atropine, Jimsonweed, Potato Leaves, Scopolamine, Stramonium)

The effects of anticholinergic compounds include dry mouth; thirst; decreased sweating with hot, dry, red skin; high fever; and tachycardia that may be preceded by bradycardia. The pupils are dilated, and vision is blurred. Speech and swallowing may be impaired. Hallucinations, delirium, and coma are common. Leukocytosis may occur, confusing the diagnosis.

Atropinism has been caused by normal doses of atropine or homatropine eye drops, especially in children

with Down syndrome. Many common plants and over-the-counter medications contain belladonna alkaloids.

Treatment

Emesis or lavage should be followed by activated charcoal. Gastric emptying is slowed by anticholinergics, so that gastric decontamination may be useful even if delayed. Physostigmine, 0.5–2 mg IV, administered slowly, dramatically reverses the central and peripheral signs of atropinism but should be used only as a diagnostic agent. High fever must be controlled. Catheterization may be needed if the patient cannot void.

Schultz U et al: Central anticholinergic syndrome in a child undergoing circumcision. *Acta Anesthesiol Scand* 2002;46:224 [PMID: 11942877].

CARBON MONOXIDE

The degree of toxicity correlates well with the carboxyhemoglobin level taken soon after acute exposure but not after oxygen has been given or when there has been some time since exposure. Onset of symptoms may be more rapid and more severe if the patient lives at a high altitude, has a high respiratory rate (ie, infants), is pregnant, or has myocardial insufficiency or lung disease. Normal blood may contain up to 5% carboxyhemoglobin (10% in smokers).

The most prominent early symptom is headache. Other effects include confusion, unsteadiness, and coma. Proteinuria, glycosuria, elevated serum aminotransferase levels, or electrocardiogram (ECG) changes may be present in the acute phase. Permanent cardiac, liver, renal, or CNS damage occurs occasionally. The outcome of severe poisoning may be complete recovery, vegetative state, or any degree of mental injury between these extremes. The primary mental deficits are neuropsychiatric.

Treatment

The biologic half-life of carbon monoxide on room air is approximately 200–300 minutes; on 100% oxygen, it is 60–90 minutes. Hyperbaric oxygen therapy at 2–2.5 atm of oxygen shortens the half-life to 30 minutes. After the level has been reduced to near zero, therapy is aimed at the nonspecific sequelae of anoxia. Dexamethasone, 0.1 mg/kg IV or IM every 4–6 hours, should be added if cerebral edema develops.

Walker AR: Emergency department management of house fire burns and carbon monoxide poisoning in children. *Curr Opin Pediatr* 1996;8:239 [PMID: 8814401].

CAUSTICS

1. Acids (Hydrochloric, Hydrofluoric, Nitric, & Sulfuric Acids; Sodium Bisulfate)

Strong acids are commonly found in metal and toilet bowl cleaners, batteries, and other products. Hydrofluoric acid is the most toxic and hydrochloric acid the least toxic of these household substances. However, even a few drops can be fatal if aspirated into the trachea.

Painful swallowing, mucous membrane burns, bloody emesis, abdominal pain, respiratory distress due to edema of the epiglottis, thirst, shock, and renal failure can occur. Coma and convulsions sometimes are seen terminally. Residual lesions include esophageal, gastric, and pyloric strictures as well as scars of the cornea, skin, and oropharynx.

Hydrofluoric acid is a particularly dangerous poison. Dermal exposure creates a penetrating burn that can progress for hours or days. Large dermal exposure or ingestion may produce life-threatening hypocalcemia abruptly as well as burn reactions.

Treatment

Emetics and lavage are contraindicated. Water or milk (< 15 mL/kg) is used to dilute the acid, because a heat-producing chemical reaction does not occur. Take care not to induce emesis by excessive fluid administration. Alkalies should not be used. Burned areas of the skin, mucous membranes, or eyes should be washed with copious amounts of warm water. Opioids for pain may be needed. An endotracheal tube may be required to alleviate laryngeal edema. Esophagoscopy should be performed if the patient has significant burns or difficulty in swallowing. Acids are likely to produce gastric burns or esophageal burns. Evidence is not conclusive, but corticosteroids have not proved to be of use.

Hydrofluoric acid burns on skin are treated with 10% calcium gluconate gel or calcium gluconate infusion. Severe exposure may require large doses of IV calcium. Therapy should be guided by calcium levels, the ECG, and clinical signs.

2. Bases (Clinitest Tablets, Clorox, Drano, Liquid-Plumr, Purex, Sani-Clor)

Alkalies produce more severe injuries than acids. Some substances, such as Clinitest tablets or Drano, are quite toxic, whereas the chlorinated bleaches (3–6% solutions

of sodium hypochlorite) are usually not toxic. When sodium hypochlorite comes in contact with acid in the stomach, hypochlorous acid, which is very irritating to the mucous membranes and skin, is formed. Rapid inactivation of this substance prevents systemic toxicity. Chlorinated bleaches, when mixed with a strong acid (toilet bowl cleaners) or ammonia, may produce irritating chlorine or chloramine gas, which can cause serious lung injury if inhaled in a closed space (eg, bathroom).

Alkalies can burn the skin, mucous membranes, and eyes. Respiratory distress may be due to edema of the epiglottis, pulmonary edema resulting from inhalation of fumes, or pneumonia. Mediastinitis or other intercurrent infections or shock can occur. Perforation of the esophagus or stomach is rare.

Treatment

The skin and mucous membranes should be cleansed with copious amounts of water. A local anesthetic can be instilled in the eye if necessary to alleviate blepharospasm. The eye should be irrigated for at least 20–30 minutes. Ophthalmologic consultation should be obtained for all alkaline eye burns.

Ingestions should be treated with water as a diluent. Routine esophagoscopy is no longer indicated to rule out burns of the esophagus due to chlorinated bleaches unless an unusually large amount has been ingested or the patient is symptomatic. The absence of oral lesions does not rule out the possibility of laryngeal or esophageal burns following granular alkali ingestion. The use of corticosteroids is controversial, but has not been shown to improve long-term outcome except possibly in partial-thickness esophageal burns. Antibiotics may be needed if mediastinitis is likely, but they should not be used prophylactically. (See Caustic Burns of the Esophagus section in Chapter 20).

COCAINE

Cocaine is absorbed intranasally or via inhalation or ingestion. Effects are noted almost immediately when the drug is taken intravenously or smoked. Peak effects are delayed for about an hour when the drug is taken orally

or nasally. Cocaine prevents the reuptake of endogenous catecholamines, thereby causing an initial sympathetic discharge, followed by catechol depletion after chronic abuse.

Clinical Findings

A local anesthetic and vasoconstrictor, cocaine is also a potent stimulant to both the CNS and the cardiovascular system. The initial tachycardia, hyperpnea, hypertension, and stimulation of the CNS are often followed by coma, seizures, hypotension, and respiratory depression. In severe cases of overdose, various dysrhythmias may be seen, including sinus tachycardia, atrial arrhythmias, premature ventricular contractions, bigeminy, and ventricular fibrillation. If large doses are taken intravenously, cardiac failure, dysrhythmias, rhabdomyolysis, or hyperthermia may result in death.

In addition to those poisoned through recreational use of cocaine, others are at risk of overdose. A “body stuffer” is one who quickly ingests the drug, usually poorly wrapped, to avoid discovery. A “body packer” wraps the drug carefully for prolonged transport. A stuffer typically manifests toxicity within hours of ingestion; a packer is asymptomatic unless the package ruptures, usually days later.

Treatment

Except in cases of body stuffers or body packers, decontamination is seldom possible. Activated charcoal should be administered, and whole bowel irrigation may be useful in selected cases. Testing for cocaine in blood or plasma is generally not clinically useful, but a qualitative analysis of the urine may aid in confirming the diagnosis. For severe cases, an ECG is indicated. In suspected cases of body packing, radiographs of the GI tract may show multiple packets. X-ray films are usually not helpful for identifying stuffers. Seizures are treated with IV diazepam titrated to response. Hypotension is treated with standard agents. Because cocaine abuse may deplete norepinephrine, an indirect agent such as dopamine may be less effective than a direct agent such as norepinephrine. Agitation is best treated with a benzodiazepine.

CONTRACEPTIVE PILLS

The only known toxic effects following acute ingestion of oral contraceptive agents are nausea, vomiting, and vaginal bleeding in girls.

COSMETICS & RELATED PRODUCTS

The relative toxicities of commonly ingested products in this group are listed in Table 12–2. Permanent wave neutralizers may contain bromates, peroxides, or perborates. Bromates have been removed from most products because they can cause nausea, vomiting, abdominal pain, shock, hemolysis, renal failure, and convulsions. Perborates can cause boric acid poisoning. Four grams of bromate salts is potentially lethal.

Poisoning is treated by gastric lavage with 1% sodium thiosulfate followed by demulcents to relieve gastric irritation. Sodium bicarbonate, 2%, in the lavage fluid may reduce hydrobromic acid formation. Sodium thiosulfate, 25%, 1.65 mL/kg, can be given intravenously, but methylene blue should not be used to treat methemoglobinemia in this situation, because it increases the toxicity of bromates. Dialysis is indicated in renal failure but does not enhance excretion of bromate.

Fingernail polish removers used to contain toluene, but now usually have an acetone base, which does not require specific treatment other than monitoring CNS status.

Cobalt, copper, cadmium, iron, lead, nickel, silver, bismuth, and tin are sometimes found in metallic hair dyes. In large amounts, they can cause skin sensitiza-

Table 12–2. Relative toxicities of cosmetics and similar products.

High toxicity	Low toxicity
Permanent wave neutralizers	Perfume
	Hair removers
	Deodorants
	Bath salts
Moderate toxicity	No toxicity
Fingernail polish	Liquid makeup
Fingernail polish remover	Vegetable hair dye
Metallic hair dyes	Cleansing cream
Home permanent wave lotion	Hair dressing
Bath oil	(nonalcoholic)
Shaving lotion	Hand lotion or cream
Hair tonic (alcoholic)	Lipstick
Cologne, toilet water	

tion, urticaria, dermatitis, eye damage, vertigo, hypertension, asthma, methemoglobinemia, tremors, convulsions, and coma. Treatment for ingestions is to administer demulcents and, only with large amounts, the appropriate antidote for the heavy metal involved.

Home permanent wave lotions, hair straighteners, and hair removers usually contain thioglycolic acid salts, which cause alkaline irritation and perhaps CNS depression.

Shaving lotion, hair tonic, hair straighteners, cologne, and toilet water contain denatured alcohol, which can cause CNS depression and hypoglycemia.

Deodorants usually consist of an antibacterial agent in a cream base. Antiperspirants are aluminum salts, which frequently cause skin sensitization. Zirconium oxide can cause granulomas in the axilla with chronic use.

CYCLIC ANTIDEPRESSANTS

Cyclic antidepressants (eg, amitriptyline, imipramine) have a very low ratio of toxic to therapeutic doses, and even a moderate overdose can have serious effects. Cyclic antidepressant overdosage causes dysrhythmias, coma, convulsions, hypertension followed by hypotension, and hallucinations. These effects may be life-threatening and require rapid intervention. One agent, amoxapine, differs in that it causes fewer cardiovascular complications, but it is associated with a higher incidence of seizures.

Treatment

Decontamination should include gastric lavage and administration of activated charcoal.

An ECG should be taken in all patients. A QRS interval greater than 100 ms specifically identifies patients at risk to develop dysrhythmias. If dysrhythmias are demonstrated, the patient should be admitted and monitored until free of irregularity for 24 hours. Another indication for monitoring is persistent tachycardia of more than 110 beats/min. The onset of dysrhythmias is rare beyond 24 hours after ingestion.

Alkalinization with sodium bicarbonate, 0.5–1.0 mEq/kg IV, or hyperventilation may dramatically reverse ventricular dysrhythmias and narrow the QRS interval. Lidocaine may be added for treatment of arrhythmias. Bolus administration of sodium bicarbonate is recommended for all patients with QRS widening to above 120 ms and for those with significant dysrhythmias, to achieve a pH of 7.5–7.6. Forced diuresis is contraindicated. A benzodiazepine should be given for convulsions.

Hypotension is a major problem. Cyclic antidepressants block the reuptake of catecholamines, thereby

producing initial hypertension followed by hypotension. Treatment with physostigmine is contraindicated. Vasopressors are generally effective. Dopamine is the agent of choice because it is readily available. If dopamine is ineffective, norepinephrine (0.1–1 µg/kg/min, titrated to response) should be added. Diuresis and hemodialysis are not effective.

McKinney PE et al: Reversal of severe tricyclic antidepressant-induced cardiotoxicity with intravenous hypertonic saline solution. *Ann Emerg Med* 2003;42:20 [PMID: 12827118].

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Toxicity is typically the result of incorrect dosing or unrecognized renal insufficiency. Clinical features include nausea, vomiting, diarrhea, headache, delirium, confusion, and, occasionally, coma. Cardiac dysrhythmias typically involve bradydysrhythmias, but every type of dysrhythmia has been reported in digitalis intoxication, including atrial fibrillation, paroxysmal atrial tachycardia, and atrial flutter. Death usually is the result of ventricular fibrillation. Transplacental intoxication by digitalis has been reported.

Treatment

If vomiting has not occurred, induce emesis or provide lavage followed by charcoal. Potassium is contraindicated in acute overdosage unless there is laboratory evidence of hypokalemia. In acute overdosage, hyperkalemia is more common. Hypokalemia is common in chronic toxicity.

The patient must be monitored carefully for ECG changes. The correction of acidosis better demonstrates the degree of potassium deficiency present. Bradycardias have been treated with atropine. Phenytoin, lidocaine, magnesium salts (not in renal failure), amiodarone, and bretylium have been used to correct arrhythmias.

Definitive treatment is with digoxin immune Fab (ovine) (Digibind). Indications for its use include hypotension or any dysrhythmia, typically ventricular dysrhythmias and progressive bradydysrhythmias that produce clinical concern. Elevated T-waves indicated high potassium and may be an indication for digoxin immune Fab (Digibind, DigiFab) use. Techniques of determining dosage and indications related to levels, when available are described in product literature.

Woolf AD et al: The use of digoxin-specific Fab fragments for severe digitalis intoxication in children. *N Engl J Med* 1992;326:1739 [PMID: 1997016].

DIPHENOXYLATE WITH ATROPINE (LOMOTIL)

Lomotil contains diphenoxylate hydrochloride, a synthetic narcotic, and atropine sulfate. Small amounts are potentially lethal in children; it is contraindicated in children younger than age 2 years. Early signs of intoxication with this preparation result from its anticholinergic effect and consist of fever, facial flushing, tachypnea, and lethargy. However, the miotic effect of the narcotic predominates. Later, hypothermia, increasing CNS depression, and loss of the facial flush occur. Seizures are probably secondary to hypoxia.

Treatment

Prolonged monitoring (24 hours) with pulse oximetry is sufficient in most cases. If respiratory depression occurs, an airway should be established with an endotracheal tube. Gastric lavage and administration of activated charcoal may be useful because of the prolonged delay in gastric emptying time.

Naloxone hydrochloride (0.4–2 mg IV in children and adults) should be given. A transient improvement in respiration may be followed by respiratory depression. Repeated doses may be required because the duration of action of diphenoxylate is considerably longer than that of naloxone. The anticholinergic effects do not usually require treatment.

McCarron MM et al: Diphenoxylate-atropine (Lomotil) overdose in children: An update. *Pediatrics* 1991;87:694 [PMID: 2020516].

DISINFECTANTS & DEODORIZERS

1. Naphthalene

Naphthalene is commonly found in mothballs, disinfectants, and deodorizers. Naphthalene's toxicity is often not fully appreciated. It is absorbed not only when ingested but also through the skin and lungs. It is potentially hazardous to store baby clothes in naphthalene, because baby oil is an excellent solvent that may increase dermal absorption. **Note:** Most moth balls contain *para*-dichlorobenzene and not naphthalene—see next section. Metabolic products of naphthalene may cause severe hemolytic anemia, similar to that due to primaquine toxicity, 2–7 days after ingestion. Other physical findings include vomiting, diarrhea, jaundice, oliguria, anuria, coma, and convulsions. The urine may contain hemoglobin, protein, and casts.

Treatment

Induced vomiting should be followed by activated charcoal. Urinary alkalization may prevent blocking of

the renal tubules by acid hematin crystals. Anuria may persist for 1–2 weeks and still be completely reversible.

Ostlere L et al: Haemolytic anaemia associated with ingestion of naphthalene-containing anointing oil. *Postgrad Med J* 1988;64:444 [PMID: 3211822].

Siegel E, Wason S: Mothball toxicity. *Pediatr Clin North Am* 1986;33:369 [PMID: 3515301].

2. *p*-Dichlorobenzene, Phenolic Acids, & Others

Disinfectants and deodorizers containing *p*-dichlorobenzene or sodium sulfate are much less toxic than those containing naphthalene. Disinfectants containing phenolic acids are highly toxic, especially if they contain a borate ion. Phenol precipitates tissue proteins and causes respiratory alkalosis followed by metabolic acidosis. Some phenols cause methemoglobinemia.

Local gangrene occurs after prolonged contact with tissue. Phenol is readily absorbed from the GI tract, causing diffuse capillary damage and, in some cases, methemoglobinemia. Pentachlorophenol, which has been used in terminal rinsing of diapers, has caused infant fatalities.

The toxicity of alkalis, quaternary ammonium compounds, pine oil, and halogenated disinfectants varies with the concentration of active ingredients. Wick deodorizers are usually of moderate toxicity. Iodophor disinfectants are the safest. Spray deodorizers are not usually toxic, because a child is not likely to swallow a very large dose.

Signs and symptoms of acute quaternary ammonium compound ingestion include diaphoresis, strong irritation, thirst, vomiting, diarrhea, cyanosis, hyperactivity, coma, convulsions, hypotension, abdominal pain, and pulmonary edema. Acute liver or renal failure may develop later.

Treatment

Activated charcoal may be used prior to gastric lavage. Castor oil dissolves phenol and may retard its absorption. This property of castor oil, however, has not been proved clinically. Mineral oil and alcohol are contraindicated because they increase the gastric absorption of phenol. The metabolic acidosis must be managed carefully. Anticonvulsants or measures to treat shock may be needed.

Because phenols are absorbed through the skin, exposed areas should be irrigated copiously with water. Undiluted polyethylene glycol may be a useful solvent as well.

Mucklow ES: Accidental feeding of dilute antiseptic solution (chlorhexidine 0.05% with cetrimide 1%) to five babies. *Hum Toxicol* 1988;7:567 [PMID: 3229768].

Van Berkel M, de Wolff FA: Survival after acute benzalkonium chloride poisoning. *Hum Toxicol* 1988;7:191 [PMID: 3378808].

DISK-SHAPED BATTERIES

Small, flat, smooth disk-shaped batteries measure between 10 and 25 mm in diameter. About 69% of them pass through the GI tract in 48 hours and 85% in 72 hours. Some may become entrapped. These batteries contain caustic materials and heavy metals.

Batteries impacted in the esophagus may cause symptoms of refusal to take food, increased salivation, vomiting with or without blood, and pain or discomfort. Aspiration into the trachea may also occur. Fatalities have been reported in association with esophageal perforation.

When a history of disk battery ingestion is obtained, radiographs of the entire respiratory tract and GI tract should be taken so that the battery can be located and the proper therapy determined.

Treatment

If the disk battery is located in the esophagus, it must be removed immediately. If the battery has been in the esophagus for more than 24 hours, the risk of caustic burn is greater.

Location of the disk battery below the esophagus has been associated with tissue damage, but the course is benign in most cases. Perforated Meckel diverticulum has been the major complication. It may take as long as 7 days for spontaneous passage to occur, and lack of movement in the GI tract may not require removal in an asymptomatic patient. Some researchers have suggested repeated radiographs and surgical intervention if passage of the battery pauses, but this approach may be excessive. Batteries that have opened in the GI tract have been associated with some toxicity due to mercury, but the patients have recovered.

Emesis is ineffective. Asymptomatic patients may simply be observed and stools examined for passage of the battery. If the battery has not passed within 7 days or if the patient becomes symptomatic, radiographs should be repeated. If the battery has come apart or appears not to be moving, a purgative, enema, or nonabsorbable intestinal lavage solution should be administered. If these methods are unsuccessful, surgical intervention may be required. Levels of heavy metals (mainly mercury) should be measured in patients in whom the battery has opened or symptoms have developed.

Litovitz TL, Schmitz BF: Ingestion of cylindrical and button batteries: An analysis of 2382 cases. *Pediatrics* 1992;89:747 [PMID: 2304794].

GAMMA-HYDROXYBUTYRATE, GAMMA-BUTYROLACTONE, & BUTANEDIOL

Gamma-hydroxybutyrate (GHB), γ -butyrolactone (GBL), and butanediol have become popular drugs of abuse in adolescents and adults. GHB is a CNS depressant that is structurally similar to the inhibitory neurotransmitter γ -aminobutyric acid. GBL and butanediol are converted in the body to GHB. These drugs cause deep but short-lived coma; the coma often lasts only 1–4 hours. Treatment consists of supportive care with close attention to airway and endotracheal intubation if respiratory depression or decreased gag reflex complicates the poisoning. Atropine has been used successfully for symptomatic bradycardia.

Withdrawal from GHB, GBL, or butanediol can cause several days of extreme agitation, hallucination, or tachycardia. Treatment with high doses of benzodiazepines or with butyrophenones (eg, haloperidol or droperidol) or secobarbital may be needed for several days.

Dyer JE et al: Gamma-hydroxybutyrate withdrawal syndrome. *Ann Emerg Med* 2001;37:147 [PMID: 11174231].

Sporer KA et al: Gamma-hydroxybutyrate serum levels and clinical syndrome after severe overdose. *Ann Emerg Med* 2003;42:3 [PMID: 12827115].

HYDROCARBONS (Benzene, Charcoal Lighter Fluid, Gasoline, Kerosene, Petroleum Distillates, Turpentine)

Ingestion of hydrocarbons may cause irritation of mucous membranes, vomiting, blood-tinged diarrhea, respiratory distress, cyanosis, tachycardia, and fever. Although a small amount (10 mL) of certain hydrocarbons is potentially fatal, patients have survived ingestion of several ounces of other petroleum distillates. The more aromatic a hydrocarbon is and the lower its viscosity rating, the more potentially toxic it is. Benzene, gasoline, kerosene, and red seal oil furniture polish are the most dangerous. A dose exceeding 1 mL/kg is likely to cause CNS depression. A history of coughing or choking, as well as vomiting, suggests aspiration with resulting hydrocarbon pneumonia. This is an acute hemorrhagic necrotizing disease that usually develops within 24 hours of the ingestion and resolves without sequelae in 3–5 days. However, several weeks may be required for full resolution of a hydrocarbon pneumonia. Pneumonia may be caused by the aspira-

tion of a few drops of petroleum distillate into the lung or by absorption from the circulatory system. Pulmonary edema and hemorrhage, cardiac dilatation and dysrhythmias, hepatosplenomegaly, proteinuria, and hematuria can occur following large overdoses. Hypoglycemia is occasionally present. A chest radiograph may reveal pneumonia within hours after the ingestion. An abnormal urinalysis in a child with a previously normal urinary tract suggests a large overdose.

Treatment

Both emetics and lavage should be avoided when only a small amount has been ingested. Mineral oil should not be given, because it can cause a low-grade lipoid pneumonia.

Epinephrine should not be used with halogenated hydrocarbons because it may affect an already sensitized myocardium. The usefulness of corticosteroids is debated, and antibiotics should be reserved for patients with infections. Oxygen and mist are helpful. Extracorporeal membrane oxygenation has been successful in at least two cases of failure with standard therapy.

IBUPROFEN

Most exposures in children do not produce symptoms. In one study, for example, children ingesting up to 2.4 g remained asymptomatic. When symptoms occur, the most common are abdominal pain, vomiting, drowsiness, and lethargy. In rare cases, apnea (especially in young children), seizures, metabolic acidosis, and CNS depression leading to coma have occurred.

Treatment

If a child has ingested less than 100 mg/kg, dilution with water or milk may be all that is necessary to minimize the GI upset. In children, the volume of liquid used for dilution should be less than 4 oz. When the in-

gested amount is more than 400 mg/kg, seizures or CNS depression may occur; therefore, gastric lavage may be preferred to emesis. Activated charcoal may also be of value. There is no specific antidote. Neither alkalization of the urine nor hemodialysis is helpful.

INSECT STINGS (Bee, Wasp, & Hornet)

Insect stings are painful but not usually dangerous; however, death from anaphylaxis may occur. Bee venom has hemolytic, neurotoxic, and histamine-like activities that can on rare occasion cause hemoglobinuria and severe anaphylactoid reactions. Massive envenomation from numerous stings may cause hemolysis, rhabdomyolysis, and shock leading to multiple organ failure.

Treatment

The physician should remove the stinger, taking care not to squeeze the attached venom sac. For allergic reactions, epinephrine 1:1000 solution, 0.01 mL/kg, should be administered IV or SQ above the site of the sting. Three to four whiffs from an isoproterenol aerosol inhaler may be given at 3- to 4-minute intervals as needed. Corticosteroids (hydrocortisone), 100 mg IV, and diphenhydramine, 1.5 mg/kg IV, are useful ancillary drugs but have no immediate effect. Ephedrine or antihistamines may be used for 2 or 3 days to prevent recurrence of symptoms.

A patient who has had a potentially life-threatening insect sting should be desensitized against the Hymenoptera group, because the honey bee, wasp, hornet, and yellow jacket have common antigens in their venom. For the more usual stings, cold compresses, aspirin, and diphenhydramine 1 mg/kg PO, are sufficient.

INSECTICIDES

The petroleum distillates or other organic solvents used in these products are often as toxic as the insecticide itself. Decontamination may be performed by aspirating the stomach with a nasogastric tube.

1. Chlorinated Hydrocarbons (eg, Aldrin, Carbinol, Chlordane, DDT, Dieldrin, Endrin, Heptachlor, Lindane, Toxaphene)

Signs of intoxication include salivation, GI irritability, abdominal pain, vomiting, diarrhea, CNS depression, and convulsions. Inhalation exposure causes irritation of the eyes, nose, and throat; blurred vision; cough; and pulmonary edema.

Chlorinated hydrocarbons are absorbed through the skin, respiratory tract, and GI tract. Decontamination of skin with soap and evacuation of the stomach contents are critical. All contaminated clothing should be removed. Castor oil, milk, and other substances containing fats or oils should not be left in the stomach because they increase absorption of the chlorinated hydrocarbons. Convulsions should be treated with diazepam, 0.1–0.3 mg/kg IV. Epinephrine should not be used because it may cause cardiac arrhythmias.

2. Organophosphate (Cholinesterase-Inhibiting) Insecticides (eg, Chlorthion, Co-Ral, DFP, Diazinon, Malathion, Paraoxon, Parathion, Phosdrin, TEPP, Thio-TEPP)

Dizziness, headache, blurred vision, miosis, tearing, salivation, nausea, vomiting, diarrhea, hyperglycemia, cyanosis, sense of constriction of the chest, dyspnea, sweating, weakness, muscular twitching, convulsions, loss of reflexes and sphincter control, and coma can occur.

The clinical findings are the result of cholinesterase inhibition, which causes an accumulation of acetylcholine. The onset of symptoms occurs within 12 hours of the exposure. Red cell cholinesterase levels should be measured as soon as possible. (Some normal individuals have a low serum cholinesterase level.) Normal values vary in different laboratories. In general, a decrease of red cell cholinesterase to below 25% of normal indicates significant exposure.

Repeated low-grade exposure may result in sudden, acute toxic reactions. This syndrome usually occurs after repeated household spraying rather than agricultural exposure.

Although all organophosphates act by inhibiting cholinesterase activity, they vary greatly in their toxicity. Parathion, for example, is 100 times more toxic than malathion. The toxicity is influenced by the specific compound, the type of formulation (liquid or solid), the vehicle, and the route of absorption (lungs, skin, or GI tract).

Treatment

Decontamination of skin, nails, hair, and clothing with soapy water is extremely important. Atropine plus a cholinesterase reactivator, pralidoxime, is an antidote for organophosphate insecticide poisoning. After assessment and management of the ABCs, atropine should be given and repeated every few minutes until airway secretions diminish. An appropriate starting dose of atropine is 2–4 mg IV in an adult and 0.05 mg/kg in a child. The patient should receive enough atropine to stop secretions (mydriasis in not an appropriate stopping point). Severe poisoning may require gram quantities of atropine administered over 24 hours.

Because atropine antagonizes the muscarinic parasympathetic effects of the organophosphates but does not affect the nicotinic receptor, it does not improve muscular weakness. Pralidoxime should also be given immediately in more severe cases and repeated every 6–12 hours as needed (25–50 mg/kg diluted to 5% and infused over 5–30 minutes at a rate of no more than 500 mg/min). Pralidoxime should be used in addition to—not in place of—atropine if red cell cholinesterase is less than 25% of normal. Pralidoxime is most useful within 48 hours after the exposure but has shown some effects 2–6 days later. Morphine, theophylline, aminophylline, succinylcholine, and tranquilizers of the reserpine and phenothiazine types are contraindicated. Hyperglycemia is common in severe poisonings.

Eisenstein EM, Amitai Y: Index of suspicion: Case 1. Organophosphate intoxication. *Pediatr Rev* 2000;21:205 [PMID: 10854316].

Lifshitz M et al: Carbamate and organophosphate; poisoning in young children. *Pediatr Emerg Care* 1999;15:102 [PMID: 10220078].

3. Carbamates (eg, Carbaryl, Sevin, Zectran)

Carbamate insecticides are reversible inhibitors of cholinesterase. The signs and symptoms of intoxication are similar to those associated with organophosphate poisoning but are generally less severe. Atropine titrated to effect is sufficient treatment. Pralidoxime should not be used with carbaryl poisoning but is of value with

other carbamates. In combined exposures to organophosphates, give atropine but reserve pralidoxime for cases in which the red cell cholinesterase is depressed below 25% of normal or marked effects of nicotinic receptor stimulation are present.

4. Botanical Insecticides (eg, Black Flag Bug Killer, Black Leaf CPR Insect Killer, Flit Aerosol House & Garden Insect Killer, French's Flea Powder, Raid)

Allergic reactions, asthma-like symptoms, coma, and convulsions have been reported. Pyrethrins, allethrin, and rotenone do not commonly cause signs of toxicity. Antihistamines, short-acting barbiturates, and atropine are helpful as symptomatic treatment.

IRON

Five stages of intoxication may occur in iron poisoning: (1) Hemorrhagic gastroenteritis, which occurs 30–60 minutes after ingestion and may be associated with shock, acidosis, coagulation defects, and coma. This phase usually lasts 4–6 hours. (2) Phase of improvement, lasting 2–12 hours, during which patient looks better. (3) Delayed shock, which may occur 12–48 hours after ingestion. Metabolic acidosis, fever, leukocytosis, and coma may also be present. (4) Liver damage with hepatic failure. (5) Residual pyloric stenosis, which may develop about 4 weeks after the ingestion.

Once iron is absorbed from the GI tract, it is not normally eliminated in feces but may be partially excreted in the urine, giving it a red color prior to chelation. A reddish discoloration of the urine suggests a serum iron level greater than 350 mg/dL.

Treatment

GI decontamination is based on clinical assessment. Syrup of ipecac may be administered at home, with appropriate follow-up, provided the history does not warrant an emergency department visit. The patient should be referred to a health care facility if symptomatic or if the history indicates toxic amounts. Gastric lavage and whole bowel irrigation should be considered in these patients.

Shock is treated in the usual manner. Sodium bicarbonate and Fleet Phospho-Soda left in the stomach to form the insoluble phosphate or carbonate have not shown clinical benefit and have caused lethal hypernatremia or hyperphosphatemia. Deferoxamine, a specific chelating agent for iron, is a useful adjunct in the treatment of severe iron poisoning. It forms a soluble complex that is excreted in the urine. It is contraindicated

in patients with renal failure unless dialysis can be used. Institute IV deferoxamine chelation therapy if the patient is symptomatic and a serum iron determination cannot be obtained readily, or if the peak serum iron exceeds 400 µg/dL (62.6 µmol/L) at 4–5 hours after ingestion.

Deferoxamine should not be delayed until serum iron levels are available in serious cases of poisoning. IV administration is indicated if the patient is in shock, in which case it should be given at a dosage of 15 mg/kg/h. Infusion rates up to 35 mg/kg/h have been used in life-threatening poisonings. Rapid IV administration can cause hypotension, facial flushing, urticaria, tachycardia, and shock. Deferoxamine, 90 mg/kg IM every 8 hours (maximum, 1 g), may be given if IV access cannot be established, but the procedure is painful. The indications for discontinuation of deferoxamine have not been clearly delineated. Generally, it can be stopped after 12–24 hours if the acidosis has resolved and the patient is improving.

Hemodialysis, peritoneal dialysis, or exchange transfusion can be used to increase the excretion of the dialyzable complex. Urine output should be monitored and urine sediment examined for evidence of renal tubular damage. Initial laboratory studies should include blood typing and cross-matching; total protein; serum iron, sodium, potassium, and chloride; PCO₂; pH; and liver function tests. Serum iron levels fall rapidly even if deferoxamine is not given.

After the acute episode, liver function studies and an upper GI series are indicated to rule out residual damage.

LEAD

Lead poisoning (plumbism) causes vague symptoms, including weakness, irritability, weight loss, vomiting, personality changes, ataxia, constipation, headache, and colicky abdominal pain. Late manifestations consist of retarded development, convulsions, and coma associated with increased intracranial pressure, which is a medical emergency.

Plumbism usually occurs insidiously in children younger than age 5 years. The most likely sources of lead include flaking leaded paint, artist's paints, fruit tree sprays, solder, brass alloys, home-glazed pottery,

and fumes from burning batteries. Only paint containing less than 1% lead is safe for interior use (eg, furniture, toys). Repetitive ingestions of small amounts of lead are far more serious than a single massive exposure. Toxic effects are likely to occur if more than 0.5 mg of lead per day is absorbed.

Blood lead levels are used to assess the severity of exposure. A complete blood count and serum ferritin concentration should be obtained; iron deficiency increases absorption of lead. Glycosuria, proteinuria, hematuria, and aminoaciduria occur frequently. Blood lead levels usually exceed 80 µg/dL in symptomatic patients. Abnormal blood lead levels should be repeated in asymptomatic patients to rule out laboratory error. Specimens must be meticulously obtained in acid-washed containers. A normocytic, slightly hypochromic anemia with basophilic stippling of the red cells and reticulocytosis may be present in plumbism. Stippling of red blood cells is absent in cases involving only recent ingestion.

The CSF protein is elevated, and the white cell count is usually less than 100 cells/mL. CSF pressure may be elevated in patients with encephalopathy; lumbar punctures must be performed cautiously to prevent herniation.

Treatment

Standard GI decontamination is indicated if an acute ingestion has occurred or lead is noted on the abdominal radiograph. Succimer is an orally administered chelator approved for use in children and reported to be as efficacious as calcium edetate. Treatment for blood lead levels of 20–45 µg/dL in children has not been determined. Succimer should be initiated at blood lead levels over 45 µg/dL. The initial dose is 10 mg/kg (350 mg/m²) every 8 hours for 5 days. The same dose is then given every 12 hours for 14 days. At least 2 weeks should elapse between courses. Blood lead levels increase somewhat (ie, rebound) after discontinuation of therapy. Courses of dimercaprol (4 mg/kg/dose) and calcium edetate may still be used but are no longer the preferred method, except in cases of lead encephalopathy.

Anticonvulsants may be needed. Mannitol or corticosteroids and volume restriction are indicated in patients with encephalopathy. A high-calcium, high-phosphorus diet and large doses of vitamin D may remove lead from the blood by depositing it in the bones. A public health team should evaluate the source of the lead. Necessary corrections should be completed before the child is returned home.

MUSHROOMS

Toxic mushrooms are often difficult to distinguish from edible varieties. Contact a poison center to obtain identification assistance. Symptoms vary with the species ingested, time of year, stage of maturity, quantity eaten, method of preparation, and interval since ingestion. A mushroom that is toxic to one individual may not be toxic to another. Drinking alcohol and eating certain mushrooms may cause a reaction similar to that seen with disulfiram and alcohol. Cooking destroys some toxins but not the deadly one produced by *Amanita phalloides*, which is responsible for 90% of deaths due to mushroom poisoning. Mushroom toxins are absorbed relatively slowly. Onset of symptoms within 2 hours of ingestion suggests muscarinic toxin, whereas a delay of symptoms for 6–48 hours after ingestion strongly suggests *Amanita* (amanitin) poisoning. Patients who have ingested *A phalloides* may relapse and die of hepatic or renal failure following initial improvement.

Mushroom poisoning may produce muscarinic symptoms (salivation, vomiting, diarrhea, cramping abdominal pain, tenesmus, miosis, and dyspnea), coma, convulsions, hallucinations, hemolysis, and delayed hepatic and renal failure.

Treatment

Induce vomiting and follow with activated charcoal. If the patient has muscarinic signs, give atropine, 0.05 mg/kg IM (0.02 mg/kg in toddlers), and repeat as needed (usually every 30 minutes) to keep the patient atropinized. Atropine, however, is used only when cholinergic effects are present and not for all mushrooms. Hypoglycemia is most likely to occur in patients with delayed onset of symptoms. Try to identify the mushroom if the patient is symptomatic. Consultation with a certified poison center is recommended. Local botanical gardens, university departments of botany, and societies of mycologists may be able to help. Supportive care is usually all that is needed; however, in the case of *A phalloides*, penicillin, silibinin, or hemodialysis may be indicated.

NITRITES, NITRATES, ANILINE, PENTACHLOROPHENOL, & DINITROPHENOL

Nausea, vertigo, vomiting, cyanosis (methemoglobinemia), cramping abdominal pain, tachycardia, cardiovascular collapse, tachypnea, coma, shock, convulsions, and death are possible manifestations of nitrite or nitrate poisoning.

Nitrite and nitrate compounds found in the home include amyl nitrite, butyl nitrates, isobutyl nitrates, nitroglycerin, pentaerythritol tetranitrate, sodium nitrite, nitrobenzene, and phenazopyridine. Pentachlorophenol and dinitrophenol, which are found in wood preservatives, produce methemoglobinemia and high fever because of uncoupling of oxidative phosphorylation. Headache, dizziness, and bradycardia have been reported. High concentrations of nitrites in well water or spinach have been the most common cause of nitrite-induced methemoglobinemia. Symptoms do not usually occur until 15–50% of the hemoglobin has been converted to methemoglobin. A rapid test is to compare a drop of normal blood with the patient's blood on a dry filter paper. Brown discoloration of the patient's blood indicates a methemoglobin level of more than 15%.

Treatment

Induce vomiting and administer activated charcoal. Decontaminate affected skin with soap and water. Oxygen and artificial respiration may be needed. If the blood methemoglobin level exceeds 30%, or if levels cannot be obtained and the patient is symptomatic, give a 1% solution of methylene blue, 0.2 mL/kg IV over 5–10 minutes. Avoid perivascular infiltration, because it causes necrosis of the skin and subcutaneous tissues. A dramatic change in the degree of cyanosis should occur. Transfusion is occasionally necessary. Epinephrine and other vasoconstrictors are contraindicated. If reflex bradycardia occurs, atropine should be used.

Kennedy N et al: Faulty sausage production causing methaemoglobinemia. *Arch Dis Child* 1997;76:367 [PMID: 9166036].

OPIOIDS (Codeine, Heroin, Methadone, Morphine, Propoxyphene)

Opioid-related medical problems may include drug addiction, withdrawal in a newborn infant, and accidental overdoses. Unlike other narcotics, methadone is absorbed readily from the GI tract. Most opioids, including heroin, methadone, meperidine, morphine, and codeine, are excreted in the urine within 24 hours and can be detected readily.

Narcotic-addicted adolescents often have other medical problems, including cellulitis, abscesses, thrombophlebitis, tetanus, infective endocarditis, HIV infection, tuberculosis, hepatitis, malaria, foreign body emboli, thrombosis of pulmonary arterioles, diabetes mellitus, obstetric complications, nephropathy, and peptic ulcer.

Treatment of Overdosage

Opioids can cause respiratory depression, stridor, coma, increased oropharyngeal secretions, sinus bradycardia, and urinary retention. Pulmonary edema rarely occurs in children; deaths usually result from aspiration of gastric contents, respiratory arrest, and cerebral edema. Convulsions may occur with propoxyphene overdosage.

Although suggested doses for naloxone hydrochloride range from 0.01 to 0.1 mg/kg, it is generally unnecessary to calculate the dosage on this basis. This extremely safe antidote should be given in sufficient quantity to reverse opioid binding sites. For children under age 1 year, 1 ampoule (0.4 mg) should be given initially; if there is no response, five more ampoules (2 mg) should be given rapidly. Older children should be given 0.4–0.8 mg, followed by 2–4 mg if there is no response. An improvement in respiratory status may be followed by respiratory depression, because the antagonist's duration of action is less than 1 hour. Neonates poisoned in utero may require 10–30 mg/kg to reverse the effect.

Withdrawal in the Addict

Diazepam, 10 mg every 6 hours PO, has been recommended for the treatment of mild narcotic withdrawal in ambulatory adolescents. Management of withdrawal in the confirmed addict may be accomplished with the administration of clonidine, by substitution with methadone, or with reintroduction of the original addicting agent, if available through a supervised drug withdrawal program. A tapered course over 3 weeks will accomplish this goal. Death rarely, if ever, occurs. The abrupt discontinuation of narcotics (cold turkey

method) is not recommended and may cause severe physical withdrawal signs.

Withdrawal in the Newborn

A newborn infant in opioid withdrawal is usually small for gestational age and demonstrates yawning, sneezing, decreased Moro reflex, hunger but uncoordinated sucking action, jitteriness, tremor, constant movement, a shrill protracted cry, increased tendon reflexes, convulsions, vomiting, fever, watery diarrhea, cyanosis, dehydration, vasomotor instability, seizure, and collapse. The onset of symptoms commonly begins in the first 48 hours but may be delayed as long as 8 days depending on the timing of the mother's last fix and her pre-delivery medication. The diagnosis can be confirmed easily by identifying the narcotic in the urine of the mother and the baby.

Several treatment methods have been suggested for narcotic withdrawal in the newborn. Phenobarbital, 8 mg/kg/d IM or PO in four doses for 4 days and then reduced by one third every 2 days as signs decrease, may be continued for as long as 3 weeks. Methadone may be necessary in those infants with congenital methadone addiction who are not controlled in their withdrawal by large doses of phenobarbital. Dosage should be 0.5 mg/kg/d in two divided doses but can be increased gradually as needed. After control of the symptoms is achieved, the dose may be tapered over 4 weeks.

It is unclear whether prophylactic treatment with these drugs decreases the complication rate. The mortality rate of untreated narcotic withdrawal in the newborn may be as high as 45%.

PHENOTHIAZINES (Chlorpromazine, Prochlorperazine, Trifluoperazine)

Clinical Presentations

A. EXTRAPYRAMIDAL CRISIS

Episodes characterized by torticollis, stiffening of the body, spasticity, poor speech, catatonia, and inability to communicate although conscious are typical manifestations. These episodes usually last a few seconds to a few minutes but have rarely caused death. Extrapyramidal crises may represent idiosyncratic reactions and are aggravated by dehydration. The signs and symptoms occur most often in children who have received

prochlorperazine. They are commonly mistaken for psychotic episodes.

B. OVERDOSE

Lethargy and deep prolonged coma commonly occur. Promazine, chlorpromazine, and prochlorperazine are the drugs most likely to cause respiratory depression and precipitous drops in blood pressure. Occasionally, paradoxical hyperactivity and extrapyramidal signs as well as hyperglycemia and acetonemia are present. Seizures are uncommon.

C. NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome is a rare idiosyncratic complication of phenothiazine use that may be lethal. It is a syndrome involving mental status change (confusion, coma), motor abnormalities (lead pipe rigidity, clonus), and autonomic dysfunction (tachycardia, hyperpyrexia).

Treatment

Extrapyramidal signs are alleviated within minutes by the slow IV administration of diphenhydramine, 1–2 mg/kg (maximum, 50 mg), or benztropine mesylate, 1–2 mg IV (1 mg/min). No other treatment is usually indicated.

Patients with overdoses should receive conservative supportive care. Activated charcoal should be administered. Hypotension may be treated with standard agents, starting with isotonic saline administration. Agitation is best treated with diazepam. Neuroleptic malignant syndrome is treated by discontinuing the drug, giving aggressive supportive care, and administering dantrolene or bromocriptine.

PLANTS

Many common ornamental, garden, and wild plants are potentially toxic. Only in a few cases will small amounts of a plant cause severe illness or death. Table 12–3 lists the most toxic plants, symptoms and signs of poisoning, and treatment. Contact your poison center for assistance with identification.

Table 12–3. Poisoning due to plants.^a

	Symptoms and Signs	Treatment
Arum family: <i>Caladium</i> , <i>Dieffenbachia</i> , calla lily, dumb-cane (oxalic acid)	Burning of mucous membranes and airway obstruction secondary to edema caused by calcium oxalate crystals.	Accessible areas should be thoroughly washed. Corticosteroids relieve airway obstruction. Apply cold packs to affected mucous membranes.
Castor bean plant (ricin—a toxalbumin) Jequinty bean (abrin—a toxalbumin)	Mucous membrane irritation, nausea, vomiting, bloody diarrhea, blurred vision, circulatory collapse, acute hemolytic anemia, convulsions, uremia.	Fluid and electrolyte monitoring. Saline cathartic. Forced alkaline diuresis will prevent complications due to hemagglutination and hemolysis.
Foxglove, lily of the valley, and oleander ^b	Nausea, diarrhea, visual disturbances, and cardiac irregularities (eg, heart block).	See treatment for digitalis drugs in text.
Jimsonweed: See Belladonna Alkaloids section in text	Mydriasis, dry mouth, tachycardia, and hallucinations.	Activated charcoal.
Larkspur (ajacine, <i>Delphinium</i> , delphinine)	Nausea and vomiting, irritability, muscular paralysis, and central nervous system depression.	Symptomatic. Atropine may be helpful.
Monkshood (aconite)	Numbness of mucous membranes, visual disturbances, tingling, dizziness, tinnitus, hypotension, bradycardia, and convulsions.	Activated charcoal, oxygen. Atropine is probably helpful.
Poison hemlock (coniine)	Mydriasis, trembling, dizziness, bradycardia. Central nervous system depression, muscular paralysis, and convulsions. Death is due to respiratory paralysis.	Symptomatic. Oxygen and cardiac monitoring equipment are desirable. Assisted respiration is often necessary. Give anticonvulsants if needed.
<i>Rhododendron</i> (grayanotoxin)	Abdominal cramps, vomiting, severe diarrhea, muscular paralysis. Central nervous system and circulatory depression. Hypertension with very large doses.	Atropine can prevent bradycardia. Epinephrine is contraindicated. Antihypertensives may be needed.
Yellow jessamine (active ingredient, geisemine, is related to strychnine)	Restlessness, convulsions, muscular paralysis, and respiratory depression.	Symptomatic. Because of the relation to strychnine, activated charcoal and diazepam for seizures are worth trying.

^aMany other plants cause minor irritation but are not likely to cause serious problems unless large amounts are ingested. See Lampe KF, McCann MA: *AMA Handbook of Poisonous and Injurious Plants*. PSYCHOTROPIC DRUGS

Psychotropic drugs consist of four general classes: stimulants (amphetamines, cocaine), depressants (eg, narcotics, barbiturates), antidepressants and tranquilizers, and hallucinogens (eg, LSD, PCP).

Clinical Presentations

The following clinical findings are commonly seen in patients abusing drugs. See also other entries discussed in alphabetic order in this chapter.

A. STIMULANTS

Agitation, euphoria, grandiose feelings, tachycardia, fever, abdominal cramps, visual and auditory hallucinations, mydriasis, coma, convulsions, and respiratory depression.

B. DEPRESSANTS

Emotional lability, ataxia, diplopia, nystagmus, vertigo, poor accommodation, respiratory depression, coma, apnea, and convulsions. Dilatation of conjunctival blood vessels suggests marijuana ingestion. Narcotics cause miotic pupils and, occasionally, pulmonary edema.

C. ANTIDEPRESSANTS AND TRANQUILIZERS

Hypotension, lethargy, respiratory depression, coma, and extrapyramidal reactions.

D. HALLUCINOGENS AND PSYCHOACTIVE DRUGS

Belladonna alkaloids cause mydriasis, dry mouth, nausea, vomiting, urinary retention, confusion, disorientation, paranoid delusions, hallucinations, fever, hypotension, aggressive behavior, convulsions, and coma. Psychoactive drugs such as LSD cause mydriasis, unexplained bizarre behavior, hallucinations, and generalized undifferentiated psychotic behavior.

Management of the Patient Who Abuses Drugs

Only a small percentage of the persons using drugs come to the attention of physicians; those who do are usually experiencing adverse reactions such as panic states, drug psychoses, homicidal or suicidal thoughts, or respiratory depression.

Even with cooperative patients, an accurate history is difficult to obtain. A drug history is most easily obtained in a quiet spot by a gentle, nonthreatening, honest examiner, and without the parents present. The user often does not really know what drug has been taken or how much. Street drugs are almost always adulterated with one or more other compounds. Multiple drugs are often taken together. Friends may be a useful source of information.

The patient's general appearance, skin, lymphatics, cardiorespiratory status, GI tract, and CNS should be focused on during the physical examination, because they often provide clues suggesting drug abuse.

Hallucinogens are not life-threatening unless the patient is frankly homicidal or suicidal. A specific diagnosis is usually not necessary for management; instead, the presenting signs and symptoms are treated. Does the patient appear intoxicated? In withdrawal? "Flashing back?" Is some illness or injury (eg, head trauma) being masked by a drug effect? (Remember that a known drug user may still have hallucinations from meningencephalitis.)

The signs and symptoms in a given patient are a function not only of the drug and the dose but also of the level of acquired tolerance, the "setting," the patient's physical condition and personality traits, the potentiating effects of other drugs, and many other factors.

A common drug problem is the "bad trip," which is usually a panic reaction. This is best managed by "talking the patient down" and minimizing auditory and visual stimuli. Allowing the patient to sit with a friend while the drug effect dissipates may be the best treatment. This may take several hours. The physician's job

is not to terminate the drug effect but to help the patient through the bad experience.

Drug therapy is often unnecessary and may complicate the clinical course of a drug-related panic reaction. Although phenothiazines have been commonly used to treat bad trips, they should be avoided if the specific drug is unknown, because they may enhance toxicity or produce unwanted side effects. Diazepam is the drug of choice if a sedative effect is required. Physical restraints are rarely indicated and usually increase the patient's panic reaction.

For treatment of life-threatening drug abuse, consult the section on the specific drug elsewhere in this chapter and the section on general management at the beginning of the chapter.

After the acute episode, the physician must decide whether psychiatric referral is indicated; in general, patients who have made suicidal gestures or attempts and adolescents who are not communicating with their families should be referred.

SALICYLATES

The use of childproof containers and publicity regarding accidental poisoning have reduced the incidence of acute salicylate poisoning. Nevertheless, serious intoxication still occurs and must be regarded as an emergency. In recent years, the frequency of poisoning has begun to rise again.

Salicylates uncouple oxidative phosphorylation, leading to increased heat production, excessive sweating, and dehydration. They also interfere with glucose metabolism and may cause hypoglycemia or hyperglycemia. Respiratory center stimulation occurs early.

Patients usually have signs of hyperventilation, sweating, dehydration, and fever. Vomiting and diarrhea sometimes occur. In severe cases, disorientation, convulsions, and coma may develop.

The severity of acute intoxication can in some measure be judged by serum salicylate levels. High levels are always dangerous irrespective of clinical signs, and low levels may be misleading in chronic cases. Other laboratory values usually indicate metabolic acidosis despite hyperventilation, low serum K^+ values, and often abnormal serum glucose levels.

In mild and moderate poisoning, stimulation of the respiratory center produces respiratory alkalosis. In severe intoxication (occurring in severe acute ingestion with high salicylate levels and in chronic toxicity with

lower levels), respiratory response is unable to overcome the metabolic overdose.

Once the urine becomes acidic, progressively smaller amounts of salicylate are excreted. Until this process is reversed, the half-life will remain prolonged, because metabolism contributes little to the removal of salicylate.

Chronic severe poisoning may occur as early as 3 days after a regimen of salicylate is begun. Findings usually include vomiting, diarrhea, and dehydration.

Treatment

Charcoal binds salicylates well, and, after emesis or lavage, it should be given for acute ingestions. Mild poisoning may require only the administration of oral fluids and confirmation that the salicylate level is falling. Moderate poisoning involves moderate dehydration and depletion of potassium. Fluids must be administered at a rate of 2–3 mL/kg/h to correct dehydration and produce urine with a pH of greater than 7.0. Initial IV solutions should be isotonic, with sodium bicarbonate constituting half the electrolyte content. Once the patient is rehydrated, the solution can contain more free water and approximately 40 mEq of K⁺ per liter.

Severe toxicity is marked by major dehydration. Symptoms may be confused with those of Reye syndrome, encephalopathy, and metabolic acidosis. Salicylate levels may even be in the therapeutic range. Major fluid correction of dehydration is required. Once this has been accomplished, hypokalemia must be corrected and sodium bicarbonate given. Usual requirements are sodium bicarbonate, 1–2 mEq/kg/h over the first 6–8 hours, and K⁺, 20–40 mEq/L. A urine flow of 2–3 mL/kg/h should be established. Despite this treatment some patients will develop the paradoxical aciduria of salicylism. This is due to hypokalemia and the saving of K⁺ and excretion of H⁺ in the renal tubule. Correction of K⁺ will allow the urine to become alkaline and ionize the salicylate, resulting in excretion rather than reabsorption of nonionized salicylate in acid urine.

Renal failure or pulmonary edema is an indication for dialysis. Hemodialysis is most effective, and peritoneal dialysis relatively ineffective. Hemodialysis should be used in all patients with altered mental status or deteriorating clinical status. Acetazolamide should not be used.

SCORPION STINGS

Scorpion stings are common in arid areas of the southwestern United States. Scorpion venom is more toxic than most snake venoms, but only minute amounts are injected. Although neurologic manifestations may last a week, most clinical signs subside within 24–48 hours.

The most common scorpions in the United States are *Vejovis*, *Hadrurus*, *Androctonus*, and *Centruroides* species. Stings by the first three produce edema and pain. Stings by *Centruroides* (the Bark scorpion) cause tingling or burning paresthesias that begin at the site of the sting; other findings include hypersalivation, restlessness, muscular fasciculation, abdominal cramps, opisthotonos, convulsions, urinary incontinence, and respiratory failure.

Treatment

Sedation is the primary therapy. Antivenom is reserved for severe poisoning. In severe cases, the airway may become compromised by secretions and weakness of respiratory muscles. Endotracheal intubation may be required. Patients may require treatment for seizures, hypertension, or tachycardia.

The prognosis is good as long as the patient's airway is managed appropriately.

SNAKEBITE

Despite the lethal potential of venomous snakes, human morbidity and mortality rates are surprisingly low. The outcome depends on the size of the child, the site of the bite, the degree of envenomation, the type of snake, and the effectiveness of treatment.

Nearly all poisonous snakebites in the United States are caused by pit vipers (rattlesnakes, water moccasins, and copperheads). A few are caused by elapids (coral snakes), and occasional bites occur from cobras and other nonindigenous exotic snakes kept as pets. Snake venom is a complex mixture of enzymes, peptides, and proteins that may have predominantly cytotoxic, neurotoxic, hemotoxic, or cardiotoxic effects but other effects as well. Up to 25% of bites by pit vipers do not result in venom injection. Pit viper venom causes predominantly local injury with pain, discoloration, edema, and hemorrhage.

Swelling and pain occur soon after rattlesnake bite and are a certain indication that envenomation has oc-

curred. During the first few hours, swelling and ecchymosis extend proximally from the bite. The bite is often obvious as a double puncture mark surrounded by ecchymosis. Hematemesis, melena, hemoptysis, and other manifestations of coagulopathy develop in severe cases. Respiratory difficulty and shock are the ultimate causes of death. Even in fatal rattlesnake bite, a period of 6–8 hours usually elapses between the bite and death; as a result, there is usually enough time to start effective treatment.

Coral snake envenomation causes little local pain, swelling, or necrosis; and systemic reactions are often delayed. The signs of coral snake envenomation include bulbar paralysis, dysphagia, and dysphoria; these signs may appear in 5–10 hours and may be followed by total peripheral paralysis and death in 24 hours.

Treatment

Children in snake-infested areas should wear boots and long trousers, should not walk barefoot, and should be cautioned not to explore under ledges or in holes.

A. EMERGENCY (FIRST AID) TREATMENT

The most important first aid measure is transportation to a medical facility. Splint the affected extremity and minimize the patient's motion. Tourniquets and ice packs are contraindicated. Incision and suction are not useful for either crotalid or elapid snake bite.

B. DEFINITIVE MEDICAL MANAGEMENT

Blood should be drawn for hematocrit, clotting time and platelet function, and serum electrolyte determinations. Establish two secure IV sites for the administration of antivenom and other medications.

Specific antivenom is indicated when signs of progressive envenomation are present. Two antivenoms are available for treating pit viper envenomation: polyvalent pit viper antivenom and polyvalent Crotalidae Fab (CroFab). Both are effective, but their indications differ. For coral snake bites, an eastern coral snake antivenom (Wyeth Laboratories) is available. Patients with pit viper bites should receive antivenom if progressive local injury, coagulopathy, or systemic signs (eg, hypotension, confusion) are present. (Antivenom should not be given IM or SQ.) See package labeling or call your certified poison center for details of use. Hemorrhage, pain, and shock diminish rapidly with adequate amounts of antivenom. For coral snake bites, give three to five vials of antivenom in 250–500 mL of isotonic saline solution. An additional three to five vials may be required.

To control pain, administer a narcotic analgesic, such as meperidine, 0.6–1.5 mg/kg/dose, given PO or IM. Cryotherapy is contraindicated because it com-

monly causes additional tissue damage. Early physiotherapy minimizes contractures. In rare cases, fasciotomy to relieve pressure within muscular compartments is required. The evaluation of function and of pulses will better predict the need for fasciotomy. Antihistamines and corticosteroids (hydrocortisone, 1 mg/kg, given PO for a week) are useful in the treatment of serum sickness or anaphylactic shock. Antibiotics are not needed unless clinical signs of infection occur. Tetanus status should be evaluated and the patient immunized, if needed.

SOAPS & DETERGENTS

1. Soaps

Soap is made from salts of fatty acids. Some toilet soap bars contain both soap and detergent. Ingestion of soap bars may cause vomiting and diarrhea, but they have a low toxicity. Induced emesis is unnecessary.

2. Detergents

Detergents are nonsoap synthetic products used for cleaning purposes because of their surfactant properties. Commercial products include granules, powders, and liquids. Dishwasher detergents are very alkaline and can cause caustic burns. Low concentrations of bleaching and antibacterial agents as well as enzymes are found in many preparations. The pure compounds are moderately toxic, but the concentration used is too small to alter the product's toxicity significantly, although occasional primary or allergic irritative phenomena have been noted in persons who frequently use such products and in employees manufacturing these products.

Cationic Detergents (Ceepryn, Diaperene, Phemerol, Zephiran)

Cationic detergents in dilute solutions (0.5%) cause mucosal irritation, but higher concentrations (10–15%) may cause caustic burns to mucosa. Clinical effects include nausea, vomiting, collapse, coma, and convulsions. As little as 2.25 g of some cationic agents have caused death in an adult. In four cases, 100–400 mg/kg of benzalkonium chloride caused death. Cationic detergents are rapidly inactivated by tissues and ordinary soap.

Because of the caustic potential and rapid onset of seizures, emesis is not recommended. Activated char-

coal should be administered. Anticonvulsants may be needed.

Anionic Detergents

Most common household detergents are anionic. Laundry compounds have water softener (sodium phosphate) added, which is a strong irritant and may reduce ionized calcium. Anionic detergents irritate the skin by removing natural oils. Although ingestion causes diarrhea, intestinal distention, and vomiting, no fatalities have been reported.

The only treatment usually required is to discontinue use if skin irritation occurs and replace fluids and electrolytes. Induced vomiting is not indicated following ingestion of electric dishwasher detergent, because of its alkalinity. Dilute with water or milk.

Nonionic Detergents (Brij Products; Tritons X-45, X-100, X-102, & X-144)

These compounds include lauryl, stearyl, and oleyl alcohols and octyl phenol. They have a minimal irritating effect on the skin and are almost nontoxic when swallowed.

SPIDER BITES

Most medically important bites in the United States are caused by the black widow spider (*Latrodectus mactans*) and the North American brown recluse (violin) spider (*Loxosceles reclusa*). Positive identification of the spider is helpful, because many spider bites may mimic those of the brown recluse spider.

Black Widow Spider

The black widow spider is endemic to nearly all areas of the United States. The initial bite causes sharp fleeting pain. Local and systemic muscular cramping, abdominal pain, nausea and vomiting, and shock can occur. Convulsions occur more commonly in small children than in older children. Systemic signs of black widow spider bite may be confused with other causes of acute abdomen. Although paresthesias, nervousness, and transient muscle spasms may persist for weeks in sur-

vivors, recovery from the acute phase is generally complete within 3 days. In contrast to popular opinion, death is extremely rare.

Most authors recommend calcium gluconate as initial therapy (50 mg/kg IV per dose, up to 250 mg/kg/24 h), although it is often not effective and the effects are of short duration. Methocarbamol (15 mg/kg PO) or diazepam titrated to effect is useful. Morphine or barbiturates may occasionally be needed for control of pain or restlessness, but they increase the possibility of respiratory depression. Antivenom is available but should be reserved for severe cases in which the above therapies have failed. Local treatment of the bite is not helpful.

Brown Recluse Spider (Violin Spider)

The North American brown recluse spider is most commonly seen in the central and Midwestern areas of the United States. Its bite characteristically produces a localized reaction with progressively severe pain within 24 hours. The initial bleb on an erythematous ischemic base is replaced by a black eschar within 1 week. This eschar separates in 2–5 weeks, leaving an ulcer that heals slowly. Systemic signs include cyanosis, morbilliform rash, fever, chills, malaise, weakness, nausea and vomiting, joint pains, hemolytic reactions with hemoglobinuria, jaundice, and delirium. Fatalities are rare. Fatal disseminated intravascular coagulation has been reported.

Although of unproved efficacy, the following therapies have been used: dexamethasone, 4 mg IV four times a day, during the acute phase; polymorphonuclear leukocyte inhibitors, such as dapsone or colchicine, and oxygen applied to the bite site; and total excision of the lesion to the fascial level.

Sams HH et al: Nineteen documented cases of *Loxosceles reclusa* envenomation. *J Am Acad Dermatol* 2001;44:603 [PMID: 11260528].

THYROID PREPARATIONS (Thyroid Desiccated, Sodium Levothyroxine)

Ingestion of the equivalent of 50–150 g of desiccated thyroid can cause signs of hyperthyroidism, including irritability, mydriasis, hyperpyrexia, tachycardia, and diarrhea. Maximal clinical effect occurs about 9 days after ingestion—several days after the protein-bound iodine level has fallen dramatically.

Induce vomiting. If the patient develops clinical signs of toxicity, propranolol, 0.01–0.1 mg/kg (maximum, 1 mg), is useful because of its antiadrenergic activity.

Golightly LK et al: Clinical effects of accidental levothyroxine ingestion in children. *Am J Dis Child* 1987;141:1025 [PMID: 2887106].

TOXIC ALCOHOLS

Ethylene glycol and methanol are the toxic alcohols. The primary source of ethylene glycol is antifreeze, while methanol is present in windshield wiper fluid and also as an ethanol denaturant. Ethylene glycol causes severe metabolic acidosis and renal failure. Methanol causes metabolic acidosis and blindness. Onset of symptoms with both agents occurs within several hours after ingestion, longer if ethanol was ingested simultaneously.

Treatment

The primary treatment is to block the enzyme alcohol dehydrogenase which converts both agents to their toxic metabolites. This is accomplished with fomepizole (loading dose of 15 mg/kg) or ethanol. Fomepizole is preferred for children, due to its reduced side effects in this age group.

Barceloux DG et al: American Academy of Clinical Toxicology Practice Guidelines on the Treatment of Methanol Poisoning. *J Toxicol Clin Toxicol* 2002;40:415 [PMID: 12216995].

Brent J et al: Fomepizole for the treatment of ethylene glycol poisoning: Methylpyrazole for toxic alcohols study group. *N Engl J Med* 1999;40:832 [PMID: 10080845].

VITAMINS

Accidental ingestion of excessive amounts of vitamins rarely causes significant problems. Occasional cases of

hypervitaminosis A and D do occur, however, particularly in patients with poor hepatic or renal function. The fluoride contained in many multivitamin preparations is not a realistic hazard, because a 2- or 3-year-old child could eat 100 tablets, containing 1 mg of sodium fluoride per tablet, without experiencing serious symptoms. Iron poisoning has been reported with multivitamin tablets containing iron. Pyridoxine abuse has caused neuropathies; nicotinic acid, myopathy.

Fraser DR: Vitamin D. *Lancet* 1995;345:104 [PMID: 7815853].

WARFARIN

Warfarin is used as a rodenticide. It causes hypoprothrombinemia and capillary injury. It is absorbed readily from the GI tract but is absorbed poorly through the skin. A dose of 0.5 mg/kg of warfarin may be toxic in a child. A prothrombin time is helpful in establishing the severity of the poisoning.

If bleeding occurs or the prothrombin time is prolonged, give 1–5 mg of vitamin K₁ (phytonadione) IM or SQ. For large ingestions with established toxicity, 0.6 mg/kg may be given.

Another group of long-acting anticoagulant rodenticides (brodifacoum, difenacoum, bromadiolone, diphacinone, pinone, valone, and coumatetralyl) have been a more serious toxicologic problem than warfarin. They also cause hypoprothrombinemia and a bleeding diathesis that responds to phytonadione, although the anticoagulant activity may persist for periods ranging from 6 weeks to several months. Treatment with vitamin K1 may be needed for weeks.

Todd C. Carpenter, MD, Emily L. Dobyms, MD, Stephanie N. Mateev, MD, Peter M. Mourani, MD, Margaret A. Ferguson, MD, & Kurt R. Stenmark, MD

Caring for critically ill children remains one of the most demanding and challenging aspects of the field of pediatrics. The care of patients with life-threatening conditions, from serious medical illness to traumatic injuries and recovery from major surgery, requires a detailed understanding of the physiology of the body and the pathophysiology of major illnesses, as well as an understanding of and experience with the rapidly changing technologies available in a modern intensive care unit (ICU). In addition, the science of caring for the critically ill patient has evolved rapidly over the last decade, as the molecular mediators of illness have become better defined and new therapies have been devised based on those advances. As a result, critical care is more than ever a multidisciplinary field that requires a team-oriented approach, including critical care physicians and nursing staff, pharmacists, referring physicians, consulting specialists, and social services specialists.

The intensivist plays an essential role in coordinating and directing the care provided by the ICU team, and in so doing stands at the crossroads of the various participating disciplines. There are two primary models of ICU organization: “open” units, where primary responsibility for the patient remains with the referring physician and secondary responsibility lies with the intensivist as consultant; and “closed” units, where only the on-site intensivist is allowed to write orders directing the patient’s care. Although the merits of both of these organizational approaches are debated, a substantial and growing body of evidence from studies conducted in adult medical, surgical, and pediatric ICUs suggests that the closed ICU model may lead to significant reductions in ICU length of stay and resource use, as well as to reductions in mortality of as much as 15%.

An additional factor to consider in the provision of critical care services for children is the cost of those services in relation to the outcomes achieved. Critical care services in the United States are estimated to account for 30% of all acute-care hospital costs; some estimates run as high as 1% of the gross national product. One study has examined the cost-effectiveness of pediatric ICU care compared with adult ICU care. Those investigators found that the short- and long-term mortality among pediatric patients was three times lower than it was among adult ICU patients, despite similar ICU

costs and length of stay. These findings suggest that pediatric critical care services are relatively cost-effective compared with similar services provided to adult patients. Along with the preceding discussion of the intensivist’s role in ICU practice, the findings of these studies serve to highlight the complexities of this growing field, as well as the key role of the ICU specialist in caring for the sickest children.

ACUTE RESPIRATORY FAILURE

Acute respiratory failure, defined as the inability of the respiratory system to adequately deliver oxygen or remove CO₂, contributes significantly to the morbidity and mortality of critically ill children. This condition accounts for approximately 50% of deaths in children younger than age 1 year. Anatomic and developmental differences place infants at higher risk than adults for respiratory failure. An infant’s thoracic cage is more compliant than that of the adult or older child. The intercostal muscles are poorly developed and unable to achieve the “bucket handle” motion characteristic of adult breathing. Furthermore, the diaphragm is shorter, relatively flat with fewer type I muscle fibers, and therefore less effective and more easily fatigued. The infant’s airways are smaller in caliber than those in older children and adults, resulting in greater resistance to inspiratory and expiratory airflow and greater susceptibility to occlusion by mucus plugging and mucosal edema. Compared with adults, the alveoli of children are smaller and have less collateral ventilation, resulting in

a greater tendency to collapse and develop atelectasis. Finally, young infants may have an especially reactive pulmonary vascular bed, impaired immune system, or residual effects from prematurity, all of which increase the risk of respiratory failure.

Respiratory failure can be classified into two types, which usually coexist in variable proportion. The PaO_2 is low in both, whereas the PaCO_2 is high only in patients with type II respiratory failure (Table 13–1). Type I respiratory failure is a failure of oxygenation and occurs in three situations: (1) **ventilation–perfusion mismatch**, or V/Q mismatch, which occurs when blood flows to parts of the lung that are inadequately ventilated, or when ventilated areas of the lung are inadequately perfused; (2) **diffusion defects**, caused by thickened alveolar membranes or excessive interstitial fluid at the alveolar–capillary junction; and (3) **intrapulmonary shunt**, which occurs when structural anomalies in the lung allow blood to flow through the lung without participating in gas exchange. Type II respiratory failure generally results from alveolar hypoventilation and is usually secondary to situations such as central nervous system (CNS) dysfunction, oversedation, or neuromuscular disorders (see Table 13–1).

Table 13–1. Types of respiratory failure.

Findings	Causes	Examples
Type I Hypoxia Decreased PaO_2 Normal PaCO_2	Ventilation/perfusion defect	Positional (supine in bed), adult respiratory distress syndrome (ARDS), atelectasis, pneumonia, pulmonary embolus, bronchopulmonary dysplasia
	Diffusion impairment	Pulmonary edema, ARDS, interstitial pneumonia
	Shunt	Pulmonary arteriovenous malformation, congenital adenomatoid malformation
Type II Hypoxia Hypercapnia Decreased PaO_2 Increased PaCO_2	Hypoventilation	Neuromuscular disease (polio, Guillain-Barré syndrome), head trauma, sedation, chest wall dysfunction (burns), kyphosis, severe reactive airways

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical findings in respiratory failure are caused by the low PaO_2 , high PaCO_2 , and pH changes affecting the lungs, heart, kidneys, and brain. The clinical features of progressive respiratory failure are summarized in Table 13–2. Hypercapnia depresses the CNS, and also results in acidemia that depresses myocardial function. Patients in respiratory failure can exhibit significant changes in CNS and cardiac function. Features of respiratory failure are not always clinically evident, however, and some signs or symptoms may have non-respiratory causes. Furthermore, a strictly clinical assessment of arterial hypoxemia or hypercapnia is not reliable. As a result, the precise assessment of the adequacy of oxygenation and ventilation must be based on both clinical and laboratory data.

B. LABORATORY FINDINGS

Laboratory findings are helpful in assessing the severity and acuity of respiratory failure and in determining specific treatment. Arterial oxygen saturation can be measured continuously and noninvasively by **pulse oximetry**, a technique that should be used in the assessment and treatment of all patients with suspected respiratory failure. **End-tidal CO_2 monitoring** provides a continuous noninvasive means of assessing arterial pCO_2 . Because carbon dioxide diffuses freely across the alveo-

lar–capillary barrier, the exhaled end-tidal CO_2 (ETCO_2) level approximates the alveolar PCO_2 , which should equal the arterial PCO_2 . Though useful for following trends in ventilation, this technique is susceptible to significant error, particularly with patients who have rapid, shallow breathing or increased dead space ventilation. **Arterial blood gas (ABG) analysis** remains the gold standard for assessment of acute respiratory failure. ABGs give information on the patient's acid–base status (with a measured pH and calculated bicarbonate level) as well as PaO_2 and PaCO_2 levels. The PaO_2 is a critical determinant of oxygen delivery to the tissues, and the PaCO_2 is a sensitive measure of ventilation related inversely to the minute ventilation (Figure 13–1). Although measurement of capillary or venous blood gases may provide some reassurance regarding ventilatory function if blood gas results are normal, these tests yield virtually no useful information regarding oxygenation and may generate highly misleading information about the ventilatory status of patients who have poor perfusion or who had blood draws that were difficult. As a result, ABG analysis is important for all patients with suspected respiratory failure, particularly those with abnormal venous or capillary gases.

Knowing the ABG values and the inspired oxygen concentration also enables one to calculate the difference between alveolar oxygen concentration and the arterial oxygen value, known as the **alveolar–arterial oxygen difference** (A–aDO_2 , or A–a gradient). The

A–a gradient is less than 15 mm Hg under normal conditions, though it widens with increasing inspired oxygen concentrations, to about 100 mm Hg in normal patients breathing 100% oxygen. This number has prognostic value in severe hypoxemic respiratory failure, with A–a gradients over 400 mm Hg being strongly associated with mortality. Diffusion impairment, shunts, and V/Q mismatch all increase the A–aDO_2 (Table 13–3).

In addition to the calculation of the A–aDO_2 , assessment of intrapulmonary shunting (the percentage of pulmonary blood flow that passes through nonventilated areas of the lung) may be helpful. Normal individuals have less than a 5% physiologic shunt from bronchial, thebesian, and coronary circulations. Shunt fractions greater than 15% usually indicate the need for aggressive respiratory support. When intrapulmonary shunt reaches 50% of pulmonary blood flow, PaO_2 does not increase regardless of the amount of supplemental oxygen used.

Treatment

A. OXYGEN SUPPLEMENTATION

Patients with hypoxemia induced by respiratory failure may respond to **supplemental oxygen** administration alone (Table 13–4). Those with hypoventilation and diffusion defects respond better than do patients with shunts or V/Q mismatch. Severe V/Q mismatch generally responds only to aggressive airway management and mechanical ventilation. Patients with severe hypoxemia, hypoventilation, or apnea require assistance with bag and mask ventilation until the airway is successfully intubated and controlled artificial ventilation can be provided. Ventilation may be maintained for some time with a mask of the proper size, but gastric distention, emesis, and inadequate tidal volumes are possible complications. An artificial airway may be lifesaving for patients who fail to respond to simple oxygen supplements.

B. INTUBATION

Intubation of the trachea in infants and children requires experienced personnel and the right equipment. A patient in respiratory failure whose airway must be stabilized should first be positioned properly to facilitate air exchange while supplemental oxygen is given. The sniffing position is used in infants. Head extension with jaw thrust is used in older children without neck injuries. If obstructed by secretions or vomitus, the airway must be cleared by suction. When not obstructed, the airway should open easily with proper positioning and placement of an oral or nasopharyngeal airway of the correct size. Patients with a normal airway may be intubated under intravenous (IV) anesthesia by experi-

enced personnel (Table 13–5). Patients with obstructed upper airways (eg, patients with croup, epiglottitis, foreign bodies, or subglottic stenosis) should be awake when intubated unless trained airway specialists decide otherwise.

The size of the endotracheal tube is of critical importance in pediatrics (see Table 11–3 for sizes). An inappropriately large endotracheal tube can cause pressure necrosis of the tissues in the subglottic region, leading in some cases to scarring and permanent stenosis of the subglottic region that can require surgical repair. An inappropriately small endotracheal tube can result in inadequate pulmonary toilet and excessive air leak around the endotracheal tube, making optimal ventilation and oxygenation difficult. Two useful methods for calculat-

ing the correct size of endotracheal tube for a child are (1) measuring the child's height with a Broselow tape and then reading the corresponding endotracheal tube size on the tape, or (2) in children older than age 2 years, choosing a tube size equal to the simple computation $(16 + \text{age in years}) \div 4$.

Correct placement of the endotracheal tube should be confirmed by auscultation for the presence of equal bilateral breath sounds and if using a colorimetric filter (pH-sensitive indicator that changes from purple to yellow when exposed to carbon dioxide) by the detection of carbon dioxide. An assessment of air leakage around the endotracheal tube is also important. To do this, connect an anesthesia bag and pressure manometer to the endotracheal tube and allow it to inflate, creating

Table 13–4. Supplemental oxygen therapy.

Source	Maximum % O ₂	Range of Rates	Advantages	Disadvantages
Nasal cannula	35–40%	0.125–4 L/min	Easily applied, relatively comfortable	Uncomfortable at higher flow rates, requires open nasal airways, easily dislodged, lower % O ₂ , nosebleeds
Simple mask	50–60%	5–10 L/min	Higher % O ₂ , good for mouth breathers	Uncomfortable, dangerous for patients with poor airway control and at risk for emesis, hard to give airway care, unsure of % O ₂
Face tent	40–60%	8–10 L/min	Higher % O ₂ , good for mouth breathers, less restrictive	Uncomfortable, dangerous for patients with poor airway control and at risk for emesis, hard to give airway care, unsure of % O ₂
Rebreathing mask	80–90%	5–10 L/min	Higher % O ₂ , good for mouth breathers, highest O ₂ concentration	Uncomfortable, dangerous for patients with poor airway control and at risk for emesis, hard to give airway care, unsure of % O ₂
Oxyhood	90–100%	5–10 L/min (mixed at wall)	Stable and accurate O ₂ concentration	Difficult to maintain temperature, hard to give airway care

Table 13–5. Drugs commonly used for controlled intubation.

Drug	Class of Agent	Dose	Advantages	Disadvantages
Atropine	Anticholinergic	0.02 mg/kg, minimum of 0.1 mg	Prevents bradycardia, dries secretions	Tachycardia, fever; seizures and coma with high doses
Fentanyl	Narcotic (sedative)	1–3 µg/kg IV	Rapid onset, hemodynamic stability	Respiratory depression, chest wall rigidity with rapid administration in neonates
Midazolam	Benzodiazepine (sedative)	0.1–0.2 mg/kg IV	Rapid onset, amnestic	Respiratory depression, hypotension
Thiopental	Barbiturate (anesthetic)	3–5 mg/kg IV	Rapid onset, lowers intracranial pressure	Hypotension, decreased cardiac output, no analgesia provided
Ketamine	Dissociative anesthetic	1–2 mg/kg IV 2–4 mg/kg IM	Rapid onset, bronchodilator, hemodynamic stability	Increases oral and airway secretions, may increase ICP and pulmonary artery pressure
Rocuronium	Nondepolarizing muscle relaxant	1 mg/kg	Rapid onset, suitable for rapid sequence intubation, lasts 30 minutes	Requires refrigeration
Pancuronium	Nondepolarizing muscle relaxant	0.1 mg/kg	Longer duration of action (40–60 min)	Tachycardia, slow onset (2–3 min)

IV = intravenously, IM = intramuscularly.

positive pressure. Check for the leak by auscultating over the throat, noting the pressure at which air escapes around the endotracheal tube. Leaks at pressures of 15–20 cm H₂O are acceptable. Leaks at lower pressures may lead to ineffective ventilation, and the endotracheal tube should be upsized if continued mechanical ventilation is needed. Leaks at higher pressures are acceptable only with patients who have severe lung disease and poor compliance and who thus require high pressures to ventilate and oxygenate. A chest radiograph is necessary for final assessment of endotracheal tube placement.

MECHANICAL VENTILATION

The increased compliance of an infant's chest wall, the relative alveolar hypoplasia in early childhood, the small caliber of the airways, and the small tidal volumes of young children make mechanical ventilation of the pediatric patient challenging. The goals of mechanical ventilation are to facilitate the movement of gas into and out of the lungs (ventilation) and to improve oxygen uptake into the bloodstream (oxygenation). Modern mechanical ventilators can accomplish these objectives in a variety of ways. Depending on the mode of ventilation selected, the ventilator can deliver a machine-controlled breath (control ventilation), or can assist the patient's own spontaneous respiratory efforts (support ventilation), or can do both (mixed mode ventilation). Additionally, ventilator breaths can be delivered as a targeted tidal volume (volume ventilation) or as a targeted airway pressure (pressure ventilation). Ongoing advances in microprocessor control and ventilator design give the clinician increasingly complex

choices in tailoring a mode of mechanical ventilation to particular clinical scenarios. This section will describe the modes of mechanical ventilation most commonly used in pediatric intensive care units.

Pressure Ventilation

In pressure-controlled modes of ventilation, air flow is begun at the start of the inspiratory cycle and continues until a preset airway pressure is reached. That airway pressure is then maintained until, at the end of the set inspiratory time, the exhalation valve on the ventilator opens and gas exits into the machine. Because airway pressure is the controlling variable with this mode of ventilation, changes in the compliance of the respiratory system will lead to fluctuations in the actual tidal volume delivered to the patient. The advantage of pressure-controlled ventilation lies primarily in the avoidance of high airway pressures that might cause lung injury or barotrauma, particularly in those patients with fragile lung parenchyma, such as premature infants. The main disadvantage of pressure-controlled ventilation is the possibility of delivering either inadequate or excessive tidal volumes during periods of changing lung compliance, as described earlier.

Volume Ventilation

Volume-controlled ventilation is the most commonly used mode of mechanical ventilation in most pediatric intensive care units (PICUs). In contrast to pressure-controlled modes, volume ventilation delivers a preset tidal volume to the patient. Changes in lung compliance will lead to fluctuations in the airway pressure generated by the tidal volume. The main advantage of volume ventilation is more reliable delivery of the desired tidal volume and thus better control of ventilation. More reliable tidal volume delivery may also help prevent atelectasis from hypoventilation. Disadvantages of volume ventilation include the risk of barotrauma from excessive airway pressures and difficulties overcoming leaks in the ventilator circuit. Older volume ventilators also suffered from a lack of continuous gas flow through the circuit, thus increasing the patient's work of breathing on spontaneous breaths. Most modern machines have overcome that problem by providing a continuous flow through the circuit and by improved triggering mechanisms to deliver the breaths in synchrony with the patient's demands.

Modes of Ventilation

Most modern ventilators can deliver either a pressure-controlled or a volume-controlled breath in several manners. **Assist-control** modes deliver breaths at a se-

lected rate and duration (inspiratory time) and can be targeted for either volume or pressure set by the clinician (as opposed to the patient). Spontaneous breaths are not assisted, and the patient's own respiratory efforts are not considered. **Synchronized intermittent mandatory ventilation (SIMV)** is a mode in which the rate, inspiratory time, and volume or pressure settings are set by the clinician. But the ventilator allows a window of time around each breath in which it waits for the patient to make an inspiratory effort. The machine breath is then synchronized with the patient's effort, to improve the comfort of those who are breathing spontaneously. In **pressure support**, the patient's own efforts are assisted by the delivery of gas flow to achieve a certain airway pressure. This mode of ventilation allows the patient to determine the rate and inspiratory time of breaths, thus improving patient comfort and decreasing the work of breathing. Perhaps the most common mode of ventilation in PICUs is **SIMV with pressure support**, a mixed mode allowing pressure-supported breaths between the synchronized machine breaths. Whether such mixed modes of ventilation provide any measurable advantage over single modes remains unclear, despite their popularity.

Setting the Ventilator

When initiating mechanical ventilation, the clinician will vary the parameters according to the mode of ventilation selected. Volume-controlled modes of ventilation generally require a set tidal volume, inspiratory time, rate, and level of positive end-expiratory pressure (PEEP). A typical initial tidal volume is 8–12 mL/kg, as long as that volume does not cause excessive airway pressures. The inspiratory time is typically set at 1 second or 33% of the respiratory cycle, whichever is shorter. Rate can be adjusted to patient comfort and blood gas measurements of ventilation, but generally patients starting on mechanical ventilation will require full support at least initially with a rate of 20–30 breaths/min.

Pressure-controlled ventilation is set up in similar fashion, though the sufficiency of the inspiratory pressure to provide an adequate tidal volume is assessed by observing the patient's chest rise and by measuring the returned tidal volume. Typically, patients without lung disease will require pressures of 15–20 cm H₂O, and patients with respiratory illnesses will initially require 20–30 cm H₂O pressure to provide adequate ventilation.

Positive End-Expiratory Pressure

The PEEP level is the final major setting required to initiate mechanical ventilation. All mechanical ventila-

tors open their expiratory limbs at the end of inspiration until a preset pressure is achieved; this is the PEEP value. During ventilation of normal lungs, physiologic PEEP is in the range of 2–4 cm H₂O pressure. This pressure helps to prevent the end-expiratory collapse of open lung units, thus preventing atelectasis and shunting. In disease states such as pulmonary edema, pneumonia, or acute respiratory distress syndrome (ARDS), a higher PEEP may increase the patient's functional residual capacity (FRC), open previously collapsed alveoli, increase mean airway pressure, and improve oxygenation. High levels of PEEP, although often valuable in improving oxygenation, may also cause CO₂ retention, barotrauma with resultant air leaks, decreased central venous return and thus decreased cardiac output, and increased intracranial pressure (ICP). In general, PEEP should be set at 3–5 cm H₂O initially and titrated up to maintain adequate oxygenation at an acceptable fractional inspiratory oxygen (FiO₂), while watching carefully for the adverse effects listed earlier.

Monitoring the Ventilated Patient

Ventilated patients must be monitored carefully for respiratory rate and activity, chest wall movement, and quality of breath sounds. Oxygenation should be measured either by ABGs or by continuous pulse oximetry. Ventilation should be assessed by blood gas analysis or by noninvasive means, such as transcutaneous monitoring or end-tidal sampling. Transcutaneous PO₂ (PtO₂) or PCO₂ (PtCO₂) measurements are most useful with younger patients who have good skin perfusion, but they become problematic with poorly perfused or obese patients. End-tidal CO₂ monitoring is done by placing a gas-sampling port on the endotracheal tube and analyzing expired gas for CO₂. This technique appears to be more valuable for patients with large tidal volumes, lower respiratory rates, and without leaks around the endotracheal tube. In practice, end-tidal CO₂ values may differ significantly from measured PaCO₂ values and thus are most useful for following relative fluctuations in ventilation. Frequent, preferably continuous, blood pressure monitoring is also necessary for patients receiving oxygen at a high PEEP, given the risk of adverse cardiovascular effects.

Adjusting the Ventilator

Mechanical ventilation can assist with both ventilation (PCO₂) and oxygenation (PO₂). Ventilation is most closely associated with the delivered minute-volume, or the tidal volume multiplied by the respiratory rate. Abnormal PCO₂ values can be most effectively addressed by changes in the respiratory rate or the tidal volume. Increased rate or tidal volume should increase minute-

volume and thus decrease $p\text{CO}_2$ levels; decreases in rate or tidal volume should act in the opposite fashion. In some circumstances, additional adjustments may also be necessary. For example, for patients with disease characterized by extensive alveolar collapse, increasing PEEP may improve ventilation by rerecruiting collapsed lung units. Also, for patients with disease characterized by significant airway obstruction, decreases in respiratory rate may allow more time for exhalation and improve ventilation despite an apparent decrease in the minute-volume provided.

The variables most closely associated with oxygenation are the inspired oxygen concentration and the mean airway pressure during the respiratory cycle. Increases in inspired oxygen concentration will generally increase arterial oxygenation, unless right-to-left intracardiac or intrapulmonary shunting is a significant component of the patient's illness. Concentrations of inspired oxygen above 60–65%, however, may lead to hyperoxic lung injury. Patients with hypoxemic respiratory failure requiring those levels of oxygen or higher to maintain adequate arterial saturations should have their hypoxemia addressed by increases in mean airway pressure.

Mean airway pressure is affected by PEEP, peak inspiratory pressure, and inspiratory time. Increases in any one of those factors will increase mean airway pressure and should improve arterial oxygenation. It is important to bear in mind, however, that increases in mean airway pressure may also lead to decreases in cardiac output. In this circumstance, raising mean airway pressure may increase arterial oxygenation but actually compromise oxygen delivery to the tissues. For patients with severe hypoxemic respiratory failure, these trade-offs highlight the need for careful monitoring of these variables by experienced personnel.

Managing the Ventilated Patient

Patients undergoing mechanical ventilation generally require the same meticulous supportive care given to all PICU patients. Since mechanical ventilation is often frightening and uncomfortable for patients, leading to dyssynchrony with the ventilator and impaired ventilation and oxygenation, they deserve careful attention directed toward optimizing comfort and decreasing anxiety. Sedative-anxiolytics are typically provided as intermittent doses of benzodiazepines, with or without opioids. Some patients respond better to the steady state of sedation provided by continuous infusion of these agents, although oversedation of the ventilated patient may lead to longer durations of ventilation and difficulties with weaning from the ventilator.

For a patient with severe respiratory illnesses, even small movements by the patient may compromise ventilation and oxygenation. In such cases, muscle paralysis

may facilitate oxygenation and ventilation. Nondepolarizing neuromuscular blocking agents are most commonly used for this purpose, and they may be given as intermittent doses or as continuous infusions. When muscle relaxants are given, extra care must be taken to ensure that levels of sedation are adequate, as many of the usual signs of patient discomfort are masked by the paralytics.

Alternative Methods of Ventilation

High-frequency oscillatory ventilation (HFOV) is a mode of mechanical ventilation in which the ventilator provides very small, very rapid tidal volumes. Respiratory rates used during oscillatory ventilation typically range from 5 to 10 Hz (rates of 300–600 breaths/min) in most PICU patients. This mode of ventilation has been used successfully for neonates, older pediatric patients, and adults, and for diseases as diverse as pneumonia, pulmonary contusion, ARDS, and asthma. HFOV is increasingly being used as initial therapy in severe, diffuse lung diseases, such as ARDS, which require high mean airway pressures to maintain oxygenation. The advantage of HFOV is that these high levels of mean airway pressure can be achieved without high peak inspiratory pressures or large tidal volumes, thus theoretically protecting the lung from ventilator-induced lung injury. Disadvantages of HFOV include generally poor tolerance by patients who are not heavily sedated or even paralyzed, the risk of cardiovascular compromise due to high mean airway pressures, and the risk of barotrauma in patients with heterogeneous lung disease. Although HFOV clearly may be useful for selected patients, it remains unsettled whether HFOV provides a clear benefit in outcome compared with carefully managed conventional modes of ventilation.

Inverse ratio ventilation is another strategy sometimes employed with patients who have severe hypoxemic respiratory failure. This approach entails increasing the inspiratory time until it exceeds the expiratory time in the respiratory cycle, thus “inverting” the I:E ratio from the usual 1:2 or 1:3 to 2:1 or even 3:1. This practice, most commonly done while using a pressure-controlled mode of ventilation, leads to significant increases in mean airway pressure and may improve oxygenation in selected patients. Disadvantages of this approach are the increased need for sedation and paralysis due to patient discomfort, hypercarbia due to less effective ventilation, and the risk of cardiovascular compromise from high mean airway pressures. While useful for selected patients as a rescue strategy, inverse-ratio ventilation has not yet been shown to provide any significant advantage over conventional modes of ventilation or HFOV in managing severe hypoxemic respiratory failure.

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is a syndrome of acute respiratory failure characterized by increased pulmonary capillary permeability and pulmonary edema that results in refractory hypoxemia, decreased lung compliance, and bilateral diffuse alveolar infiltrates on chest radiography. Statistics of ARDS reflect one of the true successes of current ICU management, as mortality has decreased over the past decade from approximately 50–60% to less than 40%.

Our understanding of this illness has been hampered over the years by inconsistencies in the case definitions used by various authors. An international consensus conference was convened in 1997 to establish the current guidelines defining diagnostic criteria for ARDS. The diagnosis of ARDS rests on four features: (1) an underlying illness or injury that predisposes to ARDS; (2) bilateral infiltrates on chest radiograph; (3) an absence of evidence of heart failure and, in particular, left ventricular (LV) failure; and, most importantly, (4) severe hypoxemic respiratory failure. Hypoxemia is assessed using the ratio of the arterial oxygen level (PaO₂) to the inspired oxygen concentration (FiO₂). When the PaO₂/FiO₂ ratio is less than 200, and the other two criteria are met, the case is defined as ARDS. When the PaO₂/FiO₂ ratio is between 200 and 300, and the other two criteria are met, the case is defined as acute lung injury. This definition is debated, however, particularly since the current criteria do not include any assessment of the airway pressure needed to

oxygenate the patient. Numerous other diagnostic systems have been proposed.

In addition, because the clinical disorder or disorders that led to the development of acute lung injury clearly influence the patient's prognosis for recovery, precise definition of the underlying problem is important. Although the average mortality in this population is 40%, the rate is quite variable and dependent on the associated clinical disorder. Mortality can be as high as 90% among adult ARDS patients with underlying liver failure, and less than 10% among pediatric ARDS associated with respiratory syncytial virus infection. The development of multisystem organ failure is a frequent complicating factor in the care of the patient with ARDS, and the failure of organs outside the lung has a large role in determining the prognosis. In fact, nonpulmonary organ failures are the leading cause of death in the most recent studies of adult or pediatric ARDS patients.

Clinical Presentation & Pathophysiology

ARDS may be precipitated by a variety of insults (Table 13–6), of which infection is the most common. Despite the diversity of causes, the clinical presentation is remarkably similar in most cases. ARDS can be divided roughly into four clinical phases (Table 13–7). In the earliest phase, the patient may have dyspnea and tachypnea with a relatively normal PO₂ and a hyperventilation-induced respiratory alkalosis. No significant abnormalities are noted on physical or radiologic examination of the chest. Experimental studies suggest that neutrophils accumulate in the lungs at this stage and that their products damage lung endothelium.

Over the next few hours, hypoxemia increases and respiratory distress becomes clinically apparent, with

Table 13–6. Acute respiratory distress syndrome risk factors.

Direct Lung Injury	Indirect Lung Injury
Aspiration of gastric contents	Sepsis
Hydrocarbon ingestion or aspiration	Shock
Inhalation injury (heat or toxin)	Pancreatitis
Pulmonary contusion	Burns
Pneumonia	Trauma
Near-drowning	Fat embolism
	Drug overdoses (including aspirin, opioids, barbiturates, tricyclic antidepressants)
	Transfusion of blood products

Table 13–7. Pathophysiologic changes of modern acute respiratory distress syndrome (low-pressure pulmonary edema).

	Symptoms	Laboratory Findings	Pathophysiology
Phase 1 (early changes) Normal radiograph	Dyspnea, tachypnea, normal chest examination	Mild pulmonary hypertension, normoxemic or mild hypoxemia, hypercapnia.	Neutrophil sequestration, no clear tissue damage
Phase 2 (onset of parenchymal changes)^a Patchy alveolar infiltrates beginning in dependent lung No perivascular cuffs (unless a component of high-pressure edema is present) Normal heart size	Dyspnea, tachypnea, cyanosis, tachycardia, coarse rales	Pulmonary hypertension, normal wedge pressure, increased lung permeability, increased lung water, increasing shunt, progressive decrease in compliance, moderate to severe hypoxemia.	Neutrophil infiltration, vascular congestion, fibrin strands, platelet clumps, alveolar septal edema, intraalveolar protein, white cells, type I epithelial damage
Phase 3 (acute respiratory failure with progression, 2–10 days) Diffuse alveolar infiltrates Air bronchograms Decreased lung volume No bronchovascular cuffs Normal heart	Tachypnea, tachycardia, hyperdynamic state, sepsis syndrome, signs of consolidation, diffuse rhonchi	Phase 2 changes persist. Progression of abnormalities, increasing shunt fraction, further decrease in compliance, increased minute ventilation, impaired oxygen extraction of hemoglobin.	Increased interstitial and alveolar inflammatory exudate with neutrophil and mononuclear cells, type II cell proliferation, beginning fibroblast proliferation, thromboembolic occlusion
Phase 4 (pulmonary fibrosis, pneumonia with progression, > 10 days)^b Persistent diffuse infiltrates Superimposed new pneumonic infiltrates Recurrent pneumothorax Normal heart size Enlargement with cor pulmonale	Symptoms as above, recurrent sepsis, evidence of multiple organ system failure	Phase 3 changes persist. Recurrent pneumonia, progressive lung restriction, impaired tissue oxygenation, impaired oxygen extraction. Multiple organ system failure.	Type II cell hyperplasia, interstitial thickening; infiltration of lymphocytes, macrophages, fibroblasts; loculated pneumonia or interstitial fibrosis; medial thickening and remodeling of arterioles

^aThe process is readily reversible at this stage if the initiating factor is controlled.

^bMultiple organ system failure is common. The mortality rate is greater than 80% at this stage, since resolution is more difficult.

Modified slightly and reproduced, with permission, from Demling RH: Adult respiratory distress syndrome: Current concepts. *New Horizons* 1993;1:388.

cyanosis, tachycardia, irritability, and dyspnea. Radiographic evidence of early parenchymal change is noted by “fluffy” alveolar infiltrates initially appearing in dependent lung fields, indicative of pulmonary edema. The edema fluid typically has a high concentration of protein (75–95% of plasma protein concentration), which is characteristic of an increased permeability-type edema and differentiates it from cardiogenic or hydrostatic pulmonary edema. Protein in the airspaces acts to inactivate surfactant, which, combined with damage to type 2 alveolar pneumocytes, leads to a marked deficiency in surfactant content in the lung. As a result, the lung is particularly prone to collapse and to shearing injuries due to the high surface tension required to open collapsed alveoli.

Alveolar epithelial injury in ARDS lowers the threshold for alveolar edema formation and impairs gas exchange. The functional integrity of the alveolar epithelium, as measured by the ability of the alveoli to clear liquid out of the airspaces, has prognostic importance in ARDS. Those patients who still show evidence of functional alveolar liquid clearance mechanisms during the first day of their illness have a much higher survival rate than those with evidence of severe epithelial impairment.

Pulmonary hypertension, decreases in lung compliance, and increases in airway resistance are also commonly noted. Clinical studies suggest that airway resistance may be increased in 50% of patients with ARDS.

Computed tomography (CT) studies of adult patients in the acute phases of ARDS have established that

this illness is characterized by heterogeneous collapse of the lung, with typical areas of dependent consolidation, overinflation in the upper zones, and relatively small areas of normally expanded lung. These findings have led to the opinion that the lung in ARDS is best viewed as “small” rather than stiff, prompting a shift toward ventilating these patients with smaller tidal volumes and tolerating the relative hypercarbia that may ensue. In addition, a large body of research in recent years has shown that ventilation with large tidal volumes and low PEEP levels allows a pattern of cyclic alveolar overdistention and collapse, which causes a lung injury histologically similar to ARDS even in normal lungs. This phenomenon is now called ventilator-induced lung injury. Taken together, these findings have given rise to the view that acute ARDS can best be treated by rerecruiting those areas of dependent collapse and minimizing the stretch-induced injury, or volutrauma, in the nondependent areas of the lung. This approach has been termed the open-lung strategy and has been the subject of intense scrutiny in recent years (see below).

The subacute phase of ARDS (5–10 days after lung injury) is characterized by type II cell and fibroblast proliferation in the interstitium of the lung. This results in decreased lung volumes and signs of consolidation that are noted clinically and radiographically. Worsening of the hypoxemia with an increasing shunt fraction, as well as a further decrease in lung compliance, are noted. Some patients develop an accelerated fibrosing alveolitis in which fibroblasts and collagen formation in the interstitium are markedly increased. The mechanisms responsible for these changes are unclear. Current investigation centers on the role of growth and differentiation factors, such as transforming growth factor- β and platelet-derived growth factor released by resident and nonresident lung cells such as alveolar macrophages, mast cells, neutrophils, alveolar type II cells, and fibroblasts.

During the chronic phase of ARDS (10–14 days after lung injury), fibrosis, emphysema, and pulmonary vascular obliteration occur. During this phase of the illness, oxygenation defects generally improve, and the lung becomes more fragile and susceptible to barotrauma. Air leak is common among patients still ventilated with high levels of airway pressure at this late stage in their illness. Also, patients have increased amounts of dead space, and difficulties with ventilation are common. Airway compliance remains low, perhaps because of ongoing pulmonary fibrosis and insufficient surfactant production.

Secondary infections are common in the subacute and chronic phases of ARDS and significantly influence the outcome. The mechanisms responsible for increased host susceptibility to infection during this phase are not well understood.

Mortality in the late phase of ARDS exceeds 80%. Death is usually caused by multiple organ failure and

systemic hemodynamic instability rather than by hypoxemia.

Treatment

A. MONITORING

Multiorgan system monitoring is mandatory for patients with ARDS. ABG analysis is required for accurate assessment of oxygenation and ventilation and for the rational titration of ventilator strategies that may have profound adverse effects. Hemodynamic monitoring should include, at a minimum, central venous pressure (CVP) measurements to help determine the level of cardiac preload, and an indwelling arterial catheter for continuous blood pressure measurements and ABG sampling. For patients with severe disease or concurrent cardiac dysfunction, consideration can be given to pulmonary artery catheterization to help with fluid management and to allow assessment of mixed venous blood saturation as an index of overall tissue oxygenation. Obtaining chest films daily is important for patients receiving vigorous support because severe ARDS is associated with a 40–60% incidence of air leaks. Secondary infections are common and increase mortality rates strikingly. Thus surveillance for infection is important, requiring appropriate cultures and following the temperature curve and white blood cell count. Renal, liver, and gastrointestinal (GI) function should be watched closely because of the great likelihood of multiple organ dysfunction.

B. FLUID MANAGEMENT

Given the increases in pulmonary capillary permeability in ARDS, pulmonary edema accumulation is likely with any elevation in pulmonary hydrostatic pressures. In this setting, most clinicians reduce intravascular volume to the lowest level that is still compatible with an adequate cardiac output and adequate oxygen delivery to the tissues.

C. HEMODYNAMIC SUPPORT

Hemodynamic support is directed toward increasing perfusion and oxygen delivery. In those circumstances when volume expansion is necessary to improve oxygen delivery, this can best be achieved by giving packed red blood cells to maintain the hematocrit between 35% and 40%, and by giving colloid or crystalloid solutions to nonanemic volume-depleted patients. Inotropes should be used as needed to optimize oxygen delivery to the tissues.

D. VENTILATORY SUPPORT

Basic principles of ventilator management were described earlier (see Adjusting the Ventilator section). In addition to those principles, current ventilatory manage-

ment of ARDS is directed at the rerecruitment of areas of dependent alveolar collapse and the protection of noncollapsed areas from overdistention. Since an FiO_2 greater than 60% over 24 hours can cause additional injury to the lung, mean airway pressure should be increased to provide an adequate PaO_2 (> 55 mm Hg) at an FiO_2 of 60% or less. In general, this can be accomplished by incremental increases in PEEP every 15–30 minutes until adequate oxygenation is achieved or until a limiting side effect of the PEEP is reached. Ventilation with high levels of PEEP acts by helping to prevent dependent collapse of edematous lung units. PEEP levels of 12–14 cm H_2O are not unusual, and levels as high as 20–25 cm H_2O have been used successfully in these patients. Before increasing PEEP significantly, the physician should optimize conditions by making sure that the patient's intravascular volume is appropriate, the endotracheal tube does not leak, and the patient is heavily sedated and paralyzed.

The actual mode of ventilation employed (volume or pressure) with an ARDS patient is probably unimportant. However, recent work from a large multicenter trial sponsored by the National Institutes of Health suggests that the tidal volumes used may be important. Using a PEEP strategy similar to that described in the preceding paragraph, the investigators compared the effects of a low (6 mL/kg) tidal volume versus a normal (12 mL/kg) tidal volume in 861 adult ARDS patients. Those patients ventilated with the lower tidal volume demonstrated fewer extrapulmonary organ failures and an overall 25% decrease in mortality. In keeping with these findings and with experimental data demonstrating ventilator-induced lung injury at alveolar pressures greater than 30 cm H_2O , we suggest that current practice for pediatric ARDS patients should consist of ventilation with tidal volumes in the 6–8 mL/kg range, or at least with tidal volumes small enough to keep alveolar pressures below 30–35 cm H_2O .

E. OTHER THERAPIES

As previously described, HFOV is an increasingly popular technique that has been used successfully in pediatric patients with ARDS. When used as part of a strategy of aggressive increases in mean airway pressure to rerecruit deflated areas of the lung and to prevent cyclic overdistention and collapse, HFOV is a physiologically rational approach to this illness. It has not yet been determined whether HFOV provides additional benefits compared with open-lung strategy ventilation with conventional ventilator modes.

Prone positioning is a technique of changing the patient's position in bed from supine to prone, with the goal of allowing postural drainage and improving ventilation of collapsed dependent lung units. This technique often dramatically improves oxygenation, particu-

larly for patients early in the course of ARDS. The oxygenation improvements are often not sustained, however, necessitating repeat position changes to maintain the effect. Whether prone positioning contributes to improved outcomes for patients with ARDS remains uncertain.

Based on the ability of inhaled **nitric oxide** (iNO) to reduce pulmonary artery pressure and to improve the matching of ventilation with perfusion without producing systemic vasodilation, iNO has been proposed as a beneficial therapy for ARDS. Several recent multicenter trials of iNO in the treatment of ARDS, both in adults and in children, have shown acute improvements in oxygenation in subsets of patients but no significant improvement in overall survival. As a result, the current role of iNO in the treatment of ARDS remains unclear. Additional studies are now focusing on the anti-inflammatory role (by reducing neutrophil adhesion and activation) iNO may play in ARDS. Studies to evaluate the combined effects of several of these alternative therapies are also being planned.

Surfactant replacement therapy has been tried with some success in patients with ARDS. Surfactant replacement, in some instances, improves lung compliance and oxygenation, and hastens weaning from mechanical ventilation. In randomized trials of surfactant replacement, there were no differences in outcome (death, length of ventilation, or hospitalization), but there was some evidence of decreased inflammation. A multicenter trial of surfactant treatment for pediatric ARDS is currently in progress.

Although **corticosteroids** have not been found to be beneficial in early stage ARDS, these agents may reduce the inflammation and fibrosis associated with later stage ARDS. Indeed, the use of methylprednisolone in adults whose lung injury was not improving after 7 days of ARDS was associated with improvement of lung injury and multiple organ dysfunction. Mortality was also reduced, when compared with control subjects receiving placebo. A large multicenter trial is under way to further evaluate the use of steroids in the late phase of ARDS.

Extracorporeal membrane oxygenation (ECMO) has been used in pediatric patients with severe ARDS. In older studies, patients who received ECMO had better survival rates than did control subjects. ECMO has not been studied in comparison with current conventional ventilation strategies. In addition, recent improvements in outcome for pediatric ARDS patients receiving conventional therapies have made the role of ECMO less clear and have made further prospective randomized studies of ECMO difficult to complete. For now, ECMO remains a rescue therapy for patients with severe ARDS unresponsive to other modalities.

F. FOLLOW-UP

Information regarding the long-term outcome of pediatric patients with ARDS remains limited. One report of 10 children followed 1–4 years after severe ARDS showed 3 still symptomatic and 7 with hypoxemia at rest. Until further information is available, all patients with a history of ARDS need close follow-up of pulmonary function.

ASTHMA (LIFE-THREATENING)

Status asthmaticus may be defined as reversible small airway obstruction that is refractory to sympathomimetic and anti-inflammatory agents and that may progress to respiratory failure without prompt and ag-

gressive intervention. Life-threatening asthma is caused by severe bronchospasm, excessive mucous secretion, inflammation, and edema of the airways (see Chapter 17). Reversal of these mechanisms is the key to successful treatment. Status asthmaticus remains a common diagnosis among children admitted to the PICU, and asthma continues to be associated with surprisingly high mortality rates.

The physical examination helps determine the severity of illness. Accessory muscle (sternocleidomastoid) use correlates well with a forced expiratory volume (FEV₁) and peak expiratory flow rates (PEFRs) less than 50% of normal predicted values. A pulsus paradoxus of over 22 mm Hg has been correlated with elevated PaCO₂ levels. The absence of wheezing may be misleading because, in order to produce a wheezing sound, the patient must take in a certain amount of air. The ABG analysis remains the single most important laboratory determination in the evaluation of a child in severe status asthmaticus. Patients with severe respiratory distress, signs of exhaustion, alterations in consciousness, elevated PaCO₂, or acidosis should be admitted to the PICU.

Treatment

Much of the morbidity associated with the treatment of severe asthma is related to the complications of mechanical ventilation that occur in patients with severe airflow obstruction. As a result, the goal of initial treatment of the patient with life-threatening status asthmaticus is to improve the patient's ability to ventilate without resorting to intubation and mechanical ventilation. The medical therapies described in the following discussion should be undertaken swiftly and aggressively with the goal of reversing the bronchospasm before respiratory failure necessitates invasive ventilation.

Due to inadequate minute-ventilation and V/Q mismatching, patients with severe asthma are almost always hypoxemic and should receive supplemental **humidified oxygen** immediately.

Inhaled β_2 -agonist therapy with agents such as albuterol remains first-line therapy to reverse acute bronchoconstriction. If the patient is in severe distress and has poor inspiratory flow rates, thus preventing adequate delivery of nebulized medication, subcutaneous injection of epinephrine or terbutaline may be considered. The frequency of β_2 -agonist administration varies according to the severity of the patient's symptoms and the occurrence of adverse side effects. Nebulized albuterol may be given intermittently at a dose of 0.1 mg/kg per nebulization up to 2.5 mg, or it can be administered continuously at a dose of 0.5 mg/kg/h to a maximum of 20 mg/h, usually without serious side effects. The heart rate and blood pressure of these pa-

tients should be monitored closely, because excessive tachycardia and ventricular ectopy may occur.

Systemic **corticosteroids** act by decreasing inflammation, stabilizing mast cells, and increasing β_2 -receptor expression. These agents speed the resolution of severe asthma exacerbations refractory to bronchodilator therapy and should be given to all patients admitted to the hospital with severe asthma. The optimal dose is unknown, although a frequently used dosage is 1 mg/kg of IV methylprednisolone every 6 hours. The acute complications of corticosteroid usage include GI bleeding, hyperglycemia, and hypertension.

Inhaled **anticholinergic agents** may also be helpful in patients with severe asthma. In some patients, cholinergic-related bronchoconstriction is more marked than in others, so not all patients respond. Nebulized ipratropium bromide is the drug of choice, and is given at a dose of 250–500 μg /dose.

Intravenous β -agonists should be considered in patients with severe bronchospasm unresponsive to inhaled bronchodilators. The agent most commonly used in the United States is terbutaline, a relatively specific β_2 -agonist, which can be given as a bolus dose or as a continuous infusion. Owing to its relative specificity for β_2 -receptors, terbutaline has fewer cardiac side effects than previously available IV β -agonists like isoproterenol. Terbutaline is given as a bolus or loading dose of 10 μg /kg followed by a continuous infusion of 0.5–5 μg /kg/min. In general, patients receiving IV β_2 -agonist therapy should have indwelling arterial lines for continuous blood pressure and blood gas monitoring.

Theophylline remains a controversial agent in the management of severe asthma. Although some studies suggest this drug may confer some additional benefit when given with steroids and β_2 -agonists, other studies of children hospitalized with moderate to severe asthma have not shown a clear benefit in adding theophylline to other therapy. Besides causing bronchodilation, this agent decreases mucociliary inflammatory mediators and reduces microvascular permeability. When the decision to add theophylline to high-dose β_2 -agonist therapy for severe status asthmaticus is being weighed, the increased risk of serious side effects such as tachycardia and cardiac arrhythmias must be considered. Theophylline is given IV as aminophylline. Each 1 mg/kg of aminophylline given as a loading dose will increase the serum level by approximately 2 mg/dL. For a patient who has not previously received aminophylline or oral (PO) theophylline preparations, load with 7–8 mg/kg of aminophylline in an attempt to achieve a level of 10–15 mg/dL; then start a continuous infusion of aminophylline at a dosage of 0.8–1 mg/kg/h. Watch closely for toxicity (gastric upset, tachycardia, seizures) and follow serum levels closely, trying to maintain steady-state levels of 12–16 mg/dL.

Magnesium sulfate has been reported to be an effective bronchodilator in patients with severe status asthmaticus and may be considered for patients in danger of worsening respiratory failure. The mechanism of action of magnesium is unclear, but its smooth muscle relaxation properties are probably caused by interference with calcium flux in the bronchial smooth muscle cell. Magnesium sulfate is given IV at a dose of 25–50 mg/kg/dose. Though it is usually well tolerated, hypotension and flushing are side effects.

If the previously described aggressive management fails to result in significant improvement, **mechanical ventilation** may be necessary. In general, if there is steady deterioration (increased acidosis, rising PaCO_2) despite intensive therapy for asthma, the patient should be intubated and ventilated mechanically. Mechanical ventilation for patients with asthma is difficult because the severe airflow obstruction often leads to very high airway pressures, air trapping, and resultant barotrauma. The goal of mechanical ventilation with an intubated asthmatic patient is to maintain adequate oxygenation and ventilation with the least amount of barotrauma until other therapies become effective. Worsening hypercarbia after intubation should be anticipated and aggressive efforts to normalize blood gases should be moderated, as such efforts may only lead to complications. Due to the severe air flow obstruction, these patients will require long inspiratory times to deliver a breath and long expiratory times to avoid air trapping. In general, the ventilator rate should be decreased until the expiratory time is long enough to allow emptying prior to the next machine breath. Ventilator rates of 8–12 breaths/min are typical initially. Either volume- or pressure-targeted modes of ventilation can be used effectively in these patients. PEEP should be kept low (0–2 cm H_2O). Isolated reports have noted patients who respond to greater PEEP, but these cases are the exception. These ventilator strategies and the resulting hypercarbia typically are uncomfortable, requiring that patients be heavily sedated. Barbiturates should be avoided if possible. If fentanyl and midazolam (Versed) are inadequate, or if ventilating the patient is difficult, bolus or continuous infusion of ketamine should be considered because it has been shown to be beneficial in certain circumstances. Most patients, at least initially, will also require neuromuscular blockade to optimize ventilation and minimize airway pressures.

Monitoring

Severely asthmatic patients should be monitored for heart rate, blood pressure, O_2 saturation, and arterial pH and PaCO_2 . Continuous blood pressure monitoring is necessary because air-trapping can lead to increased levels of occult PEEP (“auto-PEEP”), an effect that can

impair venous return and decrease cardiac output. Close ventilator monitoring is necessary because increases in inspiratory pressure or decreases in pulmonary compliance may signal worsening bronchoconstriction, mucus plugging, or an extrapleural air leak. Chest films of ventilated asthmatic patients should be obtained daily and immediately with sudden changes in patient condition, due to the risk of pneumothorax and pneumomediastinum. In addition, if the patient is receiving neuromuscular blocking agents, the degree of nerve block should be monitored closely because nondepolarizing agents such as pancuronium, when given with corticosteroids, can cause prolonged paralysis and muscle weakness.

SHOCK

Shock may be defined as failure of the cardiovascular system to deliver critical substrates and to remove toxic metabolites. This failure leads to anaerobic metabolism in cells and ultimately to irreversible cellular damage. Shock has been categorized into a series of recognizable stages: compensated, uncompensated, and irreversible. Patients in compensated shock have relatively normal cardiac output and normal blood pressures, but they have alterations in the microcirculation that increase flow to some organs and reduce flow to others. In infants, compensatory increases in cardiac output are achieved primarily by tachycardia rather than by increases in stroke volume. Heart rates of 190–210/min are common in infants with compensated shock, but heart rates over 220/min raise the possibility of supraventricular tachycardia. In older patients, cardiac contractility (stroke volume) and heart rate increase to improve cardiac output. Blood pressure remains normal initially because of peripheral vasoconstriction and increased systemic vascular resistance. Thus hypotension occurs late and is more characteristic of the uncompensated stage of shock. In the uncompensated stage, the oxygen and nutrient supply to the cells deteriorates fur-

ther with subsequent cellular breakdown and release of toxic substances, causing further redistribution of flow. At this point, the patient is hypotensive, with poor cardiac output.

Shock can be classified by mechanism into hypovolemic (including distributive), cardiogenic, and septic. Often, two or three of these occur together.

A. HYPOVOLEMIC SHOCK

Hypovolemic shock is caused by decreased circulating blood volume or preload. This may result from loss of whole blood or plasma or from fluid loss from the kidney or gut. These patients usually have intact compensatory mechanisms that maintain normal blood pressure by increasing cardiac output and shunting blood away from certain organs. These responses protect blood flow to the heart and brain. Untreated, hypovolemic shock can progress to an irreversible stage. Additionally, a relative hypovolemia occurs when arterial and capillary shunting past tissue beds occurs with an increase in venous capacitance, causing blood to pool—so-called distributive shock. This results from anaphylaxis or vasodilating drugs.

B. CARDIOGENIC SHOCK/FAILURE

Age-dependent differences occur in myocardial physiology that are relevant to therapy. Neonatal myocardium has reduced systolic performance and contractility. The sarcolemma, sarcoplasmic reticulum, and T-tubules are less well developed, resulting in a greater dependency on transsarcolemma Ca^{2+} flux (ie, serum Ca^{2+}) for contraction. A high resting state of myocardial contractility occurs that limits the response to inotropic agents. Relatively minor increases in afterload can result in diminished stroke volume. Diastolic compliance is diminished, and small changes in volume result in large changes in ventricular wall tension. Consequently preload reserve is limited, and maximization of the Frank-Starling curve occurs relatively quickly (10–15 mm Hg in animal models). Aggressive volume resuscitation beyond this is often ineffective and not tolerated. Stroke volume is relatively fixed, and greater increases in cardiac output are seen through increased heart rate.

Central to the understanding of cardiogenic failure are the progressive nature of ventricular dysfunction and the compensatory mechanisms that occur in the presence of excessive hemodynamic demands. Inadequate cardiac output activates the renin-angiotensin system. The consequent sodium and water retention augments intravascular volume and increases cardiac output through increased preload. With progression, cardiac compliance is decreased and preload augmentation via the Frank-Starling mechanism is maximized. Subsequently, small changes in ventricular volume can lead to large increases in ventricular pressure and, there-

fore, pulmonary venous pressure with resultant pulmonary edema. Thus, fluids should be cautiously administered in this setting and should possibly be guided by left atrial or pulmonary artery capillary wedge pressure monitoring. The atrial distention that occurs in the failing heart leads to increased production and release of atrial natriuretic peptide (ANP). Though the function of this molecule is not completely understood, ANP is a vasodilator and augments sodium and water excretion.

Heart failure also induces autonomic nervous system changes, including increased activation of the adrenergic sympathetic system and decreased parasympathetic stimulation. Increased adrenergic tone is associated with elevated circulating norepinephrine levels, increased vasoconstriction, and afterload. These combined factors in turn lead to a cycle of increased afterload, increased energy expenditure, decreased cardiac output, myocyte death, and progressive ventricular dysfunction. The cardiomyocyte effects of prolonged adrenergic stimulation include decreased β -receptors, decreased norepinephrine stores, and, therefore, potentially decreased responses to sympathetic stimulation. Increased cellular concentrations of cyclic adenosine monophosphate and inositol triphosphate lead to increased inward Ca^{2+} flux and at least transient increases in contractility. Subsequently, excessive unremoved calcium impairs lucitropy and augments the propensity for arrhythmias. Blood flow is redistributed away from the splanchnic system, skin, and muscles toward the heart, brain, adrenal glands, and diaphragm. Endothelial dysfunction is common and contributes to the abnormal vascular tone. Endothelin-1 production is elevated in the lung and increases pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). The release of endothelial-derived nitric oxide is also impaired. Circulating arginine vasopressin and tumor necrosis factor alpha (TNF- α) levels have also been reported to be elevated. In the later stages of heart failure, cardiomyocyte hypertrophy, fibroblast hyperplasia, and increases in altered production and accumulation occur in extracellular matrix, leading to impaired myocardial function.

Signs and symptoms of cardiac failure are produced by the body's attempts to compensate for the decreased pump function. The body compensates by activating the sympathetic nervous and renin-angiotensin-aldosterone systems. The child in acute heart failure will present with hypotension and such evidence of poor perfusion as metabolic acidosis and organ dysfunction. In response to the poor output, tachycardia and vasoconstriction will be evident with cool and mottled extremities. Although the extremities are cool, the child's core temperature will be elevated. To improve cardiac output, the body will retain fluid and sodium, resulting in generalized edema. Pul-

monary edema will cause tachypnea, and the rales can be heard on auscultation. The pulmonary edema may be severe enough to compromise respiration and lead to hypoxemia and respiratory failure.

The work-up can be performed at the same time treatment is initiated, and it should include an echocardiogram to evaluate cardiac anatomy and function. Serial echocardiograms may also be helpful to specifically assess the improvement in function with treatment. A chest radiograph can reveal the amount of cardiomegaly, pulmonary edema, and the presence of any effusions. Laboratory tests should include electrolyte measurements and renal and liver function tests.

Management of cardiogenic failure in the pediatric patient is complicated by the varied underlying causes that often require disparate therapies. The factors that influence cardiac output are preload, afterload, contractility, and heart rate and rhythm. An analysis of a low cardiac output state should consider the specific cardiac lesion and should use these factors as a framework for therapy.

Cardiogenic failure results from an imbalance of systemic oxygen delivery and demand. Therapy is aimed at restoring oxygen delivery and reducing demand. Sedation, reduced environmental stress, temperature regulation, supplemental O_2 , red cell transfusion, and augmentation of cardiac output all have roles. The overall goal of increasing cardiac output should include restoring an appropriate sinus rate and rhythm, optimizing preload, augmenting myocardial contractility with minimal increases in myocardial O_2 consumption, and maximizing afterload reduction. If bradycardia is excessive, temporary pacing with transthoracic, transesophageal, or intracardiac methods should be considered. Excessive tachycardia is to be avoided, as it shortens ventricular diastole, leading to a reduction in diastolic filling, shortened diastolic coronary perfusion, and increased myocardial O_2 consumption.

Cardiogenic failure is associated with elevated ventricular filling pressures (> 20 mm Hg). Thus, although increasing preload can result in augmented cardiac output (to a degree), volume should be administered cautiously—the Frank-Starling curve may remain flat with little further improvement possible, occurring at the expense of elevating pulmonary venous pressure with resultant pulmonary edema. Diuretics can be administered to reduce pulmonary edema and to improve pulmonary compliance, the work of breathing, and oxygenation. Contractility can be augmented through inotropic stimulation of myocardial β_1 -receptors (Table 13-8). Dopamine is an α - and β -agonist, which, at lower doses (3–5 $\mu\text{g}/\text{kg}/\text{min}$), improves blood flow to the renal, coronary, and splanchnic beds (type D1 receptor). At higher doses the α -receptor effects predominate, with vasoconstriction increasing SVR and PVR.

Table 13–8. Pharmacologic support of the shock patient.

Drug	Dose	Alpha-Adrenergic Effect ^a	Beta-Adrenergic Effect ^a	Vasodilator Effect	Actions and Advantages	Disadvantages
Dopamine	1–20 µg/kg/min	+ to +++ (dose-related)	+ to +++ (dose-related)	At low doses, renal vasodilation occurs (dopaminergic receptors)	Moderate inotrope, wide and safe dosage range, short half-life.	May cause worsening of pulmonary vasoconstriction
Dobutamine	1–10 µg/kg/min	0	+++		Moderate inotrope, less chronotropic, fewer dysrhythmias than with isoproterenol or epinephrine.	Marked variation among patients
Epinephrine	0.05–1 µg/kg/min	++ to +++ (dose-related)	+++		Significant increases in inotropy, chronotropy, and systemic vascular resistance.	Tachycardia, dysrhythmias, renal ischemia, systemic and pulmonary vascular resistance
Isoproterenol	0.05–1 µg/kg/min	0	+++	Peripheral vasodilation	Significant increase in inotropy and chronotropy. Systemic vascular resistance can drop, and pulmonary vascular resistance should not increase and may decrease.	Significant myocardial oxygen consumption increases, tachycardia, dysrhythmias
Norepinephrine	0.05–1 µg/kg/min	+++	+++		Powerful vasoconstrictor (systemic and pulmonary); rarely used except possibly in patients with very low systemic vascular resistance or in conjunction with vasodilator.	Reduced cardiac output if afterload is too high, renal ischemia
Nitroprusside	0.05–8 µg/kg/min	0	0	Arterial and venous dilation (smooth muscle relaxation)	Decreases systemic and pulmonary vascular resistance, very short-acting. Blood pressure returns to previous levels within 1–10 minutes after infusion is stopped.	Toxicities (thiocyanates and cyanide), increased intracranial pressure and ventilation/perfusion mismatch, methemoglobinemia, increased intracranial pressure
Milrinone	0.25–0.75 µg/kg/min	0	0	Blank	Phosphodiesterase III inhibition. Decreases SVR and PVR, increases myocardial contractility with only mild increase in myocardial O ₂ consumption. Usually used with low-dose dopamine or dobutamine.	

^a0 = no effect, + = small effect, ++ = moderate effect, +++ = potent effect. SVR = systemic vascular resistance; PVR = pulmonary vascular resistance.

Dobutamine is predominately a β -agonist that additionally effects a dose-dependant vasodilatation (β_2 -receptor) and has been shown to shift the ventricular pressure-volume loop toward normal, reducing LV filling pressure and hence pulmonary venous pressure. As first-line pharmacotherapy single agents or in combination, low-dose dopamine and dobutamine are often beneficial by improving contractility without increasing afterload and by limiting chronotropic effect. Isoproterenol is a pure β -agonist that causes significant tachycardia (limiting its utility), increased myocardial O_2 consumption, and systemic and pulmonary arterial vasodilatation. It is useful in instances of associated bradycardia, such as occur in heart transplantation and heart block. Epinephrine is an α - and β -agonist that causes the greatest increase in myocardial O_2 consumption of all inotropes. At a low dose ($< 0.05 \mu\text{g}/\text{kg}/\text{min}$) it increases heart rate and contractility and decreases SVR (β_2 -receptor). At higher doses the α -effects predominate, increasing afterload. Despite these drawbacks, epinephrine can be useful as a second agent in refractory cases. It should be administered in combination with a vasodilator to offset the α -effects. Milrinone ($0.25\text{--}0.75 \mu\text{g}/\text{kg}/\text{min}$) is a newer agent in the class of phosphodiesterase inhibitors. It causes a number of beneficial effects, including a limited increase in myocardial O_2 consumption, decreased SVR and PVR, increased contractility, and improved lusitropy. Theoretically it is the ideal agent and is frequently used as the first-line drug, often in combination with low-dose dopamine or dobutamine.

Afterload reduction is an important additional therapy that increases stroke volume and decreases myocardial O_2 consumption. Agents commonly used are nitroprusside, hydralazine, and the angiotensin-converting enzyme (ACE) inhibitors. Nitroprusside is a rapid-acting IV agent, which is readily titratable and causes venodilation and arteriolar dilation, resulting in decreased SVR and PVR. Venodilation can decrease preload, and volume may therefore need to be coadministered to restore an appropriate preload. Nitroprusside is a useful titratable IV agent to start while planning a transition to a PO agent. Hydralazine is a direct systemic arteriolar dilator of coronary, renal, and splanchnic vessels, which can be given IV or PO. It is less titratable intravenously than nitroprusside, and ACE inhibitors have largely replaced it as a PO agent. ACE inhibitors are now the agents of choice for oral afterload reduction and have been shown to improve survival and functional status in adults. Patients should be switched to ACE inhibitors as soon as indicated. LV afterload is a function of systolic transmural pressure (aortic pressure/intrapleural pressure), and mechanical afterload reduction can be attained by delivering positive airway pressure through mechanical ventilation or through

continuous positive airway pressure/bilevel positive airway pressure (CPAP/BIPAP). This must be taken into account when weaning a patient with significant LV dysfunction from mechanical ventilation. If cardiac output cannot be augmented sufficiently despite aggressive medical therapy, consideration should be given to mechanical circulatory support as a bridge to cardiac transplantation. Such support is provided by ECMO, ventricular access device, or intraaortic balloon pump counterpulsation.

Congenital heart defects pose special concerns. **Aortic stenosis**, for instance, obstructs flow across the LV outflow tract, elevates intraventricular pressure, and increases systolic workload and LV hypertrophy. Due to the outflow tract gradient and hypertrophy, diastolic flow in the coronaries is decreased, which can result in subendocardial ischemia. Dopamine is indicated for inotropic support. Afterload reduction is relatively contraindicated, as it may further compromise coronary flow.

Hypertrophic cardiomyopathy is associated with a hypertrophied nondilated left ventricle, often with dynamic left or biventricular outflow tract obstruction. Coronary abnormalities with luminal compromise are frequent. Systolic function is elevated, ejection fraction is increased, and diastolic dysfunction is evident. Inotropes are contraindicated due to increased dynamic gradient, coronary compromise, and subendocardial ischemia. Preload should be maximized, and pharmacotherapy with β -blockers and calcium channel antagonists is warranted.

Aortic insufficiency is associated with retrograde flow into the left ventricle during diastole. The amount of regurgitation depends in part on the pressure gradient across the aortic valve and on the heart rate. With increasing heart rates, diastole is shortened and regurgitation limited. Therapy should include inotropic support to improve overall cardiac output and aggressive afterload reduction to reduce the regurgitant fraction. Heart rate can be increased with isoproterenol or transesophageal pacing.

In **mitral regurgitation**, blood is forced back into the low-pressure left atrium during systole. The regurgitant fraction depends partly on the relative resistance to flow across the mitral and aortic valves during systole. Therapy should include inotropic support to improve total cardiac output, and aggressive afterload reduction to improve antegrade aortic flow.

Anomalous left coronary artery typically arises from the pulmonary artery. Patients with this disorder exhibit myocardial dysfunction secondary to myocardial ischemia. Pathophysiology includes blood flow from the right coronary artery to the left coronary artery and into the pulmonary artery, resulting in a "steal" phenomenon in the left coronary distribution. Medical

therapy is futile, and urgent surgical correction is indicated. Prior to surgery, limited medical therapy can include inotropic support, although care must be exercised not to reduce pulmonary arterial pressure (and increase steal) or excessively increase myocardial O₂ consumption. Dopamine and milrinone have been used with limited success.

Cardiopulmonary bypass (high/low flow) and deep hypothermic circulatory arrest are frequently required to facilitate surgical correction of congenital defects. These techniques are associated with widespread organ system effects, including increased total body water, transient myocardial dysfunction, gas exchange abnormalities, coagulation abnormalities, and hormonal and stress responses. Impairment in myocardial contractility is predictable 6–12 hours following surgery. The myocardium can be supported with increased preload, inotropes, and afterload reduction. Dopamine and milrinone are often used in combination.

C. SEPTIC SHOCK

Septic shock has components of both cardiogenic and hypovolemic shock. Septic shock is only indirectly caused by microorganisms. Rather, septic shock is the direct result of the production and secretion of inflammatory mediators. Proinflammatory mediators [TNF- α , interleukin (IL)-1, IL-6, IL-8, and platelet-activating factor] are produced and released in excess of the anti-inflammatory mediators (IL-10, glucocorticoids, and catecholamines), resulting in a proinflammatory cascade that initiates a number of pathophysiologic responses.

Septic shock caused by gram-negative organisms appears to be mediated by endotoxins (lipopolysaccharides) and the subsequent release of cytokines (TNF, IL-1, IL-10), eicosanoid products, bradykinin, and endorphins. These agents can directly mediate many of the manifestations of septic shock and also act to amplify the injury by attracting granulocytes and macrophages—cells that cause further cellular injury. Vasodilators (prostaglandin I₂, endorphins) predominate early, causing a drop in systemic vascular resistance. Cardiac output generally is increased to compensate for the decreased systemic vascular resistance. This phase has been described as warm shock, because the skin remains well perfused and warm. As septic shock progresses, the heart is no longer able to maintain such a high output, and vasoconstrictors (thromboxane, leukotrienes, endothelin) predominate, with resultant decreased peripheral perfusion. Extremities become cool, urine output decreases, and oxygen delivery falls.

Shock caused by gram-positive organisms is becoming more common in the PICU. This may be due to use of broad-spectrum empiric antibiotics, the increasing use of long-term intravascular catheters and other

surgically implanted foreign bodies, the changing epidemiology of gram-positive pathogens, and antibiotic resistance among gram-positive organisms. It is important to realize that the pathogenesis of gram-positive septic shock is different from that of gram-negative sepsis. Gram-positive infections most often arise from skin wounds, soft tissues, and catheter sites, rather than the GI and genitourinary sources associated with gram-negative infections. Gram-negative bacteria have an outer membrane composed of endotoxin that plays a key role in the pathogenesis of gram-negative infection, but the cell wall of gram-positive bacteria is embedded with molecules of lipoteichoic acid that are able to mimic some properties of endotoxin. Additionally, gram-positive bacteria make a range of soluble extracellular toxins, including the pyrogenic toxin superantigens of staphylococci and streptococci.

These superantigens are unusual because they do not require previous processing and specific presentation by antigen-presenting cells. These superantigens are able to bind and activate more lymphocytes than conventionally processed antigens. It is hypothesized that in gram-positive septic shock, toxins are released, resulting in a massive lymphocyte activation with a release of T-cell cytokines, which then causes cellular injury and organ failure.

The host response to gram-positive sepsis is also different from that to gram-negative sepsis. Gram-negative endotoxin induces a rapid (1–5 hours) release of proinflammatory cytokines. Gram-positive toxins induce a more delayed response (50–75 hours) dominated by TNF- α and interferon- α .

Other Organ Involvement

Organ dysfunction during and after an episode of shock is common. Systems most often affected include the kidney, the blood coagulation system, the lungs, the CNS, the liver, and the GI tract. The kidney responds to hypotension by increasing plasma renin and angiotensin concentrations, thereby decreasing glomerular filtration rate and urine output. This can progress to damage of the energy-consuming renal parenchyma, causing acute tubular necrosis. Coagulopathies may exist in any type of shock but are especially common in septic shock. They result from the release of mediators that activate the clotting cascade, leading ultimately to a consumptive coagulopathy (ie, disseminated intravascular coagulation). The CNS dysfunction is related to decreased cerebral perfusion pressure and thus to decreased substrate delivery to the brain. Liver dysfunction commonly occurs after shock and may be manifested by increases in liver enzymes and decreased production of clotting factors leading to a bleeding diathesis. GI problems include ileus, bleeding (eg, gas-

tritis, ulcers), and necrosis with sloughing of intestinal mucosa. Evaluation of multiorgan system dysfunction is mandatory in the work-up of shock. Multiple organ system failure secondary to shock greatly increases the mortality of the disease.

Monitoring

Both noninvasive and invasive monitoring of the patient in shock provides information on the severity, progression, and response to treatment. Extremely valuable information can be derived from examination of the cardiovascular, mucocutaneous, musculoskeletal, renal, and central nervous systems.

A. CLINICAL FINDINGS

1. Cardiovascular system—Tachycardia is not always present even when hypotension is profound. Hypotension occurs late in pediatric shock (median systolic blood pressure for a child older than age 2 years can be estimated by adding 90 mm Hg to twice the age in years). An important part of the cardiovascular examination is simultaneous palpation of distal and proximal pulses. An increase in the amplitude difference of pulses between proximal arteries (carotid, brachial, femoral) and distal arteries (radial, posterior tibial, dorsalis pedis) can be palpated in early shock and reflects increased systemic vascular resistance. Distal pulses may be thready or absent even in the presence of normal blood pressure because of poor stroke volume compensated by tachycardia and increased systemic vascular resistance. In uncompensated shock, hypotension is present and proximal pulses are also diminished. Early shock causes peripheral cutaneous vasoconstriction, which preserves flow to vital organs.

2. Skin—Because of peripheral vasoconstriction, the skin is gray or ashen in newborns and pale and cold in older patients. Capillary refilling after blanching is slow (> 3 seconds). Mottling of the skin may also be observed.

3. Musculoskeletal system—Decreased oxygen delivery to the musculoskeletal system produces hypotonia. Decreased spontaneous motor activity, flaccidity, and prostration are observed.

4. Urinary output—Urine output is directly proportionate to renal blood flow and the glomerular filtration rate and therefore is a good reflection of cardiac output. Catheterization of the bladder is necessary to give accurate and continuous information. (Normal urine output is > 1 mL/kg/h; outputs < 0.5 mL/kg/h are considered significantly decreased.)

5. Central nervous system—The patient's level of consciousness reflects the adequacy of cortical perfusion. When cortical perfusion is severely impaired, the infant or child fails to respond first to verbal stimuli,

then to light touch, and finally to pain. Lack of motor response and failure to cry in response to venipuncture or lumbar puncture should alert the clinician to the severity of the situation. In uncompensated shock in the presence of hypotension, brainstem perfusion may be decreased. Poor thalamic perfusion can result in loss of sympathetic tone. Finally, poor medullary flow produces irregular respirations followed by gasping, apnea, and respiratory arrest.

B. INVASIVE MONITORING

Patients with poor cardiac output who are hypovolemic often need invasive monitoring for diagnostic and therapeutic reasons. Arterial catheters give constant blood pressure readings, and, to an experienced interpreter, the shape of the waveform is helpful in evaluating cardiac output. CVP monitoring gives useful information about relative changes in volume status as therapy is given. CVP monitoring does not provide information about absolute volume status because intravascular volume, which is considered preload, is inferred most accurately from LV end-diastolic pressures. Therefore, intravascular volume is assessed more accurately by monitoring pulmonary capillary wedge pressure or left atrial pressure. Measurements of pulmonary capillary wedge pressure can be obtained with a pulmonary artery catheter. The pulmonary artery catheter provides additional valuable information on volume and cardiac status (Table 13–9) but is associated with a higher complication rate than CVP lines. Placement of a pulmonary artery catheter should be considered for patients with fluid-refractory (= 40–60 mL/kg) and dopamine-resistant shock. Measurements of arterial and mixed venous oxygen saturations, along with cardiac output data, are useful in calculating oxygen delivery, consumption, and extraction. Oxygen consumption is frequently reduced long before hypotension is present. With the use of a pulmonary artery catheter, the effects of manipulating hemoglobin, oxygen saturation, and cardiac output (the determinants of oxygen consumption and delivery) can be followed in attempts to achieve independence of oxygen delivery and consumption. Patients receiving significant inotropic or ventilatory support may also benefit from the placement of a pulmonary artery catheter.

Treatment

Early stabilization of hemodynamics with fluid and inotropes is similar in either gram-positive or gram-negative sepsis.

A. FLUID RESUSCITATION

Fluid infusion should start with 20-mL/kg boluses titrated to clinical monitors of cardiac output, heart

Table 13–9. Hemodynamic parameters.^a

Parameter	Formula	Normal Values	Units
Cardiac output	CO = HR × SV	Wide age-dependent range	L/min
Cardiac index	CI = CO/BSA	3.5–5.5	L/min/m ²
Stroke index	SI = SV/BSA	30–60	mL/m ²
Systemic vascular resistance	$SVR = 79.9 \frac{(MAP - CVP)}{CI}$	800–1600	dyne s/cm ⁻⁵ /m ²
Pulmonary vascular resistance	$PVR = 79.9 \frac{(MPAP - PCWP)}{CI}$	80–240	dyne s/cm ⁻⁵ /m ²

^aFormulas and normals from Katz RW, Pollack M, Weibley R: Pulmonary artery catheterization in pediatric intensive care. *Adv Pediatr* 1983;30:169.

HR = heart rate, SV = stroke volume, BSA = body surface area, MAP = mean arterial pressure, CVP = central venous pressure, MPAP = mean pulmonary artery pressure, PCWP = pulmonary capillary wedge pressure.

rate, urine output, capillary refill, and level of consciousness. Patients who do not respond rapidly to the initial fluid bolus should be considered for invasive hemodynamic monitoring (placement of a CVP, arterial line, and possibly pulmonary artery catheter).

Initially, most patients tolerate crystalloid (salt solution), which is readily available and inexpensive. However, 4 hours after a crystalloid infusion, only 20% of the solution remains in the intravascular space. Patients with serious capillary leaks and ongoing plasma losses (eg, burn cases) should initially receive crystalloid, because in these cases colloid (protein and salt solution) leaks into the interstitium. The protein draws intravascular fluid into the interstitium, thus increasing ongoing losses. Patients with hypoalbuminemia or those with intact capillaries who need to retain volume in the intravascular space (eg, patients at risk for cerebral edema) probably benefit from colloid infusions. Experience with dextran (a starch compound dissolved in salt solution) is limited. Patients with normal heart function tolerate increased volume better than those with poor function. Additionally, large volumes of fluid for acute stabilization in children with shock have not been shown to increase the incidence of ARDS or cerebral edema. Increased fluid requirements may persist for several days.

B. PHARMACOTHERAPY

Empiric antibiotics are chosen according to the most likely cause of infection. Inotropic support should be considered for patients who continue to have clinical evidence of decreased cardiac output after receiving 60 mL/kg of fluid resuscitation. Dopamine remains the first-line vasopressor. Dopamine causes vasoconstriction by stimulating the release of norepinephrine from sympathetic nerves. Infants younger than 6 months of

age may not have fully developed sympathetic vesicles and may therefore be resistant to dopamine. Dopamine can increase renal, coronary, and cerebral blood flow by its action on β -receptors and dopaminergic receptors. At higher doses (15 mg/kg/min), α -vasoconstrictor actions predominate. Dobutamine may be added to dopamine; however, children younger than 12 months of age may be less responsive. Epinephrine should be used for dopamine-refractory shock and is often considered first for patients in cold septic shock. Norepinephrine, and in some instances phenylephrine, can be used to increase peripheral vasoconstriction in patients whose perfusing pressure cannot be increased by dopamine and epinephrine (see Table 13–8). Hypocalcemia is often a contributor to cardiac dysfunction in shock. Calcium replacement should be given to normalize ionized calcium levels.

The role of inflammatory mediators in the pathogenesis of septic shock continues to be defined. Drugs that block some of these mediators appear to be beneficial when given early to animals. Human studies of these same blockers have failed to demonstrate a clear benefit. The differences in pathogenesis and host response to gram-positive or gram-negative sepsis may explain some of the differential responsiveness to anti-inflammatory agents seen in past clinical trials. Additionally, the discrepancies may result from low-affinity binding by these antibodies. The molecular mechanisms by which lipopolysaccharide activates cells are becoming better understood, which may assist in the development of more effective therapies. Modulation of T cells (with glucocorticoids, cyclosporine, and antibodies directed at cytokines) in models of superantigen-induced injury have proven beneficial, but remain experimental. Ibuprofen, because of its ability to block cyclooxygenase (cyclooxygenase metabolites are

potent modulators of cell function), has shown a trend toward stabilizing patients with septic shock, although not enough evidence is yet available to recommend for or against the use of ibuprofen for septic shock. Recently, excess production of nitric oxide (NO) has been demonstrated to contribute to the hypotension and poor perfusion occurring in shock. Analogs of L-arginine (L-NMA) have been used to block the production of NO in animal models of septic shock with some improvement in survival. Anecdotal use in adults with severe septic shock has demonstrated some success.

Protein C is a primary regulator of coagulation, fibrinolysis, and coagulation-induced inflammation. Deficits in protein C activation correlate with morbidity and mortality in septic shock. Deficiencies of protein C have been found in children and adults with sepsis. Recombinant activated protein C reduced mortality rates in an animal model of sepsis. A large randomized, double-blind, placebo-controlled trial of recombinant activated protein C in adults with severe sepsis showed a significant reduction in mortality rates in patients treated with activated protein C. A similarly designed clinical trial of activated protein C in pediatric patients with severe sepsis is ongoing.

Corticosteroids, by virtue of their action on many mediators, are thought to play a role in shock and—based on positive results in animal models of septic shock—have been advocated for treatment of shock in humans. Children with meningococcal meningitis and AIDS patients with pneumocystis pneumonia have shown improvement in oxygenation and a trend toward improved survival when treated with corticosteroids. The use of hydrocortisone in adults with relative adrenal insufficiency and septic shock was shown to improve short-term outcome. Importantly, a low aldosterone state may be more common in children with septic shock than previously thought. Hydrocortisone (50 mg/kg) should be considered for children at risk for adrenal insufficiency—those with purpura fulminans or pituitary or adrenal abnormalities, those receiving steroids for chronic illness, and those with septic shock and multiorgan system dysfunction not responding well to traditional inotropic therapy.

ECMO has been considered in the treatment of shock in patients with recoverable cardiac and pulmonary function who require both pulmonary and cardiac support.

INDICATIONS FOR CENTRAL VENOUS & ARTERIAL CANNULATION

Placement of catheters into the central venous or arterial circulation may be justified for continuous assessment of intravascular volume or cardiac function; blood drawing for lab work; or administration of volume, drugs, or hyperalimentation. One should always weigh the risks of bleeding, infection, and clotting against the expected benefits before placing any indwelling catheter.

General Rules for Equipment Selection & Technique

1. Set up and examine all equipment needed before getting started. Use of a limited number of kits and equipment will provide greater consistency and success.
2. Apply EMLA cream (eutectic mixture of lidocaine 2.5% and prilocaine 2.5%) to the area of puncture (45 minutes before the procedure) or infiltrate with local anesthetic before prepping the skin.

3. The remainder of the procedure should occur under aseptic technique (including gown, mask, hair cover for operator and assistant).
4. Sterilize and drape the area around the point of entry.
5. When searching for the vessel, make straight passes while maintaining slight negative pressure. Advance and withdraw the needle at the same speed. Frequently, the blood return will occur during withdrawal.
6. Once there is free flow of venous blood into the syringe, remove the syringe without moving the needle and, if using the Seldinger technique, pass the J wire through the needle. When appropriate, watch the electrocardiogram for arrhythmias, because they frequently occur when the J wire touches the right side of the heart.
7. Withdraw the needle over the J wire and clean the wire of blood.
8. Make a nick with a No. 11 blade at the point where the J wire enters the skin. Pass the introducer or the intravascular catheter (or both) over the J wire.
9. With the catheters in place, remove the wire along with the introducer.
10. Check to make sure that blood can be drawn easily through the new line.
11. Verify the position of the line on radiograph.

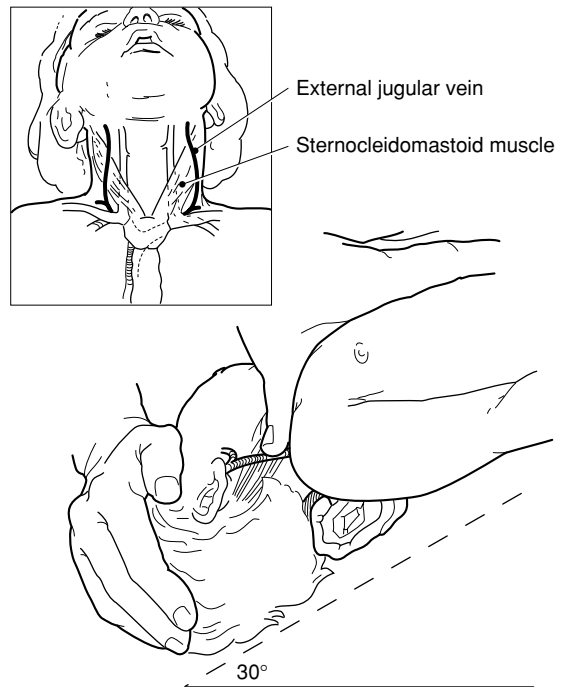

Figure 13-2. External jugular vein technique. (Reproduced, with permission, from Chameides L: *Textbook of Pediatric Advanced Life Support*. American Heart Association, 1988.)

Points of Entry for Venous Line Placement

A. EXTERNAL JUGULAR VEIN

Place a soft cloth roll beneath the patient's shoulder and turn the head to the contralateral side (Figure 13-2). The Valsalva maneuver, Trendelenburg position, and occlusion of the vessel at the clavicular level are ways of temporarily increasing jugular distention and visibility. To overcome the problems of this vessel's mobility and thick wall, apply cephalic retraction of the skin over the vessel superior to the point of needle entry. Maintain gentle negative pressure in the syringe attached to the needle as it is advanced toward the vessel. Needle entry into the vessel lumen is usually signaled by a change in resistance followed by appearance of venous blood in the hub of the needle. Remove the syringe without moving the needle and pass a soft J wire into the vessel lumen. Remove the needle and pass the central line over the J wire.

B. INTERNAL JUGULAR VEIN

Once the patient has been prepped, draped, and positioned as shown in Figure 13-3, feel for the trachea halfway between the angle of the jaw and the supraster-

nal notch and then feel lateral to the trachea for the carotid pulse. Just lateral to the carotid pulse, at a 30-degree angle from horizontal, insert a finder needle (25-gauge), aiming between the ipsilateral nipple and shoulder. Once venous return is established, remove the finder needle and repeat the procedure with the appropriate-size larger needle.

C. SUBCLAVIAN VEIN

After the patient has been prepped, draped, and positioned (Figure 13-4), move the needle flat along the chest, entering along the inferior edge of the clavicle just lateral to the midclavicular line and aiming for the suprasternal notch. Once venous return is established, use the Seldinger technique.

D. FEMORAL VEIN

With the patient's leg slightly abducted (Figure 13-5), find the femoral artery 3-4 cm below the inguinal ligament. The femoral vein is just medial and parallel to the femoral artery. Insert the needle at a 30- to 45-degree angle. Once venous return is established, use the Seldinger technique.

B

Figure 13–5. Femoral vein. **A:** Anatomy. **B:** Technique. (Reproduced, with permission, from Chameides L: *Textbook of Pediatric Advanced Life Support*. American Heart Association, 1988.)

E. ANTECUBITAL VEIN

Peripherally inserted catheter (PIC) lines (2.8–4 Fr) are long, soft, Silastic, styletated catheters most commonly threaded from an antecubital vessel to the right atrium. These lines are not difficult to insert and are easy to dress and keep clean. They are suited for long-term use because they are tolerable for the patient, good for infusion of hyperalimentation and drugs, and less thrombogenic. In general, they are not suitable for obtaining blood for laboratory analysis.

General Rules for Cannulation of the Arterial System

The Seldinger technique can be applied for arterial tree cannulation as well. Most arteries can be cannulated percutaneously.

1. Puncture the skin at the insertion site to eliminate any drag or resistance on the catheter advancement.
2. Insert the cannula at a 30-degree angle to the skin surface, advancing at a slow rate toward the arterial pulse. Watch the hub of the cannula for a flash of arterial blood.
3. When arterial flash is seen, lower the catheter to a 10-degree angle with the surface of the skin and advance the catheter into the lumen of the artery. If successful, pulsatile arterial flow will continue into the catheter.
4. Hold the catheter while removing the needle stylet. Arterial blood will pulse out of the catheter if the tip is in the arterial lumen.
5. Advance the catheter into the lumen; attach a syringe containing normal saline with 1 unit/mL of heparin; aspirate to make certain that there are no bubbles; and then gently flush the catheter.
6. If arterial flow into the needle stylet stops during catheter advancement, advance this unit an additional centimeter. Remove the needle stylet and place it on a sterile surface. Pull the catheter out slowly. When the tip of the catheter flips into the arterial lumen, the pulsatile arterial blood flow is seen. Rotate the catheter to ensure that the catheter is free within the vessel lumen, then advance the remainder of the catheter length into the vessel.
7. Suture the catheter in place while ensuring that the arterial trace is not damped.
8. Dress the insertion site with sterile gauze, and tape it to the skin.

Points of Entry for Arterial Line Placement

Always consider whether collateral arterial blood is flowing to the structures distal to the insertion point. The Allen test must be done prior to radial or ulnar artery cannulation.

Arterial sites, listed in order of preference, include:

1. Radial artery (nondominant arm first)
2. Femoral artery (morbidity is the same as for the radial artery beyond the newborn period)
3. Posterior tibial artery
4. Dorsalis pedis artery

5. Ulnar artery (if distal radial filling is present in that hand)
6. Axillary artery
7. Brachial artery (poor collateral flow, used only during cardiac surgery in newborn-sized patients with arterial access limitations)

Final Considerations

1. Patient benefit should outweigh any risks from central venous or arterial cannulation.
2. Coagulation status of the patient at the time of placement and throughout the time of use must be considered, because deep venous and arterial thrombus formation is partially related to the patient's coagulation status.
3. The incidence of catheter colonization and infection increases if central venous and arterial lines are left in for more than 6 days.

BRAIN INJURY/CEREBRAL EDEMA

Intracranial hypertension is a common feature of many illnesses treated in the PICU (Table 13–10). The early signs and symptoms of intracranial hypertension (Table 13–11) tend to be nonspecific. The classic Cushing triad of bradycardia, hypertension, and apnea occurs late and is often incomplete in children.

Accurate assessment and treatment of elevations in ICP requires an understanding of the basic pathophysiology of intracranial hypertension, as well as the current evidence supporting the various treatment options. Most of our current understanding and approach to treatment is based on studies of patients with traumatic brain injuries. Whether those concepts are directly relevant to the pathophysiologic processes involved in more global CNS injuries, such as hypoxia and metabolic disorders, remains a matter of debate.

Within the constraints of a closed skull, an enlargement of brain tissue, an increased volume of cerebrospinal fluid (CSF), or an increased volume of blood (or the presence of a space-occupying lesion such as a tumor or an abscess) will reduce the size of the other compartments or increase pressure. The factors contributing to intracranial hypertension can be understood by considering each of these three primary compartments.

The brain occupies about 80% of the volume of the skull. Apart from solid tumors, increases in the brain compartment are generally a result of cerebral edema. Cerebral edema can be divided into three forms: vasogenic, hydrostatic, and cytotoxic. *Vasogenic* edema occurs in areas of inflamed tissue characterized by increased capillary permeability, and is most typical

Table 13–11. Signs and symptoms of intracranial hypertension in children.

around CNS tumors, abscesses, and infarcts. This form of edema is thought to be at least partially responsive to corticosteroid therapy. *Hydrostatic*, or interstitial, edema is a result of elevated CSF hydrostatic pressures. It occurs primarily in lesions associated with obstruction to CSF flow, and in a typical periventricular distribution. This form of edema is best treated by CSF drainage. The third form of cerebral edema, *cytotoxic* edema, is the most common of the three forms seen in the PICU and is, unfortunately, the least easily treated. Cytotoxic edema occurs as a result of direct injury to brain cells, often leading to irreversible cell swelling and death. This form of cerebral edema is typical of traumatic brain injuries as well as hypoxic-ischemic injuries and metabolic disease.

CSF occupies an estimated 10% of the intracranial space. Intracranial hypertension due primarily to increases in CSF volume (eg, hydrocephalus, primary or secondary) is generally easily diagnosed by CT scan and easily treated with appropriate drainage and shunting.

Cerebral blood volume comprises the final 10% of the intracranial space. Changes in cerebral blood volume generally result from alterations in vascular diameter in response to local metabolic demands or to local vascular pressures—so-called metabolic and pressure autoregulation. These physiologic responses are the means by which the CNS circulation regulates and maintains adequate blood flow to the brain. Given the difficulty in effectively treating cytotoxic brain swelling and the relative rarity of uncomplicated CSF obstructive lesions in the PICU, most of the current therapies aimed at controlling intracranial hypertension rely on altering cerebral blood volume.

Several factors interact to control cerebral blood volume via the autoregulatory responses of the cerebral vasculature. The rate of cerebral metabolism is an important

determinant of cerebral blood volume. High metabolic rates lead to vasodilation and increased blood volume, whereas low metabolic rates allow the vessels to constrict and reduce blood flow and blood volume. Partial pressure of carbon dioxide is another important determinant of cerebral blood volume, as elevations in blood PCO_2 lead to cerebral vasodilation and decreases in PCO_2 lead to vasoconstriction. Finally, cerebral blood volume is linked to cerebral blood flow through the phenomenon of pressure autoregulation. As shown in Figure 13–6, at low systolic blood pressures, the cerebral vessels are maximally dilated and blood flow is only increased by increasing blood pressure. Within the range of autoregulation, the cerebral vessels attempt to maintain a constant flow rate over a range of blood pressures; increased blood pressure results in vasoconstriction, in turn reducing cerebral blood volume. Once the cerebral vessels are maximally constricted, continued increases in pressure may further increase cerebral blood flow and volume.

Treatments for intracranial hypertension are largely derived from experience with traumatic brain injury. An important concept in this regard is that of a “primary” as opposed to a “secondary” brain injury. In this context, primary injury refers to direct damage to brain tissue resulting from the original insult to the CNS, such as physical damage from trauma. This injury is complete before the patient reaches the health care system. As the injured brain swells due to cytotoxic edema, intracranial hypertension develops, potentially limiting cerebral blood flow to portions of the brain and leading to extension of the initial injury (ie, secondary injury). Medical treatment of the patient with intracranial hypertension aims to prevent or reduce secondary injuries.

The primary goal of treatment is to optimize perfusion of areas of the brain that are salvageable. This can

Figure 13–6. Pressure autoregulation in the cerebral vasculature.

be accomplished by reducing ICP and by ensuring adequate perfusion. Rational guidance of treatment requires invasive monitoring so that it can be effectively titrated. Although a complete discussion of the indications for ICP monitoring is beyond the scope of this chapter, the topic can be briefly summarized with the suggestion that an ICP monitor be used for patients at significant risk for intracranial hypertension, in whom the treatment of elevated CNS pressures is planned. Monitoring other parameters of CNS oxygen delivery (ie, blood pressure, ABGs, intravascular volume) generally mandates the placement of arterial and central venous catheters. Little evidence exists to support the utility of ICP-directed therapies in conditions associated with global CNS injuries (eg, anoxic brain injuries).

Maintenance of adequate cardiac output and oxygen delivery to the CNS is critical in treating patients with intracranial hypertension. Studies in both adult and pediatric head injury patients show that even a single episode of hypotension or arterial hypoxemia is associated with a marked increase in mortality rates. Although studies have not delineated clear age-appropriate thresholds for blood pressure and arterial PO_2 in this setting, a rational starting point for therapy would seem to be maintenance of an adequate circulating blood volume, a blood pressure at least well within the normal range for age, and an arterial PO_2 of at least 60 mm Hg. Hypotension and hypoxemia should be treated urgently and aggressively.

In general, the threshold at which treatment for intracranial hypertension should be started is in the range of 15 to 20 cm H_2O pressure. Above this pressure, the compliance of the skull worsens dramatically (Figure 13-7), and very minor increases in intracranial contents lead to large increases in ICP. Initial therapy for intracranial hypertension should always consist of secur-

ing the airway and providing adequate sedation. Additional measures would include the removal of any mass lesions (eg, tumors, abscesses, hematomas) and adequate ventricular drainage. Further efforts are then largely directed at reducing cerebral blood volume.

Osmotic diuretics such as mannitol are often used to treat intracranial hypertension. They are thought to act first by decreasing blood viscosity, allowing for increased flow and subsequent autoregulatory vasoconstriction. The osmotic effects on the cells and interstitium of the brain prolong the reduction in ICP. Although mannitol has never been subjected to a placebo-controlled trial, it has been shown to lead to better outcomes than barbiturate therapy in patients with refractory ICP elevations. Current guidelines suggest the use of mannitol in doses of 0.25 to 0.5 g/kg for intracranial hypertension unresponsive to sedation. Renal failure due to acute tubular necrosis can be a treatment-limiting side effect, particularly if serum osmolarity is allowed to rise above 320 and intravascular volume depletion occurs.

Hyperventilation—long a mainstay in the treatment of intracranial hypertension—is controversial. Although acutely effective in causing cerebral vasoconstriction, hyperventilation leads to much larger decreases in blood flow than in blood volume, such that hyperventilation to the point necessary to control ICP may actually compromise CNS perfusion and lead to worsened secondary injury. This concept has been confirmed by studies showing worse outcomes in head-injured patients consistently hyperventilated to a PCO_2 of 25 mm Hg or less. Current guidelines suggest that moderate hyperventilation (PCO_2 of 30–35 mm Hg) may be used for mild to moderate intracranial hypertension but that extreme hyperventilation ($PCO_2 < 30$ mm Hg) should be reserved for patients with ICP

Figure 13-7. Compliance curve of the skull with changing volume of intracranial contents.

elevations unresponsive to other measures, including sedation, paralysis, ventricular drainage, and osmotic diuretics. Due to the risks of worsened CNS ischemia, monitoring cerebral perfusion by blood flow studies or jugular bulb saturation is recommended for patients undergoing extreme hyperventilation.

The use of barbiturates in this setting is based on their suppression of cerebral metabolism and the subsequent metabolic autoregulation effects on cerebral blood volume. Although effective in many instances for ICP elevations, these agents are potent cardiac depressants, and their use often leads to hypotension, necessitating the use of a pressor to maintain perfusion. In addition, plasma barbiturate levels correlate poorly with effect on ICP, suggesting that monitoring of CNS electrical activity by electroencephalography (EEG) is necessary to accurately titrate the use of these agents. Current guidelines suggest the use of barbiturates for treating intracranial hypertension refractory to sedation, paralysis, ventricular drainage, and osmotic diuretics.

Another important concept in the management of intracranial hypertension is that of the cerebral perfusion pressure (CPP). The CPP is the driving pressure across the cerebral circulation and is defined as mean airway pressure – CVP (or ICP, whichever is higher). Some authors have suggested that careful attention to maintenance of a supranormal cerebral perfusion pressure may lead to better outcomes for head-injured patients. Although there are no well-controlled trials to draw from (particularly for pediatric patients), current guidelines suggest that maintenance of a “normal” CPP for age (50–70 mm Hg) is a valid secondary goal of treatment, as long as it is included in a plan to use the other ICP-directed therapies discussed earlier.

A suggested treatment algorithm for patients with documented intracranial hypertension is presented in Figure 13–8. As mentioned earlier, this algorithm represents the current best evidence for the management of intracranial hypertension. The information is largely drawn from experience with traumatic brain injuries, and the direct applicability of these concepts to other illnesses associated with intracranial hypertension remains unclear.

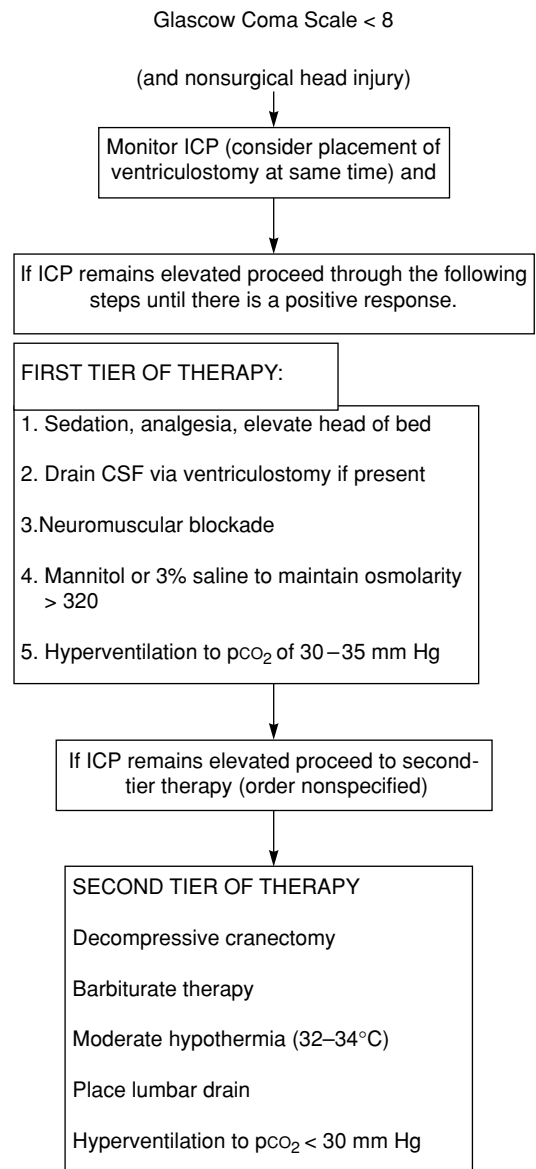

Figure 13–8. Proposed treatment algorithm for intracranial hypertension in head injury. JvO₂ = jugular venous oxygen saturation.

ETHICAL DELIBERATION AND END-OF-LIFE CARE IN THE PICU

Bioethics Consultation in the PICU

Advances in critical care medicine give PICU practitioners the ability to prolong life without being able to ensure a reasonable quality of life. Health care professionals in this setting are often called on to help patients and families wrestle with questions of medical futility. As conflict surrounding care and decision making has arisen, the introduction of ethics consultation in the ICU setting has served to improve the process by helping to identify, analyze, and resolve ethical problems. Ethics consultation can independently clarify views and allow the health care team, patient, and family to make decisions that respect patient autonomy and promote maximum benefit and minimal harm to the patient.

Managed Withdrawal of Treatment

With increasing frequency, PICU deaths are predictable and result from the withholding or withdrawing of life-sustaining medical therapy (LSMT). Discussions with patients and families regarding the decision to limit resuscitation or to withdraw LSMT should respect the following basic principles:

- Deliberations begin with a clear statement that the patient's good is the goal.
- With the assistance of the health care team, the patient and family can make reasonable decisions about limitation or withdrawal of LSMT based on goals of care for the patient.
- The burden of continued life (pain and suffering) should outweigh any potential benefit from continued therapy.
- Discussions with the patient and family are conducted by experienced personnel with the ability to communicate in a clear and compassionate manner at an appropriate time and place.

- It should be emphasized that decisions are not irrevocable; if at any time the family or health care providers wish to reconsider the decision, full medical therapy should be reinstated until the situation is clarified.

Palliative Care

Helping a patient experience a dignified and pain-free death is one of the many unique challenges facing caregivers in the PICU. Pediatric death is characterized by its relative infrequency, by the prognostic uncertainties of many pediatric illnesses, and by the fine line between congenital disorder and incurable disease. When a predictable early death is likely, intensivists are often called on to care for the patient and family during the final days and hours of the patient's life.

In the past several years, palliative medicine has developed as a specialized field of practice to address the needs of dying children. The practice of providing supportive care at end-of-life in pediatrics is fundamentally different from that in adult medicine. In-hospital deaths in pediatrics encompass a more heterogeneous patient population with developmental issues and family dynamics that complicate the process.

Once the inclusive decision is made to limit or withdraw LSMT, a palliative care plan should be agreed on and instituted. The plan should address the following basic principles:

- Adequate pain control and sedation
- Provision of warmth and cleanliness
- Nutrition
- Ongoing patient and family support

The decision to withhold or withdraw LSMT from a pediatric patient does not suggest a plan to hasten the death. The goal of palliative care remains optimization of the patient's and family's experience prior to and following the death.

Tissue & Organ Donation

Organ transplantation has become standard therapy. Although the demand for tissue and solid organs has increased, donations have remained largely unchanged. The prospect of organ or tissue donation should be considered with all patients dying in the PICU. To be a solid organ donor, the patient must be clinically brain dead and have no conditions contraindicating donation. With patients from whom life-support must be withdrawn, tissue (heart valves, corneas, skin, bone) can be obtained after cardiac death. The Required Request Law mandates that health care professionals approach all donor-eligible families to inquire about organ procurement. The decision to donate must be made free of

coercion, with informed consent, and without financial incentive.

Brain Death (See Chapter 23.)

The development of criteria and expertise in the clinical brain death exam is borne out of the demand for solid organs from patients still receiving LSMT. Currently, the diagnosis of brain death is based on national guidelines that render some clarity and standardization to this critical task.

Clinical Brain Death Exam

Establish the cause of the disease or injury and exclude potentially reversible syndromes that may produce signs similar to brain death. Also establish the following:

- Coexistence of coma and apnea^a (“apnea test” – 3 minutes with $PCO_2 > 60$ mm Hg)
- Absence of brainstem function
- Normal blood pressure and temperature
- Flaccid muscle tone, no spontaneous movements
- Exam consistent throughout observation period

Recommended observation periods for children of the following ages:

- Seven days to 2 months old—Two exams over 48 hours; with EEG
- Two months to 1 year—Two exams over 24 hours; with EEG
- Over 1 year—Two exams over 12 to 24 hours

NUTRITIONAL SUPPORT OF THE CRITICALLY ILL CHILD

Metabolic and Physiologic Responses

When severely ill pediatric patients are admitted to the intensive care unit, the initial therapy is directed at the primary or underlying problem and at providing cardiorespiratory and hemodynamic support. Although this management is critical to sustaining life in these patients, provision of adequate nutritional support is often overlooked early in the course of therapy. As increasing evidence demonstrates that nutritional status and support affect the morbidity and mortality of critically ill patients, it is vital that this aspect of care be addressed early in the hospital course.

Trauma, surgery, burns, and sepsis impose metabolic and physiologic disturbances that vary in degree, but have many similarities. The insult triggers the afferent limb of the neurophysiologic reflex, which is composed of pain and neurosensory pathways. In response, the efferent limb consisting of neurologic and endocrine pathways, increases autonomic sympathetic activity with norepinephrine and epinephrine secretions and increases pituitary release of a host of hormones including adrenocorticotropic hormone (ACTH), growth hormone (GH), and antidiuretic hormone (ADH). Release of catecholamines inhibits insulin secretion and activity, and stimulates glucagon and ACTH production. ACTH and ADH increase corticosteroid release, inhibit insulin activity, and increase aldosterone. The overall effect is to direct an end-organ increase in metabolic rate and to provide increased substrate availability for energy use (Table 13–12). In addition, the body has a cellular response to tissue injury. Cells migrate to the damaged area to facilitate wound healing and aid in infection control with the release of inflammatory mediators. These cells are mainly dependent on glucose for their energy source, which is an important reason the hypermetabolic state is necessary. These events initiate a hypermetabolic response that influences the mobilization and use of nutrients as substrates. Although all substrates undergo increased use, the fraction of calories derived from glucose is reduced, and the

^aCerebral angiography, radionuclide scanning, or transcranial Doppler ultrasonography can be used to assess brain function if apnea testing cannot be performed or if there is need for corroborative studies.

Table 13–12. Metabolic and physiologic responses to severe illness.**Physiologic****Cardiovascular**

- Increased cardiac output
- Peripheral vasodilatation and capillary leak
- Expansion of vascular compartment

Pulmonary

- Increased minute ventilation
- Ventilation/perfusion mismatch
- Inefficient gas exchange
- Increased carbon dioxide responsiveness

Skeletal muscle

- Easier fatigability
- Slower relaxation
- Altered force-frequency pattern

Renal

- Salt and water retention
- Impaired concentrating ability

Metabolic**Hormone and hormone-like levels**

- Increased insulin
- Increased glucocorticoids
- Increased catecholamines
- Increased interleukin-1
- Increased tumor necrosis factor

Carbohydrate metabolism

- Increased blood glucose
- Increased gluconeogenesis
- Increased glucose turnover
- Glucose intolerance

Fat metabolism

- Increased lipid turnover and utilization
- Insuppressible lipolysis
- Decreased ketogenesis

Protein metabolism

- Increased muscle protein catabolism
- Increased muscle branched-chain amino acid oxidation
- Increased serum amino acids
- Increased mitogen losses

fraction derived from protein and lipid breakdown is increased.

Hyperglycemia and glucose intolerance are characteristic traits of the hypermetabolic state. Although glucose use is increased, serum glucose levels are elevated, reflecting neuroendocrine stimulation of glycogenolysis and gluconeogenesis. Gluconeogenesis occurs primarily from lactate, alanine, glutamine, and other amino acids derived from muscle breakdown and from glycerol derived from lipolysis. The hepatic production of glucose is increased, and fails to respond to increased plasma concentrations of glucose or insulin when these sub-

stances are infused intravenously. Hyperglycemia and secondary hyperinsulinemia also inhibit ketosis despite the increased rate of lipolysis. The hyperglycemia does, however, maintain glucose supply to the brain. An elevated glucagon/insulin ratio and increased secretion and plasma concentrations of catecholamines produce relative peripheral insulin resistance. Inefficient glucose and fatty acid uptakes are inadequate to meet increased energy needs, leading to increased oxidation of branched-chain amino acids. Because branched-chain amino acids are essential amino acids, their oxidation depletes a valuable pool of precursors for protein synthesis. Administration of excess glucose can lead to hyperosmolar complications, excess energy expenditure, increased CO₂ production, cholestasis, and fatty infiltration of the liver.

Lipids are the major source of energy used during periods of stress starvation. Thus, lipolysis is increased and lipogenesis is decreased despite high levels of glucose and insulin. During stress starvation, peripheral tissues, such as skeletal muscle, myocardium, and respiratory muscles are able to use lipids as their primary energy source. Turnover of medium- and long-chain fatty acids is increased, although the clearance rate of long-chain fatty acid and triglycerides is reduced, primarily through a reduction in peripheral lipoprotein lipase activity that is inhibited by TNF. If excess lipids are administered, complications such as hyperlipidemia, bacteremia, and suppression of *in vitro* tests of polymorphonuclear and lymphocyte function may occur.

Protein catabolism is the hallmark of the metabolic stress response. Although the rate of protein synthesis is actually increased in the hypermetabolic state, it is significantly reduced compared with the rate of protein breakdown. Protein is broken down mainly to provide carbon skeletons for use in gluconeogenesis, but amino acids are also used to support the cellular inflammatory response, the hepatic synthesis of acute-phase reactant proteins, and wound healing. Thus, the contribution of protein to total caloric expenditure increases from 10% in normal children to 15–20% in critically ill children. The discrepancy between protein catabolism and synthesis leads to a negative nitrogen balance and loss of lean body mass. This condition can be reduced or even reversed with increased nonprotein calorie and protein nutrition. Increased nutrient intake appears to make a difference in the ability of the patient to tolerate stress.

Nutritional Assessment

The pediatric patient is at a marked disadvantage compared with adults during periods of stress starvation. The child is a growing organism with little metabolic reserve to compensate for the metabolic stresses created by surgery, trauma, and sepsis. Preexisting nutritional status

and the degree of stress imposed by the disease process are important factors in estimating nutritional requirements of the critically ill patient. Accurate assessment of nutritional requirements is important as both overfeeding and underfeeding can lead to increased morbidity. One way to estimate nutritional requirements is to apply US recommended dietary allowances (RDA). However, since these recommendations are based on populations of normal healthy subjects, applying RDAs to critically ill patients significantly overestimates their caloric requirements. Therefore, several equations have been formulated in an attempt to predict basal energy needs of the critically ill patient. Some of these formulas estimate the basal metabolic rate (BMR), which is the energy requirement for a fasting (10–12 hours) person who recently awoke from sleep and is at rest with a normal body temperature in the absence of any stress. Other formulas estimate the resting energy expenditure (REE), which is the energy expenditure of a person at rest with a normal body and ambient temperature, but not necessarily fasting. The BMR and REE are similar, usually differing by less than 10%. Harris-Benedict and the World Health Organization have recommended formulas that are among the most commonly used (Table 13–13). Once the basal metabolic demands have been estimated, it is then multiplied by a stress factor correlating to underlying disease process to determine the ultimate energy requirements for the patient (Table 13–14). Compared with RDAs, these formulas better estimate energy requirements in sick patients. However, recent evidence

Table 13–13. Estimating needs for critically ill pediatric patients.

	Age	Resting Energy Expenditure (REE) kcal/kg	Average Range of Energy Needs kcal/kg	Average Range of Protein Needs g/kg
Infants	0–6 mo	55	90–120	2–3.5
	6–12 mo	55	90–120	1.5–2.5
Children	1–3 y	55	75–100	1.5–2.5
	4–6 y	45	65–90	1.5–2.0
	7–10 y	40	55–70	1.0–2.0
Males	11–14 y	30	40–55	1.0–2.0
	15–18 y	30	40–45	1.0–1.5
	19–24 y	25	30–40	1.0–1.5
Females	11–14 y	30	40–55	1.0–2.0
	15–18 y	25	30–40	1.0–1.5
	19–24 y	25	30–40	1.0–1.5

Based on WHO formulas for protein and energy requirements.

Table 13–14. Activity and stress factors (× REE).

Condition	Factor	Condition	Factor
ICU on vent	Activity 1.0–1.15	Peritonitis	Stress 1.2–1.5
Confined to bed	Activity 1.1–1.2	Cardiac failure	Stress 1.25–1.5
Light activity	Activity 1.2–1.3	Head injury	Stress 1.3–1.4
Fever, per 1°C	Stress 1.12–1.13	Liver failure	Stress 1.4–1.5
Major surgery	Stress 1.2–1.3	Sepsis	Stress 1.4–1.5
Multiple fractures	Stress 1.2–1.35	Burns	Stress 1.5–2.0

REE = resting energy expenditure.

suggests that even they may not be accurate enough to use in critically ill children.

Indirect calorimetry has been used to measure patients’ REE and appears to reflect a more accurate method of determining nutritional requirements. Indeed, indirect calorimetry measurements were used to derive the stress factors used with prediction formulas. Though this method was once used strictly for research, technology has enabled the production of portable, accurate devices that can be used anywhere in the hospital. Indirect calorimetry measures the amount of oxygen absorbed across the lung. This value is assumed to be equal to the amount of oxygen consumed in metabolic processes. The metabolic rate determined in milliliters of oxygen consumed per minutes can be converted to calories per hour, thereby providing a measure of REE. Carbon dioxide production is also measured. The ratio of CO₂ production to O₂ consumption yields the respiratory quotient (RQ), which is a measure of substrate use. Inefficiencies in substrate use can be discovered and corrected by modification of RQ through alteration of energy substrates that are provided to the patient. A recent study with 55 critically ill children was performed comparing two well-known prediction formulas with indirect calorimetry. The data suggest that prediction methods are unreliable for clinical use, and that indirect calorimetry is the only useful way of determining REE in sick children.

Provision of Nutrition

Once energy requirements are determined, the practitioner must decide to deliver nutritional support through either the enteral or the parenteral route. En-

teral feeding is preferred because it is more physiologic, associated with fewer complications, and in some cases, the only way to safely deliver some nutrients. More knowledge exists about enteral feeding in relation to both energy requirements and utilization; and practically, it is less expensive than parental nutrition.

Patients should be screened shortly after admission for nutritional requirements and preferred route of administration. Over the years, many practice patterns have been developed that list specific conditions or therapies in which enteral feeding may not be well tolerated by patients. Recent studies are proving that these may not be based on true physiologic differences and that a majority of patients who are critically ill can tolerate enteral feedings. The list of absolute contraindications for enteral feeding is shrinking and now may include just diseases of the GI tract.

Because it provides for a more physiologic digestive process, direct gastric feeding is preferable to the intestinal route. Patients supported with gastric feeds can usually tolerate higher osmotic loads and larger volumes, and have a lower frequency of diarrhea. Gastric acid also has a bactericidal effect that may decrease a patient's susceptibility to infection. However, for severely ill patients sedated and on mechanical ventilation, the high risk of reflux and aspiration becomes an increasing concern with this manner of feeding. Therefore, transpyloric feeding has been instituted in these patients and in any patient at high risk for aspiration. Although transpyloric feeding may limit reflux and aspiration, it does not entirely eliminate it.

The choice of formulas must be based on age, GI function, history of feeding tolerance, nutrient requirements, and route of feeding. The osmolality, nutrient

complexity, caloric density, and cost are all factors that should be taken into consideration. An increasing number of commercially made formulas and additives are now available to meet the nutritional needs of the critically ill patient (Table 13–15).

Parenteral nutrition (PN) is indicated for patients who are unable to meet nutritional needs with enteral feeds. It consists of the IV delivery of nutrients, fluid, carbohydrates, protein, fat, electrolytes, vitamins, minerals, and trace elements. The proportions of these elements are individualized to suit the patient's specific nutritional needs. PN often requires central venous access, and thus this method also carries the risks associated with central venous catheters (infection, clots, and insertion-related complications).

PN can be ordered in many ways, as nutrients can be ordered based on a child's weight or per liter, or a combination of both. Standard ranges and guidelines are usually provided on order forms. Parenteral energy needs can be approximately 10–15% lower than estimated enteral needs due to reduced energy required for digestion, absorption, and fecal losses. The percentage of protein, carbohydrate, and fat that contributes to ideal total energy intake varies with the individual and the disease condition. General guidelines for energy distribution are 8–15% protein, 45–60% carbohydrate, and 25–40% fat. Solutions should be instituted slowly and advanced gradually over several days as tolerated by the patient. Guidelines for the administration of a balanced parenteral diet are provided in Chapter 10. A constant flow rate is important to maintaining steady glucose delivery. If PN must be stopped abruptly, a 10% glucose solution should be started to prevent hypoglycemia. Administration of high glucose and amino

Table 13–15. Pediatric enteral formulas.

Formula Category	Formula Examples	Typical Uses
Standard, milk protein-based	Pediasure Pediasure with Fiber Kindercal (with/without fiber) Nutren Junior	Nutritionally complete for ages 1–10 years. Can be used for tube feeds or oral supplements.
Food based	Compleat Pediatric	Made with beef protein, fruits, and vegetables—does contain lactose. Fortified with vitamins/minerals.
Semielemental	Peptamen Jr.	Indicated for impaired gut function with peptides as protein source, and high MCT content with lower total fat % than standard pediatric formulas.
Elemental	Pediatric Vivonex (24 kcal/oz) Elecare Neocate One Plus	Indicated for impaired gut function or protein allergy, and contains free amino acids and lower fat with majority as MCT.

MCT = medium-chain triglycerides.

acid concentrations in total parenteral nutrition requires central venous access.

Immunonutrition is an area of growing interest and research. The term describes a point of view that dietary factors can confer an advantage to the immune system or other adaptive functions in infants and children. The claims of health benefits ascribed to foods or dietary supplements are not new, but until recently, these claims have not been supported by scientific review. Breast milk, the model for infant formula manufacturers, has long been recognized for its immunonutritive properties, containing such nutrients as secretory immunoglobulins, lysozyme, interferon, and growth factors. However, the contribution of specific components to a positive outcome has yet to be elucidated. Growing evidence supports the immunomodulatory effects of minerals (eg, iron, zinc, selenium, vitamin A), amino acids (arginine and glutamine), and nucleotides. Evidence also points to the emergence of prebiotics, nondigestible food components that favor the colonization and growth of bacteria normally resident in the colon; and probiotics, live microbial feed supplements with beneficial effects to the host. Although some of these concepts hold promise, it is still too early to advocate any specific guidelines, because some of these nutrients used in high doses have been reported to produce possible harmful effects.

PAIN & ANXIETY CONTROL

Anxiety control and pain relief are important responsibilities of the critical care physician. It is well recognized that infants and children experience pain and re-

quire pain relief. Indeed, outcomes are improved in children receiving appropriate pain control. A child's anxiety in the PICU may heighten perception of pain to a level that causes deterioration of his or her condition. It is important to distinguish between anxiety and pain, because pharmacologic therapy may be directed at one or both of these symptoms (Table 13–16). Further, before initiating or increasing sedative drugs, it is important to exclude or address physiologic causes of agitation, such as hypoxemia, hypercapnia, and cerebral hypoperfusion caused by low cardiac output.

Sedation

Sedative (anxiolytic) drugs are used to induce calmness without producing sleep—although at high doses, all anxiolytics will cause drowsiness and sleep. The five indications for the use of sedative drugs are (1) to allay fear and anxiety; (2) to manage acute confusional states; (3) to facilitate treatment or diagnostic procedures; (4) to facilitate mechanical ventilation; and (5) to obtund physiologic responses to stress—that is, reduce tachycardia, hypertension, or increases in ICP. Parenteral administration (bolus or infusion) allows titration of response in the critically ill child. Sedatives fall into several classes, with the opioid and benzodiazepine classes serving as the mainstay of anxiety treatment in the ICU.

A. BENZODIAZEPINES

Benzodiazepines possess anxiolytic, hypnotic, anticonvulsant, and skeletal muscle relaxant properties. Although their exact mode of action is unknown, it appears to be located within the limbic system of the CNS and to involve the neuroinhibitory transmitter γ -amino butyric acid. Most benzodiazepines are metabolized in the liver, with their metabolites subsequently excreted in the urine; thus, patients in liver failure are likely to have long elimination times.

Benzodiazepines can cause respiratory depression if given rapidly in high doses, and they potentiate the analgesic and respiratory depressive effects of opioids and barbiturates. Therefore, it is important to monitor cardiorespiratory status and have resuscitation equipment available. Three benzodiazepines with differing half-lives are presently used in the ICU setting:

1. Midazolam—Midazolam has the shortest half-life (1½–3½ hours) of the benzodiazepines and is the only benzodiazepine that should be administered as a continuous IV infusion. It produces excellent retrograde amnesia lasting for 20–40 minutes after a single IV dose. Therefore, it can be used either for short-term sedation or for “awake” procedures such as endoscopy or as a continuous infusion in the anxious, restless patient.

Table 13–16. Pain and anxiety control.

Drug	Dose and Method of Administration ^a	Advantages	Disadvantages	Usual Duration of Effect
Morphine	IV, 0.1 mg/kg; continuous infusion, 0.01–0.05 mg/kg/h	Excellent pain relief, reversible	Respiratory depression, hypotension, nausea, suppression of intestinal motility, histamine release	2–4 h
Meperidine	IV, 1 mg/kg	Good pain relief, reversible	Respiratory depression, histamine release, nausea, suppression of intestinal motility	2–4 h
Fentanyl	IV, 1–2 µg/kg; continuous infusion, 0.5–2 µg/kg/h	Excellent pain relief, reversible, short half-life	Respiratory depression, chest wall rigidity, severe nausea and vomiting	30 min
Diazepam	IV, 0.1 mg/kg	Sedation and seizure control	Respiratory depression, jaundice, phlebitis	1–3 h
Lorazepam	IV, 0.1 mg/kg	Longer half-life, sedation and seizure control	Nausea and vomiting, respiratory depression, phlebitis	2–4 h
Midazolam	IV, 0.1 mg/kg	Short half-life, only benzodiazepine given as continuous infusion	Respiratory depression	30–60 min

^aIntravenous (IV) administration is most common in the ICU. The effects of morphine, meperidine, and fentanyl are reversible by administration of naloxone (opioid antagonist).

The single IV dose is 0.1 mg/kg, whereas a continuous infusion should be started at a rate of 0.1 mg/kg/h after an initial loading dose of 0.1 mg/kg. The midazolam infusion dosage must be titrated upward to achieve the desired effect. Midazolam is not an analgesic; therefore, small doses of an analgesic such as morphine or fentanyl may be needed.

2. Diazepam—Diazepam has a longer half-life than midazolam and can be given PO as well as by the IV route. Its disadvantage in the ICU is its intermediary metabolite, nordazepam, which has a very long half-life and may accumulate, prolonging sedation. It produces excellent anxiolysis and amnesia. Additionally, it is used to treat acute status epilepticus. The IV dose is 0.1 mg/kg and can be repeated every 15 minutes to achieve the desired effect or until undesirable side effects (somnolence and respiratory depression) occur.

3. Lorazepam—Lorazepam possesses the longest half-life of the three benzodiazepines discussed here and can be used to achieve sedation for as long as 6–8 hours. It has less effect on the cardiovascular and respiratory systems than other benzodiazepines and can be given PO, IV, or intramuscularly (IM). The IV route is the most common. The IV dosage is 0.1 mg/kg. Lorazepam can also be used to treat acute status epilepticus.

B. OTHER DRUGS

1. Chloral hydrate—Chloral hydrate is an enteral sedative and hypnotic agent frequently used in children. After administration, it is rapidly metabolized by the liver to its active form trichloroethanol, which has an 8-hour half-life. A sedative dose is 6–20 mg/kg per dose, usually given every 6–8 hours, whereas the hypnotic dose is up to 50 mg/kg with a maximum dose of 1 g. The hypnotic dose is frequently used to sedate young children for outpatient radiologic procedures such as computed tomography scanning and magnetic resonance imaging. There is little effect on respiration or blood pressure with therapeutic doses of chloral hydrate. The drug is irritating to mucous membranes, however, and may cause gastric upset if administered on an empty stomach.

2. Ketamine—Ketamine is a phencyclidine derivative that produces a trance-like state of immobility and amnesia known as dissociative anesthesia. After IM or IV administration, it causes central sympathetic nervous system stimulation with resultant increases in heart rate, blood pressure, and cardiac output. Respiration is not depressed at therapeutic doses. Because salivary and tracheobronchial mucous gland secretions are increased, atropine should be administered 20 minutes prior to the ketamine. A disadvantage of ketamine

usage is the occurrence of unpleasant dreams or hallucinations. The incidence is less in children than in adults, and it can be reduced even further by the concurrent administration of a benzodiazepine. Because of its inotropic properties, ketamine is useful for the sedation of certain critically ill patients whose conditions are unstable. Additionally, its bronchodilator effects make it the induction agent of choice for patients with status asthmaticus requiring intubation. It is given as an IV injection of 1–2 mg/kg over 60 seconds, with supplementary doses of 0.5 mg/kg being required every 10–30 minutes to maintain an adequate level of anesthesia. Alternatively, it can be administered as an IM injection of 3–7 mg/kg, which usually produces the desired level of anesthesia within 3–4 minutes. If prolonged anesthesia is required, ketamine can be administered by IV infusion at doses of 3–20 mg/kg/h.

3. Antihistamines—The antihistamines diphenhydramine and hydroxyzine can be used as sedatives but are not as effective as the benzodiazepines. Diphenhydramine produces sedation in only 50% of those patients receiving it. It can be given IV, IM, or PO at a dose of 1 mg/kg. Hydroxyzine can be given either IM or PO. It is frequently used concurrently with morphine or meperidine, adding anxiolysis and potentiating the effects of the opioid. The sedative effects of both drugs can last from 4 to 6 hours following a single dose.

4. Propofol—Propofol is an anesthetic induction agent whose main advantages are a rapid recovery time and no cumulative effects resulting from its rapid hepatic metabolism. It has no analgesic properties and frequently causes pain on injection. Dose-related hypotension and metabolic acidosis have been reported in pediatric patients, and a recent FDA bulletin has recommended against the use of propofol in pediatric patients outside the controlled environment of the operating room.

5. Barbiturates—Barbiturates (phenobarbital, thiopental) can cause direct myocardial and respiratory depression and are, in general, poor choices for sedation of seriously ill patients. Phenobarbital has a very long half-life (up to 4 days), and recovery from thiopental, although it is a short-acting barbiturate, can be prolonged because remobilization of tissue stores occurs.

Analgesia

A. OPIOID ANALGESICS

Opioid analgesics (morphine, fentanyl, codeine, meperidine) are the mainstays of therapy for most forms of acute severe pain as well as chronic cancer pain management. They possess both analgesic and dose-related sedative effects, although a range of plasma con-

centrations produce analgesia without sedation. In addition, opioids can cause respiratory depression, nausea, pruritus, slowed intestinal motility, miosis, urinary retention, cough suppression, biliary spasm, and vasodilation. The dose of opioid required to produce adequate analgesia varies greatly from one individual to the next. Therefore, in the intensive care setting, a continuous infusion of morphine or fentanyl allows dosages to be easily titrated to achieve the desired effect.

In general, infants younger than age 3 months are more susceptible than older children to the respiratory depressant effects of opioids. Starting dosages for these patients should be about one third to one half the usual pediatric dose. Most opioids (except meperidine) have minimal cardiac depressive effects, and critically ill patients generally tolerate them well. Fentanyl does not cause the histamine release that morphine does and thus produces less vasodilation and drop in systemic blood pressure. Opioids are metabolized in the liver, with metabolites excreted in the urine. Thus patients with hepatic or renal impairment may have a prolonged response to their administration. Patients who receive regular doses of opioids for 2 weeks or more frequently develop a physiologic dependence with the development of withdrawal symptoms (agitation, tachypnea, tachycardia, sweating, diarrhea) upon acute termination of the drug. In these patients, gradual tapering of the opioid dosage over a 5- to 10-day period will prevent withdrawal symptoms. As with any potent sedative or analgesic used in the ICU setting, appropriate patient monitoring (pulse oximetry, cardiorespiratory monitoring, blood pressure monitoring) should be used during the period of opioid administration, and equipment should be available to support prompt intervention if undesired side effects occur.

The ICU regimen for sedation and analgesia must be carefully modified when the patient is transferred to the ward or a lower vigilance area. Patients with baseline respiratory, hepatic, or renal insufficiencies are most predisposed to respiratory insufficiency from sedatives or opioid analgesics.

Advantages of continuous infusions of sedatives are that it provides a more constant level of sedation, increases patient comfort, and allows better tolerance of newer approaches to mechanical ventilation. Prolongation of mechanical ventilation, hospitalization, and inability to assess neurologic function and mental status have been recognized as disadvantages of continuous infusions. A recent study of the daily interruption of continuous sedation, allowing the adult patient to “wake up,” was associated with a decrease in duration of mechanical ventilation and length of stay in the ICU. Currently, similar data are not available for pediatric patients.

Frequently pediatric patients will require relatively deep levels of sedation while undergoing a procedure

(eg, vascular line placement, radiographic studies). Often these patients are not intubated and are not expected to require intubation and ventilatory support—so called conscious sedation. (New American Academy of Pediatrics guidelines will recommend a change in terminology to “moderate sedation/analgesia”.) A systematic approach should include the following:

1. Pertinent history to elicit underlying illnesses
2. Physical exam focusing on the anatomy and adequacy of the child’s airway (ie, large tonsils or facial deformity)
3. Informed consent
4. Appropriate patient fasting from solids (6 hours) and liquids (2 hours)
5. Age- and size-appropriate equipment
6. Drug dosages calculated on a milligram per kilogram basis
7. Monitoring and documentation of vital signs (including continuous pulse oximetry, respiratory rate and pattern, level of arousability)
8. Separate observer to monitor deeply sedated patients
9. Practitioner capable of intubating and treating patients who enter a deeper state of sedation than initially anticipated
10. Discharge criteria ensuring the patient has recovered to his or her baseline level of consciousness.

Short-acting agents are preferred. Agents typically used include an opioid (usually fentanyl or morphine) and a benzodiazepine (most often midazolam). Another option is ketamine and midazolam. It is important to select and become comfortable with a specific combination; learn the indications and potential complications. Using a familiar agent and following the systematic approach outlined earlier have reduced anesthetic complications in this population of patients.

Patient-controlled analgesia (PCA) is a computer-governed infusion pump for constant infusion or patient-regulated bolus infusion of opioid analgesics. The basal infusion mode is intended to provide a constant serum level of analgesic. The bolus mode allows the patient, by pushing a button, to self-administer additional doses for breakthrough pain. The patient is usually permitted six boluses an hour, with 10-minute lockouts. If the patient is using allotted hourly boluses, this usually means that the basal infusion rate is too low. The patient must understand the concept of PCA in order to be a candidate for its use. In some circumstances in pediatrics it is more appropriate for the nurse or parent to administer the bolus dose.

Naloxone reverses the analgesia, sedative, and respiratory depressive effects of opioid agonists. Its adminis-

tration should be titrated to achieve the desired effect (eg, reversal of respiratory depression) because full reversal using 1–10 $\mu\text{g}/\text{kg}$ may cause acute anxiety, dysphoria, nausea, and vomiting. Furthermore, because the duration of effect of naloxone is shorter (30 minutes) than that of most opioids, the patient must be observed carefully for reappearance of the undesired effect.

B. NONOPIOID ANALGESICS

Nonopioid analgesics used in the treatment of mild to moderate pain include acetaminophen, aspirin, and other nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and naproxen.

1. Acetaminophen—Acetaminophen is the most commonly used analgesic in pediatrics in the United States and is the drug of choice for mild to moderate pain because of its low toxicity and lack of effect on bleeding time. It is metabolized by the liver. Suggested doses are 10–15 mg/kg PO to approximately 10–20 mg/kg PR every 4 hours.

2. Aspirin—Aspirin is also an effective analgesic for mild to moderate pain at doses of 10–15 mg/kg PO every 4 hours. However, its prolongation of bleeding time, association with Reye syndrome, and propensity to cause gastric irritation limit its usefulness in pediatric practice. Aspirin and other NSAIDs are still useful, especially for pain of inflammatory origin, bone pain, and pain associated with rheumatic conditions.

3. Other NSAIDs—Ibuprofen and naproxen are NSAIDs whose use has been limited in pediatrics to date. Naproxen is FDA approved for children aged 2–12 years (5–7 mg/kg PO every 8–12 hours), whereas ibuprofen requires more frequent dosing intervals (4–10 mg/kg PO every 6–8 hours).

All of the NSAIDs have a therapeutic ceiling after which no increase occurs in analgesic potency above the recommended dose. They all can cause gastritis and should be given with antacids or with meals, and they should be used with caution in people at risk for renal compromise. In addition, the analgesic effects of acetaminophen, aspirin, and other NSAIDs are additive to those of opioids. Thus, if additional analgesia is required, their use should be continued and an appropriate PO opioid (codeine, morphine) or parenteral opioid (morphine, fentanyl) begun.

■ GENERAL PRINCIPLES OF DIAGNOSIS OF SKIN DISORDERS

Examination of the skin requires that the entire surface of the body be palpated and inspected in good light. The onset and duration of each symptom should be recorded, together with a description of the primary lesion and any secondary changes, using the terminology set forth in Table 14–1. In practice, the characteristics of skin lesions are described in an order opposite that shown in the table. Begin with distribution, then configuration, color, secondary changes, and primary changes. For example, guttate psoriasis could be described as generalized, discrete, red, scaly papules.

■ GENERAL PRINCIPLES OF TREATMENT OF SKIN DISORDERS

TOPICAL THERAPY

Treatment should be simple and aimed at preserving normal skin physiology, keeping in mind that one is treating the child and not the anxious parent or grandparent. Topical therapy is often preferred because medication can be delivered in optimal concentrations to the desired site.

Water is an important therapeutic agent, and optimally hydrated skin is soft and smooth. This occurs at approximately 60% environmental humidity. Because water evaporates readily from the cutaneous surface, skin hydration (stratum corneum of the epidermis) is dependent on the water concentration in the air, and sweating contributes little. However, if sweat is prevented from evaporating (eg, in the axilla, groin), local humidity and hydration of the skin are increased. As humidity falls below 15–20%, the stratum corneum shrinks and cracks; the epidermal barrier is lost and allows irritants to enter the skin and induce an inflamma-

tory response. Replacement of water will correct this condition if evaporation is prevented. Therefore, dry and scaly skin is treated by soaking the skin in water for 5 minutes and then adding a barrier to evaporation (Table 14–2). Oils and ointments prevent evaporation for 8–12 hours, so they must be applied once or twice a day. In areas already occluded (axilla, diaper area), ointments or oils will merely increase retention of water and should not be used.

Overhydration (maceration) can also occur. As environmental humidity increases to 90–100%, the number of water molecules absorbed by the stratum corneum increases and the tight lipid junctions between the cells of the stratum corneum are gradually replaced by weak hydrogen bonds; the cells eventually become widely separated, and the epidermal barrier falls apart. This occurs in immersion foot, diaper areas, axillae, and the like. It is desirable to enhance evaporation of water in these areas by air drying.

WET DRESSINGS

By placing the skin in an environment where the humidity is 100% and allowing the moisture to evaporate to 60%, pruritus is relieved. Evaporation of water stimulates cold-dependent nerve fibers in the skin, and this may prevent the transmission of the itching sensation via pain fibers to the central nervous system. It also is vasoconstrictive, thereby helping to reduce the erythema and also decreasing the inflammatory cellular response.

The simplest form of wet dressing consists of one set of wet underwear (eg, long johns) worn under a dry pair. The underwear should be soaked in warm (not hot) water and wrung out until no more drops come out. When covered by the dry layer, the wet dressings need to be changed only every 4–6 hours.

TOPICAL GLUCOCORTICOIDS

Twice-daily application of topical steroids is the mainstay of treatment for all forms of dermatitis (Table 14–3). Topical steroids can also be used under wet dressings. Wet dressings are removed every 4–6 hours, and a topical steroid is applied; the skin is then covered again with wet dressings. If treatment is applied

Table 14–1. Examination of the skin.

Clinical Appearance	Description and Examples
Primary lesions (first to appear)	
Macule	Any circumscribed color change in the skin that is flat. Examples: white (vitiligo), brown (café au lait spot), purple (petechia).
Papule	A solid, elevated area less than 1 cm in diameter whose top may be pointed, rounded, or flat. Examples: acne, warts, small lesions of psoriasis.
Plaque	A solid, circumscribed area more than 1 cm in diameter, usually flat-topped. Example: psoriasis.
Vesicle	A circumscribed, elevated lesion less than 1 cm in diameter and containing clear serous fluid. Example: blisters of herpes simplex.
Bulla	A circumscribed, elevated lesion more than 1 cm in diameter and containing clear serous fluid. Example: bullous erythema multiforme.
Pustule	A vesicle containing a purulent exudate. Examples: acne, folliculitis.
Nodule	A deep-seated mass with indistinct borders that elevates the overlying epidermis. Examples: tumors, granuloma annulare. If it moves with the skin on palpation, it is intradermal; if the skin moves over the nodule, it is subcutaneous.
Wheal	A circumscribed, flat-topped, firm elevation of skin resulting from tense edema of the papillary dermis. Example: urticaria.
Secondary changes	
Scales	Dry, thin plates of keratinized epidermal cells (stratum corneum). Examples: psoriasis, ichthyosis.
Lichenification	Induration of skin with exaggerated skin lines and a shiny surface resulting from chronic rubbing of the skin. Example: atopic dermatitis.
Erosion and oozing	A moist, circumscribed, slightly depressed area representing a blister base with the roof of the blister removed. Examples: burns, bullous erythema multiforme. Most oral blisters present as erosions.
Crusts	Dried exudate of plasma on the surface of the skin following acute dermatitis. Examples: impetigo, contact dermatitis.
Fissures	A linear split in the skin extending through the epidermis into the dermis. Example: angular cheilitis.
Scars	A flat, raised or depressed area of fibrotic replacement of dermis or subcutaneous tissue. Examples: acne scar, burn scar.
Atrophy	Depression of the skin surface caused by thinning of one or more layers of skin. Example: lichen sclerosis.
Color	The lesion should be described as red, yellow, brown, tan, or blue. Particular attention should be given to the blanching of red lesions. Failure to blanch suggests bleeding into the dermis (petechiae).
Configuration of lesions	
Annular (circular)	Annular nodules represent granuloma annulare; annular scaly papules are more apt to be caused by dermatophyte infections.
Linear (straight lines)	Linear papules represent lichen striatus; linear vesicles, incontinentia pigmenti; linear papules with burrows, scabies.
Grouped	Grouped vesicles occur in herpes simplex or zoster.
Discrete	Discrete lesions are independent of each other.
Distribution	Note whether the eruption is generalized, acral (hands, feet, buttocks, face), or localized to a specific skin region.

Table 14–2. Bases used for topical preparations.

Base	Combined With	Uses
Liquids		Wet dressings: relieve pruritus, vasoconstrict
	Powder	Shake lotions, drying pastes: relieve pruritus, vasoconstrict
	Grease and emulsifier; oil in water	Cream: penetrates quickly (10–15 min) and thus allows evaporation
	Excess grease and emulsifier; water in oil	Emollient cream: penetrates more slowly and thus retains moisture on skin
Grease		Ointments: occlusive (hold material on skin for prolonged time) and prevent evaporation of water
Gel		Transparent, colorless, semisolid emulsion: non-greasy, more drying and irritating than cream
Powder		Enhances evaporation

Characteristics of bases for topical preparations:

1. Most greases are triglycerides (eg, Aquaphor, petrolatum, Eucerin).
2. Oils are fluid fats (eg, Alpha Keri, olive oil, mineral oil).
3. True fats (eg, lard, animal fats) contain free fatty acids that cause irritation.
4. Ointments (eg, Aquaphor, petrolatum) should not be used in intertriginous areas such as the axillae, between the toes, and in the perineum, because they increase maceration. Lotions or creams are preferred in these areas.
5. Oils and ointments hold medication on the skin for long periods and are therefore ideal for barriers or prophylaxis and for dried areas of skin. Medication gets into the skin more slowly from ointments.
6. Creams carry medication into skin and are preferable for intertriginous dermatitis.
7. Solutions, gels, or lotions should be used for scalp treatments.

throughout the 24-hour period, maximum benefit is obtained after 72 hours; if treatment is applied only at night, maximum benefit is obtained after 7 days. When the condition has improved, the wet dressings are discontinued and a steroid ointment is applied twice daily. Daily application of steroids is not to be continued for more than 1 month. Only low-potency steroids (see Table 14–3) are applied to the face or intertriginous areas.

Table 14–3. Topical glucocorticoids.

Glucocorticoid	Concentrations
Low potency^a = 1–9	
Hydrocortisone	0.5% and 1%
Desonide	0.05%
Moderate potency = 10–99	
Mometasone furoate	0.1%
Hydrocortisone valerate	0.2%
Fluocinolone acetonide	0.025%
Triamcinolone acetonide	0.01%
Amcinonide	0.1%
High potency = 100–499	
Desoximetasone	0.25%
Fluocinonide	0.05%
Halcinonide	0.1%
Super potency = 500–7500	
Betamethasone dipropionate	0.05%
Clobetasol propionate	0.05%

^a1% hydrocortisone is defined as having a potency of 1.

DISORDERS OF THE SKIN IN NEWBORNS

TRANSIENT DISEASES IN NEWBORNS

Milia

Multiple white papules 1 mm in diameter scattered over the forehead, nose, and cheeks are present in up to 40% of newborn infants. Histologically, they represent superficial epidermal cysts filled with keratinous material associated with the developing pilosebaceous follicle. Their intraoral counterparts are called Epstein pearls and are even more common than facial milia. All of these cystic structures spontaneously rupture and exfoliate their contents.

Sebaceous Gland Hyperplasia

Prominent yellow macules at the opening of each pilosebaceous follicle, predominantly over the nose, represent overgrowth of sebaceous glands in response to the same androgenic stimulation that occurs in adolescence.

Acne Neonatorum

Open and closed comedones, erythematous papules, and pustules identical in appearance to adolescent acne may occur in infants over the forehead, cheeks, and chin. The lesions may be present at birth but usually do not appear until age 4–6 weeks. Spontaneous resolution occurs over a period of 6 months to 1 year. Rarely, severe neonatal acne may be a manifestation of a virilizing syndrome.

Harlequin Color Change

A cutaneous vascular phenomenon unique to neonates in the first week of life occurs when the infant (particularly one of low birth weight) is placed on one side. The dependent half develops an erythematous flush with a sharp demarcation at the midline, and the upper half of the body becomes pale. The color changes usually subside within a few seconds after the infant is placed supine but may persist for as long as 20 minutes.

Mottling

A lace-like pattern of dilated cutaneous vessels appears over the extremities and often the trunk of neonates exposed to lowered room temperature. This feature is transient and usually disappears completely on rewarming.

Erythema Toxicum

Up to 50% of full-term infants develop erythema toxicum. Usually at 24–48 hours of age, blotchy erythematous macules 2–3 cm in diameter appear, most prominently on the chest but also on the back, face, and extremities. These are occasionally present at birth. Onset after 4–5 days of life is rare. The lesions vary in number from a few up to as many as 100. Incidence is much higher in full-term infants than in premature ones. The macular erythema may fade within 24–48 hours or may progress to formation of urticarial wheals in the center of the macules or, in 10% of cases, pustules. Examination of a Wright-stained smear of the lesion will reveal numerous eosinophils. No organisms are seen on Gram stain. This may be accompanied by peripheral blood eosinophilia of up to 20%. All of the lesions fade and disappear within 5–7 days. A similar

eruption in newborns of African descent, benign pustular melanosis, shows mostly neutrophils and leaves hyperpigmentation. Herpes simplex virus infection is in the differential diagnosis, but the infants are not ill and multinucleated giant cells are not present.

Sucking Blisters

Bullae, either intact or as an erosion with a blister base without inflammatory borders, may occur over the forearms, wrists, thumbs, or upper lip. These presumably result from vigorous sucking in utero. They resolve without complications.

Miliaria

Obstruction of the eccrine sweat ducts occurs often in neonates and produces one of two clinical pictures. Obstruction in the stratum corneum causes miliaria crystallina, characterized by tiny (1- to 2-mm), superficial grouped vesicles without erythema over intertriginous areas and adjacent skin (eg, neck, upper chest). More commonly, obstruction of the eccrine duct deeper in the epidermis results in erythematous grouped papules in the same areas and is called miliaria rubra. Rarely, these may progress to pustules. Heat and high humidity predispose the patient to eccrine duct pore closure. Removal to a cooler environment is the treatment of choice.

Subcutaneous Fat Necrosis

Reddish or purple, sharply circumscribed, firm nodules occurring over the cheeks, buttocks, arms, and thighs and occurring between 1 and 7 days of life represent subcutaneous fat necrosis. Cold injury is thought to play an important role. These lesions resolve spontaneously over a period of weeks, although as in all instances of fat necrosis they may calcify.

Verbov J: Common skin conditions in the newborn. *Semin Neonatol* 2000;5:303 [PMID: 11841650].

PIGMENT CELL BIRTHMARKS, NEVI, & MELANOMA

Birthmarks may involve an overgrowth of one or more of any of the normal components of skin (eg, pigment cells, blood vessels, lymph vessels). A nevus is a hamartoma of highly differentiated cells that retain their normal function.

Mongolian Spot

A blue-black macule found over the lumbosacral area in 90% of infants of Native American, African, and Asian descent is called a mongolian spot. These spots are occasionally noted over the shoulders and back and may extend over the buttocks. Histologically, they consist of spindle-shaped pigment cells located deep in the dermis. The lesions fade somewhat with time as a result of darkening of the overlying skin, but some traces may persist into adult life.

Café au Lait Macule

A café au lait macule is a light brown, oval macule (dark brown on brown or black skin) that may be found anywhere on the body. Café au lait spots over 1.5 cm in greatest diameter are found in 10% of white and 22% of black children. These lesions persist throughout life and may increase in number with age. The presence of six or more such lesions over 1.5 cm in greatest diameter may be a clue to neurofibromatosis 1 (NF-1). Patients with Albright syndrome (see Chapter 30) also have increased numbers of café au lait macules. Most newborns with NF-1 will acquire the macules later.

Spitz Nevus

A reddish brown solitary nodule appearing on the face or upper arm of a child represents a Spitz nevus. Histologically, it consists of pigment-producing cells of bizarre shape with numerous mitoses.

Junctional Nevus & Compound Nevus

Dark brown or black macules, usually few in number at birth but becoming more numerous with age, represent junctional nevi. Histologically, these lesions are clones of melanocytes at the junction of the epidermis and dermis. With aging, they may become raised (papules) and contain intradermal melanocytes, creating a compound nevus. The surface may at times become irregular and roughened.

Brown to blue solitary papules with smooth surfaces represent intradermal nevi. When pigmentation is present deeper in the dermis, the lesions appear blue or blue-black and are called blue nevi.

Melanoma

Pigmented lesions with variegated colors (red, white, blue), notched borders, and nonuniform, irregular surfaces should arouse a suspicion of melanoma. Ulceration and bleeding are advanced signs of melanoma. If melanoma is suspected, excisional biopsy for pathologic examination should be done as the treatment of choice.

Giant Pigmented Nevus (Bathing Trunk Nevus)

An irregular dark brown to black plaque over at least 5% of the body surface represents a giant pigmented nevus. Often the lesions are of such size as to cover the entire trunk (bathing trunk nevi). Histologically, they are compound nevi. Transformation to malignant melanoma has been reported in as many as 10% of cases in some series, although the true incidence is probably much lower. Malignant change may occur in the neonatal period or at any time thereafter. Two thirds of melanoma in children with giant congenital pigmented nevi develop in areas other than the skin.

Tissue expanders may be useful in excision of large lesions. The risk of melanoma and the potential for cosmetic improvement should be evaluated carefully for each patient.

Fishman C et al: Diagnosis and management of nevi and cutaneous melanoma in infants and children. *Clin Dermatol* 2002;20:44 [PMID: 11849894].

Makkar HS, Frieden IJ: Congenital melanocytic nevi: An update for the pediatrician. *Curr Opin Pediatr* 2002;14:397 [PMID: 12130901].

VASCULAR BIRTHMARKS

Capillary Malformations

Flat vascular birthmarks can be divided into two types: those that are orange or light red (salmon patch) and those that are dark red or bluish red (port-wine stain).

The salmon patch is a light red macule found over the nape of the neck, upper eyelids, and glabella. Fifty percent of infants have such lesions over their necks. Eyelid lesions fade completely within 3–6 months; those on the neck fade somewhat but usually persist into adult life.

Port-wine stains are dark red or purple macules appearing anywhere on the body. A bilateral facial port-wine stain or one covering the entire half of the face may be a clue to Sturge–Weber syndrome, which is characterized by seizures, mental retardation, glaucoma, and hemiplegia (Chapter 23). Most infants with smaller, unilateral facial port-wine stains do not have Sturge–Weber syndrome. Similarly, a port-wine stain over an extremity may be associated with hypertrophy of the soft tissue and bone of that extremity (Klippel–Trénaunay syndrome). The pulsed dye laser is the treatment of choice for infants and children with port-wine stains.

Rothfleisch JE et al: Laser treatment of congenital and acquired vascular lesions: A review. *Dermatol Clin* 2002;20:1 [PMID: 11859585].

Hemangioma

A red, rubbery nodule with a roughened surface is a hemangioma. The lesion is often not present at birth but is represented by a permanent blanched area on the skin that is supplanted at age 2–4 weeks by red nodules. Histologically, these are benign tumors of capillary endothelial cells. Hemangiomas may be superficial, deep, or mixed. The terms strawberry and cavernous are misleading and should not be used. The biologic behavior of a hemangioma is the same despite its location. Fifty percent resolve spontaneously by age 5 years, 70% by age 7 years, and 90% by age 9 years, leaving redundant skin, hypopigmentation, and telangiectasia. Local complications include superficial ulceration and secondary pyoderma.

Complications that require immediate treatment are (1) airway obstruction (hemangiomas of the head and neck may be associated with subglottic hemangiomas), (2) visual obstruction (with resulting amblyopia), and (3) cardiac decompensation (high-output failure). In these instances, the treatment of choice is with prednisone, 2–4 mg/kg orally daily for 4–6 weeks. Interferon alfa-2a has been used to treat serious hemangiomas unresponsive to prednisone. Ten percent of patients with hemangiomas treated with interferon alfa-2a have developed spastic diplegia. Therefore, interferon alfa-2a therapy should be reserved for truly life-threatening hemangiomas. If the lesion is ulcerated or bleeding, pulsed dye laser treatment may be helpful. The Kasabach–Merritt syndrome, which is platelet trapping with consumption coagulopathy, does not occur with hemangiomas. It is seen only with the very rare vascular tumors called hemangioendotheliomas and tufted angiomas.

David LR et al: *Br J Plast Surg* 2003;56:317 [PMID: 12873458].

Lymphatic Malformations

Lymphatic malformations may be superficial or deep. Superficial lymphatic malformations present as fluid-filled vesicles often described as looking like frog spawn. Deep lymphatic malformations are rubbery, skin-colored nodules occurring in the parotid area (cystic hygromas) or on the tongue. They often result in grotesque enlargement of soft tissues. Surgical excision is the only treatment, although the results are not satisfactory.

Fliegelman LJ et al: Lymphatic malformations: Predictive factors for recurrence. *Otolaryngol Head Neck Surg* 2000;123:706 [PMID: 11112962].

EPIDERMAL BIRTHMARKS

Epidermal Nevus

Linear or groups of linear, warty, papular, unilateral lesions represent overgrowth of epidermis since birth. These areas may range from dirty yellow to brown or may be darkly pigmented. The histologic features of the lesions include thickening of the epidermis and elongation of the rete ridges and hyperkeratosis. Clinically, widespread lesions may be associated with focal motor seizures, mental subnormality, and skeletal anomalies.

Treatment once or twice daily with topical calcipotriene may improve the lesions.

Dosik JS: Epidermal nevus. *Dermatol Online J* 2001;7:14 [PMID: 11328635].

Happle R, Rogers M: Epidermal nevi. *Adv Dermatol* 2002;18:175 [PMID: 12528406].

Lee SH, Rogers M: Inflammatory linear verrucous epidermal naevi: A review of 23 cases. *Australas J Dermatol* 2001;42:252 [PMID: 11903156].

Nevus Comedonicus

The lesion known as nevus comedonicus consists of linear groups of widely dilated follicular openings plugged with keratin, giving the appearance of localized noninflammatory acne. The treatment of choice is surgical removal. If this is not feasible, topical retinoic acid may be helpful.

Lefkowitz A et al: Nevus comedonicus. *Dermatology* 1999;199:204 [PMID: 10592398].

Nevus Sebaceus

The nevus sebaceus of Jadassohn is a hamartoma of sebaceous glands and underlying apocrine glands that is diagnosed by the appearance at birth of a yellowish, hairless, smooth plaque in the scalp or on the face. The lesion may be contiguous with an epidermal nevus on the face and constitute part of the linear epidermal nevus syndrome.

Histologically, nevus sebaceus represents an overabundance of sebaceous glands without hair follicles. At puberty, with androgenic stimulation, the sebaceous cells in the nevus divide, expand their cellular volume, and synthesize sebum, resulting in a warty mass. Because 15% of these lesions become basal cell carcinomas after puberty, excision is recommended before puberty.

Cribier B et al: Tumors arising in nevus sebaceus: A study of 596 cases. *J Am Acad Dermatol* 2000;42:263 [PMID: 10642683].

CONNECTIVE TISSUE BIRTHMARKS (Juvenile Elastoma, Collagenoma)

Connective tissue nevi are smooth, skin-colored papules 1–10 mm in diameter that are grouped on the trunk. A solitary, larger (5–10 cm) nodule is called a shagreen patch and is histologically indistinguishable from other connective tissue nevi that show thickened, abundant collagen bundles with or without associated increases of elastic tissue. Although the shagreen patch is a cutaneous clue to tuberous sclerosis (Chapter 23), the other connective tissue nevi occur as isolated events. These nevi remain throughout life and need no treatment.

Batta K: Management of large birthmarks. *Semin Neonatol* 2000;5:325 [PMID: 11032717].

HEREDITARY SKIN DISORDERS

Ichthyosis

Ichthyosis is a term applied to several heritable diseases characterized by the presence of excessive scales on the skin. Major categories are listed in Table 14–4. Treatment consists of controlling scaling with lactic acid with ammonium hydroxide (Lac-Hydrin) 12% applied once daily. Restoring water to the skin is also very helpful.

DiGiovanni JJ, Robinson-Bostom L: Ichthyosis: Etiology, diagnosis and management. *Am J Clin Dermatol* 2003;4:81 [PMID: 12553849].

Table 14–4. Four major types of ichthyosis.

Name	Age at Onset	Clinical Features	Genetic Defect	Inheritance
Ichthyosis with normal epidermal turnover				
Ichthyosis vulgaris	Childhood	Fine scales, deep palmar and plantar markings	Filaggrin/profilaggrin	Autosomal-dominant
X-linked ichthyosis	Birth	Palms and soles spared; thick scales that darken with age; corneal opacities in patients and carrier mothers	Cholesterol sulfatase	X-linked
Ichthyosis with increased epidermal turnover				
Epidermolytic hyperkeratosis	Birth	Verrucous, yellow scales in flexural areas and palms and soles	Keratins 1 and 10	Autosomal-dominant
Lamellar ichthyosis	Birth, collodion baby	Erythroderma, ectropion, large coarse scales; thickened palms and soles	Transglutaminase 1	Autosomal-recessive

Epidermolysis Bullosa

The diagnostic feature of this group of diseases is the formation of blisters in response to slight trauma. They can be divided into scarring and nonscarring types (Table 14–5).

Treatment usually consists of systemic antibiotics for infection, protection of the skin with petrolatum, zinc oxide, or synthetic dressings, and cooling the skin. If hands and feet are involved, reducing skin friction with 5% glutaraldehyde every 3 days is helpful.

Fine JD et al: Revised classification system for inherited epidermolysis bullosa: Report of the Second International Consensus Meeting on etiology and classification of epidermolysis bullosa. *J Am Acad Dermatol* 2000;42:1051 [PMID: 10827412].

Moss C: Genetic skin disorders. *Semin Neonatol* 2000;5:311 [PMID: 11036715].

Pai S, Marinkovich MP: Epidermolysis bullosa: New and emerging trends. *Am J Clin Dermatol* 2002;3:371 [PMID: 12113646].

COMMON SKIN DISEASES IN INFANTS, CHILDREN, & ADOLESCENTS

ACNE

The common forms of acne in pediatric patients occur at two ages: in the newborn period and in adolescence. Neonatal acne is a response to maternal androgen, first appearing at age 4–6 weeks and lasting until age 4–6 months. The lesions are primarily on the face, upper chest, and back, in a distribution similar to that

Table 14–5. Types of epidermolysis bullosa.

Name	Age at Onset	Clinical Features	Genetic Defect	Inheritance
Nonscarring types				
Epidermolysis bullosa simplex	Birth	Hemorrhagic blisters over the lower legs; cooling prevents blisters	Keratins 5 and 14	Autosomal-dominant
Recurrent bullous eruption of the hands and feet (Weber–Cockayne syndrome)	First few years of life	Blisters brought out by walking	Keratins 5 and 14	Autosomal-dominant
Junctional bullous dermolysis (Herlitz disease)	Birth	Erosions on legs, oral mucosa; severe perioral involvement	Laminin V	Autosomal-recessive
Scarring types				
Epidermolysis bullosa dystrophica, dominant	Infancy	Numerous blisters on hands and feet; milia formation	Type VII collagen	Autosomal-dominant
Epidermolysis bullosa dystrophica, recessive	Birth	Repeated episodes of blistering, secondary infection and scarring—“mitten hands and feet”	Type VII collagen	Autosomal-recessive

seen in adolescent acne. It has been hypothesized, but not proved, that infants who have severe neonatal acne will develop severe adolescent acne.

The onset of adolescent acne is between ages 8 and 10 years in 40% of children. The early lesions are usually limited to the face and are primarily closed comedones (whiteheads; see following discussion). Eventually, 85% of adolescents develop some form of acne.

Clinical Findings

Acne occurs in sebaceous follicles, which, unlike hair follicles, have large, abundant sebaceous glands and usually lack hair. They are located primarily on the face, upper chest, back, and penis. Obstruction of the sebaceous follicle opening produces the clinical lesion of acne. If the obstruction occurs at the follicular mouth, the clinical lesion is characterized by a wide, patulous opening filled with a plug of stratum corneum cells. This is the open comedo, or blackhead. Open comedones are the predominant clinical lesion in early adolescent acne. The black color is caused not by dirt but by oxidized melanin within the stratum corneum cellular plug. Open comedones do not often progress to inflammatory lesions. Closed comedones, or whiteheads, are caused by obstruction just beneath the follicular opening in the neck of the sebaceous follicle, which produces a cystic swelling of the follicular duct directly beneath the epidermis. The stratum corneum produced

accumulates continuously within the cystic cavity. The resultant lesion is an enlarging sphere just beneath the skin surface. Most authorities believe that closed comedones are precursors of inflammatory acne. If open or closed comedones are the predominant lesions on the skin in adolescent acne, the condition is called comedonal acne.

In typical adolescent acne, several different types of lesions are present simultaneously, for example, open and closed comedones and inflammatory lesions such as papules, pustules, and cysts. Inflammatory lesions may also rarely occur as interconnecting, draining sinus tracts. Adolescents with cystic acne require prompt medical attention, because ruptured cysts and sinus tracts result in severe scar formation. New acne scars are highly vascular and have a reddish or purplish hue. Such scars return to normal skin color after several years. Acne scars may be depressed beneath the skin level, raised, or flat to the skin. In adolescents with a tendency toward keloid formation, keloidal scars can occur following acne lesions, particularly over the sternal area.

Differential Diagnosis

Consider rosacea, nevus comedonicus, flat warts, milia, molluscum contagiosum, and the angiofibromas of tuberous sclerosis.

Pathogenesis

The primary event in acne formation is obstruction of the sebaceous follicle. Ordinarily the lining of such follicles contains one or two layers of stratum corneum cells, but in acne the stratum corneum is overproduced. This phenomenon is androgen-dependent in adolescent acne. The sebaceous follicles contain an enzyme, testosterone 5 α -reductase, which converts plasma testosterone to dihydrotestosterone. This androgen is a potent stimulus for nuclear division of the follicular germinative cells and subsequently of excessive cell production. Thus obstruction requires the presence of both circulating androgens and the converting enzyme. After the production or administration of androgens, a delay results until cellular proliferation occurs, followed by follicular obstruction.

The pathogenesis of inflammatory acne is not well understood. Undoubtedly, physical manipulation of a closed comedo could lead to rupture of the cavity contents into the dermis with a subsequent inflammatory response. Spontaneous inflammation also occurs in obstructed follicles, but the reason for this is unclear. An attractive hypothesis is that overgrowth of gram-positive bacteria in the obstructed follicle (either *Propionibacterium acnes* or *Staphylococcus epidermidis*) might stimulate factors that initiate inflammation. Overproduction of sebum and free fatty acid formation seem unlikely as causes of inflammation in acne as presently understood.

Adolescent acne may be worsened by several external causes. Frictional acne caused by headbands, football helmets, or tight-fitting brassieres or other garments occurs predominantly underneath the area where the garment is worn. Oil-based cosmetics may be responsible for predominantly comedonal acne, and hair sprays may produce acne along the hair margin.

Drug-induced acne should be suspected in teenagers if all lesions are in the same stage at the same time and if involvement extends to the lower abdomen, lower back, arms, and legs. Drugs responsible for acne include corticotropin (ACTH), glucocorticoids, androgens, hydantoin, and isoniazid, each of which increases plasma testosterone.

Treatment

Different treatment options are listed in Table 14–6.

A. TOPICAL KERATOLYTIC AGENTS

The mainstay of acne therapy is the use of potent topical keratolytic agents applied to the skin to relieve follicular obstruction. The most effective keratolytic agents are the retinoids; tretinoin (retinoic acid), adapalene, and tazarotene. The agents may be used once

Table 14–6. Acne treatment.

Comedonal acne	One of the following: Retinoic acid, 0.025, 0.05, or 0.1% cream; 0.01 or 0.025% gel; or 0.1% microgel
Papular inflammatory acne	Adapalene, 0.1% gel or solution One from first grouping, plus one of the following: Topical antibiotics Benzoyl peroxide, 2.5, 4, 5, 8, or 10% gel or lotion; 4 or 8% wash Azaleic acid, 20% cream Clindamycin, 1% lotion, solution, or gel
Pustular inflammatory acne	One from first grouping, plus one of the following: Oral antibiotics Tetracycline or erythromycin, 250–500 mg, bid Minocycline or doxycycline, 50–100 mg, bid
Nodulocystic acne	Accutane, 1 mg/kg/day

daily, or the combination of a retinoid applied to acne-bearing areas of the skin once daily in the evening and a benzoyl peroxide gel or azaleic acid applied once daily in the morning may be used. This regimen will control 80–85% of cases of adolescent acne.

B. TOPICAL ANTIBIOTICS

Topical antibiotics are used to avoid the side effects caused by systemic antibiotics. Topical antibiotics are less effective than systemic antibiotics and at best are equivalent in potency to 250 mg of tetracycline orally once a day. One percent clindamycin phosphate solution is the most efficacious topical antibiotic. Most *P. acnes* are now resistant to topical erythromycin solutions.

C. SYSTEMIC ANTIBIOTICS

Antibiotics that are concentrated in sebum, such as tetracycline, minocycline, and doxycycline, are very effective in inflammatory acne. The usual dose of tetracycline is 0.5–1 g; of minocycline and doxycycline, 50–100 mg taken once or twice daily on an empty stomach (nothing to eat 1 hour before or after the medication). Treatment should be continued for 2–3 months until the acne lesions are suppressed.

D. ORAL RETINOIDS

An oral retinoid, 13-*cis*-retinoic acid (isotretinoin; Accutane), is the most effective treatment for severe cystic

acne. The precise mechanism of its action is unknown, but decreased sebum production, decreased follicular obstruction, decreased skin bacteria, and general anti-inflammatory activities have been described. The initial dosage is 40 mg once or twice daily. This drug is not effective in comedonal acne or other mild forms of acne. Side effects include dryness and scaliness of the skin, dry lips, and, occasionally, dry eyes and dry nose. Up to 10% of patients experience mild, reversible hair loss. Elevated liver enzymes and blood lipids have rarely been described. Acute depression may occur. Isotretinoin is teratogenic in young women of child-bearing age. Because of this and the other side effects, it is not recommended unless strict adherence to the FDA guidelines is ensured. Accutane prescribers must now be certified.

E. OTHER ACNE TREATMENTS

No convincing evidence supports the contention that dietary management, mild drying agents, abrasive scrubs, oral vitamin A, ultraviolet light, cryotherapy, and incision and drainage have any beneficial effects in the management of acne.

F. AVOIDANCE OF COSMETICS AND HAIR SPRAY

Acne can be aggravated by a variety of external factors that result in further obstruction of partially occluded sebaceous follicles. Discontinuing the use of oil-based cosmetics, face creams, and hair sprays may alleviate the comedonal component of acne within 4–6 weeks.

Patient Education & Follow-Up Visits

The mechanism of acne formation and the treatment plan must be explained to adolescent patients. Time should be set aside at the first visit to answer questions. Explain that there will not be much improvement for 4–8 weeks. Fifty percent improvement at 8–12 weeks is considered average. Establish guidelines for ideal control and explain that the best result the patient can expect is the appearance of only one or two new pimples a month. No drug is available that will prevent an adolescent from ever having another acne lesion. A written education sheet is useful.

Follow-up visits should be made every 6–8 weeks. The criterion for ideal control is a few lesions every 4 weeks. Explain again what medications are being used and what the treatment is intended to achieve, and question the patient to determine whether the medications are being used properly.

Gollnick H, Cunliffe W: Management of acne: A report from a global alliance to improve outcomes in acne. *J Am Acad Dermatol* 2003;49:S1 [PMID: 12833004].

BACTERIAL INFECTIONS OF THE SKIN

Impetigo

Erosions covered by honey-colored crusts are diagnostic of impetigo. Staphylococci and group A streptococci are important pathogens in this disease, which histologically consists of superficial invasion of bacteria into the upper epidermis, forming a subcorneal pustule.

Impetigo should be treated with an antimicrobial agent effective against *Staphylococcus aureus* (β -lactamase-resistant penicillins or cephalosporins, clindamycin, amoxicillin–clavulanate) for 7–10 days. Topical mupirocin (three times daily) is also effective.

Bullous Impetigo

All impetigo is bullous, with the blister forming just beneath the stratum corneum, but in bullous impetigo there is, in addition to the usual erosion covered by a honey-colored crust, a border filled with clear fluid. Staphylococci may be isolated from these lesions, and systemic signs of circulating exfoliatin are absent. Bullous varicella is a disorder that represents bullous impetigo as a superinfection in varicella lesions. Treatment with oral antistaphylococcal drugs for 7–10 days is effective. Application of cool compresses to debride crusts is a helpful symptomatic measure.

Ecthyma

Ecthyma is a firm, dry crust, surrounded by erythema that exudes purulent material. It represents deep invasion by group A β -hemolytic streptococci through the epidermis to the superficial dermis. Treatment is with systemic penicillin. This should not be confused with ecthyma gangrenosum. Lesions of ecthyma gangrenosum may be similar in appearance, but they are seen in a severely ill or immunocompromised patient and are due to systemic dissemination of bacteria, usually *Pseudomonas aeruginosa*, through the bloodstream.

Cellulitis

Cellulitis is characterized by erythematous, hot, tender, ill-defined, edematous plaques accompanied by regional lymphadenopathy. Histologically, this disorder represents invasion of microorganisms into the lower dermis and sometimes beyond, with obstruction of local lymphatics. Group A β -hemolytic streptococci and coagulase-positive staphylococci are the most common causes; pneumococci and *Haemophilus influenzae* are rare causes. Staphylococcal infections are usually more localized and more likely to have a purulent center; streptococcal infections spread more rapidly, but these characteristics cannot be used to specify the in-

fecting agent. An entry site of prior trauma or infection (eg, varicella) is often present. Septicemia is a potential complication. Treatment is with an appropriate systemic antibiotic.

Folliculitis

A pustule at a follicular opening represents folliculitis. If the pustule occurs at eccrine sweat orifices, it is correctly called poritis. Staphylococci and streptococci are the most frequent pathogens. Treatment consists of measures to remove follicular obstruction—either cool, wet compresses for 24 hours or keratolytics such as those used for acne.

Abscess

An abscess occurs deep in the skin, at the bottom of a follicle or an apocrine gland, and is diagnosed as an erythematous, firm, acutely tender nodule with ill-defined borders. Staphylococci are the most common organisms. Treatment consists of incision and drainage and systemic antibiotics.

Scalded Skin Syndrome

This entity consists of the sudden onset of bright red, acutely painful skin, most obvious periorally, periorbitally, and in the flexural areas of the neck, the axillae, the popliteal and antecubital areas, and the groin. The slightest pressure on the skin results in severe pain and separation of the epidermis, leaving a glistening layer (the stratum granulosum of the epidermis) beneath. The disease is caused by a circulating toxin (exfoliatin) elaborated by phage group II staphylococci. The site of action of the exfoliatin is the intracellular area of the granular layer, resulting in a separation of cells. The causative staphylococci may be isolated not from the skin but rather from the nasopharynx, an abscess, sinus, blood culture, and so on. Treatment is with systemic antistaphylococcal drugs.

Oumeish I et al: Acute bacterial skin infections in children. *Clin Dermatol* 2000;18:667 [PMID: 11173202].

FUNGAL INFECTIONS OF THE SKIN

1. Dermatophyte Infections

Dermatophytes become attached to the superficial layer of the epidermis, nails, and hair, where they proliferate. They grow mainly within the stratum corneum and do not invade the lower epidermis or dermis. Release of

toxins from dermatophytes, especially those whose natural host is animals or soil, for example, *Microsporum canis* and *Trichophyton verrucosum*—results in dermatitis. Fungal infection should be suspected with any red and scaly lesion.

Classification & Diagnosis

A. TINEA CAPITIS

Thickened, broken-off hairs with erythema and scaling of underlying scalp are the distinguishing features (Table 14-7). In epidemic ringworm, hairs are broken off at the surface of the scalp, leaving a “black dot” appearance. Pustule formation and a boggy, fluctuant mass on the scalp occur in *M canis* and *T tonsurans* infections. This mass, called a kerion, represents an exaggerated host response to the organism. Diffuse scaling of the scalp may also be seen. Fungal culture should be performed in all cases of suspected tinea capitis.

B. TINEA CORPORIS

Tinea corporis presents either as annular marginated papules with a thin scale and clear center or as an annular confluent dermatitis. The most common organisms are *Trichophyton mentagrophytes* and *M canis*. The diagnosis is made by scraping thin scales from the border of the lesion, dissolving them in 20% KOH, and examining for hyphae.

C. TINEA CRURIS

Symmetrical, sharply marginated lesions in inguinal areas occur with tinea cruris. The most common organisms are *Trichophyton rubrum*, *T mentagrophytes*, and *Epidermophyton floccosum*.

D. TINEA PEDIS

The diagnosis of tinea pedis in a prepubertal child must always be regarded with skepticism; atopic feet or con-

Table 14-7. Clinical features of tinea capitis.

Most Common Organisms	Clinical Appearance	Microscopic Appearance in KOH
<i>Trichophyton tonsurans</i> (90%)	Hairs broken off 2–3 mm from follicle; “black dot”; no fluorescence	Hyphae and spores within hair
<i>Microsporum canis</i> (10%)	Thickened broken-off hairs that fluoresce yellow-green with Wood’s lamp	Small spores outside of hair; hyphae within hair

tact dermatitis is a more likely diagnosis in this age group. Tinea pedis occurs most commonly in postpubertal males with blisters on the instep of the foot. Fissuring between the toes is occasionally seen.

E. TINEA UNGUIUM (ONYCHOMYCOSIS)

Loosening of the nail plate from the nail bed (onycholysis), giving a yellow discoloration, is the first sign of fungal invasion of the nails. Thickening of the distal nail plate then occurs, followed by scaling and a crumbly appearance of the entire nail plate surface. *T rubrum* and *T mentagrophytes* are the most common causes. The diagnosis is confirmed by KOH examination and fungal culture. Usually only one or two nails are involved. If every nail is involved, psoriasis, lichen planus, or idiopathic trachyonychia is a more likely diagnosis than fungal infection.

Treatment

The treatment of dermatophytosis is quite simple: If hair is involved, griseofulvin is the treatment of choice. Topical antifungal agents do not enter hair or nails in sufficient concentration to clear the infection. The absorption of griseofulvin from the gastrointestinal tract is enhanced by a fatty meal; thus, whole milk or ice cream taken with the medication increases absorption. The dosage of griseofulvin is 20 mg/kg/d. With hair infections, cultures should be done every 4 weeks, and treatment should be continued for 6–8 weeks following a negative culture. The side effects are few, and the drug has been used successfully in the newborn period. Itraconazole and terbinafine have been used when response to griseofulvin is unsatisfactory. For nails, daily administration of topical ciclopirox 8% (Penlac nail lacquer) can be considered, as can pulsed-dose itraconazole given in three 1-week pulses separated by 3 weeks.

Tinea corporis, tinea pedis, and tinea cruris can be treated effectively with topical medication after careful inspection to make certain that the hair and nails are not involved. Treatment with clotrimazole (Lotrimin), miconazole (Micatin), econazole (Spectazole), terbinafine (Lamisil), or haloprogin (Halotex) applied twice daily for 3–4 weeks is recommended.

Pomeranz AJ, Sabnis SS: Tinea capitis: Epidemiology, diagnosis and management strategies. *Paediatr Drugs* 2002;4:779 [PMID: 1241130].

2. Tinea Versicolor

Tinea versicolor is a superficial infection caused by *Pityrosporum orbiculare* (also called *Malassezia furfur*), a yeast-like fungus. It characteristically causes polycyclic connected hypopigmented macules and very fine scales

in areas of sun-induced pigmentation. In winter, the polycyclic macules appear reddish brown.

Treatment consists of application of selenium sulfide (Selsun), 2.5% suspension, or topical antifungals. Selenium sulfide should be applied to the whole body and left on overnight. Treatment can be repeated again in 1 week and then monthly thereafter. It tends to be somewhat irritating, and the patient should be warned about this difficulty.

VanderStraten MR et al: Cutaneous infections dermatophytosis, onychomycosis and tinea versicolor. *Infect Dis North Am* 2003;17:87 [PMID: 12751262].

3. Candida albicans Infections (See also Chapter 39.)

In addition to being a frequent invader in diaper dermatitis, *Candida albicans* also infects the oral mucosa, where it appears as thick white patches with an erythematous base (thrush); the angles of the mouth, where it causes fissures and white exudate (perleche); and the cuticular region of the fingers, where thickening of the cuticle, dull red erythema, and distortion of growth of the nail plate suggest the diagnosis of candidal paronychia. *Candida* dermatitis is characterized by sharply defined erythematous patches, sometimes with eroded areas. Pustules, vesicles, or papules may be present as satellite lesions. Similar infections may be found in other moist areas, such as the axillae and neck folds. This infection is more common in children who have recently received antibiotics.

A topical imidazole cream is the drug of first choice for *C albicans* infections. In diaper dermatitis, the cream form can be applied every 3–4 hours. In oral thrush, nystatin suspension should be applied directly to the mucosa with the parent's finger or a cotton-tipped applicator, because it is not absorbed and acts topically. In candidal paronychia, the antifungal agent is applied over the area, covered with occlusive plastic wrapping, and left on overnight after the application is made airtight. Refractory candidiasis will respond to a brief course of oral fluconazole.

Hay RJ: The management of superficial candidiasis. *J Am Acad Dermatol* 1999;40:S35 [PMID: 10367915].

VIRAL INFECTIONS OF THE SKIN (See Chapter 36.)

Herpes Simplex

Grouped vesicles or grouped erosions suggest herpes simplex. The microscopic finding of epidermal giant cells after scraping the vesicle base with a No. 15 blade,

smearing on a slide, and staining with Wright stain (Tzanck smear) suggests herpes simplex or varicella-zoster. Rapid immunofluorescent tests for herpes simplex virus and varicella-zoster virus are available. In infants, lesions resulting from herpes simplex type 1 are seen on the gingiva and lips, periorbitally, or on the thumb in children who suck their thumbs. Recurrent erosions in the mouth are usually aphthous stomatitis in children rather than recurrent herpes simplex. Herpes simplex type 2 lesions are seen on the genitalia and in the mouth in adolescents. Cutaneous dissemination of herpes simplex occurs in patients with atopic dermatitis (eczema herpeticum, Kaposi varicelliform eruption). The treatment of herpes simplex virus infections is discussed in Chapter 36.

Whitley RJ: Herpes simplex virus in children. *Curr Treat Options Neurol* 2002;4:231 [PMID: 11931730].

Varicella-Zoster

Grouped vesicles in a dermatome, usually on the trunk or face, suggest varicella-zoster infection. Zoster in children may not be painful and usually has a mild course. In patients with compromised host resistance, the appearance of an erythematous border around the vesicles is a good prognostic sign. Conversely, large bullae without a tendency to crusting and systemic illness imply a poor host response to the virus. Varicella-zoster and herpes simplex lesions undergo the same series of changes: papule, vesicle, pustule, crust, slightly depressed scar. Varicella appears in crops, and many different stages of lesions are present at the same time.

Itching is usually the only symptom, and cool baths as frequently as necessary or drying lotions such as calamine lotion are sufficient to relieve symptoms. In immunosuppressed children, intravenous or oral acyclovir should be used.

Chen TM et al: Clinical manifestations of varicella-zoster virus infection. *Dermatol Clin* 2002;20:267 [PMID: 12120440].

Emmert DH: Treatment of common cutaneous herpes simplex virus infections. *Am Fam Physician* 2000;15:1697 [PMID: 10750877].

Human Immunodeficiency Virus Infection (See also Chapter 37.)

The average time of onset of skin lesions after perinatally acquired human immunodeficiency virus (HIV) infection is 4 months; after transfusion-acquired infection, it is 11 months. Persistent oral candidiasis and recalcitrant candidal diaper rash are the most frequent cutaneous features of infantile HIV infection. Severe or recurrent herpetic gingivostomatitis, varicella-zoster infection, and molluscum contagiosum infection occur.

Recurrent staphylococcal pyodermas, tinea of the face, and onychomycosis are also observed. A generalized dermatitis with features of seborrhea is extremely common. In general, persistent, recurrent, or extensive skin infections should make one suspicious of HIV infection.

Virus-Induced Tumors

A. MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a poxvirus that induces the epidermis to proliferate, forming a pale papule. Molluscum contagiosum consists of umbilicated, white or whitish yellow papules in groups on the genitalia or trunk. They are common in sexually active adolescents and in infants and preschool children. Molluscum lesions in general are treated in the same manner as warts. Treatment for molluscum includes benign neglect, topical imiquimod, topical cantharidin, oral cimetidine, and curettage.

Smith KJ, Skelton H: Molluscum contagiosum: Recent advances in pathogenic mechanisms and new therapies. *Am J Clin Dermatol* 2002;3:535 [PMID: 12358555].

B. WARTS

Warts are skin-colored papules with irregular (verruccous) surfaces. They are intraepidermal tumors caused by infection with human papillomavirus. This DNA virus induces the epidermal cells to proliferate, thus resulting in the warty growth. Flat warts are smoother and smaller than common warts and are often seen on the face.

No therapy for warts is ideal, and some types of therapy should be avoided because the recurrence rate of warts is high. For flat warts, a good response to 0.05% tretinoin cream or topical imiquimod (Aldara) cream, applied once daily for 3–4 weeks, has been reported.

The best treatment for the solitary common (vulgaris) wart is to freeze it with liquid nitrogen. The liquid nitrogen should be allowed to drip from the cotton-tipped applicator onto the wart without pressure. Pressure exaggerates cold injury by causing vasoconstriction and may produce a deep ulcer and scar. Liquid

nitrogen is applied by drip until the wart turns completely white and stays white for 20–25 seconds. Large and painful plantar warts are treated most effectively by applying 40% salicylic acid plaster cut with a scissors to fit the lesion. The sticky brown side of the plaster is placed against the lesion, taped on securely with adhesive tape, and left on for 5 days. The plaster is then removed, and the white necrotic warty tissue can be gently rubbed off with a pumice stone and a new salicylic acid plaster applied. This procedure is repeated every 5 days, and the patient is seen every 4 weeks. Most plantar warts resolve in 6–8 weeks when treated in this way. Vascular pulsed dye lasers are a useful adjunct therapy for the treatment of plantar warts.

Sharp scalpel excision, electrosurgery, and nonspecific burning laser surgery should be avoided, because the resulting scar often becomes a more difficult problem than the wart itself and the wart may recur in the area of the scar.

Venereal warts (*condylomata acuminata*) (see Chapter 40) may be treated with imiquimod, 25% podophyllum resin (podophyllin) in alcohol, or podofilox, a lower concentration of purified podophyllin. Podophyllin should be painted on the lesions and then washed off after 4 hours. Retreatment in 2–3 weeks may be necessary. Podofilox is applied daily, whereas imiquimod is used on Monday, Wednesday, and Friday. A wart not on the vulvar mucous membrane but on the adjacent skin should be treated as a common wart and frozen.

For isolated warts and periungual warts, cantharidin is effective and painless in children. It causes a blister and sometimes is difficult to control. An undesirable complication is the appearance of warts along the margins of the cantharidin blister. Cantharidin is applied to the skin, allowed to dry, and covered with occlusive tape or a bandage for 24 hours.

No wart therapy is immediately and definitively successful, and recurrences are reported in more than 30% of cases even with the best care.

INSECT INFESTATIONS

Scabies

Scabies is suggested by linear burrows about the wrists, ankles, finger webs, areolas, anterior axillary folds, genitalia, or face (in infants). Often there are excoriations, honey-colored crusts, and pustules from secondary infection. Identification of the female mite or her eggs

and feces is necessary to confirm the diagnosis. Scrape an unscratched papule or burrow with a No. 15 blade and examine microscopically in immersion oil to confirm the diagnosis. In a child who is often scratching, scrape under the fingernails. Examine the parents for unscratched burrows.

Lindane (γ -benzene hexachloride; Kwell) and permethrin are excellent scabicides. However, because lindane is concentrated in the central nervous system, where toxicity from systemic absorption in infants has been reported, the following restricted use of this agent is recommended: (1) For adults and older children, one treatment of lindane lotion or cream applied to the entire body and left on for 4 hours, followed by showering, is sufficient. (2) Infants tend to have more organisms and many more lesions and may have to be retreated in 7–10 days. All family members should be treated simultaneously. Permethrin 5% cream (Elimite) may be substituted for lindane in infants.

Pediculoses (Louse Infestations)

The presence of excoriated papules and pustules and a history of severe itching at night suggest infestation with the human body louse. This louse may be discovered in the seams of underwear but not on the body. In the scalp hair, the gelatinous nits of the head louse adhere tightly to the hair shaft. The pubic louse may be found crawling among pubic hairs, or blue-black macules may be found dispersed through the pubic region (*maculae ceruleae*). The pubic louse is often seen on the eyelashes of newborns.

Lindane (γ -benzene hexachloride; Kwell) is recommended: For head lice, a shampoo preparation is left on the scalp for 5 minutes and rinsed out thoroughly. The hair is then combed with a fine-tooth comb to remove nits. This may be repeated in 7 days. Lindane cream or lotion applied to the body for 4 hours may be necessary for body lice, but boiling the clothing for 10 minutes followed by ironing the seams with a hot iron usually eliminates them. Permethrin 1% creme rinse also eliminates lice. Lindane cream or lotion applied to the pubic area for 24 hours is sufficient to treat pediculosis pubis. It may be repeated in 4–5 days. Permethrin 5% cream (Elimite) may be substituted for lindane in infants.

Papular Urticaria

Papular urticaria is characterized by grouped erythematous papules surrounded by an urticarial flare and distributed over the shoulders, upper arms, and buttocks in infants. Although not a true infestation, these lesions represent delayed hypersensitivity reactions to stinging or biting insects and can be reproduced by patch testing with the offending insect. Fleas from dogs and cats are the usual offenders. Less commonly, mosquitoes, lice, scabies, and bird and grass mites are involved. The sensitivity is transient, lasting 4–6 months. Usually no other family members are affected. It is often difficult for the parents to understand why no one else is affected. The logical therapy is to remove the offending insect, although in most cases it is very difficult to identify the exact cause. Topical corticosteroids and oral antihistamines will control symptoms.

DERMATITIS (ECZEMA)

The terms *dermatitis* and *eczema* are currently used interchangeably in dermatology, although the term *eczema* truly denotes an acute weeping dermatosis. All forms of dermatitis, regardless of cause, may present with acute edema, erythema, and oozing with crusting, mild erythema alone, or lichenification. Lichenification is diagnosed by thickening of the skin with a shiny surface and exaggerated, deepened skin markings. It is the response of the skin to chronic rubbing or scratching.

Although the lesions of the various dermatoses are histologically indistinguishable, clinicians have nonetheless divided the disease group called dermatitis into several categories based on known causes in some cases and differing natural histories in others.

1. Atopic Dermatitis

Atopic dermatitis is a general term for chronic superficial inflammation of the skin that can be applied to a heterogeneous group of patients. Many (not all) patients go through three clinical phases. In the first, infantile eczema, the dermatitis begins on the cheeks and scalp and frequently expresses itself as oval patches on the trunk, later involving the extensor surfaces of the extremities. The usual age at onset is 2–3 months, and this phase ends at age 18 months to 2 years. Only one third of all infants with atopic eczema progress to phase 2 childhood or flexural eczema in which the predominant involvement is in the antecubital and popliteal fossae, the neck, the wrists, and sometimes the hands or

feet. This phase lasts from age 2 years to adolescence. Some children will have involvement only of the soles of the feet, with cracking, redness, and pain, so-called atopic feet. Only one third of children with typical flexural eczema will progress to adolescent eczema, which is usually manifested by hand dermatitis only. Atopic dermatitis is quite unusual after age 30 years.

Atopic dermatitis results from an interaction between susceptibility genes, the host environment, skin barrier defects, pharmacologic abnormalities and immunologic response. The case for food and inhalant allergens as specific causes of atopic dermatitis is not strong. However, since the cause of atopic dermatitis remains unknown, there is debate between dermatologists and allergists on the exact role of allergy in atopic dermatitis (see Chapter 34).

A few patients with atopic dermatitis have immunodeficiency with recurrent pyodermas, unusual susceptibility to herpes simplex viruses, hyperimmunoglobulinemia E, defective neutrophil and monocyte chemotaxis, and impaired T-lymphocyte function (see Chapter 29).

A faulty epidermal barrier may predispose the patient with atopic dermatitis to itchy skin. Inability to hold water within the stratum corneum results in rapid evaporation of water, shrinking of the stratum corneum, and cracks in the epidermal barrier. Such skin forms an ineffective barrier to the entry of various irritants—and, indeed, it may be clinically useful to regard atopic dermatitis as a primary-irritant contact dermatitis and simply tell the patient, you have sensitive skin. Chronic atopic dermatitis is frequently infected secondarily with *Staphylococcus aureus* or *Streptococcus pyogenes*.

Treatment

A. ACUTE STAGES

Application of wet dressings and topical corticosteroids is the treatment of choice for acute, weeping atopic eczema. A topical steroid preparation is applied two times daily and covered with wet dressings as outlined at the beginning of this chapter. Superinfection or colonization with *S aureus* is common, and appropriate systemic antibiotics may be necessary. If the expected improvement is not seen, bacterial cultures should be obtained to identify the possibility of an organism resistant to standard therapy.

B. CHRONIC STAGES

Treatment is aimed at avoiding irritants and restoring water to the skin. No soaps or harsh shampoos should be used, and the patient should avoid woolen or any rough clothing. Bathing is minimized to every second or third day. Twice-daily lubrication of the skin is very important.

Nonperfumed lotions or creams are suitable lubricants. Plain petrolatum is an acceptable lubricant, but

some people find it too greasy and it may also cause considerable sweat retention. Liberal use of Cetaphil lotion as a soap substitute four or five times a day is also satisfactory as a means of lubrication. A bedroom humidifier is often helpful. Topical corticosteroids should be limited to medium strength (see Table 14–3). There is never any reason to use super- or high-potency corticosteroids in atopic dermatitis. In superinfected atopic dermatitis, systemic antibiotics for 10–14 days are necessary.

Topical tacrolimus and pimecrolimus are new topical immunosuppressive agents that are effective in atopic dermatitis. Tacrolimus should be reserved for children older than 2 years of age with atopic dermatitis unresponsive to medium-potency topical steroids. Pimecrolimus is helpful for chronic eczema of the face.

Treatment failures in chronic atopic dermatitis are most often the result of patient noncompliance. This is a frustrating disease for parent and child.

Lewis-Jones: Atopic dermatitis in childhood. *Hosp Med* 2001;62:136 [PMID: 11291461].

2. Nummular Eczema

Nummular eczema is characterized by numerous symmetrically distributed coin-shaped patches of dermatitis, principally on the extremities. These may be acute, oozing, and crusted or dry and scaling. The differential diagnosis should include tinea corporis, impetigo, and atopic dermatitis.

The same topical measures should be used as for atopic dermatitis, although treatment is often more difficult.

3. Primary Irritant Contact Dermatitis (Diaper Dermatitis)

Contact dermatitis is of two types: primary irritant and allergic eczematous. Primary irritant dermatitis devel-

ops within a few hours, reaches peak severity at 24 hours, and then disappears. Allergic eczematous contact dermatitis (described in the next section) has a delayed onset of 18 hours, peaks at 48–72 hours, and often lasts as long as 2–3 weeks even if exposure to the offending antigen is discontinued.

Diaper dermatitis, the most common form of primary irritant contact dermatitis seen in pediatric practice, is caused by prolonged contact of the skin with urine and feces, which contain irritating chemicals such as urea and intestinal enzymes. The diagnosis of diaper dermatitis is based on the picture of erythema and scaling of the skin in the perineal area and the history of prolonged skin contact with urine or feces. This is frequently seen in the “good baby” who sleeps many hours through the night without waking. In 80% of cases of diaper dermatitis lasting more than 3 days, the affected area is colonized with *C albicans* even before appearance of the classic signs of a beefy red, sharply marginated dermatitis with satellite lesions.

Treatment consists of changing diapers frequently. Because rubber or plastic pants prevent evaporation of the contactant and enhance its penetration into the skin, they should be avoided as much as possible. Air drying is useful. Streptococcal perianal cellulitis and infantile psoriasis should be included in the differential diagnosis. Treatment of long-standing diaper dermatitis should include application of nystatin or an imidazole cream with each diaper change.

Levy M: Diaper rash syndrome or dermatitis. *Cutis* 2001;67:37 [PMID: 11398268].

4. Allergic Eczematous Contact Dermatitis (Poison Ivy Dermatitis)

Plants such as poison ivy, poison sumac, and poison oak cause most cases of allergic contact dermatitis in children. Allergic contact dermatitis has all the features of delayed-type (T-lymphocyte-mediated) hypersensitivity. Many substances may cause such a reaction; nickel sulfate, potassium dichromate, and neomycin are the most common causes. Nickel is found to some degree in all metals. Nickel allergy is commonly seen on the ears secondary to the wearing of earrings, and near the umbilicus from pants snaps and belt buckles. The true incidence of allergic contact dermatitis in children is unknown. Children often present with acute dermatitis with blister formation, oozing, and crusting. Blisters are often linear and of acute onset.

Treatment of contact dermatitis in localized areas is with topical corticosteroids. In severe generalized in-

volvement, prednisone, 1–2 mg/kg/d orally for 10–14 days, can be used.

Bruckner AL, Weston WL: Allergic contact dermatitis in children: A practical approach to management. *Skin Therapy Lett* 2002;7:3 [PMID: 12548328].

Weston WL, Bruckner A: Allergic contact dermatitis. *Pediatr Clin North Am* 2000;47:897 [PMID: 10943264].

5. Seborrheic Dermatitis

Seborrheic dermatitis is an erythematous scaly dermatitis accompanied by overproduction of sebum occurring in areas rich in sebaceous glands (ie, the face, scalp, and perineum). This common condition occurs predominantly in the newborn and at puberty, the ages at which hormonal stimulation of sebum production is maximal. Although it is tempting to speculate that overproduction of sebum causes the dermatitis, the exact relationship is unclear.

Seborrheic dermatitis on the scalp in infancy is clinically similar to atopic dermatitis, and the distinction may become clear only after other areas are involved. Psoriasis also occurs in seborrheic areas in older children and should be considered in the differential diagnosis.

Seborrheic dermatitis responds well to low-potency topical corticosteroids.

6. Dandruff

Physiologic scaling or mild seborrhea, in the form of greasy scalp scales, may be treated by medicated dandruff shampoos. The cause is unknown.

Warner RR et al: Dandruff has an altered stratum corneum ultrastructure that is improved with zinc pyrithione shampoo. *J Am Acad Dermatol* 2001;45:897 [PMID: 11712036].

7. Dry Skin Dermatitis (Asteatotic Eczema, Xerosis)

Newborns and older children who live in arid climates are susceptible to dry skin, characterized by large cracked scales with erythematous borders. The stratum corneum is dependent on environmental humidity for its water, and below 30% environmental humidity the stratum corneum loses water, shrinks, and cracks. These cracks in the epidermal barrier allow irritating substances to enter the skin, predisposing the patient to dermatitis.

Treatment consists of increasing the water content of the skin in the immediate external environment. House humidifiers are very useful. Minimize bathing to every second or third day.

Frequent soaping of the skin impairs its water-holding capacity and serves as an irritating alkali, and all soaps should therefore be avoided. Frequent use of emollients (eg, Cetaphil, Eucerin, Lubriderm) should be a major part of therapy.

8. Keratosis Pilaris

Follicular papules containing a white inspissated scale characterize keratosis pilaris. Individual lesions are discrete and may be red. They are prominent on the extensor surfaces of the upper arms and thighs and on the buttocks and cheeks. In severe cases, the lesions may be generalized. Such lesions are seen frequently in children with dry skin and have also been associated with atopic dermatitis and ichthyosis vulgaris.

Treatment is with keratolytics such as topical retinoic acid, lactic acid, or urea creams followed by skin hydration.

Lateef A, Schwartz RA: Keratosis pilaris. *Cutis* 1999;63:205 [PMID: 10228747]

9. Pityriasis Alba

White, scaly macular areas with indistinct borders are seen over extensor surfaces of extremities and on the cheeks in children with pityriasis alba. Suntanning exaggerates these lesions. Histologic examination reveals a mild dermatitis. These lesions may be confused with tinea versicolor. Low-potency topical steroids may help decrease any inflammatory component and may lead to faster return of normal pigmentation.

Blessman-Weber M et al: Pityriasis alba: A study of pathogenic factors. *J Eur Acad Dermatol Venereol* 2002;16:463 [PMID: 12428838].

COMMON SKIN TUMORS

If the skin moves with the nodule on lateral palpation, the tumor is located within the dermis; if the skin moves over the nodule, it is subcutaneous. Seventy-five percent of lumps in childhood will be either epidermal inclusion cysts (60%) or pilomatrichomas (15%).

Epidermal Inclusion Cysts

Epidermal inclusion cysts are smooth, dome-shaped nodules in the skin that may grow to 2 cm in diameter. In infants, they may be found near the eyes, and in older children and adolescents on the chest, back, or scalp. They are the most common superficial lumps in children. Treatment, if desired, is surgical excision.

Pilomatrichomas are benign tumors of the hair matrix. They are most commonly seen on the face and

upper trunk. They are firm and may be irregular. Their color varies from flesh-colored to pink or blue. The firmness is secondary to calcification of the tumor. Treatment is by surgical excision.

Granuloma Annulare

Circles or semicircles of nontender intradermal nodules found over the lower legs and ankles, the dorsum of the hands and wrists, and the trunk, in that order, suggest granuloma annulare. Histologically, the disease appears as a central area of tissue death (necrobiosis) surrounded by macrophages and lymphocytes. No treatment is necessary. Lesions resolve spontaneously within 1–2 years in most children.

Pyogenic Granuloma

Rapid growth of a dark red papule with an ulcerated and crusted surface over 1–2 weeks following skin trauma suggests pyogenic granuloma. Histologically, this represents excessive new vessel formation with or without inflammation (granulation tissue). It is neither pyogenic nor granulomatous but should be regarded as an abnormal healing response. Pulsed dye laser and curettage followed by electrocautery are the treatments of choice.

Keloids

Keloids are scars raised above the skin surface with many radial projections of scar tissue. They continue to enlarge over several years. They are often found on the face, earlobes, neck, chest, and back. Keloids show no racial predilection. Treatment includes intralesional injection with triamcinolone acetonide, 20 mg/mL, or excision and injection with corticosteroids.

Wyatt AJ, Hansen RC: Pediatric skin tumors. *Pediatr Clin North Am* 2000;47:937 [PMID: 10943267].

PAPULOSQUAMOUS ERUPTIONS

Papulosquamous eruptions (Table 14–8) comprise papules or plaques with varying degrees of scale.

1. Pityriasis Rosea

Erythematous papules that coalesce to form oval plaques preceded by a large oval plaque with central clearing and a scaly border (the herald patch) establish the diagnosis of pityriasis rosea. The herald patch has the appearance of ringworm and is often treated as such. It appears 1–30 days before the onset of the generalized papular eruption. The oval plaques are parallel in their long axis and follow lines of skin cleavage. In

Table 14–8. Papulosquamous eruptions in children.

Psoriasis
Pityriasis rosea

Chronic parapsoriasis
Dermatomyositis
Lupus erythematosus
Pityriasis rubra pilaris
Secondary syphilis

whites, the lesions are primarily on the trunk; in blacks, lesions are primarily on the extremities and may be accentuated in the axillary and inguinal areas. This disease is common in school-age children and adolescents and is presumed to be viral in origin. The role of human herpes virus 7 in the pathogenesis of pityriasis rosea is debated. The condition lasts 6 weeks and may be pruritic the first 7–10 days. The major differential diagnosis is secondary syphilis, and a VDRL test should be done if syphilis is suspected. A chronic variant of this disease may last 2–3 years and is called chronic parapsoriasis or pityriasis lichenoides chronica.

Exposing the skin to sunlight until a mild sunburn occurs (slight redness) will hasten the disappearance of lesions. Ordinarily, no treatment is necessary.

Karnath B et al: Pityriasis rosea. Appearance and distribution of macules aid diagnosis. *Postgrad Med* 2003;113:94 [PMID: 12764899].

Kempf W, Burg G: Pityriasis rosea—A virus-induced skin disease? An update. *Arch Virol* 2000;145:1509 [PMID: 11003465].

2. Psoriasis

Psoriasis is characterized by erythematous papules covered by thick white scales. Guttate (drop-like) psoriasis is a common form in children that often follows an episode of streptococcal pharyngitis by 2–3 weeks. The sudden onset of small papules (3–8 mm), seen predominantly over the trunk and quickly covered with thick white scales, is characteristic of guttate psoriasis. Chronic psoriasis is marked by thick, large scaly plaques (5–10 cm) over the elbows, knees, scalp, and other sites of trauma. Pinpoint pits in the nail plate are seen, as well as yellow discoloration of the nail plate resulting from onycholysis. Thickening of all 20 nails is an uncommon feature. The sacral and seborrheic areas are commonly involved.

Psoriasis has no known cause and demonstrates active proliferation of epidermal cells, with a turnover

time of 3–4 days versus 28 days for normal skin. These rapidly proliferating epidermal cells are producing excessive stratum corneum, giving rise to thick, opaque scales. Papulosquamous eruptions that present problems of differential diagnosis are listed in Table 14–8.

Treatment

All therapy is aimed at diminishing epidermal turnover time. Topical steroids are the initial treatment of choice. Penetration of topical corticosteroids through the enlarged epidermal barrier in psoriasis requires that more potent preparations be used, for example, fluocinonide 0.05% (Lidex) or clobetasol 0.05% (Temovate) ointment twice daily.

The second line of therapy is topical calcipotriene (Dovonex) applied twice daily or the combination of a superpotent topical steroid twice daily on weekends and calcipotriene twice daily on weekdays for 8 weeks.

Anthralin therapy is also useful. Anthralin is applied to the skin for a short contact time (eg, 20 minutes once daily) and then washed off with a neutral soap (eg, Dove). A 6-week course of treatment is recommended.

Crude coal tar therapy is messy and stains bedclothes. The newer tar gels (Estar, psoriGel) cause less staining and are most efficacious. They are applied twice daily for 6–8 weeks. These preparations are sold over the counter and are not usually covered by insurance plans.

Scalp care using a tar shampoo requires leaving the shampoo on for 5 minutes, washing it off, and then shampooing with commercial shampoo to remove scales. It may be necessary to shampoo daily until scaling is reduced. More severe cases of psoriasis are best treated by a dermatologist.

HAIR LOSS (ALOPECIA)

Hair loss in children (Table 14–9) imposes great emotional stress on the patient and the parent. A 60% hair loss in a single area is necessary before hair loss can be detected clinically. Examination should begin with the scalp to determine whether there are color or infiltrative changes. Hairs should be examined microscopically for breaking and structural defects and to see whether growing or resting hairs are being shed. Placing removed hairs in mounting fluid (Permount) on a glass microscope slide makes them easy to examine. Three diseases account for most cases of hair loss in children:

Table 14–9. Other causes of hair loss in children.

Hair loss with scalp changes

Atrophy:

- Lichen planus
- Lupus erythematosus

Nodules and tumors:

- Epidermal nevus
- Nevus sebaceus

Thickening:

- Burn

Hair loss with hair shaft defects (hair fails to grow out enough to require haircuts)

- Monilethrix—alternating bands of thin and thick areas
- Pili annulati—alternating bands of light and dark pigmentation
- Pili torti—hair twisted 180 degrees, brittle
- Trichorrhexis invaginata (bamboo hair)—intussusception of one hair into another
- Trichorrhexis nodosa—nodules with fragmented hair

alopecia areata, tinea capitis (described earlier in this chapter), and trichotillomania.

Alopecia Areata

Loss of every hair in a localized area is called alopecia areata. This is the most common cause of hair loss in children. An immunologic pathogenic mechanism is suspected because dense infiltration of lymphocytes precedes hair loss. Ninety-five percent of children with alopecia areata completely regrow their hair within 12 months, although as many as 40% may have a relapse in 5–6 years. A rare and unusual form of alopecia areata begins at the occiput and proceeds along the hair margins to the frontal scalp. This variety, called ophiasis, often eventuates in total scalp hair loss (alopecia totalis). The prognosis for regrowth in ophiasis is poor.

Treatment of alopecia areata is difficult. Systemic corticosteroids given to suppress the inflammatory response will result in hair growth, but the hair will fall out again when the drug is discontinued. Superpotent topical steroids, minoxidil (Rogaine), and anthralin are treatment options. In children with alopecia totalis, a wig is most helpful.

Tan E et al: A clinical study of childhood alopecia areata in Singapore. *Pediatr Dermatol* 2002;19:298 [PMID: 12220271].

Trichotillomania

Traumatic hair pulling causes the hair shafts to be broken off at different lengths, with an ill-defined area of

hair loss, petechiae around follicular openings, and a wrinkled hair shaft on microscopic examination. This behavior may be merely habit, an acute reaction to severe stress, or a sign of a psychiatric disorder. Eyelashes and eyebrows rather than scalp hair may be pulled out. If the behavior has a long history, psychiatric evaluation may be helpful. Oiling the hair to make it slippery is an aid to behavior modification.

Walsh KH, McDougale CJ: Trichotillomania: Presentation, etiology, diagnosis and therapy. *Am J Clin Dermatol* 2001;2:327 [PMID: 11721651].

REACTIVE ERYTHEMAS

Erythema Multiforme

Erythema multiforme begins with papules that later develop a dark center and then evolve into lesions with central blisters and the characteristic target lesions (iris lesions) that have three concentric circles of color change. Primary injury is to endothelial cells, with later destruction of epidermal basal cells and blister formation. Erythema multiforme has sometimes been diagnosed in patients with severe mucous membrane involvement, but Stevens–Johnson syndrome is the usual term when severe involvement of conjunctiva, oral cavity, and genital mucosa also occur.

Many causes are suspected, particularly concomitant herpes simplex virus, drugs, especially sulfonamides, and *Mycoplasma* infections. Recurrent erythema multiforme is usually associated with reactivation of herpes simplex virus. In the mild form, spontaneous healing occurs in 10–14 days, but Stevens–Johnson syndrome may last 6–8 weeks.

Treatment is symptomatic in uncomplicated erythema multiforme. Removal of offending drugs is an obvious measure. Oral antihistamines such as hydroxyzine, 2 mg/kg/d orally, are useful. Cool compresses and wet dressings will relieve pruritus. Steroids have not been demonstrated to be effective. Chronic acyclovir therapy has been successful in decreasing attacks in those patients with herpes-associated recurrent erythema multiforme.

Forman R et al: Erythema multiforme, Stevens–Johnson syndrome and toxic epidermal necrolysis in children: A review of 10 years' experience. *Drug Saf* 2002;25:965 [PMID: 12381216].

Drug Eruptions

Drugs may produce urticarial, morbilliform, scarlatiniform, or bullous or fixed skin eruptions. Urticaria may appear within minutes after drug administration, but most reactions begin 7–14 days after the drug is first administered. These eruptions may occur in patients who have received these drugs for long periods, and eruptions continue for days after the drug has been discontinued. Acute drug eruptions usually do not produce fever, elevated sedimentation rate, or serum sickness. If any of these occur, a search for a concomitant infection is warranted. Drugs commonly implicated in skin reactions are listed in Table 14–10.

MISCELLANEOUS SKIN DISORDERS ENCOUNTERED IN PEDIATRIC PRACTICE

Aphthous Stomatitis

Recurrent erosions on the gums, lips, tongue, palate, and buccal mucosa are often confused with herpes simplex. A smear of the base of such a lesion stained with Wright stain will aid in ruling out herpes simplex by the absence of epithelial multinucleate giant cells. A culture for herpes simplex is also useful in this difficult differential diagnostic problem. The cause remains un-

Table 14–10. Common drug reactions.

known, but T-cell-mediated cytotoxicity to various viral antigens has been postulated.

There is no specific therapy for this condition. Rinsing the mouth with liquid antacids will provide relief in most patients. Topical corticosteroids in a gel base (eg, fluocinonide gel) may provide some relief. In severe cases that interfere with eating, prednisone, 1 mg/kg/d orally for 3–5 days, will suffice to abort an episode. Colchicine, 0.2–0.5 mg/d, sometimes reduces the frequency of attacks.

Porter SR et al: Recurrent aphthous stomatitis. *Clin Dermatol* 2000;18:569 [PMID: 11134852].

Vitiligo

Vitiligo is characterized clinically by the development of areas of depigmentation. These are often symmetri-

cal and occur mainly on extensor surfaces. The depigmentation results from a destruction of melanocytes. The basis for this destruction is unknown, but immunologically mediated damage is likely and vitiligo sometimes occurs in individuals with selective IgA deficiency, graft-versus-host disease, or autoimmune endocrinopathies. Treatment is not very effective. Potent topical steroids for 4 months are the initial treatment. Topical tacrolimus and calcipotriene have also been used. Narrow-band ultraviolet B waves (UVB 311 nm) may be used in severe cases.

Rebecca Sands, MD, Arlene Drack, MD, & Allan M. Eisenbaum, MD

Normal vision is a skill acquired during infancy and childhood. To become adept requires a normal visual environment. The child must experience equally good visual inputs from well-aligned eyes during this period while the visual nervous system is still exhibiting plasticity. Thus, pediatric ophthalmology emphasizes early diagnosis and treatment of pediatric eye diseases in order to obtain the best possible visual outcome.

But eye disease in children does not always originate in the ocular system. Abnormal eye findings in a child may be a sign of systemic disease. This chapter seeks to increase the reader's awareness of pediatric ophthalmic disease and treatment in order to achieve more favorable visual outcomes and healthier children.

COMMON NONSPECIFIC SIGNS & SYMPTOMS

Nonspecific signs and symptoms commonly occur as the chief complaint or as an element of the history of a child with eye disease. Five of these findings are presented in the following sections with a sixth—leukocoria—which often has serious implications. Do not hesitate to seek the help of a pediatric ophthalmologist when you believe the diagnosis and treatment of these signs and symptoms require in-depth clinical experience.

Redness

Redness (injection) of the bulbar conjunctiva or deeper vessels is a common presenting complaint. It may be mild and localized or diffuse and bilateral. Causes include superficial or penetrating foreign bodies, infection, allergy, and conjunctivitis associated with systemic entities such as Stevens–Johnson syndrome or Kawasaki disease. Irritating noxious agents also result in injection. Subconjunctival hemorrhage may be traumatic or spontaneous or may be associated with hematopoietic disease, vascular anomalies, or inflammatory processes. Uncommonly, an injected eye can be due to an intraocular or orbital tumor.

Tearing

In infants, tearing is usually due to nasolacrimal obstruction, but tearing may also be associated with con-

genital glaucoma, in which case photophobia and blepharospasm may also be present. Inflammation, allergic and viral diseases, or conjunctival and corneal irritation can also cause tearing.

Discharge

Purulent discharge is usually associated with bacterial conjunctivitis. In infants and toddlers with nasolacrimal obstruction, a mucopurulent discharge may be present with low-grade, chronic dacryocystitis. Watery discharge occurs with viral infection, iritis, superficial foreign bodies, and nasolacrimal obstruction. Mucoid discharge may be a sign of allergic conjunctivitis or nasolacrimal obstruction. Histologically, a mucoid discharge due to allergy is expected to show eosinophils; a purulent bacterial discharge will show polymorphonuclear leukocytes.

Pain & Foreign Body Sensation

Pain in or around the eye may be due to foreign bodies, corneal abrasions, lacerations, acute infections of the globe or ocular adnexa, iritis, and angle closure glaucoma. Large refractive errors, poor accommodative ability, and sinus disease may manifest as headaches. Trichiasis (inturned lashes) and contact lens problems are also causes of ocular discomfort.

Photophobia

Acute aversion to light may occur with corneal abrasions, foreign bodies, and iritis. Squinting of one eye in bright light is a common sign of intermittent exotropia. Photophobia is present in infants with glaucoma, albinism, aniridia, and retinal dystrophies such as achromatopsia. Photophobia is common after ocular surgery and after dilation of the pupil with mydriatic and cycloplegic agents. Photophobia in individuals with no ocular pathology may be due to migraine headache, meningitis, and retrobulbar optic neuritis.

Leukocoria

Although not a common sign or complaint, leukocoria (a white pupil) is associated with serious diseases and requires prompt ophthalmologic consultation. Causes

Figure 15-1. Leukocoria of left eye caused by retrolental membrane (persistent hyperplastic primary vitreous or persistent fetal vasculature).

of leukocoria include retinoblastoma, retinopathy of prematurity (ROP), pupillary membrane, cataract, vitreous opacities, retinal detachment, *Toxocara* infection, and retinal dysplasia (Figure 15-1).

REFRACTIVE ERRORS

Refractive error refers to the optical state of the eye (Figure 15-2). It is a physical characteristic like height or weight and can be quantitated. Not all refractive er-

rors require correction, but severe errors can cause amblyopia. Those that do can usually be corrected with glasses. Less often, contact lenses are required, usually for very high or asymmetrical refractive errors, or for adolescents who do not want to wear spectacles. Laser refractive surgery is not currently indicated for most children, although studies are being reported. There are three common refractive errors: myopia, hyperopia, and astigmatism. Inequality of the refractive state between the two eyes (anisometropia) can cause amblyopia (reduced vision with or without an organic lesion; see Amblyopia & Strabismus section). Children at particular risk for refractive errors requiring correction with spectacles include those who were born prematurely, who have Down syndrome, who are offspring of parents with refractive errors, or who have certain systemic conditions such as Stickler, Marfan, or Ehlers-Danlos syndrome.

Myopia (Nearsightedness)

For the myopic or nearsighted individual, objects nearby are in focus; those at a distance are blurred. This is because the plane of focus is anterior to the retina. The onset is typically at about age 8 years and may progress throughout adolescence and young adulthood. A myopic person may squint to produce a pinhole effect, which improves distance vision. Divergent lenses

Figure 15-2. Different refractive states of the eye. **A:** Emmetropia. Image plane from parallel rays of light falls on retina. **B:** Myopia. Image plane focuses anterior to retina. **C:** Hyperopia. Image plane focuses posterior to retina. **D:** Astigmatism, myopic type. Images in horizontal and vertical planes focus anterior to retina. **E:** Astigmatism, hyperopic type. Images in horizontal and vertical planes focus posterior to retina. **F:** Astigmatism, mixed type. Images in horizontal and vertical planes focus on either side of the retina.

provide clear distance vision. Many studies have been done to determine whether treatment can slow or stop myopic progression. Atropine eyedrops have shown some effect, but produce many side effects. A newer drug, perenzipine, has shown promise in animal studies, and human studies are underway.

Saw SM et al: Myopia: Attempts to arrest progression. *Br J Ophthalmol* 2002 Nov;86(11):1306 Review [PMID: 12386095].

Hyperopia (Farsightedness)

Saying that the hyperopic child is sighted for far (not near) is somewhat misleading, because the child can focus on near objects if the hyperopia is not excessive. Large amounts of uncorrected hyperopia can cause esotropia (inward deviation, or crossing, of the eyes) and amblyopia (see Amblyopia & Strabismus section). Most infants have a hyperopic refraction that begins to diminish during the toddler years and does not require correction.

Astigmatism

When either the cornea or the crystalline lens is not perfectly spherical, an image will not be sharply focused in one plane. Schematically, there will be two planes of focus. Both of the planes can be either in front of or behind the retina, or one of the planes can be in front of the retina and the other behind it. This refractive state is described as astigmatism. Large amounts of astigmatism not corrected at an early age can cause decreased vision from amblyopia, but proper refractive correction can prevent this.

DeRespinis PA: Eyeglasses: Why and when do children need them? *Pediatr Ann* 2001;30:455 [PMID: 11510343].

EXAMINATION

Ophthalmic examination of the pediatric patient begins with a calm demeanor and reassuring voice. Having a parent present is invaluable. The examination includes a history, assessment of visual acuity, external examination, observation of ocular alignment and motility, and ophthalmoscopic examination. Intraocular pressure is less frequently measured. Testing of binocular status and near point is desirable when age and cooperation permit.

Circumstances will dictate the use of ancillary procedures such as instilling fluorescein dye and radiologic tests (magnetic resonance imaging [MRI] and computed tomography [CT] scan). Electroretinography and electrooculography test retinal function. Visual evoked response testing assesses the function of the cortical visual pathways. Visual field testing demonstrates the

presence or absence of scotomas and visual field defects occurring anywhere along the visual pathway. In the office setting, visual field testing may be done in a gross manner by confrontation, that is, bringing an object from the periphery of the child's field of vision in each of four quadrants or by having an older child count the examiner's fingers as they are presented in two quadrants simultaneously. It must be emphasized that accurate results can be difficult to achieve in young children.

History

Evaluation begins by ascertaining the chief complaint and taking a history of the present illness. Elements of the history include onset of the complaint, its duration, whether it is monocular or binocular, treatment received thus far, and associated systemic symptoms. If an infectious disease is suspected, ask about possible contact with others having similar findings. The ocular history is obtained, as is the perinatal and developmental history and any history of allergy. The family history should be explored for ocular disorders that may be familial or inherited.

Visual Acuity

Visual acuity testing is the single most important test of visual function and should be part of every general physical examination. This is the nonophthalmologist's most definitive test for amblyopia, refractive errors, and lesions along the optic pathways. The child's visual acuity should be tested and recorded after ocular trauma and before and after any ophthalmologic treatment. Acuity should be tested in each eye individually, using an adhesive eyepatch to prevent peeking. If latent nystagmus, which becomes apparent when one eye is occluded, is present (see Nystagmus section), vision should be tested simultaneously in both eyes and in each eye individually. Vision is usually recorded with glasses in place (corrected vision). In older children who can cooperate, use of a pinhole will improve vision in children not wearing the appropriate spectacle prescription.

The type of test used to determine visual acuity is dictated by the child's age. In the sleeping newborn, the presence of a blepharospastic response to bright light is an adequate response. At age 6 weeks, eye-to-eye contact with slow following movements is becoming established and can be detected. By age 3 months, the infant should demonstrate fixing and following ocular movements for objects at a distance of 2–3 feet. At age 6 months, interest in movement across the room is the norm. Vision can be recorded for the presence or absence of fixing and following behavior and for whether

vision is steady (unsteady when nystagmus is present) and maintained. Vision should be tested and recorded for each eye. Visual acuity can be quantified in infants using other techniques, such as the 15-diopter prism test, preferential looking technique, or the pattern visual evoked response.

In the verbal child, the use of familiar icons will allow for a quantitative test. Allen or Lea symbols with familiar pictures can be used to test children age 2½–3 years. Four-year-olds are often ready to play the tumbling E game (in which the child identifies the orientation of the letter E, which is turned in one of four directions) or the HOTV letters game (in which these four letters are shown individually at a distance and matched on a board that the child is holding). Literate children are tested with letters. Typical acuity levels in developmentally appropriate children are approximately 20/60 or better in 2½- to 3 year-olds, 20/40–20/30 in 3-year-olds, 20/30–20/25 in 4-year-olds, and 20/20 in literate 5- to 6-year-olds. Perhaps more important than the absolute visual acuity is the presence of a difference of acuity between the two eyes, which might be a sign of amblyopia, uncorrected refractive error, or disease. As little as one line difference in acuity should be considered significant.

The practitioner should be aware of two situations complicated by nystagmus. Children who require a face turn or torticollis (in which the head is tilted to the right or left) to quiet the nystagmus will have poor visual acuity results when tested in the absence of the compensatory head posture.

When latent nystagmus is present, acuity testing is particularly challenging (see Nystagmus section). Nystagmus appears or worsens when an eye is occluded, degrading central vision. To minimize the nystagmus, the occluder should be held about 12 inches in front of the eye not being tested. Testing both eyes simultaneously without occlusion often gives a better visual acuity measurement than when either eye is tested individually.

External Examination

Inspection of the anterior segment of the globe and its adnexa requires adequate illumination and often magnification. A penlight provides good illumination and should be used in both straight-ahead and oblique illumination. A Wood lamp or a blue filter cap placed over a penlight is needed for evaluation after applying a fluorescent stain. Immobilization of the child may be necessary. A drop of topical anesthetic may facilitate the ex-

amination. Assessment of the entire anterior segment except the trabecular meshwork and, to a lesser extent, the lens is possible.

In cases of suspected foreign body, pulling down on the lower lid provides excellent visualization of the inferior cul-de-sac (palpebral conjunctiva). Visualizing the upper cul-de-sac and superior bulbar conjunctiva is possible by having the patient look inferiorly while the upper lid is pulled away from the globe and the examiner peers into the upper recess. Illumination with a penlight is necessary. The upper lid should be everted to evaluate the superior tarsal conjunctiva (Figure 15–3).

When indicated for further evaluation of the cornea, a small amount of fluorescein solution should be instilled into the lower cul-de-sac. Blue light will stain defects yellow-green. Disease-specific staining patterns may be observed. For example, herpes simplex lesions of the corneal epithelium produce a dendrite or branch-like pattern. A foreign body lodged beneath the upper lid shows one or more vertical lines of stain on the cornea due to the constant movement of the foreign body over the cornea. Contact lens overwear produces a central staining pattern. A fine, scattered punctate pattern may be a sign of viral keratitis or medication toxicity. Punctate erosions of the inferior third of the cornea can be seen with staphylococcal blepharitis or exposure keratitis secondary to incomplete lid closure.

Figure 15–3. Eversion of the upper lid. **A:** The patient looks downward. **B:** The fingers pull the lid down, and an index finger or cotton-tip is placed on the upper tarsal border. **C:** The lid is pulled up over the finger. **D:** The lid is everted.

Pupils

The child’s pupils should be evaluated for reaction to light, regularity of shape, and equality of size as well as for the presence of afferent pupillary defect. This defect, occurring in optic nerve disease, is evaluated by the swinging flashlight test (see Diseases of the Optic Nerve section). Irregular pupils are associated with iritis, trauma, pupillary membranes, and structural defects such as iris coloboma (see Iris Coloboma section).

Pupils vary in size due to lighting conditions and also age. In general, infants have miotic (constricted) pupils. Children have larger pupils than either infants or adults, whereas the elderly have miotic pupils.

Anisocoria, a size difference between the two pupils, may be physiologic if the size difference is within 1 mm and is the same in light and dark. Anisocoria occurs with Horner syndrome, third nerve palsy, Adie tonic pupil, iritis, and trauma. Medication could also cause abnormal pupil size or reactivity. For example, contact with atropine-like substances (belladonna alkaloids) will cause pupillary dilation with little or no pupillary reaction. Systemic antihistamines and scopolamine patches, among other medicines, can dilate the pupils and interfere with accommodation (focusing).

Alignment & Motility Evaluation

Alignment and motility should be tested because amblyopia is associated with strabismus, a misalignment of the visual axes of the eyes. Besides alignment, ocular rotations should be evaluated in the six cardinal positions of gaze (Table 15–1; Figure 15–4). A small toy is an interesting target for testing ocular rotations in infants; a penlight works well in older children.

Alignment can be assessed in several ways. In order of increasing accuracy, these methods are observation, the corneal light reflex test, and cover testing. Observation includes an educated guess about whether the eyes are properly aligned. Corneal light reflex evaluation (Hirschberg test) is performed by shining a beam of a light at the patient’s eyes, observing the reflections off each cornea, and estimating whether these “reflexes” appear to be positioned properly. If the reflection of light is noted temporally on the cornea, esotropia is suspected (Figure 15–5). Nasal reflection of the light suggests exotropia (outward deviation). Accuracy of these tests increases with increasing angles of misalignment.

Another way of evaluating alignment is with the cover test, in which the patient fixes on a target while one eye is covered. If an esotropia or an exotropia is present, the deviated eye will make a corrective movement to fixate on the target when the previously fixating eye is occluded. The other eye is tested similarly. When the occluder is removed from the eye just uncov-

Table 15–1. Function and innervation of each of the extraocular muscles.

Muscle	Function	Innervation
Medial rectus	Adductor	Oculomotor (third)
Lateral rectus	Abductor	Abducens (sixth)
Inferior rectus	Depressor Adductor Extorter	Oculomotor
Superior rectus	Elevator Adductor Intorter	Oculomotor
Inferior oblique	Elevator Abductor Extorter	Oculomotor
Superior oblique	Depressor Abductor Intorter	Trochlear (fourth)

ered, a refixation movement of that eye indicates a phoria, or latent deviation if alignment is reestablished. If the uncovered eyes picks up fixation and strabismus is still present, then that eye can be presumed to be dominant and the nonpreferred eye possibly amblyopic. If the eye remains deviated after the occluder is removed, a tropia is noted to be present (Figure 15–6). A deviated eye that is blind or has very poor vision will not fixate on a target. Consequently, spurious results to cover testing may occur, as can happen with disinterest on the part of the patient, small-angle strabismus, and inexperience in administering cover tests.

Figure 15–4. Cardinal positions of gaze and muscles primarily tested in those fields of gaze. Arrow indicates position in which each muscle is tested.

Figure 15-5. Temporal displacement of light reflection showing esotropia (inward deviation) of the right eye. Nasal displacement of the reflection would show exotropia (outward deviation).

Ophthalmoscopic Examination

A handheld direct ophthalmoscope allows visualization of the ocular fundus. As the patient's pupil becomes more constricted, viewing the fundus becomes more difficult. Although it is taught that pupillary dilation can precipitate an attack of closed-angle glaucoma in the predisposed adult, children are very rarely predisposed to angle closure. Exceptions include those with a dislocated lens, past surgery, or an eye previously com-

promised by a retrolental membrane, such as in ROP. Therefore, if an adequate view of the fundus is precluded by a miotic pupil, use of a dilating agent (eg, 1 drop each eye of 2.5% phenylephrine or 0.5% or 1% tropicamide) should provide adequate mydriasis (dilation). In infants, 1 drop of a combination of 1% phenylephrine with 0.2% cyclopentolate (Cyclomydril) is safer. Structures to be observed during ophthalmoscopy include the optic disk, blood vessels, the macular reflex, and retinal changes if present, as well as the clarity of the vitreous media. By increasing the amount of plus lens dialed into the instrument, the point of focus moves anteriorly from the retina to the lens and finally to the cornea.

Ophthalmoscopy should include assessment of the clarity of the ocular media, that is, the quality of the red reflex. The practitioner should take the time to become familiar with this reflex. The red reflex test (Brückner test) is useful for identifying disorders such as media opacities (eg, cataracts), large refractive errors, tumors such as retinoblastoma, and strabismus. A difference in quality of the red reflexes between the two eyes constitutes a positive Brückner test and requires referral to an ophthalmologist.

Eyes straight (maintained in position by fusion).

Position of eye under cover in orthophoria (fusion-free position). The right eye under cover has not moved.

Position of eye under cover in esophoria (fusion-free position). Under cover, the right eye has deviated inward. Upon removal of cover, the right eye will immediately resume its straight-ahead position.

Position of eye under cover in exophoria (fusion-free position). Under cover, the right eye had deviated outward. Upon removal of the cover, the right eye will immediately resume its straight-ahead position.

Figure 15-6. Cover testing. The patient is instructed to look at a target at eye level 20 feet away. Note that in the presence of constant strabismus (ie, a tropia rather than a phoria), the deviation will remain when the cover is removed. (Reproduced, with permission, from *General Ophthalmology*, 15th ed. Originally published by Appleton & Lange. Copyright © 1999 by The McGraw-Hill Companies, Inc.)

The red reflex of each eye can be compared simultaneously when the observer is approximately 4 feet away from the patient. The largest diameter of light is shown through the ophthalmoscope, and no correction (zero setting) is dialed in the ophthalmoscope unless it is to compensate for the examiner's uncorrected refractive error. A red reflex chart is available through the American Academy of Pediatrics.

OCULAR TRAUMA

A foreign body of the globe or adnexa may be difficult to visualize due to its small size or location. The clinician should always maintain a high index of suspicion for an occult or intraocular foreign body if the history suggests this. In cases such as these, ophthalmologic referral needs to be considered.

Foreign bodies on the globe and palpebral conjunctiva usually cause discomfort and red eye. Magnification may be needed for inspection. Foreign bodies that lodge on the upper palpebral conjunctiva are best viewed by everting the lid on itself and removing the foreign body with a cotton applicator. The conjunctival surface (palpebral conjunctiva) of the lower lid presents no problem with visualization. After simple removal of a foreign body that is thought not to be contaminated, no other treatment is needed if no corneal abrasion has occurred.

When foreign bodies are noted on the bulbar conjunctiva or cornea (Figure 15-7), removal is facilitated by using a topical anesthetic. If the foreign body is not too adherent, it can be dislodged with a stream of irrigating solution (Dacriose or saline) or with a cotton applicator after instillation of a topical anesthetic. Otherwise, a foreign body spud or needle is used to undermine the foreign body. This must be done with adequate magnification and illumination. An antibiotic ointment is then instilled. Ferrous corneal bodies often have an associated rust ring, which may be removed under slitlamp visualization in cooperative children or under anesthesia if necessary.

Corneal abrasions are evaluated with fluorescein dye and treated with a topical antibiotic, but not necessarily a pressure patch. Patching is not advised for corneal abrasions caused by contact lens wear, and it is being used less frequently for corneal abrasions and after removal of corneal foreign bodies since the moist, hypoxic environment predisposes to bacterial infection. One drop of topical cycloplegic agent such as 5% homatropine, 1% atropine (with appropriate warnings to parents about systemic side effects), or 0.25% scopolamine is useful to relieve the discomfort of ciliary spasm and iritis. Daily follow-up is required until healing is complete.

A

B

Figure 15-7. **A:** Corneal foreign body at the nasal edge of the cornea. **B:** Subconjunctival foreign body of graphite.

Suspected intraocular foreign bodies and corneal and scleral lacerations require emergency referral to an ophthalmologist. In cases of suspected perforation of the globe, it may be best to keep the child at rest, gently shield the eye with a metal shield or cut-down paper cup, and keep the extent of examination to a necessary minimum to prevent expulsion of intraocular contents. In this setting, the child should be given nothing by mouth in case eye examination under anesthesia or surgical repair is required. The diagnosis may be difficult if the signs of obvious corneal perforation (shallow anterior chamber with hyphema and irregular pupil) are not present (Figure 15-8). Furthermore, nonradiopaque materials such as glass will not be seen on x-ray film. A CT scan may be useful in evaluating ocular trauma, including bony injury and foreign body wound. MRI will

Figure 15-8. Corneal laceration with irregular pupil and vitreous loss.

Figure 15-9. Laceration involving right lower lid and canaliculus.

not provide bony detail and must be avoided if a magnetic foreign body is suspected.

Zaidman GW et al: Successful surgical rehabilitation of children with traumatic corneal laceration and cataract. *Ophthalmology* 2001;108:338 [PMID: 11158810].

INJURIES TO THE EYELIDS

Ecchymosis

Orbital and soft tissue trauma may produce so-called black eye or ecchymosis (blue or purplish hemorrhagic areas) of the eyelids. The extent of the injury to the eye and orbit may not correlate fully with its appearance. Blowout fracture, which occurs from blunt trauma fracturing the walls of the orbit, must be suspected. Ocular motility must be assessed, the globe examined, and intraocular pressure measured, usually by an ophthalmologist. Cold compresses or ice packs for brief periods (eg, 10 minutes at a time) are recommended in older children in the first 24 hours after injury to reduce hemorrhage and swelling. Abuse needs to be considered when orbital injury is poorly explained.

Lacerations

The lids and lacrimal apparatus are susceptible to laceration. Except for superficial lacerations away from the globe, repair in children is best performed in the operating room under general anesthesia. Special consideration must be given to lacerations involving the lid margin, to through-and-through lacerations, to lacerations that may involve the levator muscle in the upper lid, and to those that may involve the canaliculus (Figure

15-9). These injuries are best repaired by an ophthalmologist.

Burns

Eyelid burns can occur in toddlers from contact with a lighted cigarette. The cornea is often involved as well. Curling irons can cause similar burns. These burns usually heal following application of antibiotic ointment. Severe thermal or chemical burns can cause scars resulting in ectropion or entropion of the lid and scarring of the conjunctiva and cul-de-sac.

Burns of the conjunctiva and cornea may be thermal, radiant, or chemical. Superficial thermal burns cause pain, tearing, and injection. Management is with topical antibiotics and patching. Add a cycloplegic agent if corneal involvement is present, because pain from ciliary spasm and iritis may accompany the injury.

Radiant energy causes ultraviolet keratitis. Typical examples are welder's burn and burns associated with skiing without goggles in bright sunlight. The fluorescein dye pattern will show a uniformly stippled appearance of the corneal epithelium. Antibiotic ointment, pressure patches, and a cycloplegic agent such as 5% homatropine are usually followed by recovery within 24 hours.

Chemical burns with strong acid and alkaline agents can be blinding and constitute a true ocular emergency. Examples are burns caused by exploding batteries, spilled drain cleaner, and bleach. Alkali burns may not cause significant injection because the conjunctival vessels become damaged. Alkalis tend to penetrate deeper than acids into ocular tissue. Immediate treatment consists of copious irrigation and removal of precipitates as

soon as possible after the injury. The patient should be referred to an ophthalmologist after immediate first aid has been given.

Forbes BJ: Management of corneal abrasions and ocular trauma in children. *Pediatr Ann* 2001;30:465 [PMID: 11510344].

Hyphema

Blunt trauma to the globe may cause hyphema, or bleeding within the anterior chamber from a ruptured vessel located near the root of the iris or in the anterior chamber angle. Bleeding may be microscopic or may fill the entire anterior chamber (Figure 15–10). Blunt trauma severe enough to cause hyphema may be associated with other ocular injury, including iritis, lens subluxation, retinal edema or detachment, and glaucoma. In patients with sickle cell anemia or trait, even moderate elevations of intraocular pressure may quickly lead to optic atrophy and permanent vision loss. Therefore, all African-Americans whose sickle cell status is unknown should be tested if hyphema is observed. These patients require extra vigilance in diagnosing and treating hyphema.

Management of hyphema in an otherwise uninjured patient should include testing of visual acuity and assessment of the integrity of the globe and orbit. A shield should be placed over the eye, the head elevated, and arrangements made for ophthalmologic referral.

Nontraumatic causes of hyphema include juvenile xanthogranuloma and blood dyscrasias. Rarely, hyphema is noted in the newborn after a stressful birth.

Figure 15–10. Hyphema filling approximately 20% of the anterior chamber.

Lai JC et al: Traumatic hyphema in children. Risk factors for complications. *Arch Ophthalmol* 2001;119:64 [PMID: 11709038].

Nonaccidental Trauma & Shaken Baby Syndrome

From an ocular standpoint, in both nonaccidental trauma and shaken baby syndrome, the hallmark of diagnosis is retinal hemorrhage, although it need not be present with rotational injury severe enough to cause subdural hematoma. In general, the presence and severity of the retinal hemorrhages correlates with the level of brain injury. Careful evaluation of the posterior and peripheral retina requires pupillary dilation and indirect ophthalmoscopy.

The history of how the injuries or retinal findings occurred is often vague and not well correlated with the extent of injury. Hemorrhages may be unilateral or bilateral and may be located in the posterior pole or periphery. Whereas retinal hemorrhages tend to resolve fairly quickly, those in the vitreous do not. If a blood clot lies over the macula, deprivation amblyopia may occur. Retinal and vitreous hemorrhages associated with intracranial hemorrhage from skull injury are known as Terson syndrome. Retinal hemorrhages are rarely associated with cardiopulmonary resuscitation or seizures. As a rule, retinal hemorrhages do not occur from major accidental trauma such as motor vehicle accidents unless a compressive chest injury is present, but they have been associated with low fibrinogen levels and blood dyscrasias. Other ocular findings associated with nonaccidental trauma include lid ecchymosis, subconjunctival hemorrhage, and hyphema. Additional retinal findings include retinal folds and retinoschisis. Acute-onset esotropia can also occur.

Prevention of Ocular Injuries

Air rifles, paint balls, and fireworks are responsible for many serious eye injuries in children. Golf injuries can also be very severe. Bungee cords have been associated with multiple types of severe ocular trauma, including

corneal abrasion, iris tears, hyphema, vitreous hemorrhage, retinal detachment, and blindness. These activities should be avoided or very closely supervised. Safety goggles should be used in laboratories and industrial arts classes and when operating snow blowers, power lawn mowers, and power tools or when using hammers and nails. Sports-related eye injuries can be prevented with protective eyewear. Sports goggles and visors of polycarbonate plastic will prevent injuries in games using fast projectiles such as tennis or racquet balls, or where opponents may swing elbows or poke at the eye.

The one-eyed individual should be specifically advised to wear polycarbonate eyeglasses full time and goggles for all sports. High-risk activities such as boxing and the martial arts should be avoided by one-eyed children.

DISORDERS OF THE OCULAR STRUCTURES

Diseases of the Eyelids

Blepharitis is inflammation of the lid margin characterized by crusty debris at the base of the lashes; varying degrees of erythema at the lid margins; and, in severe cases, secondary corneal changes such as punctate erosions, vascularization, and ulcers. When conjunctival injection accompanies blepharitis, the condition is known as blepharoconjunctivitis. *Staphylococcus* is the most common bacterial cause. Treatment includes lid scrubs with a nonburning baby shampoo several times a week and application of a topical antibiotic ointment such as erythromycin or bacitracin at bedtime.

Rosacea can also occur in the pediatric age group and cause chronic blepharoconjunctivitis with corneal changes that decrease vision. Systemic antibiotics and local treatment are required.

Pediculosis of the lids (phthiriasis palpebrarum) is caused by *Phthirus pubis*. Nits and adult lice can be seen on the eyelashes when viewed with appropriate magnification. Mechanical removal and application to the lid margins of phospholine iodide or 1% mercuric oxide

ointment can be effective. Other bodily areas of involvement must also be treated if involved. Family members and contacts may also be infected (see Chapter 14).

Papillomavirus may infect the lid and conjunctiva. Warts may be recurrent, multiple, and difficult to treat. Treatment modalities include cryotherapy, cautery, carbon dioxide laser, and surgery.

Localized staphylococcal infections of the glands of Zeis within the lid cause a sty (hordeolum) (Figure 15–11). When the infection coalesces and points internally or externally, it may discharge itself or require incision. The lesion is tender and red. Warm compresses help to hasten the acute process. Some practitioners prescribe a topical antibiotic ointment. Any coexisting blepharitis should be treated.

A chalazion is an inflammation of the meibomian glands, which may produce a tender nodule over the tarsus of the upper or lower lid. In addition to localized erythema of the corresponding palpebral conjunctiva, there may be a yellow lipogranuloma (Figure 15–12). Treatment includes warm compresses for 10–15 minutes four times a day for up to 6 weeks. If incision and curettage are needed because the lesion is slow to resolve, the child will require a general anesthetic.

Viral Lid Disease

Herpes simplex virus may involve the lids at the time of primary herpes simplex infection. Vesicular lesions with an erythematous base occur. Primary herpes simplex blepharoconjunctivitis should be treated with systemic acyclovir (liquid formulation available), valacyclovir, or famciclovir. When either the conjunctiva or the cornea is involved, treatment should include topical 1% trifluridine or 3% vidarabine.

Figure 15–11. Hordeolum and blepharitis, left upper lid.

A

B

Figure 15-12. Chalazion. **A:** Right lower lid, external view. **B:** Right lower lid conjunctival surface.

Herpes zoster causes vesicular disease in association with a skin eruption in the dermatome of the ophthalmic branch of the trigeminal nerve. In older children, treatment of ophthalmic herpes zoster with oral acyclovir, valacyclovir, or famciclovir within 5 days after onset may reduce the morbidity. When vesicles are present on the tip of the nose with herpes zoster (Hutchinson sign), ocular involvement, including iritis, may develop. Herpes simplex or herpes zoster can be diagnosed by rapid viral culture (24–48 hours) or detection of antigen in skin lesions (3 hours). Impetigo is in the differential diagnosis of vesicular lid disease.

Molluscum contagiosum lesions are typically umbilicated papules. If near the lid margin, the lesions may shed and cause conjunctivitis. Caution or excision of lesions at the lid margin is useful.

Lid Ptosis

Ptosis—a droopy upper lid (Figure 15-13)—may be congenital or acquired but is usually congenital in chil-

Figure 15-13. Congenital ptosis of severe degree, left upper lid.

dren owing to a defective levator muscle. Other causes of ptosis are myasthenia gravis, lid injuries, third nerve palsy, and Horner syndrome (see next section). Surgical correction is indicated for moderate to severe ptosis. Mild cases require operative management less often than do more severe cases, and comesis may be better if surgery is delayed until most of the facial growth has occurred, usually around 5 years old. Ptosis may be associated with astigmatism and amblyopia.

An interesting association sometimes seen with congenital ptosis is the Marcus Gunn jaw-winking phenomenon. An intermittent reduction of the ptosis occurs during mastication or sucking. It is due to a synkinesis or simultaneous firing of either the external or internal pterygoid muscle (innervated by the trigeminal nerve) and the levator muscle (innervated by the oculomotor nerve).

Horner Syndrome

Horner syndrome, which may be congenital or acquired, is the triad of miosis, ptosis, and anhidrosis. The ptosis is usually mild with a well-defined upper lid crease. This differentiates it from congenital ptosis, which typically has a poorly defined lid crease. Another key finding of congenital Horner syndrome is heterochromia of the two irides, with the lighter colored iris occurring on the same side as the lesion (Figure 15-14). Anhidrosis can occur in congenital and acquired cases. Of note, not all of the three signs must be present to make the diagnosis. The syndrome is caused by an abnormality or lesion to the sympathetic chain. The congenital variety is most commonly the result of birth trauma. Acquired cases may occur in children who have had cardiothoracic surgery, trauma, or brain-stem vascular malformation. Most worrisome is a Horner syndrome caused by neuroblastoma of the sympathetic chain in the apical lung region. An excellent screening test for this is the spot urine vanillylmandelic acid/creatinine ratio.

Figure 15-14. Congenital Horner syndrome. Ptosis, miosis, heterochromia. Lighter colored iris is on affected left side.

Pharmacologic assessment of the pupils with topical cocaine and hydroxyamphetamine or epinephrine will help determine whether the Horner syndrome is due to a preganglionic or postganglionic lesion of the sympathetic chain. Physical examination, including palpation of the neck and abdomen for masses, and MRI of structures in the head, neck, chest and abdomen should be considered.

McDonnell JF et al: Pediatric Horner syndrome due to cervical thymic rest. *J Pediatr Ophthalmol Strabismus* 2002;39(3):185 [PMID: 12051288].

Eyelid Tics

Eyelid tics may occur as a transient phenomenon lasting several days to months. Although a tic may be an isolated finding in an otherwise healthy child, it may also occur in children with multiple tics, attention-deficit/hyperactivity disorder, or Tourette syndrome. Caffeine consumption may cause or exacerbate eyelid tics. If the disorder is a short-lived annoyance, no treatment is needed.

DISORDERS OF THE NASOLACRIMAL SYSTEM

Nasolacrimal Duct Obstruction

Nasolacrimal obstruction occurs in up to 6% of infants. Most cases clear spontaneously during the first year. Signs and symptoms include a wet eye with mucoid discharge, erythema of one or both lids, and conjunctivitis (Figure 15-15). Obstruction in any part of the drainage system may result from incomplete canalization of the duct or membranous obstructions. Nasolacrimal obstruction may also occur in individuals with craniofacial abnormalities or amniotic band syndrome. Differential diagnosis of tearing includes congenital glaucoma, foreign bodies, nasal disorders, and, in older children, allergies.

Massage over the nasolacrimal sac may empty debris from the nasolacrimal sac and may clear the obstruction, although the efficacy of massage in clearing naso-

Figure 15-15. Nasolacrimal obstruction, right eye. Matting on upper and lower lids.

lacrimal obstruction is debated. Cleansing the lids and medial canthal area decreases the likelihood of infection and irritation. Superinfection may occur, and treatment with topical antibiotics may help decrease the discharge. The mainstay of surgical treatment is probing, which is successful 80% or more of the time, but the success rate may decrease after the infant reaches age 1 year. Other surgical procedures, including infraction of the inferior nasal turbinate, balloon dilation, and silicone tube intubation, may be necessary if probing fails. Much less often, dacryocystorhinostomy is required.

Mandeville JT et al: Obstruction of the lacrimal drainage system. *Curr Opin Ophthalmol* 2002;13(5):303 [PMID 12218461].

Wagner RS: Management of congenital nasolacrimal obstruction. *Pediatr Ann* 2001;30:481 [PMID: 11510346].

Congenital Dacryocystocele

Congenital dacryocystocele is thought to result from obstructions proximal and distal to the nasolacrimal sac. An intranasal duct cyst may be present beneath the inferior turbinate at the valve of Hasner. These cysts may be associated with respiratory distress. At birth, the nasolacrimal sac is distended and has a bluish hue that often leads to an erroneous diagnosis of hemangioma. The tense and swollen sac displaces the medial canthus superiorly (Figure 15-16). Massage and warm compresses are sometimes effective, but probing of the nasolacrimal system often is necessary. Repeated probing and endoscopic marsupialization of the intranasal cyst under general anesthesia may be required. Dacryocystitis and sepsis can result from dacryocystocele.

Figure 15-16. Congenital dacryocystocele on left side. Raised, bluish discolored mass of enlarged nasolacrimal sac. Note superiorly displaced medial canthus.

Levin AV et al: Nasal endoscopy in the treatment of congenital lacrimal sac mucoceles. *Int J Pediatr Otorhinolaryngol* 2003;67(3):255 ?PMID: 12633925?.

Dacryocystitis

Acute and chronic dacryocystitis are typically bacterial and caused by organisms such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, viridans streptococci, *Moraxella catarrhalis*, and *Haemophilus* species. Attempts at identifying the offending organism by culture and staining should be made when possible. Acute dacryocystitis presents with inflammation, swelling, tenderness, and pain over the lacrimal sac (located inferior to the medial canthal tendon). Fever may be present. The infection may point externally (Figure 15-17). A purulent discharge and tearing can be expected, because the cause of infection is almost always nasolacrimal obstruction.

Signs of chronic dacryocystitis are mucopurulent debris on the lids and lashes, tearing, injection of the palpebral conjunctiva, and reflux of pus at the puncta when pressure is applied over the sac. Chronic dacryocystitis and recurrent episodes of low-grade dacryocystitis are caused by nasolacrimal obstruction.

Treatment of severe acute dacryocystitis is with intravenous antibiotics. Oral antibiotics can be tried in milder cases. Topical antibiotic administration is ad-

Figure 15-17. Acute dacryocystitis in an 11-week-old infant.

junctive and is also used with recurrent chronic infections. Warm compresses are beneficial. After the acute episode subsides—and in chronic cases—the nasolacrimal obstruction must be relieved surgically. If it cannot be drained via the intranasal portion of the nasolacrimal duct, external drainage may be necessary. This should be done as a last resort since a fistula may develop.

DISEASES OF THE CONJUNCTIVA

Conjunctivitis may be infectious, allergic, or associated with systemic disease. Trauma, irritation of the conjunctiva, and intraocular inflammation also can result in injection of conjunctival vessels that can be confused with conjunctivitis (Table 15-2).

Ophthalmia Neonatorum

Ophthalmia neonatorum (conjunctivitis in the newborn) occurs during the first month of life. It is characterized by redness and swelling of the lids and conjunctiva and by discharge (Figure 15-18). Ophthalmia neonatorum may be due to inflammation resulting from silver nitrate prophylaxis given at birth, bacterial infection (gonococcal, staphylococcal, pneumococcal, chlamydial), or viral infection. In developed countries, *Chlamydia* is the most common cause. Neonatal conjunctivitis is visually threatening if caused by *Neisseria gonorrhoeae*. Herpes simplex is a rare but serious cause of neonatal conjunctivitis. Gram staining, Giemsa staining for elementary bodies, enzyme immunoassay for chlamydia, and bacterial and viral cultures aid in making an etiologic diagnosis.

Although no single prophylactic medication can eliminate all cases of neonatal conjunctivitis, povidone-iodine may provide broader coverage against the organisms causing this disease than silver nitrate or erythromycin ointment. Silver nitrate is not effective against chlamydia. The choice of prophylactic agent is often dictated by local epidemiology and cost considerations.

Treatment of these infections requires specific systemic antibiotics because they can cause serious infections in other organs. Specifically, *Chlamydia* can cause a delayed-onset pneumonitis. Parents should be examined and receive treatment when a sexually associated pathogen is present.

Bacterial Conjunctivitis

In general, bacterial conjunctivitis is accompanied by a purulent discharge and viral infection by a watery discharge. One or both eyes may be involved. Regional lymphadenopathy is not a common finding in bacterial

Table 15–2. Clinical and laboratory features of conjunctivitis.

	Viral	Bacterial	Chlamydial	Allergic
Itching	Minimal	Minimal	Minimal	Severe
Hyperemia	Generalized	Generalized	Generalized	Generalized
Tearing	Profuse	Moderate	Moderate	Moderate
Exudation	Minimal, mucoid	Profuse, purulent	Profuse; mucoid or mucopurulent	Minimal, slight mucus
Preauricular adenopathy	Common	Uncommon	Common in inclusion conjunctivitis	None
Stained conjunctival smears and scrapings	Lymphocytes, plasma cells, multinucleated giant cells, eosinophilic intranuclear inclusions	Neutrophils, bacteria	Neutrophils, plasma cells, basophilic intracytoplasmic inclusions	Eosinophils
Associated systemic signs and symptoms	Rash, sore throat, fever in some patients	Occasional fever, sore throat	Pneumonia in neonates	Variable—may or may not be present

Modified from Vaughan D, Asbury T, Riordan-Eva P (eds): *General Ophthalmology*, 15th ed. Appleton & Lange, 1999.

conjunctivitis except in cases of oculoglandular syndrome due to *S aureus*, group A β -hemolytic streptococci, *Mycobacterium tuberculosis* or atypical mycobacteria, *Francisella tularensis* (the agent of tularemia), and *Bartonella henselae* (the agent of cat-scratch fever).

Common bacterial causes of conjunctivitis in older children include nontypable *Haemophilus* species, *S pneumoniae*, *M catarrhalis*, and *S aureus*. If conjunctivitis is not associated with systemic illness, topical antibiotics such as erythromycin, polymyxin–bacitracin, sulfacetamide, tobramycin, and fluoroquinolones are

usually adequate. Systemic therapy is recommended for conjunctivitis associated with *Chlamydia trachomatis*, *N gonorrhoeae*, and *N meningitidis*.

Viral Conjunctivitis

Adenovirus infection is often associated with pharyngitis, a follicular reaction of the palpebral conjunctiva, and preauricular adenopathy (pharyngoconjunctival fever). Epidemics of adenoviral keratoconjunctivitis occur. Treatment is supportive. Children with presumed adenoviral keratoconjunctivitis are considered contagious 10–14 days from the day of onset. They should stay out of school and group activities as long as their eyes are red and tearing. Strict handwashing precautions are recommended.

During the prodromal period of measles infection, conjunctivitis occurs; this is preceded by a transverse marginal line of conjunctival injection across the lower lids.

Herpes simplex virus may cause conjunctivitis or blepharoconjunctivitis. Treatment is with topical trifluridine 1% drops or 3% vidarabine ointment. Oral acyclovir may be used prophylactically in children to reduce recurrence of herpes simplex ocular disease.

Altemeier III WA: The importance of adenoviral infections in pediatrics. *Pediatr Ann* 2001;30:439 [PMID: 11510341].

Figure 15–18. Ophthalmia neonatorum due to *Chlamydia trachomatis* infection in a 2-week-old infant. Note marked lid and conjunctival inflammation.

Allergic Conjunctivitis

In hay fever conjunctivitis, the eyes are red and itchy, with mucoid discharge. Symptomatic treatment is with

Table 15–3. Common ocular allergy medications.

Generic Name	Brand Name	Mechanism of Action	Side Effects	Dosage	Indications
Lodoxamide tromethamine 0.1%	Alomide	Mast-cell stabilizer	Transient burning or stinging	1 drop 4 times daily—taper	Vernal keratoconjunctivitis
Cromolyn Na 4%	Crolom, Opticrom	Mast-cell stabilizer	Transient burning or stinging	1 drop 4–6 times daily	Vernal keratoconjunctivitis
Olopatidine	Patanol	Mast-cell stabilizer, H1 receptor antagonist	Headache, burning or stinging	twice daily (interval 6–8 hrs)	Itching due to allergic conjunctivitis
Ketorolac tromethamine 0.5%	Acular	NSAID	Transient burning or stinging	1 drop 4 times daily	Itching due to seasonal allergic conjunctivitis
Levocabastine HCl 0.05%	Livostin	H1 receptor antagonist	Transient burning or stinging, headache	1 drop 4 times daily	Relief of symptoms of seasonal allergic conjunctivitis
Naphazoline HCl 0.1%	AK-con, Naphcon, Opcon, Vasocon	Ocular decongestant, vasoconstrictor	Mydriasis, increased redness, irritation, discomfort, punctate keratitis, increased intraocular pressure, dizzy, HA, nausea, nervousness, HTN, weakness, cardiac effects, hyperglycemia	Varies by preparation	Temporary relief of redness due to minor eye irritants
Pheniramine maleate	Component in AK-Con A, Opcon-A, Naphcon-A	Antihistamine		1 drop every 3–4 h, as needed	Relief of symptoms of seasonal allergic conjunctivitis

a combination topical vasoconstrictor plus an antihistamine (naphazoline–antazoline); a nonsteroidal anti-inflammatory drug such as ketorolac tromethamine 0.5%; a mast cell stabilizer such as lodoxamide tromethamine 0.1%; or prednisolone 0.125% (Table 15–3). Corticosteroids should be used with caution because their extended use causes glaucoma and or cataracts in some patients. Central nervous system (CNS) depression has been reported with accidental ingestion of naphazoline.

Vernal conjunctivitis is a seasonal form of allergic conjunctivitis associated with tearing, itching, and a stringy discharge. It is more common in males. In the palpebral form, dramatic changes of the superior palpebral conjunctiva occur, with cobblestone papillae (Figure 15–19). Corneal ulcers can occur. Topical treatments include a mast cell stabilizer such as 4% cromolyn sodium or 0.1% lodoxamide tromethamine and limited use of a topical corticosteroid. One form of

Figure 15–19. Vernal conjunctivitis. Cobblestone papillae in superior tarsal conjunctiva.

vernal conjunctivitis (limbal vernal) presents with nodules at the limbus (the corneal–conjunctival junction). Contact lens wear may induce a conjunctivitis that appears similar to the palpebral form of vernal conjunctivitis.

Mucocutaneous Diseases

Conjunctivitis and conjunctival changes are associated with a number of systemic syndromes. Examples are erythema multiforme (Stevens–Johnson syndrome; see Chapter 14), Reiter syndrome (Chapter 40), and Kawasaki disease (Chapter 19), which is also associated with iritis. With Stevens–Johnson syndrome, conjunctival changes include erythema, vesicular lesions that frequently rupture, and symblepharon (adhesions) between the raw edges of the bulbar and palpebral (lid) conjunctiva. Management may include artificial tears and lubricants to provide comfort and a topical corticosteroid to prevent adhesions and dry eye in severe cases of erythema multiforme. Lysis of adhesions or use of a scleral ring by an ophthalmologist may be required. Surgical treatment of severe cases of symblepharon with amniotic membrane grafts are under investigation. Cycloplegic agents and topical corticosteroids are prescribed for iritis in Kawasaki disease.

Honavar SG et al: Amniotic membrane transplantation for ocular surface reconstruction in Stevens–Johnson syndrome. *Ophthalmology* 2000 May;107(5):975–979 [PMID 10811093].

DISORDERS OF THE IRIS

Iris Coloboma

Iris coloboma is a developmental defect due to incomplete closure of the anterior embryonal fissure. The child's pupil will have an elongated shape reminiscent of a keyhole or cat's eye (Figure 15–20). The affected area is located inferonasally but may extend posteriorly, involving the retina and choroid. The effect on visual acuity is variable. Iris coloboma may be an isolated defect or may be associated with a number of chromosomal abnormalities and syndromes. Variable genetic expression of coloboma can include a broad spectrum, from iris coloboma, to microphthalmia-with-cyst, and even clinical anophthalmia.

Aniridia

Aniridia is a bilateral disorder that includes macular hypoplasia and absence of almost all of the iris (Figure 15–21). Cataract, corneal changes, and glaucoma are often seen. Photophobia and nystagmus occur.

Aniridia may occur as an autosomal dominant inheritance pattern or in a sporadic form that is associated

Figure 15–20. Iris coloboma located inferiorly.

with Wilms tumor. Repeated examination and abdominal ultrasonography are thus indicated. The aniridia gene has been isolated to the 11p13 chromosome region. Aniridia, genitourinary abnormalities, and mental retardation have been linked to an 11p deletion.

Albinism

Albinism is caused by defective melanogenesis. Most cases of albinism are autosomal recessive, but an X-linked form does occur. Tyrosinase is an essential enzyme in the production of melanin. Many cases of complete albinism are caused by mutations of the tyrosinase gene. Albinism with some pigment production, especially in people of African descent, is more commonly caused by mutations of the *p* gene.

Affected individuals are usually legally blind and have nystagmus (see nystagmus section). Iris, skin, and hair color varies according to the type and severity of albinism as well as the individual's race. Iris transillumination may be obvious or may require slitlamp examination with retroillumination to detect focal areas of

Figure 15–21. Bilateral aniridia. Iris remnants present temporarily in each eye.

transillumination. Other ocular abnormalities include foveal hypoplasia, abnormal optic pathway projections, strabismus, and poor stereoacuity. These children should be evaluated by a pediatric ophthalmologist in order to optimize their visual function.

Albinism may be associated with other systemic manifestations. Bleeding problems occur in individuals with Hermansky–Pudlak syndrome (chromosome 10q23 or 5q13), in which oculocutaneous albinism is associated with a platelet abnormality. Chédiak–Higashi syndrome (chromosome 1q42–44) is characterized by neutrophil defects, recurrent infections, and oculocutaneous albinism. Other conditions associated with albinism are Waardenburg, Prader–Willi, and Angelman syndromes.

The risk of skin cancer is much higher in individuals with albinism. Parents and patients must be advised to use sunscreen and wear protective clothing.

Dorey SE et al: The clinical features of albinism and their correlation with visual evoked potentials. *Br J Ophthalmol* 2003; 87(6):767–772 [PMID 12770978].

Russell-Eggitt I: Albinism. *Ophthalmol Clin North Am* 2001; 14(3):533–546 [PMID 11705153].

Other Iris Conditions

Heterochromia, or a difference in iris color, can occur in congenital Horner syndrome, after iritis, or with tumors and nevi of the iris and use of topical prostaglandins. Malignant melanoma of the iris may also cause iris heterochromia. Acquired iris nodules (Lisch nodules), which occur in type I neurofibromatosis, usually become apparent by age 8 years. When seen on slitlamp examination, Lisch nodules are 1–2 mm in diameter and often beige in color, although their appearance can vary. Iris xanthogranuloma occurring with juvenile xanthogranuloma can cause hyphema and glaucoma. Patients with juvenile xanthogranuloma should be evaluated by an ophthalmologist for ocular involvement.

DeBella K et al: Use of the National Institutes of Health criteria for diagnosis of neurofibromatosis 1 in children. *Pediatrics* 2000;105:608 [PMID: 10699117].

GLAUCOMA

Glaucoma is increased intraocular pressure, which causes damage to ocular structures and loss of vision. Signs of glaucoma presenting within the first year of life include buphthalmos (enlargement of the globe due to low scleral rigidity in the infant eye) as well as tearing, photophobia, blepharospasm, corneal clouding due to edema, and optic nerve cupping. After age 3 years, usually only optic nerve changes occur.

Pediatric glaucoma can be congenital or acquired and unilateral or bilateral. In general, do not expect to see a red, inflamed eye with congenital or infantile glaucoma. Although acute pupillary block glaucoma causes a red, painful eye, pupillary block is quite rare in the pediatric age group.

Glaucoma may be inherited. Glaucoma can be classified on an anatomic basis into two types: open-angle and closed-angle. Precipitating angle-closure glaucoma in a child by dilating the pupil of an otherwise healthy eye is a very rare occurrence.

Glaucoma also occurs with ocular and systemic syndromes. Aniridia and anterior segment dysgenesis are examples. Systemic syndromes associated with glaucoma include Sturge–Weber syndrome, the oculocerebrorenal syndrome of Lowe, and the Pierre Robin syndrome. Glaucoma can also occur with hyphema, iritis, lens dislocation, intraocular tumor, and ROP. Treatment depends on the cause, but surgery is often the choice unless the rise in intraocular pressure is transient, in which case medical treatment is indicated.

Be aware that some individuals are “steroid responders” who develop increased intraocular pressure when challenged with exogenous steroids. The optic nerve of African Americans is probably prone to damage with acute increases in intraocular pressure.

UVEITIS

Inflammation of the uveal tract can be subdivided according to the uveal tissue primarily involved (iris, choroid, retina) or by location, that is, anterior, intermediate, or posterior uveitis. Perhaps the most commonly diagnosed form of uveitis in childhood is traumatic iridocyclitis (iritis).

Anterior Uveitis

Injection, photophobia, pain, and blurred vision usually accompany iritis (anterior uveitis, iridocyclitis). An exception to this is iritis associated with juvenile rheumatoid arthritis (Chapter 26), when the eye is quiet and asymptomatic, but slitlamp examination will reveal anterior chamber inflammation in which inflammatory cells and protein flare are seen.

Iridocyclitis associated with juvenile rheumatoid arthritis occurs most often in girls with pauciarticular arthritis and a positive antinuclear antibody. All children with juvenile rheumatoid arthritis need to be screened according to a schedule recommended by the American Academy of Pediatrics (www.aap.org). Treatment with a topical corticosteroid and a cycloplegic agent is aimed at quieting the inflammation and preventing or delaying the onset of cataract and glaucoma.

Methotrexate and other immunosuppressive agents can be used in refractory cases.

Inflammatory bowel disease is also associated with iritis—perhaps more commonly with Crohn disease than with ulcerative colitis. Other ocular findings of the anterior segment that can be associated with inflammatory bowel disease include conjunctivitis, episcleritis, and sterile corneal infiltrates. Posterior segment findings may include central serous retinopathy, panuveitis (inflammation of all uveal tissue), choroiditis, ischemic optic neuropathy, retinal vasculitis, neuroretinitis, and intermediate uveitis (see section on Intermediate Uveitis).

Posterior subcapsular cataracts can develop in patients with or without ocular inflammation. Most, if not all, of these patients have been taking corticosteroids as part of the long-term treatment of inflammatory bowel disease. Children with Crohn disease or ulcerative colitis should have routine periodic ophthalmologic examinations to rule out ocular inflammation, which may be asymptomatic, and cataracts associated with systemic corticosteroids.

Other causes of anterior uveitis in children include syphilis, tuberculosis, sarcoidosis, relapsing fever (borreliosis), and Lyme disease, all but the last also causing posterior uveitis. Juvenile spondyloarthropathies, including ankylosing spondylitis, Reiter syndrome, and psoriatic arthritis, are also associated with anterior uveitis. A substantial percentage of cases are of unknown origin.

Kodsi SR et al: Time of onset of uveitis in children with juvenile rheumatoid arthritis. *J AAPOS* 2002;6(6):373 [PMID 12506279].

Oren B et al: The prevalence of uveitis in juvenile rheumatoid arthritis. *J Am Assoc Pediatr Ophthalmol Strabismus* 2001;5:2 [PMID: 11182663].

Posterior Uveitis

The terms *choroiditis*, *retinitis*, and *retinochoroiditis* denote the tissue layer primarily involved in posterior uveitis. Characteristic features occur with posterior uveitis as a result of certain organisms. Active toxoplasmosis (see Chapter 39) produces a white lesion appearing as a “headlight in the fog” owing to the overlying vitritis. Inactive lesions have a hyperpigmented border. Contiguous white satellite lesions suggest reactivation of disease. Congenital infections must be treated aggressively with a triple drug regimen (pyramethamine, sulfadiazine, and leukovorin) for 1 year. Studies have shown improved ophthalmic and neurologic outcomes with prolonged treatment. A granular “salt and pepper” retinopathy is characteristic of congenital rubella. In infants, the TORCH complex (toxoplasmosis, rubella,

cytomegalovirus [CMV], herpes simplex virus) and syphilis must be suspected in congenital infections that cause chorioretinitis.

Congenital lymphocytic choriomeningitis virus (LCMV) may also present with chorioretinitis. The virus is transmitted to humans by consumption of food contaminated with rodent urine or feces. It most closely resembles congenital toxoplasmosis in presentation. Diagnosis is done by immunofluorescent antibody or enzyme-linked immunosorbent assay (ELISA) laboratory testing. If possible, pregnant women should avoid exposure to rodents.

Ocular candidiasis occurs typically in an immunocompromised host or an infant in the intensive care nursery receiving hyperalimentation. Candidal chorioretinitis appears as multifocal, whitish yellow, fluffy retinal lesions that may spread into the vitreous and produce a so-called cotton/fungus ball vitritis.

Acute retinal necrosis syndrome is caused most often by varicella-zoster virus and occasionally by herpes simplex virus. Patients may present with a red and painful eye. Ophthalmoscopy may show unilateral or bilateral patchy white areas of retina, arterial sheathing, vitreous haze, atrophic retinal scars, retinal detachment, and optic nerve involvement.

CMV is a cause of congenital infection that may be accompanied by retinitis. CMV infection must be considered as a cause of retinitis in immunocompromised and human immunodeficiency virus (HIV)-infected children. CMV retinitis appears as a white retinal lesion, typically but not always associated with hemorrhage, or as a granular, indolent-appearing lesion with hemorrhage and a white periphery. Cotton wool spots (nerve fiber layer infarcts) also commonly occur in HIV-positive patients.

In toddlers and older youngsters, *Toxocara canis* or *T. cati* infections (ocular larva migrans; see Chapter 39) occur from ingesting soil contaminated with parasite eggs. The disease is usually unilateral. Common signs and symptoms include a red injected eye, leukocoria, and decreased vision. Fundus examination may show endophthalmitis (vitreous abscess) or localized granuloma. Diagnosis is based on the appearance of the lesion and serologic testing using ELISA for *T. canis* and *T. cati*. Treatment options include periocular corticosteroid injections and vitrectomy.

Mets MB et al: Lymphocytic choriomeningitis virus: An underdiagnosed cause of congenital chorioretinitis. *Am J Ophthalmol* 2000;130(2):209 [PMID 11004296].

Intermediate Uveitis

Pars planitis, often of uncertain cause, can be associated with vitreous floaters. The inflammation is described as snowbanking because a heaped-up white precipitate is located in the far anterior periphery of the retina and vitreous base. Pupillary dilation and indirect ophthalmoscopy are required for observation. Macular edema and decreased vision can result.

Toxocara infections with peripheral granuloma can be associated with intermediate uveitis, as can inflammatory bowel disease, multiple sclerosis, and sarcoidosis. Retinoblastoma and other neoplasms can imitate uveitis, causing a so-called masquerade syndrome.

ACQUIRED IMMUNODEFICIENCY SYNDROME & THE EYE

Ocular infections are important manifestations of acquired immunodeficiency syndrome (AIDS) (see Chapter 37). As CD4⁺ T-lymphocyte counts fall below 200/μL, opportunistic infections increase in these patients. Pathogens commonly causing eye infection include *Toxoplasma gondii* and CMV. Especially when CD4⁺ counts fall below 50/μL, the patient is at high risk for CMV retinitis, the leading cause of vision loss in AIDS patients (see Posterior Uveitis section) and blindness. Active CMV retinitis must be treated with intravenous foscarnet or ganciclovir. These medications may be required in combination if the retinitis fails to respond to a single drug regimen. Intravitreal ganciclovir or ganciclovir implants in conjunction with oral valganciclovir may be required in severe cases or in individuals intolerant to intravenous therapy. The incidence of CMV retinitis has fallen dramatically with the use of multidrug antiretroviral therapy.

Acute retinal necrosis syndrome (see Posterior Uveitis section) is a severe necrotizing retinitis in AIDS patients that often results in blindness. Most cases are thought to be caused by varicella-zoster virus. Other implicated agents are herpes simplex types 1 and 2 and occasionally CMV. Therapy with antiviral agents is required, but the prognosis is poor. A specific HIV retinopathy not associated with other known infectious agents also occurs. Various retinal abnormalities include cotton wool spots, retinal hemorrhages, microaneurysms, perivasculitis, and decreased visual acuity from ischemic maculopathy.

Jabs DA et al: Characteristics of patients with cytomegalovirus retinitis in the era of highly active antiretroviral therapy. *Am J Ophthalmol* 2002;133(1):48 [PMID 11755839].

DISORDERS OF THE CORNEA

Conditions Causing Corneal Clouding

The differential diagnosis of corneal clouding in a newborn infant includes forceps trauma, congenital glaucoma, infection, congenital malformation, and tumor. In older children, corneal clouding is associated with mucopolysaccharidoses, Wilson disease, and cystinosis. Infiltrates occur with viral infections, staphylococcal lid disease, corneal dystrophies, and interstitial keratitis due to congenital syphilis.

Microcornea & Megalocornea

Microcornea—a corneal diameter less than 10 mm in a full-term infant or older child—may be associated with other anterior segment malformations or a microphthalmic globe. Megalocornea—diameter of 12.5 mm or greater—should be regarded as due to congenital glaucoma until proved otherwise.

Keratitis

Both herpes simplex and herpes zoster can infect the cornea. When the epithelium breaks down, a dendritic or ameboid pattern can be seen with fluorescein staining. Corneal involvement with herpes simplex can be recurrent and lead to blindness. Topical antivirals such as trifluridine and vidarabine are indicated when herpes simplex infection is limited to the corneal epithelium. Topical corticosteroids may be a useful addition when stromal disease is present. The use of corticosteroids in the presence of herpetic disease should be undertaken only by an ophthalmologist because of the danger of worsening the disease. Oral acyclovir started in the early phase (first 5 days) may be helpful in treating herpes zoster eye disease. Acyclovir prophylaxis is helpful in preventing recurrent herpetic epithelial keratitis (see Viral Conjunctivitis section) and stromal keratitis caused by herpes simplex.

Adenovirus conjunctivitis may progress to keratitis 1–2 weeks after onset. Slitlamp examination reveals white infiltrates beneath the corneal epithelium. Vision may be decreased. In most cases no treatment is necessary because adenovirus keratitis is most often self-limiting. However, adenovirus is highly contagious and easily spread (see Conjunctivitis section).

Contact lens wearers are at risk for severe vision-threatening *Acanthamoeba* keratitis from contaminated contact lens solutions. Treatment is difficult and may require corneal transplantation (see Chapter 39).

The Herpetic Eye Disease Study Group: Acyclovir for the prevention of recurrent herpes simplex virus eye disease. *N Engl J Med* 1998;339:300 [PMID: 9696640].

Schwartz GS et al: Oral acyclovir for the management of herpes simplex virus keratitis in children. *Ophthalmology* 2000;107:278 [PMID: 10690825].

Corneal Ulcers

Bacterial corneal ulcers in healthy children who are not contact lens wearers are usually secondary to corneal trauma from corneal abrasion or a penetrating foreign body. Decreased vision, pain, injection, a white corneal infiltrate or ulcer (Figure 15–22), and hypopyon (pus in the anterior chamber) may all be present. Prompt referral to an ophthalmologist is necessary for culture and antibiotic treatment.

DISORDERS OF THE LENS

Lens disorders involve abnormality of clarity or position. Lens opacification—cataract can affect vision depending on its density, size, and position. Visual potential is also influenced by age at onset and the success of amblyopia treatment.

Cataracts

Cataracts in children may be unilateral or bilateral, may exist as isolated defects, or may be accompanied by other ocular disorders or systemic disease (Figure 15–23). Congenital and infantile cataracts may also be part of a chromosomal syndrome. Leukocoria, poor fixation, and strabismus or nystagmus (or both) may be the presenting complaints. In the newborn, absence of a red reflex should suggest the possibility of cataract, especially if the infant's pupil has been dilated for the examination.

The appearance of the cataract may sometimes suggest its cause. Anterior capsular cataracts are develop-

Figure 15–23. Cataract causing leukocoria.

mental, that is, not related to infection or metabolic problems. Laboratory investigation for infectious and metabolic causes is often indicated. Such investigation would include cultures or serologic tests for toxoplasmosis, rubella, CMV, herpes simplex virus, and syphilis as well as evaluation for metabolic errors as may occur with galactosemia or Lowe syndrome.

Early diagnosis and treatment are necessary to prevent deprivation amblyopia in children younger than age 9 years, because such children are visually immature. Cataracts that are visually significant require removal. Rehabilitation with an intraocular lens is commonplace, especially with cataracts removed after the age of 2 years. But contact lenses and glasses still play a role, as does occlusion of the better-seeing eye to treat the amblyopia.

Fallaha N et al: Pediatric cataracts. *Ophthalmol Clin North Am* 2001;14(3):479 [PMID 11705148].

Wilson ME et al: Paediatric cataract blindness in the developing world: Surgical techniques and intraocular lenses in the new millennium. *Br J Ophthalmol* 2003;87(1):14 [PMID 12488254].

Dislocated Lenses

Lens dislocation is usually bilateral except when caused by trauma. Subluxation causes refractive errors of large magnitude that are difficult to correct. Another ophthalmologic concern is pupillary block glaucoma. In this disorder, a malpositioned unstable lens interferes with the normal flow of aqueous humor from where it is produced in the ciliary body (posterior to the pupil) into the trabecular meshwork (anterior to the pupillary plane).

Dislocated lenses are associated with other ocular conditions and systemic syndromes, including Marfan syndrome, homocystinuria, Weill–Marchesani syndrome, sulfite oxidase deficiency, hyperlysinemia,

Figure 15–22. Corneal ulcer. Note white infiltrate located on inferior cornea.

syphilis, and Ehlers–Danlos syndrome. Work-up and treatment are multidisciplinary endeavors.

DISORDERS OF THE RETINA

Retinal Hemorrhages in the Newborn

Retinal hemorrhages are commonly seen in the otherwise healthy newborn. Although it occurs most often after vaginal delivery, this finding can also be present after suction delivery or cesarean section. The hemorrhages may be unilateral or bilateral and be located anywhere in the retina. They may appear as dot, blot, subretinal, or preretinal hemorrhages. They may also break into the vitreous.

In general, retinal hemorrhages of the newborn disappear quickly, usually within the first month of life, which may help differentiate this condition from retinal hemorrhages that occur in the shaken baby syndrome. Another cause of retinal hemorrhage is coagulopathy.

Emerson AV et al: Incidence and rate of disappearance of retinal hemorrhage in newborns. *Ophthalmology* 2001;108:36 [PMID: 11150261].

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) continues to be an important cause of blindness, especially for infants born at less than 28 weeks' gestation and weighing less than 1250 g. Premature infants with incomplete retinal vascularization are at risk for developing abnormal peripheral retinal vascularization, which may lead to retinal detachment. However, most cases of ROP do not progress to retinal detachment and require no treatment.

The CRYO-ROP study outlined a standard nomenclature to describe the progression and severity of ROP (Table 15–4). Since retinal blood vessels emanate from the optic nerve, and do not fully cover the developing

retina until term, the optic nerve is used as the central landmark. The most immature zone of retina, zone 1, is the most posterior concentric imaginary circle around the optic nerve. Further out is zone 2, and beyond that is zone 3. Zone 1 disease is, by definition, more high risk than disease in more anterior zones. Similarly, the stages of the abnormal vessels are numbered from zero, or simply incomplete vascularization, through stages I, II, and III. When 5 contiguous, or 8 noncontiguous clock hours of stage 3 disease occur, “threshold” has been reached. At this stage in the CRYO-ROP study, 50% of eyes had a bad outcome without treatment, progressing to stage IV or V. This was therefore chosen as the stage for mandatory treatment. Plus disease (+) refers to dilation and tortuosity of the vessels around the optic nerve, and is an ominous sign of active, worsening ROP. Rush disease refers to cases in which the disease skips intervening stages and goes rapidly to retinal detachment.

The risk of developing visually threatening ROP is inversely proportional to birth weight and gestational age. Infants weighing less than 1500 g at birth or born at less than 33 weeks' gestation may develop visually threatening ROP. The cause of this disorder—including the role of supplemental oxygen in the neonatal period—is still not fully understood. During the first epidemic of ROP in the 1960s, delivery of high levels of oxygen without arterial monitoring appeared to contribute significantly to the development of ROP. Pulse oximetry and better regulation led to a decline in cases, but better survival for the smallest, sickest infants has increased the numbers of affected infants once again, leading to speculation that low birth weight and gestational age may be more important than oxygen in etiology. Anecdotal reports of improvement in near-threshold ROP with high oxygen saturations led to the STOP-ROP study, which investigated whether keeping PaO₂ high at this critical stage reduced the need for laser. The results did not show a benefit. A study in which infants were kept at relatively low oxygen saturation from birth did show a reduction in severe ROP cases and showed no increase in cerebral palsy at 18 months follow-up, which had been reported in the past with oxygen curtailment. Further study and follow-up of this method is needed. Other risk factors for severe ROP are bronchopulmonary dysplasia, intraventricular hemorrhage, sepsis, apnea and bradycardia, and mutations of Norrie disease gene. White males, infants with zone 1 disease, and infants with very low birth weight and gestational age have a higher risk of reaching threshold.

Another cofactor that has been investigated is ambient light in the nursery. One early study found a correlation between light exposure and development of ROP, but the multicenter LIGHT-ROP trial found no

Table 15–4. Stages of retinopathy of prematurity.

Stage I	Demarcation line or border dividing the vascular from the avascular retina.
Stage II	Ridge. Line of stage I acquires volume and rises above the surface retina to become a ridge.
Stage III	Ridge with extraretinal fibrovascular proliferation.
Stage IV	Subtotal retinal detachment.
Stage V	Total retinal detachment.

“Plus disease” signifies arteriolar tortuosity and venular dilation of posterior pole vessels.

correlation. Recent studies suggest that the substance vascular endothelial growth factor (VEGF) may play a key role in ROP development, and methods of modulating VEGF are being investigated.

Screening guidelines and a uniform classification system have been adopted, but alternative screening paradigms have also been suggested. The first retinal examination is recommended at age 4–6 weeks after birth, or 31 weeks postmenstrual age, whichever is earlier. The frequency of follow-up examinations depends on the findings and the risk factors for developing the disease, but for most infants will be every 1–2 weeks. Acute-phase ROP begins to involute at a mean postmenstrual age of 38.6 weeks, but the range for onset of involution is wide. Examinations can be discontinued when the retinas are fully vascularized, or when the baby is 45 weeks' gestational age and has never had prethreshold disease or worse, or is vascularized out to zone 3 and never had zone 1 or 2 disease. The treatment of threshold ROP within 72 hours of diagnosis with cryotherapy reduced the occurrence of bad visual outcomes by 50%. Diode laser treatment has largely replaced cryotherapy because it provides better access for treating zone 1 disease and causes less inflammation. Reported success rates are higher than with cryotherapy. However, some patients still develop blinding retinal detachment. With smaller, sicker infants surviving, treatment guidelines may need to be amended to treat earlier than threshold in some infants. Studies investigating this are underway.

Other findings associated with ROP include strabismus, amblyopia, myopia, glaucoma, and loss of visual field.

Retinoblastoma

Retinoblastoma is the most common primary intraocular malignancy of childhood, with an incidence estimated between 1:17,000 and 1:34,000 live births (see Chapter 28). Most patients present before age 3 years; children with hereditary or bilateral retinoblastoma usually present earlier than those with unilateral, sporadic disease.

Inherited forms of retinoblastoma are autosomal dominant with high penetrance. The disease may consist of a solitary mass or multiple tumors in one or both eyes. All bilateral cases and some unilateral cases are caused by germinal mutations; however, most unilateral cases are caused by a somatic retinal mutation. In both situations, the mutation occurs in the retinoblastoma gene (*Rb*) at chromosome 13q14. This is a tumor suppressor gene. One mutated copy may be inherited in an autosomal dominant fashion (germline mutation). If a second mutation spontaneously occurs in any cell, tumorigenesis is likely. Individuals with a germinal mutation are at risk for the development of tumors other than retinoblastoma (pineal tumors, osteosarcoma, and other soft tissue sarcomas). All children with unilateral or bilateral retinoblastoma must be presumed to have the germline form, including being followed expectantly for other tumors in the remaining eye and systemically. Approximately 15% of patients with unilateral disease have germline mutations.

The most common presenting sign in a child with previously undiagnosed retinoblastoma is leukocoria (see Figure 15–1). Evaluation of the pupillary red reflex is important, although a normal red reflex does not rule out retinoblastoma. This examination requires indirect

ophthalmoscopy with scleral depression and pupillary dilation, performed by an ophthalmologist. Other children present with strabismus, red eye, glaucoma, or pseudohypopyon (appearance of pus-like material in the anterior chamber).

Treatment of unilateral cases, especially of large tumors, usually has been enucleation, because at the time of presentation the eye is filled with tumor. Vision and eyes can be salvaged in some cases. Chemoreduction of intraocular tumors is a newer treatment technique used to reduce initial tumor volume. In conjunction with local treatment such as laser photocoagulation, cryotherapy, plaque radiotherapy, and thermotherapy, it can preserve vision and spare the patient enucleation and radiation that may lead to disfigurement and the induction of secondary tumors, especially in eyes classified with less extensive disease. Agents used in chemoreduction include carboplatin, etoposide, and vincristine. Eradication of tumor before infiltration into the optic nerve or choroid carries a good prognosis for survival.

Genetic testing is available for patients with retinoblastoma. Once the causative mutation is found in an affected individual, unaffected members of the family may be tested to determine their personal and reproductive risk. This testing may avoid many unnecessary examinations under anesthesia for young relatives of patients of with retinoblastoma.

Sussman DA et al: Comparison of retinoblastoma reduction for chemotherapy vs external beam radiotherapy. *Arch Ophthalmol* 2003;121(7):979 [PMID: 12860801].

Retinal Detachment

Retinal detachment occurs infrequently in children. Common causes are trauma and high myopia. Other causes are ROP, Marfan syndrome, and Stickler syndrome.

Symptoms of detachment are floaters, flashing lights, and loss of visual field; however, children often cannot appreciate or verbalize their symptoms. A detachment may not be discovered until the child is referred after failing a vision screening examination, strabismus supervenes, or leukocoria is noted. Treatment of retinal detachment is surgical. For children with conditions predisposing to retinal detachment, or a strong family history, examinations under anesthesia by an

ophthalmologist, with prophylactic laser treatment, are often recommended.

Diabetes Mellitus

Diabetic retinopathy is a specific vascular complication of diabetes mellitus. Patients with type 1, or insulin-dependent, diabetes are at higher risk of developing severe proliferative retinopathy leading to visual loss than are those with type 2, or non-insulin-dependent, diabetes. The American Diabetes Association recommends annual screening for retinopathy 5 years after onset of diabetes in adults. In children older than age 9 years, referral to an ophthalmologist for screening of retinopathy should be begun 3–5 years after the onset of diabetes. Acute onset of diabetes may be accompanied by sudden myopia and by cataracts. Both conditions may be reversible with systemic glucose control. Young children with type 1 diabetes should be followed for the Wolfram, or DIDMOAD, syndrome, in which diabetes mellitus occurs in conjunction with diabetes insipidus, optic atrophy, and deafness.

DISEASES OF THE OPTIC NERVE

Optic nerve function is evaluated by checking visual acuity, color vision, pupillary response, and visual fields. Poor optic nerve function results in decreased central or peripheral vision, decreased color vision, strabismus, and nystagmus.

The swinging flashlight test is used to assess function of each optic nerve. It is performed by shining a light alternately in front of each pupil to check for an afferent pupillary defect or Marcus Gunn pupillary defect. An abnormal response in the affected eye is pupillary dilation when the light is directed into that eye after having been shown in the other eye with its healthy optic nerve. This results from poorer conduction along the optic nerve of the affected eye, which in turn results in less pupillary constriction of both eyes than occurs when the light is shined into the noninvolved eye. Hippus—rhythmic dilating and constricting movements of the pupil—can be confused with an afferent pupillary defect.

The optic nerve is evaluated as to size, shape, color, and vascularity. Occasionally, myelinization past the entrance of the optic nerve head occurs. It appears white, with a feathered edge (Figure 15–24). Myeliniza-

Figure 15-24. Myelinization extending from optic nerve superiorly onto the retina.

tion onto the retina can be associated with myopia and amblyopia. Anatomic defects of the optic nerve include colobomatous defects and pits.

Optic nerve hypoplasia may be associated with absence of the septum pellucidum and hypothalamic–pituitary dysfunction, which is known as septooptic dysplasia, or de Morsier syndrome. Children with septooptic dysplasia and hypocortisolism are at risk for sudden death during febrile illness from thermoregulatory disturbance and dehydration from diabetes insipidus. Optic nerve hypoplasia may occur in infants of diabetic mothers and has also been associated with alcohol use or ingestion of quinine or phenytoin during pregnancy. Anatomically, the size of the involved optic nerve may range from absent (aplasia) to almost full size, with a segmental defect. However, the nerve often appears larger than it is because it is surrounded by a depigmented halo. Visual function with optic nerve hypoplasia ranges from mildly decreased to absent light perception. If only one eye is involved, the child usually presents with strabismus. If both eyes are affected, nystagmus is usually the presenting sign.

Because the optic nerve is an outgrowth of the brain, changes in this structure often reflect CNS disease and defects of central midline structures.

Papilledema

Papilledema (optic disc edema, choked disc) is associated with increased intracranial pressure due to any

cause, such as tumor or intracranial infection. This dysfunction appears as an elevated disc with indistinct margins, increased vessel diameter, and increased capillary, giving the disc a hyperemic appearance with surrounding hemorrhages and exudates in more severe cases. Observed changes may be subtle to striking. Optic nerve head changes are bilateral and generally symmetrical.

Besides known causes such as hydrocephalus and intracranial tumor, papilledema is associated with so-called benign intracranial hypertension, also known as pseudotumor cerebri or idiopathic intracranial hypertension. Papilledema occurs almost equally in boys and girls and sometimes is associated with obesity or upper respiratory tract infection. Other associated causes are viral infections, corticosteroid use and withdrawal, sinus infection, trauma, tetracycline use, growth hormone, and venous sinus thrombosis. Early in the course of the disorder, the patient may not notice a change in vision, although the blind spot may be enlarged. Transient obscurations of vision (amaurosis fugax) may occur as the process becomes more long-standing. Further effects on vision will occur as the papilledema becomes chronic and ultimately leads to optic atrophy. Work-up and treatment are directed toward finding the underlying systemic or CNS cause. Treatment of idiopathic intracranial hypertension may be pharmacologic—for example, using acetazolamide, a carbonic anhydrase inhibitor, or a corticosteroid. Diagnostic lumbar puncture may also be curative. Optic nerve sheath fenestration and lumboperitoneal shunt are surgical interventions.

Salman MS et al: Idiopathic “benign” intracranial hypertension: Case series and report. *J Child Neurol* 2001;16:465 [PMID: 11453440].

Papillitis

Papillitis is a form of optic neuritis seen on ophthalmoscopic examination as an inflamed optic nerve head. Optic neuritis in the pediatric age group may be idiopathic, associated with multiple sclerosis, acute disseminated encephalomyelitis, Devic disease, or cat-scratch disease.

Papillitis may have the same appearance as papilledema. However, papillitis may be unilateral, whereas papilledema is almost always bilateral. Papillitis can be differentiated from papilledema by an afferent pupillary defect (Marcus Gunn pupil), by its greater ef-

fect in decreasing visual acuity and color vision, and by the presence of a central scotoma. Papilledema that is not yet chronic will not have as dramatic an effect on vision. Because increased intracranial pressure can cause both papilledema and a sixth (abducens) nerve palsy, papilledema can be differentiated from papillitis if esotropia and loss of abduction are also present. However, esotropia may also develop secondarily in an eye that has lost vision from papillitis. In pseudopapilledema, a normal variant of the optic disc, the disc appears elevated, with indistinct margins and a normal vascular pattern. Pseudopapilledema sometimes occurs in hyperopic individuals. Retrobulbar neuritis, an inflamed optic nerve but with a normal-appearing nerve head, is associated with pain and the other findings of papillitis.

Work-up of the patient with papillitis includes lumbar puncture and cerebrospinal fluid analysis. *Bartonella henselae* can be detected by serology. MRI is the preferred imaging study. An abnormal MRI is associated with a worse visual outcome. Treatment with corticosteroids is frequently used.

Optic Atrophy

Optic atrophy, noted as pallor of the nerve head with loss of capillarity, occurs in children most frequently after neurologic compromise during the perinatal period. An example would be a premature infant who develops an intraventricular hemorrhage. Hydrocephalus, glioma of the optic nerve, craniosynostosis, certain neurologic diseases, and toxins such as methyl alcohol can cause optic atrophy, as can certain inborn errors of metabolism, long-standing papilledema, or papillitis.

DISEASES OF THE ORBIT

Periorbital & Orbital Cellulitis

The fascia of the eyelids joins with the fibrous orbital septum to isolate the orbit from the lids. This septum serves as a barrier to the posterior spread of infection from preseptal infection. Infections arising anterior to the orbital septum are termed preseptal. Preseptal (peri-orbital) cellulitis, which indicates infection of the structures of the eyelid, is characterized by lid edema, erythema, swelling, pain, and mild fever. It usually arises from a local exogenous source such as an abrasion of the eyelid, from other infections (hordeolum, dacryocystitis, chalazion), or from infected varicella or insect bite lesions. *Staphylococcus aureus* and *Streptococcus pyogenes* are the most common pathogens cultured from these sources. Preseptal infections in children younger than age 3 years also occur from bacteremia, although this is much less common since *Haemophilus influenzae*

immunization became available. *Streptococcus pneumoniae* bacteremia is still an occasional cause of this infection. Children with periorbital cellulitis from presumed bacteremia must be examined for additional foci of infection.

Infection of the orbit almost always arises from contiguous sinus infection, because the walls of three sinuses make up portions of the orbital walls and infection can breach these walls or extend by way of a richly anastomosing venous system. The orbital contents can develop a phlegmon (orbital cellulitis), or frank pus can develop in the orbit (orbital abscess). When the orbit is infected, the signs of periorbital disease are joined by proptosis (a protruding eye), restricted eye movement, and pain with eye movement. Fever is usually high. CT scanning or MRI is required to establish the extent of the infection within the orbit. Sinus imaging should be obtained at the same time. The pathogenic agents are those of acute or chronic sinusitis—respiratory flora and anaerobes. *S aureus* is also frequently implicated.

Therapy for preseptal and orbital cellulitis infection is with systemic antibiotics. Treatment of orbital infections may require surgical drainage for subperiosteal abscess in conjunction with intravenous antibiotics. Drainage of infected sinuses is often part of the therapy.

Ambati BK et al: Periorbital and orbital cellulites before and after the advent of *Haemophilus influenzae* type B vaccination. *Ophthalmology* 2000;107(8):1450 [PMID 10919886].

Starkey CR et al: Medical management of orbital cellulites. *Pediatr Infect Dis J* 2001;20(10):1002 [PMID 11642617].

Craniofacial Anomalies

Craniofacial anomalies can affect the orbit and visual system. Examples of changes associated with craniofacial disease involving the orbits are proptosis, corneal exposure, hypertelorism (widely spaced orbits), strabismus, amblyopia, lid coloboma, papilledema, and optic atrophy. Craniofacial anomalies occur with craniosynostoses and midface syndromes such as Treacher Collins and Pierre Robin sequence. Fetal alcohol syndrome is associated with similar changes of the ocular adnexa.

Orbital Tumors

Both benign and malignant orbital lesions occur in children. The most common tumor is capillary hemangioma (Figure 15–25). This type of tumor may be located superficially in the lid or deep in the orbit and can cause ptosis, refractive errors, and amblyopia. Deeper lesions may cause proptosis. Capillary hemangiomas in infants initially increase in size before involuting at about age 2–4 years. Therapy with intralesional

Figure 15–25. Right upper lid hemangioma causing ptosis.

or systemic corticosteroids is indicated if the lesion is large enough to cause amblyopia.

Orbital dermoid cysts vary in size and are usually found temporally at the brow and orbital rim or supranasally. These lesions are firm, well encapsulated, and mobile. Rupture of the cyst causes a severe inflammatory reaction. Treatment is by excision. Lymphangioma occurring in the orbit is typically poorly encapsulated, increases in size with upper respiratory infection, and is susceptible to hemorrhage. Other benign tumors of the orbit are orbital pseudotumor, neurofibroma, teratoma, and tumors arising from bone, connective tissue, and neural tissue.

Of grave concern is orbital rhabdomyosarcoma, the most common primary orbital malignancy in childhood (see Chapter 28). This tumor grows rapidly and displaces the globe. The average age at onset is 6–7 years. The tumor is often initially mistaken for orbital swelling due to insignificant trauma. Radiation and chemotherapy are the mainstays of treatment after biopsy confirms the diagnosis. With expeditious diagnosis and proper treatment, the survival rate of patients with orbital rhabdomyosarcoma confined to the orbit approaches 90%.

Tumors metastatic to the orbit also occur; neuroblastoma is the most common. The patient may exhibit proptosis, orbital ecchymosis (raccoon eyes), Horner syndrome, or opsoclonus (dancing eyes). Ewing sarcoma, leukemia, Burkitt lymphoma, and the histiocytosis X group of diseases may involve the orbit.

NYSTAGMUS

Nystagmus is a rhythmic oscillation or jiggling of the eyes. It may be unilateral or bilateral, more pronounced in one eye, or gaze-dependent. Nystagmus may be associated with esotropia or may occur with ocular lesions that cause deprivation amblyopia (eg, cataract, eyelid

ptosis) or conditions in which the visual pathways are hypoplastic, sometimes referred to as “sensory nystagmus.” Both optic nerve hypoplasia and macular hypoplasia, the latter occurring with aniridia or albinism, are associated with nystagmus. Nystagmus can also occur with normal ocular structures and seemingly normal CNS development, sometimes referred to as “motor nystagmus.” In the latter instance, the nystagmus may be blocked in certain positions of gaze, in which case a face turn or torticollis may develop. Latent nystagmus occurs when one eye is occluded. This type of nystagmus occurs in patients with congenital esotropia. An associated amblyopia may be present.

Most nystagmus occurring in childhood is of ocular origin, but CNS disease and, less frequently, inner ear disease are other causes. A CNS cause is likely when the nystagmus is acquired. The clinician should evaluate the fundus for optic nerve abnormalities and the quality of the macular reflex, because both optic nerve hypoplasia and macular hypoplasia can cause nystagmus.

Evaluation of nystagmus begins with the pediatric ophthalmologist. Careful evaluation for iris transillumination defects caused by albinism should be performed. An electroretinogram (ERG) is usually required to rule out retinal pathology as the cause. Some types of nystagmus, usually motor nystagmus, can be treated, generally with surgery; less frequently, prisms are useful. Spasmus nutans, in which a rapid, shimmering, dysconjugate nystagmus occurs with head bobbing and torticollis, is said to improve with time. Glioma of the hypothalamus can mimic spasmus nutans. Neuroimaging may be necessary to determine if the cause of the nystagmus is due to a CNS disease.

AMBLYOPIA & STRABISMUS

Visual development is a learned function. For it to proceed normally, a child must experience a normal visual environment with well-aligned eyes that are free of visually threatening disease and significant refractive errors. The consequences of not meeting these requirements during the sensitive period of visual development in the first decade of life are strabismus and decreased vision, or amblyopia.

Amblyopia

Amblyopia is a unilateral or bilateral reduction in central visual acuity due to the sensory deprivation of a well-formed retinal image that occurs with or without a visible organic lesion commensurate with the degree of visual loss. Amblyopia can occur only during the critical period of visual development in the first decade of life when the visual nervous system is plastic. Approximately 3% of the population is amblyopic. Screening

for amblyopia should be a component of periodic well-child examinations. The single best screening technique to discover amblyopia is obtaining visual acuity in each eye. In preverbal children unable to respond to visual acuity assessment, amblyogenic factors are sought, including strabismus; media opacities; unequal Brückner reflexes (pupillary red reflexes); and a family history suggestive of strabismus, amblyopia, or ocular disease occurring in childhood (see Examination section).

Amblyopia is classified according to its cause. Strabismic amblyopia can occur in the nondominant eye of a strabismic child. Refractive amblyopia can occur in both eyes if significant refractive errors are untreated (ametropic or refractive amblyopia). Another type of refractive amblyopia can occur in the eye with the worse refractive error when imbalance is present between the eyes (anisometropic amblyopia). Deprivation amblyopia occurs when dense cataracts or complete ptosis prevents formation of a formed retinal image. Of the three types of amblyopia, this form of amblyopia results in the worst vision.

The earlier treatment is begun, the better the chance of improving visual acuity. Treatment is usually discontinued after age 9 years. Amblyogenic factors such as refractive errors are addressed. Because of the extreme sensitivity of the visual nervous system in infants, congenital cataracts and media opacities must be diagnosed and treated within the first few weeks of life. Visual rehabilitation and amblyopia treatment must then be started in order to foster visual development.

After eradicating amblyogenic factors, the mainstay of treatment is patching the sound eye, which causes the visual nervous system to process input from the amblyopic eye and in that way permits the development of useful vision. Other treatment modalities include “fogging” the sound eye with cycloplegic drops (atropine), lenses, and filters.

Repka MX et al: A randomized trial of patching regimens for treatment of moderate amblyopia in children. *Arch Ophthalmol* 2003;121(5):603 [PMID 12742836].

Strabismus

Strabismus is misalignment of the visual axes of the two eyes. Its prevalence in childhood is about 2–3%. Strabismus is categorized by the direction of the deviation and its frequency. Early diagnosis of strabismus and amblyopia, which often coexist, provides the best chance of reaching full visual potential. Strabismus may cause or be due to amblyopia.

Misdiagnosis of strabismus when the eyes are well aligned—pseudostabismus—can occur when relying on the gross observation of the appearance of the two eyes. If the child has prominent epicanthal folds, pseudoesotropia may be diagnosed erroneously. Observation of the reflection of a penlight on the cornea, corneal light reflex, is a more accurate means of determining if the eyes are straight. If strabismus is present, the corneal light reflex will not be centered in both eyes.

An infant whose eyes are destined to be well aligned may appear intermittently esotropic, but this should occur less frequently over the first few months of life. By age 5 or 6 months, the baby’s eyes should be constantly well aligned.

Besides its effect on visual development, strabismus may be a marker of other ocular or systemic disease. Twenty percent of patients with retinoblastoma exhibit strabismus. Patients with CNS disorders such as hydrocephalus, space-occupying lesions, and an amaurotic (blind) eye can also exhibit strabismus. In children younger than age 3 or 4 years, blind eyes tend to assume a position of esodeviation, but after about age 4 years an amaurotic eye tends to show an exotropic shift.

A. ESOTROPIA

In esotropia, the visual axes of the eyes are excessively convergent. In terms of cause and treatment, esotropia can be categorized by age at onset. Congenital esotropia (infantile esotropia) has its onset in the first year of life in healthy infants. The deviation is large and obvious. Surgery is the mainstay of treatment. Controversy exists as to how young the child should be when surgery is performed so that the child can obtain an optimal binocular result. The age range is from younger than 6 months to 2 years. Esotropia beginning in the first year also occurs in premature infants or in children with a complicated perinatal history associated with CNS problems such as intracranial hemorrhage and periventricular leukomalacia. Esotropia is associated with certain syndromes. In Möbius’ syndrome (congenital facial diplegia), a sixth nerve palsy causing esotropia is associated with palsies of the seventh and twelfth cranial nerves and limb deformities. Duane syndrome can affect the medial or lateral rectus muscles (or both). It may be an isolated defect or may be associated with a multitude of systemic defects (eg, Goldenhar syndrome). Duane syndrome is often misdiagnosed as a sixth (abducens) nerve palsy. The left eye is involved more commonly than the right, but both eyes can be involved. Girls are affected more frequently than boys. Children with unilateral paretic or restrictive causes of esotropia may develop face turns toward the affected eye in order to maintain binocularity.

A

B

C

Figure 15-26. Accommodative esotropia. Without glasses, esotropic (A). With glasses, well-aligned at distance (B) and at near with bifocal correction (C).

The most frequent type of acquired esotropia is the accommodative type (Figure 15-26). Onset is usually between ages 2 and 5 years. The deviation is variable in magnitude and constancy and is often accompanied by amblyopia. One type of accommodative esotropia is associated with a high hyperopic refraction. In another type, the deviation is worse with near than with distant vision. This type of esodeviation is usually associated with lower refractive errors. Management includes glasses with or without bifocals, amblyopia treatment, and in some cases surgery. After age 5 years, any esotropia of recent onset should arouse suspicion of CNS disease. Infratentorial masses, hydrocephalus, demyelinating diseases, and idiopathic intracranial hypertension are causes of abducens palsy, which appears as an esotropia, lateral rectus paralysis or paresis, and face turn. The face turn is an attempt to maintain binocu-

larity away from the field of action of the paretic muscle. Papilledema is often but not invariably present with increased intracranial pressure. Besides the vulnerability of the abducens nerve to increased intracranial pressure, it is susceptible to infection and inflammation. Otitis media and Gradenigo syndrome (inflammatory disease of the petrous bone) can cause sixth nerve palsy. Less commonly, migraine and diabetes mellitus are considerations in children with sixth nerve palsy. Work-up includes imaging studies and neurologic examination.

B. EXOTROPIA

Exotropia does not usually offer as many diagnostic pitfalls as esotropia. The visual axes of the two eyes are deviated in a divergent position (Figure 15-27). The deviation most often begins intermittently and occurs after age 2 years. Congenital (infantile) exotropia is extremely rare in an otherwise healthy infant. Early-onset exotropia may occur in infants and children with severe neurologic problems. All children with constant, congenital exotropia require CNS neuroimaging. Treatment of exotropia is with surgery, orthoptic exercises, patching, and occasionally glasses.

UNEXPLAINED DECREASED VISION IN INFANTS & CHILDREN

Some infants with delayed visual development during the first few months of life who are otherwise normal neurologically will reach an appropriate level of visual maturation. Occult causes of poor vision and blindness in children are those for which there are no obvious ocular defects: they include Leber congenital amaurosis, a childhood form of retinitis pigmentosa; achromatopsia, the absence of functioning cones in the retina; and optic nerve abnormalities, including optic nerve hypoplasia and atrophy as well as night blindness.

Cerebral visual impairment, also known as cortical blindness, is manifested as decreased visual attentiveness of varying degree. Cerebral visual impairment can be congenital or acquired. Insults to the optic pathways and higher cortical visual centers are responsible. Asphyxia, trauma, intracranial hemorrhage, and periventricular leukomalacia are some of the causes of cortical visual impairment.

Besides an ophthalmologic work-up, ERG and visual evoked response testing may be required in children with decreased vision of unexplained etiology. Imaging studies of the brain and a pediatric neurologic evaluation may be useful. A low-vision assessment may be indicated. Low-vision aids enhance remaining vision. Devices used include magnifiers for both distance and near vision, closed-circuit television, and large-print reading materials.

Hoyt CS: Visual function in the brain-damaged child. *Eye* 2003;17(3):369 [PMID 12724701].

THE BLIND CHILD

Vision is the principal route of sensory input. A child's development will therefore be affected profoundly by blindness or very poor vision. There are psychological consequences for the child blind from birth, as well as for the family. It can be devastating to a young family to find out that their newborn is blind. Although acquired blindness may give an individual time to grow as a sighted person and make preparations for life as a nonsighted person if loss of vision is slow and predicted, psychological consequences for the child and family must be addressed. The child blind from birth or

from very early childhood has had little or no opportunity to form visual impressions of the physical world. Blind children and their families should receive the benefit of knowledgeable therapists and support groups.

Blind infants reach developmental landmarks on a different schedule from that of sighted children. In addition, some blind children are multiply handicapped. For example, the premature child who is blind from ROP may also have cerebral palsy. Children with Usher syndrome become both deaf and blind.

Leading causes of blindness in the pediatric age group differ among regions of the world and between industrialized nations and developing countries. The most common causes of blindness in the pediatric age group are thought to be cerebral visual impairment, ROP, and optic nerve hypoplasia. Albinism, optic atrophy, cataract, retinitis pigmentosa, microphthalmia or anophthalmia, aniridia, and glaucoma are other diseases causing blindness.

LEARNING DISABILITIES & DYSLEXIA

Visits to the physician because of educational difficulties are common. Evaluation of the child with learning disabilities and dyslexia should include ophthalmologic examination to identify any ocular disorders that could cause or contribute to poor school performance. Most children with learning difficulties have no demonstrable problems on ophthalmic examination.

A multidisciplinary approach as suggested by the American Academy of Pediatrics, the American Association for Pediatric Ophthalmology and Strabismus, and the American Academy of Ophthalmology is recommended in evaluating children with learning disabilities. Although many therapies directed at "training the eyes" exist, scientific support for such approaches is weak.

Mathes PG et al: The prevention and identification of reading disability. *Semin Pediatr Neurol* 2002;9(3):185 [PMID 12350039].

VISION SCREENING

Vision screening in the pediatric age group is a challenge, especially in younger and developmentally delayed children. Accuracy of the screening test being administered to a particular population and expense in terms of time, equipment, and personnel are some of the factors that must be considered in screening individuals and groups. Vision screening is consistent with

the recommendations of the American Academy of Pediatrics (www.aap.org). Risk factors that should be screened for because they interfere with normal visual development and are amblyogenic include media opacities, strabismus, and refractive errors that are different in the two eyes (anisometropia) or of large magnitude in both eyes.

The practitioner should have an understanding of the limitations of the screening test being administered. For example, one study cites the sensitivity and specificity of visual acuity screening in preschool children as 90% and 44%, respectively. When possible, visual acuity of each eye and alignment of the two eyes should be assessed. (See Visual Acuity section for acceptable acuities at different ages.) Two caveats are to be observed when testing monocular visual acuity. First, in an amblyopic patient who demonstrates the crowding phenomenon, an amblyopic eye may score better when presented with single, isolated targets than with multiple targets on a line. Second, monocular visual acuity is worse in a patient with latent nystagmus. Preschool and young school-age children often test better when looking at a visual acuity chart at a 10-foot distance than at one placed at 20 feet or when looking into the type of machine typically used at a motor vehicle department.

When it is not possible to measure visual acuity or assess alignment in the preschool-age group, random dot stereopsis testing (for depth perception) is effective in screening for manifest strabismus and amblyopia, but this test may miss some cases of anisometropic (unequal refractive error) amblyopia and small-angle strabismus. This test is not designed to detect refractive errors.

An innovative technique that is being used more frequently in the pediatric age group and may prove useful for developmentally delayed children and perhaps infants is photoscreening. Photoscreening relies on the Brückner test of corneal light reflexes. Photoscreening does not screen directly for amblyopia but for amblyogenic factors, which include strabismus, media opacities, and refractive errors. Automated methods of pho-

toscreening are still being validated. Problems exist with sensitivity and specificity of the instruments, and the role of their use in the pediatric population remains a controversy.

William A. Mueller, DMD

The American Academy of Pediatric Dentistry (AAPD) and the American Academy of Pediatrics recommend that a child's first oral examination be performed no later than age 12 months, and optimally within 6 months after eruption of the first tooth. This recommendation is intended to establish the child's dental home and provide an opportunity to implement preventive dental health habits. Because the bacterial infection causing dental caries can be acquired as early as age 14 months, waiting until age 3 years, which was the prior recommendation, allows for significant disease progression before treatment. Pediatric dentists are knowledgeable about nursing caries and other types of caries, and their familiarity with the effectiveness of sealants, fluorides, and cariology makes them the parents' best resource for help in rearing caries-free children. Some experts have even suggested that infant oral health begin with prenatal oral health counseling.

Most oral disease in children is preventable. Oral evaluation of a child should consist of infant risk assessment and anticipatory guidance. This approach advances dental care past tooth monitoring to health promotion. Infant risk assessment determines the danger for each child of developing oral disease. Anticipatory guidance is directed toward individualized cost-effective use of dental services. Because pediatricians and other pediatric health care professionals are far more likely to encounter new mothers and infants than are dentists, it is essential that they be aware of the infectious pathophysiology and associated risk factors of early childhood dental caries to make appropriate decisions regarding effective intervention.

The primary goals for an infant oral health program are (1) to establish with parents the goals of oral health, (2) to inform parents of their role in reaching these goals, (3) to motivate parents to learn and practice good preventive dental care, and (4) to initiate a long-term dental care relationship with parents. Pediatricians should incorporate oral health into anticipatory guidance either by learning to provide this information in their offices or by referring the child to a pediatric dental colleague.

ORAL EXAMINATION OF THE NEWBORN & INFANT

The mouth of the normal newborn is lined with an intact, smooth, moist, and shiny mucosa (Figure 16–1). The alveolar ridges are continuous and relatively smooth. Within the alveolar bone are numerous tooth buds, which at birth are mostly primary teeth and a few permanent teeth just starting to calcify.

Teeth

The primary teeth begin to form at approximately 6 weeks' gestation, and their calcification starts in the second trimester. The permanent teeth are just beginning to develop at birth. There is enough development of permanent teeth to permit their damage by perinatal or antenatal insults such as anoxia, severe jaundice, or infection.

The primary teeth usually begin to erupt at approximately age 6–7 months. However, on rare occasions (1:2000), teeth are present at birth (natal teeth) or erupt within the first month (neonatal teeth). These are most common in the anterior mandible and can be "real" primary teeth or supernumerary teeth. These can be differentiated radiographically. On occasion, these teeth must be removed to facilitate nursing, heal persistent ulceration of the tongue, or eliminate the risk of aspiration.

Frena

Noticeable but small maxillary and mandibular labial frena should be present (Figure 16–2). Several small accessory frena may also be present farther posteriorly. The extreme is multiple thick tightly bound frena, as in oral–facial–digital syndrome. Decisions about if and when a labial frenum should be reduced surgically are best left until adolescence. Many thick frena need not be corrected.

The tongue is connected to the floor of the mouth by the lingual frenum (Figures 16–1 and 16–3). This

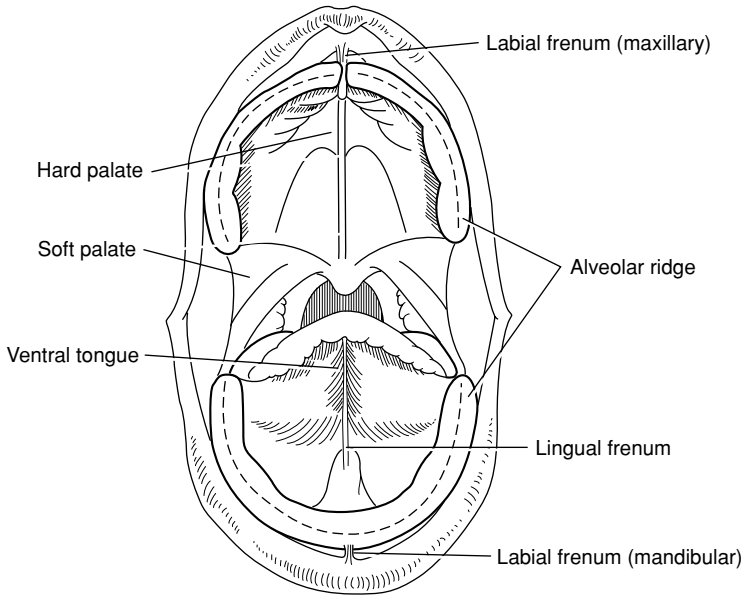

Figure 16-1. Normal anatomy of the newborn mouth.

connection should not impede the free movement of the tongue. If the attachment is tight and high up on the alveolar ridge (Figure 16-4), it may restrict movement and cause periodontal damage. This condition is called ankyloglossia (tongue-tie). If it needs to be corrected surgically, earlier (at age 3–4 years) is better than later, but there is usually no urgency for surgery in the neonatal period.

Palate

The palate of the newborn should be intact and continuous from the alveolar ridge anteriorly to the uvula (see Figure 16-1). Cleft lip and palate are common defects (1:700 live births). The cleft of the palate can be unilateral or bilateral (Figure 16-5). The cleft can involve just the alveolar ridge, as in Figure 16-5, or the ridge

Figure 16-2. The frena.

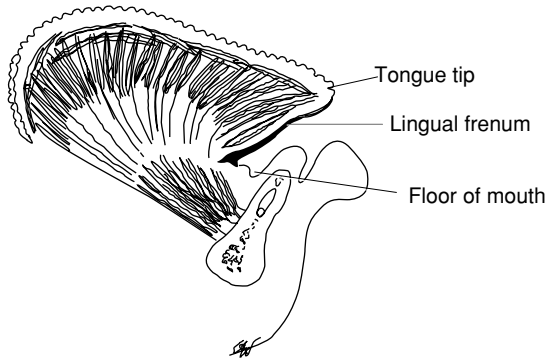

Figure 16-3. Normal position of lingual frenum.

and entire palate. Clefts can also be isolated soft palate defects. This is common in the Pierre Robin syndrome. Cleft palate may also present a submucous cleft, which may be detected by passing a finger posteriorly along the midline of the palate. Normally the posterior nasal spine is detectable, but if a submucous cleft is present, a bony notch will be found. Affected children sometimes have a bifid uvula.

Cleft lip and palate rehabilitation requires an extensive program involving many specialties and can be a lifelong endeavor. Children with cleft palate are best treated by a cleft palate team with coordinated care from relevant specialties. Cleft lip and palate treatment begins immediately after birth with fabrication of a palatal obturator as a feeding aid. This appliance also helps approximate the alveolar segments in order to facilitate the initial lip repair. In the case of bilateral cleft lip and palate, the dentist will often apply extraoral orthopedic traction to guide the protruding premaxilla back into the oral cavity to facilitate surgical lip closure.

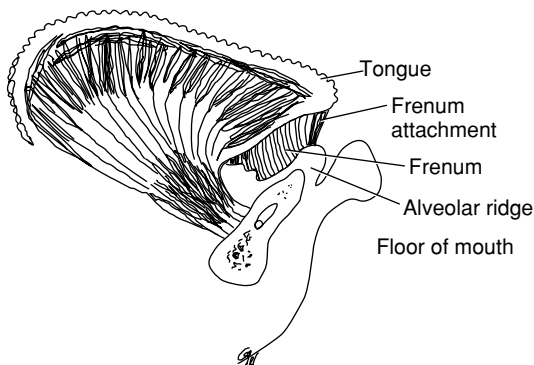

Figure 16-4. Ankyloglossia (tongue-tie).

Dental involvement in children with cleft palate is extensive and is coordinated by the cleft palate team.

Other Soft Tissue Variations

Other minor soft tissue variations can exist in the newborn mouth. Small (1–2 mm), round, smooth, whitish bumps can appear on the alveolar ridges or the palate. These are keratin cysts and are called Epstein pearls or dental lamina cysts. They are benign and require no treatment because they usually disappear.

Some newborns may have small intraoral lymphangiomas on the alveolar ridge or the floor of the mouth. These and any other soft tissue variations that are more noticeable or larger than those just described should be evaluated by a dentist familiar with neonates.

ERUPTION OF THE TEETH

Normal Eruption

As the child grows and begins to develop teeth, problems of teething may occur. Primary teeth generally begin to erupt at about age 6 months. They are usually mandibular incisors, but can be maxillary, and appear as early as age 3–4 months or as late as age 12–16 months. Many side effects are ascribed to teething, such as diarrhea, drooling, fever, and rash. But any real correlation is doubtful.

Common treatment for teething pain has been application of a topical anesthetic or “teething gel.” Most of these agents contain benzocaine or, less commonly, lidocaine. They can cause numbness of the entire oral cavity and pharynx, and suppression of the gag reflex can be a serious side effect. Systemic analgesia (acetaminophen or ibuprofen) is safer and more effective. Solid rubber or chilled fluid-filled teething toys are beneficial, if only for distraction purposes. Massaging the gums can be very soothing.

Occasionally, swelling of the gingiva is seen during teething. This condition can appear as red to purple, round, raised, smooth lesions that may be symptomatic but usually are not. They appear in the anterior or posterior alveolar ridge and on the crest. These so-called eruption cysts or eruption hematomas are fluid-filled areas immediately overlying an erupting tooth and generally disappear spontaneously.

Delayed Eruption

Premature loss of a primary tooth can either accelerate or delay eruption of the underlying secondary tooth. Early eruption occurs when the permanent tooth is beginning its active eruption and the overlying primary tooth is removed. This generally occurs when the primary tooth is within 1 year of its normal exfoliation. If,

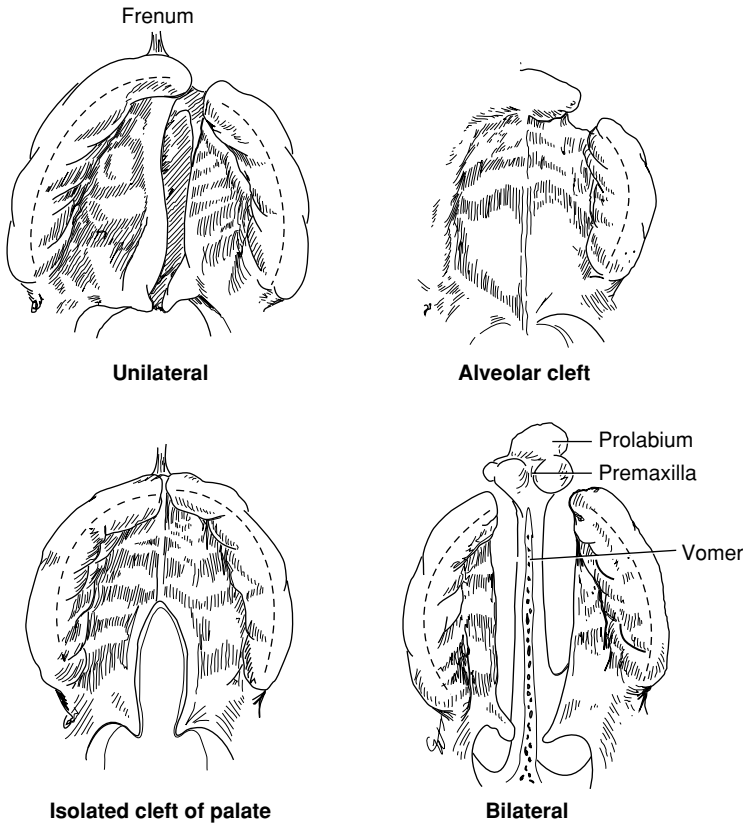

Figure 16-5. Types of clefts.

however, loss of the primary tooth occurs more than 1 year before expected exfoliation, the permanent tooth will probably be delayed in eruption owing to healing that results in filling in of bone and gingiva over the permanent tooth. The loss of a primary tooth may cause adjacent teeth to tip into the space and lead to impaction of the underlying permanent tooth. A space maintainer should be placed by a dentist to avoid this.

Other local factors delaying or preventing eruption include supernumerary teeth, cysts, tumors, overretained primary teeth, ankylosed primary teeth, and impaction. A generalized delay in eruption may be due to endocrinopathies (hypothyroidism, hypopituitarism) or other systemic conditions (cleidocranial dysplasia, rickets, trisomy 21).
