Treatment of these disorders is a challenge for transplant physicians and oncologists. The initial treatment is reduction in immunosuppression, which allows the patient's own immune effector cells to destroy the virally transformed lymphocytes. However, this is only effective in approximately half of patients. For those patients who do not respond to reduced immune suppression, chemotherapy of various regimens may succeed. EBV LPDs in some transplant recipients may be prevented or experimentally treated by infusion of EBV-specific T cells or even unmanipulated donor leukocytes. Additionally, the use of anti-B-cell antibodies, such as anti-CD20 (rituximab), for the treatment of PTLDs has been promising in early trials.

Spontaneous Lymphoproliferative Disease

Immunodeficiencies in which LPDs occur include Bloom syndrome, Chédiak–Higashi syndrome, ataxia–telangiectasia, Wiskott–Aldrich syndrome, X-linked lymphoproliferative syndrome, congenital T-cell immunodeficiencies, and HIV infection. Treatment depends on the circumstances, but unlike PTLD few therapeutic options are often available. Castleman disease is an LPD occurring in pediatric patients without any apparent immunodeficiency. The autoimmune lymphoproliferative syndrome (ALPS) is characterized by widespread lymphadenopathy with hepatosplenomegaly, and autoimmune phenomena. ALPS results from mutations in the Fas ligand pathway that is critical in regulation of apoptosis.

NEUROBLASTOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bone pain, abdominal pain, anorexia, weight loss, fatigue, fever, irritability.

- *Abdominal mass (65%), adenopathy, proptosis, periorbital ecchymosis, skull masses, subcutaneous nodules, hepatomegaly, spinal cord compression.*

General Considerations

Neuroblastoma (NB) arises from neural crest tissue of the sympathetic ganglia or adrenal medulla. It is composed of small, fairly uniform cells with little cytoplasm and hyperchromatic nuclei that may form rosette patterns. Pathologic diagnosis is not always easy, and NB must be differentiated from the other “small, round, blue cell” malignancies of childhood (Ewing sarcoma, rhabdomyosarcoma, peripheral neuroectodermal tumor, lymphoma).

NB accounts for 7–10% of pediatric malignancies and is the most common solid neoplasm outside the CNS. Fifty percent of NBs are diagnosed before age 2 years and 90% before age 5 years.

The biologic diversity of NB makes this a fascinating tumor for study. Spontaneous regression in stage 4-S disease (small primary, with metastases confined to liver, skin, or bone marrow in infants younger than age 1 year) and spontaneous or induced differentiation to a benign neoplasm are examples of the unique behavior of this tumor. Unfortunately NB is also an extremely malignant neoplasm, and the overall survival rate in advanced disease has changed little in 20 years despite significant advances in our understanding of this tumor at a cellular and molecular level.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical manifestations vary with the primary site of metastatic disease and the neuroendocrine function of the tumor. Many children present with constitutional symptoms such as fever, weight loss, and irritability. Bone pain suggests metastatic disease, which is present in 70% of children older than age 1 year at diagnosis. Physical examination may reveal a firm, fixed, irregularly shaped mass that extends beyond the midline. The margins are often poorly defined. Although most children have an abdominal primary tumor (40% adrenal gland, 25% paraspinal ganglion), NB can arise wherever there is sympathetic tissue. In the posterior mediastinum, the tumor is usually asymptomatic and discovered on a chest radiograph obtained for other reasons. Patients with cervical NB present with a neck mass, which is often misdiagnosed as infection. Horner syndrome (unilateral ptosis, myosis, and anhidrosis) or heterochromia iridis (differently colored irises) may ac-

company cervical NB. Paraspinal tumors can extend through the spinal foramina, causing cord compression. Patients may present with paresis, paralysis, and bowel or bladder dysfunction.

The most common sites of metastases are bone, bone marrow, lymph nodes (regional as well as disseminated), liver, and subcutaneous tissue. NB has a predilection for metastasis to the skull, in particular the sphenoid bone and retrobulbar tissue. This causes periorbital ecchymosis and proptosis. Liver metastasis, particularly in the newborn, can be massive. Subcutaneous nodules are bluish in color and associated with an erythematous flush followed by blanching when compressed, probably secondary to catecholamine release.

NB may also be associated with unusual paraneoplastic manifestations. Examples include chronic watery diarrhea associated with tumor secretion of vasoactive intestinal peptides and opsoclonus–myoclonus (so-called dancing eyes/dancing feet syndrome). It is postulated that the neurologic manifestations are secondary to cross-reacting antibodies and often persist even after therapy.

B. LABORATORY FINDINGS

Anemia is present in 60% of children with NB and can be due to chronic disease or marrow infiltration. Thrombocytopenia may be present. Thrombocytosis is a more common finding than thrombocytopenia, even with metastatic disease in the marrow. Urinary catecholamines (vanillylmandelic acid, homovanillic acid) are elevated in at least 90% of patients at diagnosis and should be measured prior to surgery. An elevated level of ferritin and LDH at diagnosis appears to have prognostic significance, especially when combined with age, stage, and tumor histology.

C. IMAGING

Plain radiographs of the primary tumor may show stippled calcifications. CT scanning provides more information, including the extent of the primary tumor, its effects on surrounding structures, and the presence of liver and lymph node metastases. Classically, in tumors originating from the adrenal, the kidney is displaced inferolaterally, which helps to differentiate NB from Wilms tumor. MRI is useful in determining the presence of spinal cord involvement in tumors that appear to invade neural foramina.

Both skeletal survey and technetium bone scanning are obtained in the evaluation of bone metastases. NB may often be seen on bone scan because it takes up technetium. On plain radiographs, lesions are usually symmetrical and appear irregular and lytic, and periosteal reaction and pathologic fractures may also be seen. Metaiodobenzyl-guanidine (MIBG) scanning has been shown to be very sensitive for evaluating metastatic disease in NB, particularly for detecting bone and

bone marrow metastases. Response to induction chemotherapy can also be evaluated by MIBG scanning and may be of prognostic significance.

D. STAGING

Staging of NB is performed according to the International Neuroblastoma Staging System (INSS), which has been implemented worldwide. In addition to the radiographic evaluation, a tissue diagnosis must be established. Tumors are histologically classified as either favorable or unfavorable based on a modified Shimada system. In addition, bilateral bone marrow aspirates and biopsies must be performed to evaluate marrow involvement, even if the CBC is normal.

Molecular parameters are essential to supplement clinical staging and aid in treatment planning. Amplification of the *MYCN* proto-oncogene or its gene product can be detected in approximately 20% of NBs. It is a reliable marker of aggressive clinical behavior with rapid disease progression. Tumor cell DNA content is also predictive of outcome. Hyperdiploidy is a favorable finding, whereas diploid DNA content is associated with a poorer outcome. Common cytogenetic abnormalities associated with high-risk features and adverse outcome include deletion of the short arm of chromosome 1 and gains of 17q genetic material

Treatment & Prognosis

When deciding on a treatment plan, the COG uses a risk stratification system (low, intermediate, or high) based on INSS stage, age, *MYCN* status, histology, and DNA index. The mainstay of NB therapy is surgical resection coupled with chemotherapy. The usually massive size of the tumor often makes primary resection impossible. Under these circumstances, only a biopsy may be performed. Following chemotherapy, a second surgical procedure may allow for resection of the primary tumor. Radiation is sometimes also necessary. Effective chemotherapeutic agents in the treatment of NB include cyclophosphamide, doxorubicin, etoposide, cisplatin, vincristine, and topotecan. There is clear dose-response relationship in NB. About 80% of patients achieve complete or partial remission, although in advanced disease, remission is seldom durable.

For low-risk disease (stage 1, and 2), surgical resection alone may be sufficient to affect a cure. Infants younger than 1 year with stage 4 disease may need little if any therapy although chemotherapy may be initiated because of bulky disease causing mechanical complications. In intermediate-risk NB (subsets of patients with stage 3 and 4 disease) the primary treatment approach is surgical combined with chemotherapy. High-risk patients (the majority with stage 3 and 4 disease) require multimodal therapy, including surgery, radia-

tion, chemotherapy, and even autologous stem cell transplant. In a recent CCG study, autologous HSCT was unequivocally shown to improve survival rates in this group of patients.

Several clinical trials are under way in high-risk patients using radiolabeled MIBG and ch14.18 (a human–mouse monoclonal antibody specific for ganglioside GD2, the predominant antigen on NB cells) as well as interleukin-2 (IL-2) to eradicate minimal residual disease. A phase III randomized trial conducted by CCG has shown that the administration of *cis*-retinoic acid, a differentiating agent, can prolong disease-free survival in advanced-stage NB when administered in the setting of minimal residual disease after HSCT. Current phase I and II studies are underway using fenretinide (4-HPR), a synthetic retinoid.

For children with stage 1, 2, or 4-S disease, the 5-year survival rate is 70–90%. Infants younger than age 1 year who have stage 4 disease have a greater than 60% likelihood of long-term survival. Children older than age 1 year with stage 3 disease have an intermediate prognosis (approximately 40–70%), and those with stage 4 disease have a poor prognosis (5–50% survival 5 years from diagnosis).

WILMS TUMOR (NEPHROBLASTOMA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Asymptomatic abdominal mass or swelling (83%).*
- *Fever (23%), hematuria (21%).*
- *Hypertension (25%), genitourinary malformations (6%), aniridia, hemihypertrophy.*

General Considerations

Approximately 460 new cases of Wilms tumor occur annually in the United States, representing 5–6% of cancers in children younger than age 15 years. After neuroblastoma, this is the second most common abdominal tumor in children. The tumor arises from kidney and is usually composed of three elements: blastema, epithelium, and stroma. The majority of Wilms tumors are of sporadic occurrence. However, in a few children, Wilms tumor occurs in the setting of associated malformations or syndromes, including aniridia, hemihypertrophy, genitourinary malformations (eg, cryptorchidism, hypospadias, gonadal dysgenesis, pseudohermaphroditism, horseshoe kidney), Beckwith–Wiedemann syndrome, Denys–Drash syndrome, and WAGR syndrome (Wilms tumor, aniridia, ambiguous genitalia, mental retardation). Although most patients with Wilms tumor are karyotypically normal, those with sporadic aniridia frequently have a constitutional deletion at the 11p13 locus. This deletion has also been found in the tumor cells of Wilms patients without aniridia who are karyotypically normal.

The median age at diagnosis is related both to gender and laterality, with bilateral tumors presenting at a younger age than unilateral tumors, and males being diagnosed earlier than females. Wilms tumor occurs most commonly between ages 2 and 5 years; it is unusual after age 6 years. The mean age at diagnosis is 4 years.

Clinical Findings

A. SYMPTOMS AND SIGNS

Most children with Wilms tumor present with increasing size of the abdomen or an asymptomatic abdominal mass incidentally discovered by a parent. The mass is usually smooth and firm, well demarcated, and rarely crosses the midline, though it can extend inferiorly into the pelvis. Gross hematuria is an uncommon presentation, although microscopic hematuria occurs in approximately 25% of patients.

B. LABORATORY FINDINGS

The CBC is usually normal, but some patients have anemia secondary to hemorrhage into the tumor. Blood urea nitrogen and serum creatinine are usually normal. Urinalysis may show some blood or leukocytes.

C. IMAGING AND STAGING

Ultrasonography or CT of the abdomen should establish the presence of an intrarenal mass. It is also essential to evaluate the contralateral kidney for presence and function as well as synchronous Wilms tumor. The inferior vena cava needs to be evaluated by ultrasonography for the presence and extent of tumor propagation.

The liver should be imaged for the presence of metastatic disease. A plain chest radiograph (four views) or chest CT scans (or both) should be obtained to determine whether pulmonary metastases are present. Approximately 10% of patients will have metastatic disease at diagnosis. Of these, 80% will have pulmonary disease and 15% liver metastases. Bone and brain metastases are extremely uncommon and usually associated with more aggressive renal tumors, such as clear cell sarcoma or rhabdoid tumor; hence, bone scans and brain imaging are not routinely performed. The clinical stage is ultimately decided at surgery and confirmed by the pathologist.

Treatment & Prognosis

In the United States, treatment of Wilms tumor begins with surgical exploration of the abdomen via an anterior surgical approach to allow for inspection and palpation of the contralateral kidney. The liver and lymph nodes are inspected and suspicious areas biopsied or excised. En bloc resection of tumor is performed. Every attempt is made to avoid tumor spillage at surgery. Because therapy is tailored to tumor stage, it is imperative that a surgeon familiar with the staging requirements perform the operation.

In addition to the staging, the histologic type has implications for therapy and prognosis. Favorable histology (FH; see later discussion) refers to the classic triphasic Wilms tumor and its variants. Unfavorable histology (UH) refers to the presence of diffuse anaplasia (extreme nuclear atypia) and is present in 5% of Wilms tumors. Only a few small foci of anaplasia in a Wilms tumor give a worse prognosis to patients with stage II, III, or IV tumors. Following excision and pathologic examination, the patient is assigned a stage that defines further therapy.

Although clear cell sarcoma of the kidney (CCSK) and rhabdoid tumor of the kidney were previously classified as UH Wilms tumor, they are no longer thought to be Wilms tumor variants, but rather separate renal malignancies.

Progress in the treatment of Wilms tumor stems from clinical trials by the National Wilms Tumor Study (NWTs) begun in 1969 that resulted in an overall cure rate of approximately 90%. NWTs-4 demonstrated that survival rates were improved by intensifying therapy during the initial treatment phase while shortening overall treatment duration (24 weeks vs 60 weeks of treatment). It is the first study of a pediatric population to evaluate the economic effect of two different treatment approaches.

Table 28–7 provides an overview of the current treatment recommendations in NWTs-5. Patients with stage III or IV Wilms tumor require radiation therapy

Table 28–7. Treatment of Wilms tumor

Stage/Histologic Subtype	Treatment
I–II FH and I UH	18 wk (dactinomycin and vincristine)
III–IV FH and II–IV focal anaplasia	24 wk (dactinomycin, vincristine, and doxorubicin) with radiation
II–IV UH (diffuse anaplasia)	24 wks (vincristine, doxorubicin, etoposide, and cyclophosphamide with radiation)

to the tumor bed and to sites of metastatic disease. Chemotherapy is optimally begun within 5 days after surgery, whereas radiation therapy should be started within 10 days. Stage V (bilateral Wilms tumor) disease dictates a different approach, consisting of bilateral renal biopsies followed by chemotherapy and second-look renal-sparing surgery. Radiation may also be necessary.

Using these approaches, 4-year overall survival rates through NWTS-4 are as follows: stage I FH, 96%; stage II–IV FH, 82–92%; stage I–III UH (diffuse anaplasia), 56–70%; stage IV UH, 17%. Patients with recurrent Wilms tumor have approximately a 50% salvage rate with surgery, radiation therapy, and chemotherapy (singly or in combination). HSCT is also being explored as a way to improve the chances of survival after relapse.

Future Considerations

Although progress in the treatment of Wilms tumor has been extraordinary, important questions remain to be answered. Questions are being raised regarding the role of prenephrectomy chemotherapy in the treatment of Wilms tumor. Presurgical chemotherapy seems to decrease tumor rupture at resection but may unfavorably affect outcome by changing staging. Whether pulmonary radiation can be eliminated in metastatic pulmonary disease is also being investigated.

BONE TUMORS

Primary malignant bone tumors are uncommon in childhood. Osteosarcoma accounts for 60% of cases and occurs mostly in adolescents and young adults. Ewing sarcoma is the second most common malignant tumor of bony origin. Both tumors have a male predominance.

The cardinal signs of bone tumor are pain at the site of involvement, often following slight trauma; mass formation; and fracture through an area of cortical bone destruction.

1. Osteosarcoma

General Considerations

Although osteosarcoma is the sixth most common malignancy in childhood, it ranks third among adolescents and young adults. This peak occurrence during the adolescent growth spurt suggests a causal relationship between rapid bone growth and malignant transformation. Further evidence for this relationship is found in epidemiologic data showing patients with osteosarcoma to be taller than their peers, osteosarcoma occurring most frequently at sites where the greatest increase in length and size of bone occurs, and osteosarcoma occurring at an earlier age in girls than boys, corresponding to their earlier growth spurt. The metaphyses of long tubular bones are primarily affected. The distal femur accounts for more than 40% of cases, with the proximal tibia, proximal humerus, and mid and proximal femur following in frequency.

Clinical Findings

A. SYMPTOMS AND SIGNS

Pain over the involved area is the usual presenting symptom with or without an associated soft tissue mass. Systemic symptoms (fever, weight loss) are rare. Laboratory evaluation may reveal elevated serum alkaline phosphatase or LDH levels.

B. IMAGING AND STAGING

Radiographic findings show permeative destruction of the normal bony trabecular pattern with indistinct margins. In addition, periosteal new bone formation and lifting of the bony cortex may create a Codman triangle. A soft tissue mass plus calcifications in a radial or sunburst pattern are frequently noted. MRI is more sensitive in defining the extent of the primary tumor and in many centers has replaced CT scanning. The most common sites of metastases are the lung ($\leq 20\%$

of newly diagnosed cases) and the bone (10%). A CT scan of the chest and a bone scan are essential for detecting metastatic disease. Bone marrow aspirates and biopsies are not indicated.

Despite the rather characteristic radiographic appearance, a tissue sample is needed to confirm the diagnosis. Placement of the incision for biopsy is of critical importance. A misplaced incision could preclude a limb salvage procedure and necessitate amputation. The surgeon who will carry out the definitive surgical procedure should perform the biopsy. A staging system for osteosarcoma based on local tumor extent and presence or absence of distant metastasis has been proposed, but it has not been validated.

Treatment and Prognosis

Historical studies showed that over 50% of patients receiving surgery alone developed pulmonary metastases within 6 months after surgery. This suggests the presence of micrometastatic disease at diagnosis. Adjuvant chemotherapy trials showed improved disease-free survival rates of 55–85% after 3–10 years of follow-up.

Osteosarcomas are highly radioresistant lesions; for this reason, radiation therapy has no role in its primary management. Chemotherapy is often administered prior to definitive surgery (neoadjuvant chemotherapy). This permits an early attack on micrometastatic disease and may also shrink the tumor, facilitating a limb salvage procedure. Preoperative chemotherapy also makes detailed histologic evaluation of tumor response to the chemotherapy agents possible. If the histologic response is poor (> 10% viable tumor tissue), postoperative chemotherapy can be changed accordingly. Chemotherapy may be administered intra-arterially or intravenously, although the benefits of intra-arterial chemotherapy are disputed. Agents having efficacy in the treatment of osteosarcoma include doxorubicin, cisplatin, high-dose methotrexate, and ifosfamide.

Definitive cure requires en bloc surgical resection of the tumor with a margin of uninvolved tissue. Amputation and limb salvage are equally effective in achieving local control of osteosarcoma. Contraindications to limb-sparing surgery include major involvement of the neurovascular bundle by tumor; immature skeletal age, particularly for lower extremity tumors; infection in the region of the tumor; inappropriate biopsy site; and extensive muscle involvement that would result in a poor functional outcome.

Postsurgical chemotherapy is generally continued until the patient has received 1 year of treatment. Relapses are unusual beyond 3 years, but late relapses do occur. Histologic response to neoadjuvant chemotherapy is an excellent predictor of outcome. Patients having 90% tumor necrosis have a 70–90% long-term, dis-

ease-free survival rate. Other favorable prognostic factors include distal skeletal lesions, longer duration of symptoms, age older than 20, female gender, and near-diploid tumor DNA index.

2. Ewing Sarcoma

General Considerations

Ewing sarcoma accounts for only 10% of primary malignant bone tumors; fewer than 200 new cases occur each year in the United States. It is a disease primarily of white males, almost never affects blacks, and occurs mostly in the second decade of life. Ewing sarcoma is considered a “small, round, blue cell” malignancy. The differential diagnosis includes rhabdomyosarcoma, lymphoma, and neuroblastoma. Although most commonly a tumor of bone, it may also occur in soft tissue (extraosseous Ewing sarcoma or peripheral neuroectodermal tumor [PNET]).

Clinical Findings

A. SYMPTOMS AND SIGNS

Pain at the site of the primary tumor is the most common presenting sign, with or without swelling and erythema. No specific laboratory findings are characteristic of Ewing sarcoma, but an elevated LDH may be present and is of prognostic significance.

B. IMAGING AND STAGING

The radiographic appearance of Ewing sarcoma overlaps with osteosarcoma, although Ewing sarcoma usually involves the diaphyses of long bones. The central axial skeleton gives rise to 40% of Ewing tumors. Evaluation of a patient diagnosed as having Ewing sarcoma should include CT scan or MRI (or both) of the primary lesion to define the extent of local disease as precisely as possible. This is imperative for planning future surgical procedures or radiation therapy. Metastatic disease is present in 25% of patients at diagnosis. The lung (38%), bone (particularly the spine) (31%), and the bone marrow (11%) are the most common sites for metastasis. CT scan of the chest, bone scanning, and bilateral bone marrow aspirates and biopsies are all essential to the staging work-up.

A biopsy is essential in establishing the diagnosis. Histologically, Ewing sarcoma consists of sheets of undifferentiated cells with hyperchromatic nuclei, well-defined cell borders, and scanty cytoplasm. Necrosis is common. Electron microscopy, immunocytochemistry, and cytogenetics may be necessary to confirm the diagnosis. A generous tissue biopsy specimen is often necessary for diagnosis but should not delay starting chemotherapy.

A consistent cytogenetic abnormality, t(11;22), has been identified in Ewing sarcoma and PNET and is present in 85–90% of tumors. These tumors also express the proto-oncogene *c-myc*, which may be helpful in differentiating Ewing sarcoma from neuroblastoma, where it is not expressed.

Therapy usually commences with the administration of chemotherapy after biopsy and is followed by local control measures. Depending on many factors, including the primary site of the tumor and the response to chemotherapy, local control could be achieved by surgery, radiation therapy, or a combination of these methods. Following local control, chemotherapy continues for approximately 1 year. Effective treatment for Ewing sarcoma uses combinations of dactinomycin, vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Patients with small localized primary tumors have a 50–70% long-term, disease-free survival rate. For patients with metastatic disease and large pelvic primary tumors, survival is poor. Autologous HSCT is being investigated for the treatment of these high-risk patients.

RHABDOMYOSARCOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Painless, progressively enlarging mass; proptosis; chronic drainage (nasal, aural, sinus, vaginal); cranial nerve palsies.*
- *Urinary obstruction, constipation, hematuria.*

General Considerations

Rhabdomyosarcoma is the most common soft tissue sarcoma occurring in childhood and accounts for 10% of solid tumors in childhood. The peak incidence is at age 2–5 years; 70% of children are diagnosed before age 10 years. A second smaller peak is seen in adolescents with extremity tumors. Males are affected more commonly than females.

Arising from embryonic mesenchymal cells, rhabdomyosarcoma can occur anywhere in the body. When rhabdomyosarcoma imitates striated muscle and cross-striations are seen by light microscopy, the diagnosis is straightforward. Immunohistochemistry, electron microscopy, or chromosomal analysis is sometimes necessary to make the diagnosis. Rhabdomyosarcoma is further classified into subtypes based on pathologic features: embryonal (59%), of which botryoid is a variant; alveolar (21%); undifferentiated sarcoma (8%); pleomorphic, which is seen in adults (1%); and other (11%). These subtypes occur in characteristic locations and have different metastatic potentials and outcomes (Table 28–8).

Although the pathogenesis of rhabdomyosarcoma is unknown, in rare cases a genetic predisposition has been determined. Li–Fraumeni syndrome is an inherited mutation of the *p53* tumor suppressor gene that results in a high risk of bone and soft tissue sarcomas in childhood plus breast cancer and other malignant neoplasms before age 45 years. A characteristic chromosomal translocation [t(2;13)] has been described in alveolar rhabdomyosarcoma. A recent analysis from the Intergroup Rhabdomyosarcoma Study Group-IV (IRSG-IV) suggests that the gene fusion protein associated with this translocation is of poor prognostic significance.

Clinical Findings

A. SYMPTOMS AND SIGNS

The presenting symptoms and signs of rhabdomyosarcoma result from disturbances of normal body function due to tumor growth (see Table 28–8). For example, patients with orbital rhabdomyosarcoma present with proptosis, whereas patients with rhabdomyosarcoma of the bladder can present with hematuria, urinary obstruction, or a pelvic mass.

B. IMAGING

A plain radiograph and a CT or MRI scan should be obtained to determine the extent of the primary tumor and to assess regional lymph nodes. A lung CT scan is obtained to rule out pulmonary metastasis, the most common site of metastatic disease at diagnosis. A skeletal survey and a bone scan are obtained to determine whether bony metastases are present. Bilateral bone

Table 28–8. Characteristics of rhabdomyosarcoma.

Primary Site	Frequency (%)	Symptoms and Signs	Predominant Pathologic Subtype
Head and neck	35		Embryonal
Orbit	9	Proptosis	
Parameningeal	16	Cranial nerve palsies; aural or sinus obstruction with or without drainage	
Other	10	Painless, progressively enlarging mass	
Genitourinary	22		Embryonal (botryoid variant in bladder and vagina)
Bladder and prostate	13	Hematuria, urinary obstruction	
Vagina and uterus	2	Pelvic mass, vaginal discharge	
Paratesticular	7	Painless mass	
Extremities	18	Adolescents, swelling of affected body part	Alveolar (50%), undifferentiated
Other	25	Mass	Alveolar, undifferentiated

marrow biopsies and aspirates are obtained to rule out bone marrow infiltration. Additional studies may be warranted in certain sites. For example, in parameningeal primaries, a lumbar puncture is performed to evaluate CSF for tumor cells.

Treatment

Optimal management and treatment of rhabdomyosarcoma is complex and requires combined modality therapy. When feasible, the tumor should be excised, but this is not always possible because of the site of origin and size of tumor. When only partial tumor resection is feasible, the operative procedure is usually limited to biopsy and sampling of lymph nodes. The role of debulking of unresectable tumor is unclear. Chemotherapy can often convert an inoperable tumor to a resectable one. A second-look procedure to remove residual disease and confirm the clinical response to chemotherapy and radiation therapy is generally performed at about week 20 of therapy.

Radiation therapy is an effective method of local tumor control for both microscopic and gross residual disease. It is generally administered to all patients, the only exception being those with localized tumor that has been completely resected. All patients with rhabdomyosarcoma receive chemotherapy, even when the tumor is fully resected at diagnosis. The exact regimen and duration of chemotherapy are determined by primary site, group, and tumor node metastasis (TNM) classification. Vincristine, dactinomycin, and cyclophosphamide have shown the greatest efficacy in the treatment of rhabdomyosarcoma.

Prognosis

The extent of tumor at diagnosis, the primary site, the pathologic subtype, and the response to treatment all influence the long-term, disease-free survival rate from the time of diagnosis. Children with localized disease at diagnosis have a 77% 3-year disease-free survival rate, whereas children with metastatic disease at presentation have a poorer outcome (3-year disease-free survival 39%).

Newer treatment strategies for high-risk patients include different drug combinations and dosing schedules with hematopoietic growth factor support, hyperfractionated radiation therapy, and autologous HSCT.

RETINOBLASTOMA

General Considerations

Retinoblastoma is a neuroectodermal malignancy arising from embryonic retinal cells that accounts for 3% of malignant disease in children younger than age 15 years. It is the most common intraocular tumor in pediatric patients and causes 5% of cases of childhood blindness. Two hundred to 300 new cases occur per year in the United States. This is a malignancy of early childhood, with 90% of the tumors diagnosed before age 5 years. Bilateral involvement occurs in 20–30% of children and typically is diagnosed at a younger age (median age 14 months) than unilateral disease (median age 23 months).

Retinoblastoma is the prototype of hereditary cancers due to a mutation in the retinoblastoma gene (*RBI*), which is located on the long arm of chromosome 13 (13q14). This gene is a tumor suppressor gene that normally controls cellular growth. When the gene is inactivated, as in retinoblastoma, cellular growth is uncontrolled. Uncontrolled cell growth leads to tumor formation. Inactivation of both *RBI* alleles within the same cell is required for tumor formation.

Retinoblastoma is known to arise in heritable and nonheritable forms. Based on the different clinical characteristics of the two forms, Knudson proposed a “two-hit” hypothesis for retinoblastoma tumor development. He postulated that two independent events were necessary for a cell to acquire tumor potential. Mutations at the *RBI* locus can be inherited or arise spontaneously. In heritable cases, the first mutation arises during gametogenesis, either spontaneously (90%) or through transmission from a parent (10%). This mutation is present in every retinal cell and in all other somatic and germ cells. Ninety percent of persons who carry this germline mutation will develop retinoblastoma. For tumor formation, the loss of the second *RBI* allele within a cell must occur; loss of only one allele is insufficient for tumor formation. The second mutation occurs in a somatic (retinal) cell. In nonheritable cases (60%), both mutations arise in a somatic cell after gametogenesis has taken place.

Clinical Findings

A. SYMPTOMS AND SIGNS

Children with retinoblastoma generally come to medical attention while the tumor is still confined to the globe. Although present at birth, retinoblastoma is not usually detected until it has grown to a considerable size. Leukocoria (white pupillary reflex) is the most common sign (found in 60% of patients). Parents may note an unusual appearance of the eye or asymmetry of

the eyes in a photograph. The differential diagnosis of leukocoria includes *Toxocara canis* granuloma, astrocytic hamartoma, retinopathy of prematurity, Coats disease, and persistent hyperplastic primary vitreous. Strabismus (in 20% of patients) is seen when the tumor involves the macula and central vision is lost. Rarely (in 7% of patients), a painful red eye with glaucoma, a hyphema, or proptosis is the initial manifestation. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Bilateral involvement occurs in 20–30% of children.

B. EVALUATION

Suspected retinoblastoma requires a detailed ophthalmologic examination under general anesthesia. An ophthalmologist makes the diagnosis of retinoblastoma by the appearance of the tumor within the eye without pathologic confirmation. A white to creamy pink mass protruding into the vitreous matter suggests the diagnosis; intraocular calcifications and vitreous seeding are virtually pathognomonic of retinoblastoma. A CT scan of the orbits detects intraocular calcification, evaluates the optic nerve for tumor infiltration, and detects extraocular extension of tumor. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Metastatic disease of the marrow and meninges can be ruled out with bilateral bone marrow aspirates and biopsies plus CSF cytology.

Treatment

Each eye is treated according to the potential for useful vision, and every attempt is made to preserve vision. The choice of therapy depends on the size, location, and number of intraocular lesions. Absolute indications for enucleation include no vision, neovascular glaucoma, inability to examine the treated eye, and inability to control tumor growth with conservative treatment. External beam irradiation has been the mainstay of therapy. A total dose of 35–45 Gy is administered. However, many centers are investigating the role of systemic chemotherapy for the treatment of retinoblastoma confined to the globe in an effort to eliminate the need for external beam radiotherapy. Cryotherapy, photocoagulation, and radioactive plaques can be used for local tumor control. Patients with metastatic disease receive chemotherapy.

Children with retinoblastoma confined to the retina (whether unilateral or bilateral) have an excellent prognosis, with 5-year survival rates greater than 90%. Mortality is correlated directly with extent of optic nerve involvement, orbital extension of tumor, and massive choroid invasion. Patients who have disease in the optic nerve beyond the lamina cribrosa have only a 40% 5-year survival rate. Patients with meningeal or

metastatic spread rarely survive, although intensive chemotherapy and autologous HSCT have produced long-term survivors.

Patients with the germline mutation (heritable form) have a significant risk of developing second primary tumors. Osteosarcomas account for 40% of such tumors. Second malignant neoplasms occur in both patients who have and those who have not received radiation therapy. The 30-year cumulative incidence for a second neoplasm is 35% in patients who received radiation therapy and 6% in those who did not receive radiation therapy. The risk continues to increase over time. Although radiation contributes to the risk, it is the presence of the retinoblastoma gene itself that is responsible for the development of nonocular tumors in these patients.

HEPATIC TUMORS

Two thirds of liver masses found in childhood are malignant. Ninety percent of hepatic malignancies are either hepatoblastoma or hepatocellular carcinoma. He-

patoblastomas are somewhat more frequent than hepatocellular carcinomas (51% vs 39%). A comparison of the features of these hepatic malignancies is presented in Table 28–9. Of the benign tumors, 60% are hamartomas or vascular tumors such as hemangiomas.

Children with hepatic tumors usually come to medical attention because of an enlarging abdomen. Approximately 10% of hepatoblastomas are first discovered on routine examination. Anorexia, weight loss, vomiting, and abdominal pain are associated more commonly with hepatocellular carcinoma. Serum AFP is often elevated and is an excellent marker for response to treatment.

Imaging studies should include abdominal ultrasound, CT scan, or MRI. Malignant tumors have a diffuse hyperechoic pattern on ultrasonography, whereas benign tumors are usually poorly echoic. Vascular lesions contain areas with varying degrees of echogenicity. Ultrasound is also useful for imaging the hepatic veins, portal veins, and inferior vena cava. CT scanning and, in particular, MRI are important for defining the extent of tumor within the liver. CT scanning of the chest and bone scan should be obtained to evaluate for metastatic spread.

Because bone marrow involvement is extremely rare, bone marrow aspirates and biopsies are not indicated. The prognosis for children with hepatic malignancies depends on the tumor type and the resectability of the tumor. Complete resectability is essential for survival. Chemotherapy can decrease the size of most hepatoblastomas. Following biopsy of the lesion, neoadjuvant chemotherapy is administered prior to attempting complete surgical resection. Chemotherapy can often con-

Table 28–9. Comparison of hepatoblastoma and hepatocellular carcinoma in childhood.

	Hepatoblastoma	Hepatocellular Carcinoma
Median age at presentation	1 y (0–3 y)	12 y (5–18 y)
Male-to-female ratio	1.7:1	1.4:1
Associated conditions	Hemihypertrophy, Beckwith–Wiedemann syndrome, prematurity, Gardner's syndrome	Hepatitis B virus infection, hereditary tyrosinemia, biliary cirrhosis, α_1 -antitrypsin deficiency
Pathologic features	Fetal or embryonal cells; mesenchymal component (30%)	Large pleomorphic tumor cells and tumor giant cells
Solitary hepatic lesion	80%	20–50%
Unique features at diagnosis	Osteopenia (20–30%), isosexual precocity (3%)	Hemoperitoneum, polycythemia
Laboratory features		
Hyperbilirubinemia	5%	25%
Elevated AFP	>90%	50%
Abnormal liver function tests	15–30%	30–50%

AFP = α -fetoprotein.

vert an inoperable tumor to a completely resectable one and can also eradicate metastatic disease. Approximately 50–60% of hepatoblastomas are fully resectable, whereas only one third of hepatocellular carcinomas can be completely removed. Even with complete resection, only one third of patients with hepatocellular carcinoma are long-term survivors. A recent CCG/POG trial has shown cisplatin, fluorouracil, and vincristine to be as effective as but less toxic than cisplatin and doxorubicin in treating hepatoblastoma. Other drugs that have demonstrated benefit include fluorouracil and cyclophosphamide. Etoposide, carboplatin, and ifosfamide are under investigation. Radiation as well as liver transplantation is being investigated for patients whose tumors cannot be completely resected following chemotherapy.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH; formerly called histiocytosis X) is a rare and poorly understood spectrum of disorders. It can occur as an isolated lesion or as widespread systemic disease involving virtually any body site. Eosinophilic granuloma, Hand–Schüller–Christian disease, and Letterer–Siwe disease are all syndromes encompassed by this disorder. LCH is not a true malignancy, but is a clonal, reactive proliferation of normal histiocytic cells, perhaps resulting from an immunoregulatory defect.

The distinctive pathologic feature is proliferation of histiocytic cells beyond what would be seen in a normal inflammatory process. Langerhans histiocytes have typical features: on light microscopy, the nuclei are deeply indented (coffee bean-shaped) and elongated, and the cytoplasm is pale, distinct, and abundant. Additional diagnostic characteristics include Birbeck granules on electron microscopy, expression of CD1 on the cell surface, and positive immunostaining for S-100 protein.

Clinical Findings

Because LCH encompasses a broad spectrum of diseases, its presentation can be variable, from a single asymptomatic lesion to widely disseminated disease.

Patients with localized disease present primarily with lesions limited to bone. Occasionally found incidentally on radiographs obtained for other reasons, these lesions are well-demarcated and frequently found in the skull, clavicles, ribs, and vertebrae. These lesions can be painful. Patients can also present with localized disease of the skin, often as a diaper rash that does not resolve.

Bony lesions, fever, weight loss, otitis media, exophthalmos, and diabetes insipidus occur in a small number of children with the disease. Formerly called Hand–Schüller–Christian disease, this multifocal disease commonly presents with generalized symptoms and organ dysfunction.

Children with disseminated LCH (formerly called Letterer–Siwe disease) typically present before age 2 years with a seborrheic skin rash, fever, weight loss, lymphadenopathy, hepatosplenomegaly, and hematologic abnormalities.

Diagnosis is made with biopsy of the involved organ. The work-up should include a CBC, liver and kidney function tests, a skeletal survey or technetium bone scan, and a urinalysis with specific gravity to rule out diabetes insipidus.

Treatment & Prognosis

The outcome of LCH is extremely variable, but the process usually resolves spontaneously. Isolated lesions may need no therapy at all. Intralesional corticosteroids, curettage, and low-dose radiation therapy are useful local treatment measures for symptomatic focal lesions. Patients with localized disease have an excellent prognosis.

Multifocal disease is often treated with systemic chemotherapy. Prednisone with vinblastine or etoposide can be given repeatedly or continuously until lesions heal; the drugs can then be reduced and finally stopped.

Multifocal disease is less predictable, but most cases resolve without sequelae. Age, degree of organ involvement, and response to therapy are the most important prognostic factors. Infants with disseminated disease tend to do poorly, with mortality rates approaching 50%. New treatment approaches for patients that do not respond to conventional chemotherapy have been evaluated in small studies. 2-Chlorodeoxyadenosine (2-CDA) has been used with some success. Therapeutic strategies targeting the dysregulated immune response using interferon- α or etanercept (anti-tumor necrosis factor- α) have also been reported.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Douglas K. Graham, MD, PhD, Roger H. Giller, MD, & Ralph R. Quinones, MD

Hematopoietic stem cell transplantation (HSCT), often referred to as bone marrow transplantation, involves the intravenous infusion of hematopoietic stem cells to reestablish normal hematopoiesis following marrow ablative or subablative chemotherapy or radiation therapy. The first successful human HSCTs were performed in the 1960s in ALL patients who received supralethal total body irradiation (TBI). The technology associated with HSCT subsequently has been expanded to include transplants that are either autologous (infusion of the patient's own hematopoietic stem cells) or allogeneic (infusion of another individual's hematopoietic stem cells). Different hematopoietic stem cell sources for stem cell transplantation include bone marrow, peripheral blood, and umbilical cord blood.

Advantages of peripheral and umbilical cord blood have led to increased use of these stem cell sources in recent years. Peripheral blood progenitor cells offer more rapid hematologic recovery and less supportive care after transplantation than HSCTs. One drawback of this stem cell source in allogeneic HSCT may be heightened risk of graft versus host disease (GVHD). Umbilical cord blood provides an easily accessible, rich supply of hematopoietic stem cell precursors. Use of cord blood at times can be restricted due to limited cell

doses available for large adolescent and adult patients. Registries of bone marrow and umbilical cord blood from unrelated individuals catalogue several million potential donors worldwide for patients who lack suitably matched allogeneic family member donors.

HSCT is now considered standard therapy for a variety of malignancies, hematopoietic disorders (aplastic anemia, hemoglobinopathies), storage diseases, and severe immunodeficiencies. Pediatric malignancies that are candidates for HSCT include ALL, AML, CML, juvenile myelomonocytic leukemia, Hodgkin disease and non-Hodgkin lymphoma, brain tumors, NB, and other solid tumors. In many of these instances, transplantation is recommended only in high-risk situations or when conventional treatment fails. For example, HSCT has been used in sickle cell patients with a history of stroke, recurrent acute chest syndrome, or recurrent painful crises. AML patients or ALL patients who have high-risk cytogenetic features such as monosomy 7 or the Philadelphia chromosome [t(9;22)] may be candidates for transplantation in the first clinical remission. In illnesses such as JMML, HSCT is used as primary therapy since no other curative treatment exists.

The rationale for HSCT in oncologic disorders is that much higher dose chemotherapy, often in combination with myeloablative TBI, may overcome cancer cell resistance and achieve optimal tumor cell kill. This strategy is feasible because marrow toxicity from high-dose chemotherapy is circumvented by hematopoietic rescue. In allogeneic HSCT, an additional benefit of graft versus tumor effect may occur in which the donor hematopoietic cells attack the noncompatible antigens in the malignant cells of the recipient. In patients with nonmalignant hematopoietic disorders or immunodeficiencies, HSCTs allow for replacement of defective hematopoietic or lymphoid cells. Patients with storage diseases such as Hurler disease receive HSCT to provide enzyme-making donor macrophages to populate host tissues.

A major challenge in performing allogeneic transplants is finding a closely HLA-matched sibling or unrelated donor. Also, sufficient host immunosuppression must be achieved to prevent allograft rejection and postengraftment GVHD. The primary obstacle in autologous transplantation is collecting sufficient hematopoietic progenitor cells that are not contaminated by tumor cells. Hematopoietic stem cells can be identified within the mononuclear cell subset by the CD34 cell surface marker. Anti-CD34 monoclonal antibodies are sometimes used to positively select and thus enrich the stem cell population. In addition, purging of tumor cells (negative selection) can be achieved by several methods, including pharmacologic agents, monoclonal antibodies, or cell culture techniques. Despite these advances, relapse of the original disease has been the greatest obstacle in autologous transplantation.

The selection of the most suitable donor for allogeneic transplant is critical since degree of compatibility is inversely correlated with risk for graft rejection and GVHD. The primary genes known to encode for allogeneic recognition reside within the major histocompatibility complex (MHC) located on chromosome 6. The MHC class I antigens include HLA-A, HLA-B, and HLA-C, and the important class II antigens include HLA-DR and HLA-DQ. Both class I and II antigens can mediate graft rejection or GVHD. The class I and class II antigens are transmitted as dominantly inherited mendelian traits, and each child expresses one set of paternal and one set of maternal HLA antigens. Thus, the probability of one child inheriting any specific combination is 25% (ie, the chance of a perfect match for a sibling allogeneic transplant is 1 in 4). HLA typing traditionally has been based on serologic or cellular (mixed lymphocyte culture) techniques to define cell surface antigens. More recently, molecular techniques such as restriction fragment length polymorphism (RFLP) and DNA sequencing have been employed to more precisely delineate genetic alleles which affect donor–recipient compatibility.

Transplantation has four major treatment phases: preparative therapy, lymphohematopoietic rescue, supportive care, and long-term follow-up. The preparative phase is designed to be both myeloablative and antineoplastic. In the allogeneic transplant recipient, the preparative treatment also provides the necessary immunosuppression for successful donor engraftment. Preparative regimens use one or more chemotherapy drugs, often in combination with TBI.

Preliminary clinical studies have shown that engraftment of allogeneic donor stem cells can be achieved in certain settings with immunosuppressive nonmyeloablative preparative regimens that are less toxic than traditional myeloablative regimens. In nonmyeloablative transplants, subsequent donor lymphocyte infusions (DLIs) can play an important role in enhancing donor engraftment and immune-mediated graft versus malignancy effect.

Lymphohematopoietic rescue is accomplished by the intravenous infusion of bone marrow, peripheral blood progenitor cells, or umbilical cord blood. Graft failure after allogeneic transplant is rare in patients receiving stem cells from genotypically identical donors but may be as high as 5–15% if the donor and patient are mismatched. Marrow processing prior to infusion may include removal of contaminating RBCs if an ABO incompatibility exists. T-cell depletion of the allograft is sometimes employed to reduce the risk of GVHD. In autologous transplant, tumor purging or stem cell enrichment procedures can be performed for selected indications.

Supportive care in the initial months after transplant includes transfusions of RBCs and platelets and infec-

tion prophylaxis and treatment. GVHD prophylaxis is necessary in allogeneic transplants. All blood products should be leukocyte-depleted to reduce the risk of CMV transmission. Some institutions also use CMV seronegative blood to help prevent CMV infection in selected patients. In addition, blood products are irradiated to prevent GVHD from any contaminating lymphocytes that remain in blood products. Successful engraftment usually occurs about 10–28 days following transplant. Peripheral blood stem cell transplant patients usually recover neutrophil counts earlier than patients receiving bone marrow or cord blood transplants. Platelet recovery generally occurs 6 or more weeks after HSCT. Hematopoietic growth factors such as granulocyte colony-stimulating factor or granulocyte/macrophage colony-stimulating factor may be used to hasten myeloid recovery.

The post-transplantation period can be complicated by bacterial, viral, fungal, and protozoal infections. Certain infections are typically seen at different time intervals after the transplant. The post-transplant period can be divided into an early phase (0–1 month), an intermediate phase (1–6 months), and a late phase (6–12 months) with respect to infectious risks. During the early phase when profound neutropenia and mucosal disruption occur, gram-negative and gram-positive bacteria from the patient's own aerodigestive tract flora are common culprits in bacteremia. Empiric antibiotic coverage and intravenous γ -globulin decrease the risk of gram-negative sepsis immediately following transplant. The presence of central venous catheters makes antibiotic coverage against gram-positive bacteria an important consideration in infection management. Reactivation of herpes simplex virus may occur in as many as 70% of seropositive patients due to the mucosal disruption and profound lymphopenia; thus, acyclovir prophylaxis is commonly employed. Fungal infections, particularly with *Candida* and *Aspergillus*, have made antifungal prophylaxis routine. In the intermediate post-HSCT phase (1–6 months after transplant), the patient often has reduced T-lymphocyte numbers and abnormal T-cell function and thus is susceptible to viral infections, including those from CMV, adenovirus, and respiratory syncytial virus. Prophylactic administration of acyclovir or ganciclovir helps reduce CMV and other herpesvirus (herpes simplex virus, varicella-zoster virus) infections in this post-transplant period. Protozoan infections such as *Pneumocystis jiroveci* pneumonia are also a risk in this intermediate phase. HSCT patients receive trimethoprim–sulfamethoxazole, dapsone, or pentamidine as prophylaxis against *Pneumocystis*. The late phase, 6–12 months after transplant, is characterized by infections from encapsulated bacteria such as *Pneumococcus* due to dysfunction of the reticuloendothelial system. Reactivation of varicella-

zoster virus as shingles is also common. Patients on prolonged immunosuppressive treatment for chronic GVHD have increased and protracted risk of infections.

Despite the use of immunosuppressive agents, anti-T-cell antibodies, and T-cell depletion of the donor graft, approximately 20–70% of allogeneic HSCT patients experience some degree of acute GVHD. Factors influencing GVHD risk include the degree of HLA match, stem cell source, patient age, and donor sex. Acute GVHD occurs within the first 100 days after transplant. The first manifestation typically is a maculopapular skin rash. Skin biopsies reveal epidermal basal cell vacuolization and apoptosis as well as lymphoid infiltration. Intestinal involvement results in secretory diarrhea, and hepatic involvement leads to cholestatic jaundice. Chronic GVHD occurs after day 100 and may involve multiple organ systems. Sclerotic skin, malabsorption, progressive weight loss, keratoconjunctivitis sicca, oral mucositis, chronic lung disease, and cholestatic jaundice are common manifestations. Pathologic changes of the skin include fibrosis. Treatment for GVHD consists of further use of immunosuppressive agents.

Long-term follow-up of HSCT patients is essential. Patients are at risk for numerous complications, including pulmonary disease, cataracts, endocrine dysfunction affecting growth and fertility, cardiac dysfunction, avascular necrosis of bone, developmental delay, and secondary malignancies. Although HSCT has many challenges, it represents an important advance in curative treatment for a variety of serious pediatric illnesses.

LATE EFFECTS OF PEDIATRIC CANCER THERAPY

Late effects of treatment by surgery, radiation, and chemotherapy have been identified in survivors of pediatric cancer. Current estimates are that 1 in every 900 adults younger than age 45 years is a pediatric cancer survivor. In some studies, up to 60% of survivors of pediatric cancer will have some disability secondary to

treatment. Virtually any organ system can demonstrate sequelae related to previous cancer therapy. This has necessitated the creation of specialized oncology clinics whose function it is to identify and provide treatment to these patients.

The Childhood Cancer Survivor Study, a pediatric multi-institutional collaborative project, was designed to investigate the various aspects of late effects of pediatric cancer therapy in a cohort of over 14,000 survivors of childhood cancer.

GROWTH COMPLICATIONS

Children who have received cranial irradiation are at highest risk of developing growth complications. Growth complications of cancer therapy in the pediatric survivor are generally secondary to direct damage to the pituitary gland, resulting in growth hormone deficiency. However, new evidence in children treated for ALL suggests that chemotherapy alone may result in an attenuation of linear growth without evidence of catch-up growth once therapy is discontinued. Up to 90% of patients who receive greater than 30 Gy of radiation to the CNS will show evidence of growth hormone deficiency within 2 years. Approximately 50% of children receiving 24 Gy will have growth hormone problems. The effects of cranial radiation appear to be age-related, with children younger than age 5 years at the time of therapy being particularly vulnerable. These patients usually benefit from growth hormone therapy. There is currently no evidence that such therapy causes a recurrence of cancer.

Spinal radiation inhibits vertebral body growth. In 30% of such individuals, standing heights may be less than the fifth percentile. Asymmetrical exposure of the spine to radiation may result in scoliosis.

Growth should be monitored closely, particularly in young survivors of childhood cancer. Follow-up studies should include height, weight, growth velocity, scoliosis examination, and, when indicated, growth hormone testing.

ENDOCRINE COMPLICATIONS

Thyroid dysfunction, manifesting as hypothyroidism, is common in children who received TBI, cranial radiation, or local radiation therapy to the neck. Particularly at risk are children with brain tumors who received more than 3000 cGy and those who received more than 4000 cGy to the neck region. The average time to develop thyroid dysfunction is 12 months after exposure, but the range is wide. Therefore, individuals at risk should be monitored yearly for at least 7 years from the completion of therapy. Although signs and symptoms of hypothyroidism may be present, most patients will

have a normal thyroxine level with an elevated thyroid-stimulating hormone level. These individuals should be given thyroid hormone replacement because persistent stimulation of the thyroid from an elevated thyroid-stimulating hormone level may predispose to thyroid nodules and carcinomas. In a recent report from the Childhood Cancer Survivor Study, thyroid cancer occurred at 18 times the expected rate for the general population in pediatric cancer survivors who received radiation to the neck region. Hyperthyroidism, although rare, also occurs in patients who have received neck irradiation.

Precocious puberty, delayed puberty, and infertility are all potential consequences of cancer therapy. Precocious puberty, more common in girls, is usually a result of cranial irradiation causing premature activation of the hypothalamic–pituitary axis. This results in premature closure of the epiphysis and decreased adult height. Luteinizing hormone analogue and growth hormone are used to halt early puberty and facilitate continued growth.

Gonadal dysfunction in males is usually the result of radiation to the testes. Patients who receive testicular radiation as part of their therapy for ALL, abdominal radiation for Hodgkin disease, or TBI for HSCT are at highest risk. Radiation damages both the germinal epithelium, producing azoospermia, and Leydig cells, causing low testosterone levels and delayed puberty. Alkylating agents such as ifosfamide and cyclophosphamide can also interfere with male gonadal function, resulting in oligo- or azoospermia, low testosterone levels, and abnormal follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels. Determination of testicular size, semen analysis, and measurement of testosterone, FSH, and LH levels will help identify abnormalities in patients at risk. When therapy is expected to result in gonadal dysfunction, pretherapy sperm banking should be offered to adolescent males.

Exposure of the ovaries to abdominal radiation may result in delayed puberty with a resultant increase in FSH and LH and a decrease in estrogen. Girls receiving TBI as preparation for HSCT and those receiving craniospinal radiation are at particularly high risk for delayed puberty as well as premature menopause. In patients at high risk for development of gonadal complications, a detailed menstrual history should be obtained, and LH, FSH, and estrogen levels should be monitored if indicated.

No studies to date have confirmed an increased risk of spontaneous abortions, stillbirths, premature births, congenital malformations, or genetic diseases in the offspring of childhood cancer survivors. Women who have received abdominal radiation may develop uterine vascular insufficiency or fibrosis of the abdominal and pelvic musculature or uterus, and their pregnancies should be considered high-risk.

CARDIOPULMONARY COMPLICATIONS

Pulmonary dysfunction generally manifests as pulmonary fibrosis. Therapy-related factors known to cause pulmonary toxicities include certain chemotherapeutic agents, such as bleomycin, the nitrosoureas, and busulfan, as well as lung radiation or TBI. Pulmonary toxicity due to chemotherapy is related to the total cumulative dose received. Pulmonary function tests in patients with therapy-induced toxicity show restrictive lung disease, with decreased carbon monoxide diffusion and small lung volumes. Individuals exposed to these risk factors should be counseled to refrain from smoking and to give proper notification of the treatment history if they should require general anesthesia.

Cardiac complications usually result from exposure to anthracyclines (daunorubicin, doxorubicin, mitoxantrone), which destroy myocytes and lead to inadequate myocardial growth as the child ages and eventually result in congestive heart failure. The incidence of anthracycline cardiomyopathy increases in a dose-dependent fashion. At least 5% of patients who have received a cumulative dose of more than 550 mg/m² of anthracyclines experience cardiac dysfunction. In a recent study, complications from these agents appeared 6–19 years following administration of the drugs. Pregnant women who have received anthracyclines should be followed up closely for signs and symptoms of congestive heart failure, as peripartum cardiomyopathy has been reported.

Radiation therapy to the mediastinal region, which is common as part of therapy for Hodgkin disease, has been linked to an increased risk of coronary artery disease; chronic restrictive pericarditis may also occur in these patients.

Current recommendations include an exercise echocardiogram and electrocardiogram every 1–5 years, depending on the age at therapy, total cumulative dose received, and presence or absence of mediastinal irradiation. Selective monitoring with various modalities is indicated for those who were treated with anthracyclines when they were younger than age 4 years or received more than 500 mg/m² of these drugs. Measurement of serum levels of cardiac troponin-T or atrial natriuretic peptide may be useful in assessing early cardiotoxicity of anthracyclines.

RENAL COMPLICATIONS

Long-term renal side effects stem from therapy with cisplatin, alkylating agents (ifosfamide and cyclophosphamide), or pelvic radiation. Patients who have received cisplatin may develop abnormal creatinine clearance, which may or may not be accompanied by abnormal serum creatinine levels, as well as persistent

tubular dysfunction with hypomagnesemia. Alkylating agents can cause hemorrhagic cystitis, which may continue after chemotherapy has been terminated and has been associated with the development of bladder carcinoma. Ifosfamide can also cause Fanconi syndrome, which may result in clinical rickets if adequate phosphate replacement is not provided. Pelvic radiation may result in abnormal bladder function with dribbling, frequency, and enuresis.

Patients seen in long-term follow-up who have received nephrotoxic agents should be monitored with urinalysis, appropriate electrolyte profiles, and blood pressure. Urine collection for creatinine clearance or renal ultrasound may be indicated in individuals with suspected renal toxicity.

NEUROPSYCHOLOGICAL COMPLICATIONS

Pediatric cancer survivors who have received cranial radiation for ALL or brain tumors appear to be at greatest risk for neuropsychological sequelae. The severity of cranial radiation effects varies among individual patients and depends on the dose and dose schedule, the size and location of the radiation field, the amount of time elapsed after treatment, the child's age at therapy, and the child's gender. Girls may be more susceptible than boys to CNS toxicity because of more rapid brain growth and development during childhood.

The main effects of CNS radiation appear to be related to attention capacities, ability with nonverbal tasks and mathematics, and short-term memory. Recent studies support the association between high-dose systemic methotrexate, triple intrathecal chemotherapy, and more recently, dexamethasone with more significant cognitive impairment.

Additionally, pediatric cancer patients have been reported as having more behavior problems and as being less socially competent than a sibling control group. Adolescent survivors of cancer demonstrate an increased sense of physical fragility and vulnerability manifested as hypochondriasis or phobic behaviors.

Finally, childhood cancer survivors are more likely to report symptoms of depression and somatic distress in adulthood. Pediatric cancer survivors may require ongoing counseling or other psychological interventions once they have completed therapy.

SECOND MALIGNANCIES

Approximately 3–12% of children receiving cancer treatment will develop a new cancer within 20 years of

their first diagnosis. This is a tenfold increased incidence when compared with age-matched control subjects. Particular risk factors include exposure to alkylating agents, epipodophyllotoxins (VP-16), and radiation therapy, primary diagnosis of retinoblastoma or Hodgkin disease, or the presence of an inherited genetic susceptibility syndrome (Li–Fraumeni syndrome or NF). In a recent report, the cumulative estimated incidence of second malignant neoplasms for the cohort of the Childhood Cancer Survivor Study was 3.2% at 20 years from diagnosis.

Second hematopoietic malignancies (acute myelogenous leukemia) occur as a result of therapy with epipodophyllotoxins or alkylating agents. It is unclear whether the schedule of drug administration and the total dose are related to the development of this secondary leukemia.

Children receiving radiation therapy are at risk for developing second malignancies, such as sarcomas, carcinomas, or brain tumors, in the field of radiation. A recent report examining the incidence of second neoplasms in a cohort of pediatric Hodgkin disease patients showed the cumulative risk of a second neoplasm to be as high as 8% at 15 years from diagnosis. The most common solid tumor was breast cancer (the majority located within the radiation field) followed by thyroid cancer. Girls age 10–16 years when they received radiation were at highest risk and had an actuarial incidence that approached 35% by age 40 years.

Anthony R. Hayward, MD, PhD

Recurrent or severe infection is the most common symptom of immunodeficiency, but most children with frequent minor infections (particularly otitis and sinusitis) do not have an immunodeficiency that is definable by currently available tests. Host defenses against infection depend mainly on excluding pathogens at surfaces and then decontaminating these mechanically. Specific and nonspecific immune mechanisms are needed only after an organism gains access to the body. Specific immunity in this context consists of antibody- and cell-mediated immunity (CMI). Nonspecific immune mechanisms include mechanical barriers, complement, antibacterial peptides, phagocytes, and natural killer cells. Nonspecific mechanisms may be guided by specific responses, as when antibody directs killing by natural killer cells or promotes phagocytosis by opsonizing bacteria.

Before investigating a patient for a defined primary immunodeficiency (most of which are rare), one should exclude the more common conditions that increase local susceptibility to infection, such as allergic rhinitis (causing sinusitis), cystic fibrosis, and asthma as causing pneumonia and conditions that interfere with the integrity of the skin or the normal flora of mucous membranes (Table 29–1). Common causes of secondary immunodeficiency (human immunodeficiency virus [HIV] infection, malnutrition, drugs, protein loss) must also be excluded.

Chapel H et al: Primary immunodeficiency diseases: An update. *Clin Exp Immunol* 2003;132:9 [PMID: 12653830]

■ NONSPECIFIC FACTORS IN RESISTANCE TO INFECTION

DEFECTS OF COMPLEMENT

Complement proteins are activated by certain lectins and bacterial proteins and also by surface-bound IgG or IgM antibodies. The split products of C3 and C5 activation attract neutrophils, and bound C3b opsonizes bacteria for phagocytosis by neutrophils. Deficiencies of individual classic pathway factors (C1–C9) occur as autosomal recessive traits and are rare. Deficiencies of fac-

tors 1q, 4, and 2 are associated with a 90, 75, and 20% risk of developing systemic lupus erythematosus, respectively. Chronic glomerulonephritis, dermatomyositis, and cutaneous vasculitis are also more common. Primary deficiency of C3 interferes with the opsonization of bacteria by the classic and alternative pathways of complement activation and results in recurrent bacterial infections. Deficiency of properdin (an alternative pathway factor) may also occasionally predispose to meningococcal infection. C5, C6, C7, C8, and C9 deficiencies are associated with dissemination of neisserial infections, increasing the risks for arthritis. Survivors of meningococcal meningitis should probably have their complement function screened with a hemolytic assay.

Walport MJ: Complement. First of two parts. *N Engl J Med* 2001;344:1058 [PMID: 11287977].

Walport MJ: Complement. Second of two parts. *New Engl J Med* 2001;344:1140 [PMID: 11297706].

Complement-activating lectins include mannan-binding lectin (MBL). About 7% of the population has MBL alleles associated with reduced function. Allelic variants in MBL have recently been associated with susceptibility to meningococcal meningitis. Susceptibility to other infections in infants with low MBL levels seems to decrease with age.

Ezekowitz RA: Role of the mannose-binding lectin in innate immunity. *J Infect Dis* 2003;187(Suppl 2):S335 [PMID: 12792848].

Hibberd ML et al: Association of variants of the gene for mannose-binding lectin with susceptibility to meningococcal disease: Meningococcal Research Group. *Lancet* 1999;353:1049 [PMID: 10199352].

Hereditary angioedema is a rare disorder that results from C1 esterase inhibitor deficiency in which susceptibility to infection is not increased. Transmission is autosomal dominant, and an acquired form associated with angiotensin-converting enzyme inhibitor treatment is being recognized more frequently. Persons with this disorder typically have recurrent episodes of edema lasting 48–72 hours and affecting the face or a limb.

Table 29–1. Host defense mechanisms and examples of nonspecific defects.

Protection by	Defect
Intact skin	Burns, eczema, sinus tracks, indwelling catheters
Drainage	Auditory tube obstruction, cystic fibrosis, foreign body, urinary obstruction
Normal flora	Overgrowth of antibiotic-resistant organisms causing candidiasis or diarrhea

Edema affecting the bowel can be very painful. Laryngeal edema is life-threatening and occurs in over 40% of patients. The diagnosis is suggested by decreased activity of whole complement, C4, and C2 and confirmed by direct assay of the C1 inhibitor. Symptomatic subjects have levels below 30%. The synthetic androgen danazol (50–200 mg/d) prevents attacks by increasing C1 inhibitor levels. C1-inhibitor concentrate is useful for the emergency treatment of acute edema. Liver tumors are a risk after many years of danazol treatment. Defects in other innate immune systems can cause autoinflammatory syndromes. Familial Mediterranean fever results from mutations in the pyrin protein gene and is characterized by episodes of fever and abdominal pain. Onset is generally in childhood, but substantial phenotypic variations occur, with the most severe forms leading to renal failure from amyloidosis in the teens. Related conditions and their pathogenesis likely result from failure to control the activation of inflammatory mediators such as interleukin-1 (IL-1). Mutations in cryopyrin causes a familial cold autoinflammatory syndrome.

CELLULAR DEFECTS

Defects of neutrophil function comprise adhesion defects, chemotaxis defects, and defects of bacterial killing. They are summarized here in the context of the investigation of a child with recurrent infections and are fully described in Chapter 27. Patients with leukocyte adhesion defects present with infections ranging from progressive periumbilical necrosis with onset in infancy to recurrent surface infections starting in adult life. The severity of the clinical picture depends on the underlying defect. The infections are caused by a range of organisms and, although the neutrophil count is nor-

mal or high, relatively little pus is present. In childhood, the infections are often around body orifices, but they also involve the skin, esophagus, and respiratory tract. Death in childhood is common. Other patients with a milder phenotype have survived for 20 or more years. Diagnosis is by phenotyping blood mononuclear cells for LFA-1 or Mac-1; this approach can also be used for antenatal diagnosis. Chédiak–Higashi syndrome is caused by mutations of a lysosomal trafficking gene. The cells of affected individuals have giant lysosomes, impairing chemotaxis by neutrophils and interfering with the stimulation of T cells by lymphocytes and monocytes. Abnormal pigment handling gives a characteristic partial oculocutaneous albinism. Progressive local infections (without much pus formation) occur. Later the incidence of lymphoproliferative disease is high. Most other chemotaxis defects are probably secondary. A wide variety of other conditions also can be associated with depressed motility of phagocytic cells: burns; infections such as HIV, rubella, and influenza; metabolic and nutritional disorders, including diabetes mellitus; the hypophosphatemia associated with intravenous alimentation; and uremia. The association of impaired neutrophil chemotaxis with hyperimmunoglobulinemia E (IgE levels are usually > 2000 units/mL), recurrent staphylococcal abscesses of the skin, eczema, and otitis media is clinically recognizable and sometimes called Job syndrome. These patients can have impaired CMI, and the disorder also occurs in some patients with acquired immunodeficiency syndrome (AIDS). Treatment is symptomatic. Patients with bacterial killing defects (eg, chronic granulomatous disease) usually have staphylococcal infections in the first months of life and develop groin, cervical, or axillary abscesses requiring incision and drainage. Sometimes they are infected by *Serratia* or *Nocardia* species. The infections cause high neutrophil counts and fever and sometimes spread to cause osteomyelitis or lung or liver abscesses. Colitis, leading to diarrhea and slow growth, is common. The abscesses require drainage and appropriate antibiotics for lengthy courses (3 weeks or more). As underlying tissues become damaged, fungal and *Pseudomonas cepacia* infections become increasingly common. Neutrophil granulocyte deficiency predisposes to recurrent pyogenic infections similar to chronic granulomatous disease. This defect is recognized by microscopy, and the molecular basis has recently been defined.

Neutropenia in the warts, hypogammaglobulinemia, and immunodeficiency (WHIM) syndrome occurs until infections stimulate the release of neutrophils from the marrow, so the response to antibiotics is good. Numbers of blood T and B cells vary: at least some of these patients have mutations of the *CXCR4* chemokine receptor gene that seem likely to contribute to their sus-

ceptibility to papillomavirus infections. Defects of monocyte–macrophage function occur in lysosomal storage diseases, but infections are only a minor component of their symptomatology. Natural killer (NK) cell defects are most commonly associated with severe herpesvirus infections such as the EBV-induced hemophagocytic lymphohistiocytosis (HLH) in Chédiak–Higashi and Griscelli syndromes. Disorders of granule traffic are responsible for some of these defects while defects in perforin or granzyme also impair NK cell function. A familial variety of HLH is now being reported, resulting from lack of NK cell surface receptors for IgG. Symptoms result from infection, most notably herpesvirus infections. About 20% of familial HLH cases result from deficiency of perforin—a pore-forming protein used by NK cells. Rarer are defects in the *SH2DIA* gene that cause the X-linked lymphoproliferative syndrome [q.v.]. The lymphohemophagocytic component is the result of cytokine secretion by T cells that undergo uncontrolled activation. Immunosuppression followed by bone marrow transplantation (BMT) using nonmyeloablative conditioning regimens may prove the best treatment for severe cellular defects. At least in chronic granulomatous disease, transplant treatment is easier before systemic fungal infections develop.

DEFICIENCIES OF SPECIFIC IMMUNITY

Defects of specific immunity are broadly subdivided into those affecting predominantly antibody formation, those affecting cellular immunity, and those in which both mechanisms are impaired. The classification in Table 29–2 is based on combinations of clinical and laboratory results and includes only the most common of the 80 or so primary immunodeficiencies now known. Enormous advances are being made in identifying the mechanisms of immunodeficiencies with simple mendelian inheritance. Linkages are being mapped for some multifactorial conditions (common variable immunodeficiency, selective IgA deficiency).

IMMUNOGLOBULIN & ANTIBODY DEFICIENCY SYNDROMES

1. Hypogammaglobulinemia Syndromes

Patients who do not make antibodies have low (hypogammaglobulinemia) or absent (agammaglobulinemia) levels of all immunoglobulin isotypes (IgG, IgA, IgM, IgE). They usually present with recurrent or severe bacterial infection of the respiratory tract (sinusitis, otitis, pneumonia) or skin (cellulitis, abscesses). Without antibiotic treatment, these infections tend to spread to cause septicemia and meningitis. There are several types of hypogammaglobulinemia (see Table 29–2), and in the congenital X-linked agammaglobulinemia infections usually start after age 4 months, when passively acquired maternal IgG levels have declined. *Haemophilus influenzae* and *Streptococcus pneumoniae* cause most of the infections, but following courses of antibiotics, deep tissue

infections by *Mycoplasma* family members such as *Ureaplasma* become important. Inflammatory arthritis or persistent cellulitis may be due to opportunists such as *Helicobacter cinaedi* and *Flexispira rappini* that are difficult or impossible to culture and difficult to treat. Antibody-deficient patients have had severe infections with enteroviruses, particularly vaccine strains of poliovirus and echovirus 11. Although polioviruses typically caused paralysis, the echoviruses often caused a chronic encephalitis, optic atrophy, or convulsions. Intravenous replacement of IgG provides subjects with some protection because higher IgG levels are achieved. Active enteroviral infections are generally treated with pleconaril. Some boys have asymmetrical arthritis, mostly of the knee or ankle, at the time of diagnosis, which may resolve after adequate IgG replacement. These patients typically have little or no tonsillar and adenoidal tissue. The severity of infections varies, so the diagnosis may not be made for many years. Congenital X-linked agammaglobulinemia occurs in about 1:200,000 male births and results from mutations in the B-cell tyrosine kinase gene (*btik*). Patients have few if any B cells in their blood, though they have normal blood lymphocyte counts. Almost all have very low to undetectable levels of IgG, IgA, and IgM in blood. Molecular diagnosis and carrier detection are available. Occasional patients have impaired growth hormone production. Autosomal recessive congenital agammaglobulinemia is rare: the commonest result from defects of the μ heavy-chain gene, and these patients tend to have an earlier onset of infections and complications than the *btik*-deficient boys. Acquired types of hypogammaglobulinemia are more common and may develop at any age. The diagnosis of hypogammaglobulinemia is based on low serum immunoglobulin levels for age with absence of serum isohemagglutinins and of antibody response to immunization. Blood B cells should be measured to identify the subset of patients for whom a gene defect results in failure of B-cell production. Causes of secondary hypogammaglobulinemia (nephrotic syndrome, HIV infection, and protein-losing enteropathy) should be excluded by measuring serum albumin. Morphologic disorders or associated syndromes (as with the recently described primary antibody deficiency with spondyloepiphyseal and retinal dystrophy) may point to a specific diagnosis.

Roifman CM: Antibody deficiency, growth retardation, spondyloepiphyseal dysplasia and retinal dystrophy: A novel syndrome. *Clin Genet* 1999;55:103 [PMID: 10189087].

X-linked immunodeficiency with hyper-IgM (HIGM1) occurs in fewer than 1:10⁶ male births. Affected boys have low IgG and IgA levels. Their IgM levels may start in the normal range but can rise to 1000 mg/dL or more. In addition to infections, these children often have lymphadenopathy and episodes of autoimmune neutropenia. The disease results from mutation in the CD40 ligand gene so that the patient's T cells are unable to switch their B cells from making IgM to making IgG and IgA. CMI is also impaired, so these patients have *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) infections, cryptosporidiosis of the biliary tree and intestine, sclerosing cholangitis, and a high incidence of biliary tract carcinomas. The fraction of patients surviving beyond 25 years is so low that treatment by BMT is increasingly used. Children with autosomal recessive forms of hyper-IgM immunodeficiency have normal expression of CD40L and mutations in an activation-induced cytidine deaminase.

Common Variable Immunodeficiency Syndromes

Patients with congenital or acquired antibody deficiency syndromes not classified elsewhere are often included in the group called common variable immunodeficiency syndromes (CVID), and they outnumber patients with all other types of antibody deficiency. Onset of the immunodeficiency may be at any age, and in populations of European heritage the incidence approaches 1:25,000. Susceptibility to common variable immunodeficiency and selective IgA deficiency is inherited and associated with certain HL-DR/DQ alleles, but the factors that precipitate expression of common variable immunodeficiency in susceptible individuals are unknown. The association with HLA-DR/DQ suggests an underlying autoimmune cause for CVID. Patients usually have B cells in their blood, but these do not differentiate normally. Infections follow the patterns described for other types of antibody deficiency, and lung damage leading to bronchiectasis in adult life

is common. Some patients have remarkably few infections despite long-standing very low immunoglobulin levels. The laboratory findings vary. Low levels of one or more immunoglobulin classes are associated with different degrees of impairment of T-cell proliferative responses. Autoantibody formation, raised IgE levels, and positive immediate hypersensitivity skin reactions occur, as do neutropenia and thrombocytopenia. Patients with hypogammaglobulinemia, facial dysmorphism, mental retardation, or hypertelorism may have the immunodeficiency-chromosome instability-facial anomaly (ICF) syndrome that most commonly results from mutations in DNA methyltransferase 3B at 20q11.2. Their rather variable immunodeficiency most commonly comprises low IgA, and inheritance is autosomal recessive. Abnormal serum immunoglobulins occur also in the hypohidrotic or anhidrotic ectodermal dysplasia syndromes that result from abnormal signaling through the NF- κ B molecule.

Doffinger R et al: X-linked anhidrotic ectodermal dysplasia with immunodeficiency is caused by impaired NF-kappaB signaling. *Nat Genet* 2000;27:277 [PMID: 11242109].

Wijmenga C et al: Genetic variation in ICF syndrome: Evidence for genetic heterogeneity. *Hum Mutat* 2000;16:509 [PMID: 11102980].

Complications of Hypogammaglobulinemia

Many CVID patients have B-cell hyperplasia in the gut. About 10% of patients develop diarrhea and malabsorption that may be severe enough to resemble Crohn disease. Infection is the likeliest cause of the diarrhea, and efforts should be made to exclude treatable agents such as *Giardia lamblia* or *Cryptosporidium*. In adult life, the patients often develop gastric atrophy with achlorhydria, sometimes followed by pernicious anemia. Affected boys occasionally develop optic atrophy or ataxia, evolving slowly or rapidly into fatal encephalitis. Echoviruses have sometimes been isolated from their cerebrospinal fluid or brains at biopsy or autopsy. A smaller proportion develop a dermatomyositis-like syndrome, with prominent peripheral cyanosis and myopathy but little heliotrope coloration. It is thought that both of these complications are seen less com-

monly now that much higher immunoglobulin replacements are given. An increased rate of cancer in patients with antibody deficiency has been reported. The association is predominantly with lymphoreticular proliferation and may sometimes result from Epstein-Barr virus (EBV) infection. Lymphoreticular proliferations in hypogammaglobulinemic patients are not always malignant. The incidence of hepatitis C and G virus carriage is increased, owing in part to the presence of hepatitis C virus in batches of intravenous IgG through 1995. Patients should have their aminotransferase levels checked, and, if necessary, they should be tested for hepatitis C virus antigenemia. Many infected children fail to clear the virus, and about 25% progress to liver failure. The risk of hepatitis C virus has been virtually eliminated since more stringent viral inactivation steps have been introduced (eg, solvent detergent).

Chapel HM et al: Five-year follow-up of patients with primary antibody deficiencies following an outbreak of acute hepatitis C. *Clin Immunol* 2001;99:320 [PMID: 11358426].

Treatment of Hypogammaglobulinemia

Patients with hypogammaglobulinemia should have serum IgG replaced to protect against infection. IgG is usually given by intravenous infusions of specially prepared deaggregated IgG (200–600 mg/kg every 4 weeks). If intravenous treatment is very difficult in young children, they may be temporarily treated with intramuscular injections of IgG concentrate (0.6 mL/kg every 2–3 weeks). Some adults are treated more cheaply with subcutaneous infusions of the intramuscular IgG preparation, given overnight on several nights per week. The aim of treatment must be to avoid—or minimize progression of—chronic lung disease (bronchitis, bronchiectasis). Productive cough and purulent sputum or conjunctivitis must be taken seriously, and antibiotics given until radiologic and clinical resolution occur. *Mycoplasma* infections of the respiratory or urinary tract should be sought and treated with doxycycline or other appropriate antibiotics. Minor reactions to immunoglobulin infusions or injections are common, especially with the initial infusion. They include headache, back and limb pain, anxiety, and tightness of the chest. Signs are tachycardia, shivering, fever, and, in severe cases, shock. Reactions are frequent in some patients and rare in others; their occurrence is sporadic and not generally due to hypersensitivity (anti-IgA reactions may be an exception but are rare). Skin tests are not helpful. When indicated, immunoglobulin replacement should be maintained for life, and the severity of

the reactions limited by premedication with acetaminophen, an antihistamine, or intravenous hydrocortisone immediately before the infusion. Alternative brands of IgG should be tried if reactions persist despite premedication. Intravenous IgG has been used extensively for inflammatory disorders ranging from asthma to autoimmunity. When benefit results, the mechanism may involve a suppression of inflammatory cytokine production.

Schwartz SA: Intravenous immunoglobulin treatment of immunodeficiency. *Pediatr Clin North Am* 2000;47:1355 [PMID: 11131000].

2. Other Types of Hypogammaglobulinemia

Transient Hypogammaglobulinemia

Infants' IgG levels fall during the first 4–5 months of life, as maternal IgG is diluted and catabolized. The physiologic trough that occurs before the infant's IgG production attains adult levels is accentuated in premature and dysmature infants. IgG levels of 250–300 mg/dL lie within 2 standard deviations of the mean at age 3–4 months, and the diagnosis of transient hypogammaglobulinemia is often made in infants with infections and IgG levels in this range. Immunoglobulin levels should return to normal by age 30 months, and the diagnosis can only be made retrospectively. The only diagnostic laboratory findings are low IgG—with or without low IgA and IgM—and subsequent return to normal levels. Salivary IgA is generally detectable, and, despite the low immunoglobulin levels, antibody activity (isohemagglutinin or antidipteria or tetanus antibody) is present in serum. IgG antibody is generally made following immunization, and tests for cellular immunity are normal. Usually no treatment is required, other than appropriate antibiotics for bacterial infections, for infants who make antibody following immunization. Infants with severe infection and hypogammaglobulinemia could rationally be given IgG injections, since maternal antibody to the infecting organism will be rapidly depleted, but this is rarely necessary. The prognosis for affected infants is excellent provided they do not succumb to infection before normal immunity is achieved.

Kowalcyk D et al: Intracellular cytokine production by Th1/Th2 lymphocytes and monocytes of children with symptomatic transient hypogammaglobulinaemia of infancy (THI) and selective IgA deficiency (SIgAD). *Clin Exp Immunol* 2002;127:507 [PMID: 11966768].

IgA Deficiency

This disorder, defined by a serum IgA less than 5 mg/dL, occurs in about 1:800 people of European heritage, making it the most common defect of specific immunity. Serum IgM and IgG are normal, as is IgG antibody production and CMI. Susceptibility is linked to the same HLA-DR/DQ alleles as common variable immunodeficiency (q.v.). Fifty percent or more of IgA-deficient subjects have no symptoms arising from the deficiency, perhaps because they can protect their mucosa adequately with IgG and IgM antibodies. Failure of antibody responses in the IgG4 and IgG2 subclasses is reported in many symptomatic patients, but there is no simple relationship with IgA levels. When symptoms are present, they are predominantly upper respiratory tract infections or diarrhea. There are also strong associations with inflammatory bowel disease, allergy (mainly respiratory and gut), and autoimmune disorders (thyroiditis, arthritis, vitiligo, thrombocytopenia, and diabetes). The selective lack of IgA antibody responses and the presence of normal antibody responses in other immunoglobulin classes distinguish IgA deficiency from unclassified variable immunodeficiency. IgA has a short half-life in serum, and replacement is impractical. It is conceivable but unproved that colostrum feeding could modify severe gut symptoms. Symptomatic IgA-deficient subjects who are also IgG2-deficient have sometimes been treated with IgG replacement. This approach has been both advocated and condemned on theoretical grounds but without controlled data to support the theories. A subset of IgA-deficient patients make antibodies to IgA, which are an important cause of transfusion reactions. Most IgA-deficient patients manage reasonably well with antibiotics only; atopic or autoimmune symptoms should be treated conventionally.

Aittoniemi J et al: The significance of IgG subclasses and mannan-binding lectin (MBL) for susceptibility to infection in apparently healthy adults with IgA deficiency. *Clin Exp Immunol* 1999;116:505 [PMID: 10361242].

Sundin U et al: Induction of unresponsiveness against IgA in IgA-deficient patients on subcutaneous immunoglobulin infusion therapy. *Clin Exp Immunol* 1998;112:341 [PMID: 9649200].

3. Other Selective Subclass Deficiencies

The possibility that deficiency of an IgG subclass might predispose to recurrent upper respiratory tract infections in patients who have normal serum immunoglobulin levels is not established, and the issue is confused by the absence of any prospective studies. The IgG heavy-chain genes on chromosome 11 (grouped with IgG1 close to IgG3 and IgG2 close to IgG4) are, with

rare exceptions, normal in subclass deficiencies. Normally, IgG1 comprises over 60% of total IgG and IgG2 over 10%. IgG3 accounts for about 5%, and IgG4 may be undetectable in up to 20% of healthy persons. Serum levels are age-related. When IgG1 is deficient, IgG2 and IgG3 are generally low also, giving the clinical picture of hypogammaglobulinemia. IgG1 and IgG2 contain much of the antibody to capsular polysaccharides. IgG2 (and IgG4) deficiency is also associated with IgA deficiency. IgG3 deficiency is less common but has been incriminated in subjects with antibody deficiency syndromes who have normal total IgG or IgG1 subclass levels. Even in adults it has been difficult to establish a link between IgG subclass deficiencies and any consistent pattern of infections. IgG replacement should be reserved for patients with defects of antibody production; many patients are treated with antibiotics alone.

Selective deficiencies of IgM, IgE, and κ or λ light chains due to gene deletions may be symptomless and are very rare. Selective IgM deficiency is reported in Bloom syndrome and, in adults, predisposes to septicemia. Since IgM replacement is impractical on a long-term basis, reliance is placed mainly on antibiotics.

SELECTIVE DEFECTS OF CELL-MEDIATED IMMUNITY

1. Purine Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase deficiency causes a relatively selective CMI defect. It results in increased intracellular deoxyguanosine triphosphate, which inhibits ribonucleotide reductase and interferes with DNA synthesis, especially in T cells. T-cell help to B cells is not prevented, probably because it does not depend on cell division. The gene for purine nucleoside phosphorylase is on chromosome 14, and transmission is recessive. Presenting features may be neurologic (developmental retardation, behavior disorders, and spasticity), with immunodeficiency (severe varicella infection, anemia, and growth deficiency) developing later. The age at presentation has ranged from 6 months to 7 years. Investigations show low serum uric acid levels, lymphopenia, absent delayed hypersensitivity skin responses, and low or absent lymphocyte responses to mitogens. Serum immunoglobulins and antibody responses to injected antigens may be normal. Several patients developed an

autoimmune hemolytic anemia. Diagnosis depends on enzyme measurement, and all patients with severely impaired cellular immunity who make immunoglobulin should probably be tested. Antenatal diagnosis is possible. It has been difficult to achieve stable engraftment following BMT.

Moallem HJ et al: Purine nucleoside phosphorylase deficiency: A new case report and identification of two novel mutations (Gly156A1a and Val217Ile), only one of which (Gly156A1a) is deleterious. *Clin Immunol* 2002;105:75 [PMID: 12483996].

2. Thymic Hypoplasia (DiGeorge Syndrome)

DiGeorge syndrome is one of the so-called CATCH 22 disorders (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia) caused by monosomy of the chromosome regions 22q11.2 and a haploinsufficiency of T-box1 genes. Microdeletions at 10p12–13 may cause a similar phenotype. Related syndromes are the velocardiofacial syndrome and isolated conotruncal cardiac disease. The incidence is about 1 per 3000 births, and the defective chromosome is usually inherited from the mother. The hypocalcemia results from lack of parathyroid glands, and the common major vessel abnormalities are truncus arteriosus, anomalous pulmonary venous drainage, and right-sided aortic arch. Clinically important issues include delayed speech acquisition and behavioral problems. The term “partial DiGeorge syndrome” is commonly applied to infants who have impaired rather than absent parathyroid or thymus function. Clinical presentation usually results from cardiac failure or, after 24–48 hours, from hypocalcemia, and the diagnosis is sometimes made during the course of cardiac surgery, when no thymus is found in the mediastinum. Postoperative hypocalcemia can be severe and persistent, requiring both calcium and vitamin D supplements. Despite receiving fresh blood transfusions during cardiopulmonary bypass, patients do not usually develop graft-versus-host disease (GVHD). Their susceptibility to infection varies—a few have died with septicemia, and some have had chronic candidiasis, but many appear to respond normally. This may reflect the tendency for the number of T cells in the patient’s blood to rise spontaneously over the course of several years. The differential diagnosis includes hypocalcemia and a small or absent thymus on chest radiograph secondary to infection. A subset of patients with DiGeorge syndrome has severe problems with production of autoantibodies to red cells, white cells, and platelets. These patients may respond to intravenous IgG or to corticosteroids. Treatment of other DiGeorge features may require surgery for the cardiac

defects and vitamin D and calcium to correct hypocalcemia. Blood for these patients should be irradiated. Grafting thymic hypoplasia patients with cultured thymus tissue is followed by the appearance of new, functional T cells in the blood and by resolution of infections. Infusion of HLA-matched sibling blood or marrow has been tried in a few patients who did not improve spontaneously and carries a risk for GVHD. Intrauterine ultrasound may lead to antenatal diagnosis of the congenital heart disease.

Other Defects of Cell-Mediated Immunity

Idiopathic CD4 lymphopenia is characterized by low CD4 counts with opportunistic infection but without HIV infection. Causes may include human herpesvirus 8 infections or a primary sensitivity of CD4 cells to death by apoptosis (or both). Many patients with cartilage-hair hypoplasia have a moderate degree of lymphopenia, low lymphocyte responses to mitogens, and higher than normal morbidity and mortality rates from pneumonias, herpesviruses, and *Candida* and poxvirus infections. About a third have abnormal IgG or IgA levels. They also have an increased incidence of lymphoma. The disorder results from mutation in the *RMRP* gene that encodes the RNA component of an RNase MRP complex. BMT can restore CMI but does not correct the cartilage abnormality. Short-limbed dwarfs who are immunodeficient should probably be tested for adenosine deaminase deficiency, which also is treatable. Other types of immunodeficiency affecting predominantly cellular immunity exist but are poorly classified. These are currently included in the so-called varied immunodeficiency group. Infections in affected individuals resemble those described earlier, with the frequent addition of chronic diarrhea and malabsorption and lung infections due to atypical mycobacteria, fungi, and *Pneumocystis jiroveci*. Treatment is experimental.

Defects Affecting Gamma Interferon

Almost all cells have IFN γ receptors that mediate host defense responses. Macrophage-derived IL-12 increases IFN γ production by T and NK cells that triggers Jak-1 and Stat3 messengers. Failure of any component of the IL-12 IL-12R IFN γ IFN γ Jak-Stat pathway seems to increase susceptibility to mycobacterial or salmonella infection. Most reported patients have come from North Africa, and their infections have responded to extended courses of antibiotics.

IMMUNE DYSREGULATION

Autoimmune Lymphoproliferative Syndromes

Autoimmune lymphoproliferative syndromes (ALPS) result from mutations of genes coding for death pathways (CD95, CD95 ligand, or caspase 10) for lymphocytes. Symptoms result primarily from the associated autoimmune disorder (autoimmune hemolytic anemia, neutropenia, thrombocytopenia, and sometimes arthritis) and include frequent infections in some patients. Lymphadenopathy and splenomegaly developing in the first years of life are the principal clinical findings. An increase in the number of CD4⁺CD8⁻ (double negative) T cells in blood suggests the diagnosis, and different types of ALPS are distinguished by the response of lymphocytes to Fas-induced apoptosis. Patients are often heterozygous, and inheritance is mostly dominant. Prednisone controls the lymphadenopathy, and infections, when present, should be treated. The risk of

Hodgkin and non-Hodgkin lymphomas is increased. BMT can correct the disorder by replacing the defective lymphocyte precursors.

Mutations affecting an apoptosis-related protein, caspase 8, cause an ALPS variant syndrome in which the susceptibility to infection by herpes simplex virus also increases.

Rieux-Laucat F et al: Cell-death signaling and human disease. *Curr Opin Immunol* 2003;15:325 [PMID: 12787759].

The autoimmune polyendocrinopathy candidiasis ectodermal dysplasia (APECED) syndrome is caused by defects of the autoimmune regulator (AIRE) protein encoded at 21q22.3 and expressed in lymph nodes and spleen. Candidiasis has developed around 5 years of age, hypoparathyroidism around 10 years, followed by Addison disease. Other autoimmune diseases occur, including cytopenias, probably as a consequence of T-cell dysregulation. Affected children may die of septic shock if their Addison disease is not recognized. Boys with the immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome develop severe diarrhea with failure to thrive, insulin-dependent diabetes mellitus, or severe eczema in the first months of life and progress to develop autoimmune cytopenias, lymphadenopathy, splenomegaly, and alopecia or candidiasis. Many die before their first birthday, but a few long-term survivors have developed sarcoid, pemphigoid, or glomerulonephritis. The disorder results from mutations in the *FOXP3* gene that encodes a protein with transcriptional repressor function. Leukocyte counts including T-/B-cell numbers are generally normal, as are immunoglobulin levels prior to the development of protein loss from the gut. Immunosuppression has provided temporary improvements, but early BMT may be required.

COMBINED IMMUNODEFICIENCY DISORDERS

Severe combined immunodeficiency disease (SCID) comprises a heterogeneous group of conditions that

have in common a primary severe impairment of both antibody and CMI (Table 29–3). The term “SCID” is usually restricted to infants with congenital immunodeficiency, but equally severe defects can be caused by AIDS or lymphocyte loss. The heterogeneity of the congenital forms reflects the range of underlying defects that block the development or function of different subsets of lymphocytes, modulated by the varying degrees of engraftment with maternal lymphocytes that can occur during gestation or at birth. X-linked SCID (severe combined immunodeficiency-X1) results from mutations in the γ chain shared by the cell surface receptors for the cytokines IL-2, IL-4, IL-7, IL-9, and IL-15. It accounts for 40% of SCID cases and is described as the prototype. The SCID syndromes that result from mutations in the receptor for IL-7 and in *Jak3*, the intracellular signaling molecule for the cytokine receptors, are generally similar but with an autosomal recessive inheritance. These mutations vary in their interference with γ -chain receptor function, and this allows for a range of clinical severity in cytokine receptor X-linked SCID syndromes. Diarrhea, vomiting, and cough in the first 3 months of life are common symptoms. The

Table 29–3. Gene defects causing severe combined immunodeficiency (SCID).

Gene	Phenotype
ADA deficiency	Lymphopenic; accounts for 25% of autosomal-recessive SCID
Cytokine γ chain receptor	Low T and NK cells, high B cells; accounts for most X-linked SCID
<i>Zap-70</i>	Normal/low CD3 and CD4, absent CD8; low immunoglobulins; autosomal recessive inheritance
<i>Jak3</i> ^a	Absent CD3, low NK cells, normal B cells
<i>P56lck</i> ^b	Percentages of CD3 low to normal, CD4 low, CD8 normal; NK cells present
<i>Whn</i> ^c	Hairless, dystrophic nails, absent T cells
<i>Artemis</i> ^d	Absent T and B, Athabascan

^dLi L et al: A founder mutation in *Artemis*, an SNM1-like protein, causes SCID in Athabascan-speaking native Americans. *J Immunol* 2002;168:6323.

diarrhea causes growth deficiency and, although it may briefly remit after dietary changes, it recurs after a few days. The cough is usually persistent; it is often due to *P jiroveci* infection and can cause cyanosis. Skin rashes are common and frequently evanescent, except for rash following blood transfusion, which is due to GVHD (see section on graft-versus-host disease). A *Candida* diaper rash is usual. Findings initially include absence of tonsils or palpable lymph nodes; later, emaciation occurs. All patients with SCID have some degree of hypogammaglobulinemia and failure of antibody production (though maternal IgG is present in infants). Lymphopenia is inconstant, but, with rare exceptions, all have very low or absent T (CD3, CD4, and CD8) cells, with normal numbers of NK (CD16) cells. B lymphocytes (with surface IgM) are usually increased as a percentage but normal in number. In vitro lymphocyte responses to mitogens are generally absent. Antigen-specific responses (T cell or antibody) are difficult to test for in infancy because of uncertainty about prior experience and because the tests are generally too time-consuming for clinical purposes. Antenatal diagnosis is possible.

Differential Diagnosis & Treatment

Diarrhea and hypogammaglobulinemia in infancy suggest SCID. The main differential is between severe varied immunodeficiency and a secondary immunodeficiency due to HIV infection or severe gastrointestinal disease with loss of protein and cells. Some CD3, CD4, and CD8 T cells are usually present in these secondary immunodeficiencies, with a weak lymphocyte response to phytohemagglutinin, and the serum albumin concentration may be low. Infants in whom the diagnosis of SCID is suspected should receive antibiotics for infection, trimethoprim-sulfamethoxazole for *Pneumocystis* prophylaxis, and IgG replacement. They should not be transfused with blood unless it has first been irradiated. Confirmation of the diagnosis usually requires specialist help and should include screening for SCID subtypes listed in Table 29–3. BMT offers the best hope for cure of SCID and other severe immunodeficiencies. If an HLA-matched sibling is available, the chance of success is high; the treatment can be given without depleting the marrow of T cells or immunosuppressing the recipient. Most SCID patients do not have HLA-matched donors and are given grafts of parental bone marrow from which the T cells are removed by lectins or monoclonal antibodies. Umbilical cord blood stem cells are increasingly used as a source. Pregraft suppression, with the attendant hazards of thrombocytopenia and neutropenia, may be required; reconstitution takes 4 months; but the overall rate of T-cell engraftment is approaching 80%. Reconstitution

for antibody responses occurs in only 50% even if B cells are produced. X-linked SCID was successfully treated by autologous transplants with stem cells transfected with cytokine receptor DNA, but the integration of the retroviral vectors resulted in some oligoclonal T-cell proliferations. The development of safer vectors is awaited.

Barker JN et al: Survival after transplantation of unrelated donor umbilical cord blood is comparable to that of human leukocyte antigen-matched unrelated donor bone marrow: Results of a matched-pair analysis. *Blood* 2001;97:2957 [PMID: 11342417].

VARIANTS OF SEVERE COMBINED IMMUNODEFICIENCY

1. Adenosine Deaminase Deficiency

Adenosine deaminase (ADA) converts adenosine and deoxyadenosine to inosine and deoxyinosine, respectively. Individuals homozygous for a null gene account for about 20% of cases of SCID. ADA deficiency impairs immunity through inhibition of ribonucleotide reductase by raised deoxy-ATP, so that T lymphocytes are prevented from dividing. DNA fragmentation, interference with methylation reactions, and aberrant receptor signaling also increase. Affected infants may be near-normal at birth (presumably because their mothers keep deoxyadenosine levels down in utero). Their cellular immunity fails first; they become lymphopenic and then become antibody-deficient, though they may continue to make immunoglobulin for months or years. Diagnosis is by assay of ADA in red cell lysates. A bone marrow transplant from a matched normal sibling is the ideal treatment (see section on HSCT in Chapter 28). Immune competence is also restored by weekly infusions of polyethylene glycol-stabilized ADA enzyme conjugate. Transfection of stem cells with a retroviral construct has been successful, but the development of safer vectors is awaited.

Aiuti A et al: Correction of ADA-SCID by stem cell gene therapy combined with nonmyeloablative conditioning. *Science* 2002;296:2410 [PMID: 14612670].

Hershfield MS: Adenosine deaminase deficiency: Clinical expression, molecular basis, and therapy. *Semin Hematol* 1998;35: 291 [PMID: 9801258].

2. SCID with Leukopenia (Reticular Dysgenesis)

SCID with leukopenia occurs in infants with SCID who also have severe leukopenia, often with reduced numbers of granulocyte precursors in the marrow. Only about 20 cases have been reported. There is a familial trend, but the severity of the leukopenia varies and may result from deficiency of a cytokine.

Cham B et al: Neutropenia associated with primary immunodeficiency syndromes. *Semin Hematol* 2002;39:107 [PMID: 11957193].

3. SCID Due to DNA Repair Defects

SCID in a subset of patients results from failure to repair the breaks in DNA that lymphocytes need to make in the course of generating a receptor for antigen. NK cell numbers are normal though cultured fibroblasts are unusually sensitive to irradiation. Examples include the *Artemis* deficiency in the Na-dene American Indian population and the SCID with reticuloendotheliosis, or Omenn syndrome, caused by defects in *RAG1* and *RAG2* genes. Omenn syndrome patients have a severe eczematoid skin rash, lymphadenopathy, hepatosplenomegaly with diarrhea, and failure to thrive. Most of these patients have eosinophilia with high IgE and low IgG and IgM levels; blood B cells are low or absent. Blood T cells are low and the repertoire restricted. Many of the cells are activated and make IL-4 and IL-5. Some cases have been treated successfully by marrow ablation followed by transplantation. Other defects of DNA repair that interfere with T- and B-cell production include DNA-ligase deficiency: identical mutations in *RAG1* or *RAG2* genes leading to defective V(D)J recombinase activity can cause either T-B-SCID or Omenn syndrome.

4. SCID with Defective Expression of HLA Antigens

Deficiency of class II (HLA-DR, -DP, and -DQ) histocompatibility antigen expression is difficult to diagnose because affected patients generally make immunoglobulins and have low to normal numbers of B and T cells in their blood, together with positive responses to phytohemagglutinin stimulation. Their clinical symptoms are nevertheless those of SCID, and the T cells do not make antigen-specific responses, so the patients remain antibody-deficient. At least four complementation groups occur, and diagnosis is by testing blood lymphocytes for HLA-DR antigen expression. A number of affected families has been of North African descent. BMT for these children can be difficult. Defects of class

I histocompatibility antigen range from abnormalities of antigen transport inside the cell to abnormal or unstable expression of HLA-A or HLA-B at the cell surface. In general, these conditions are associated with milder degrees of immunodeficiency.

Gadola SD et al: TAP deficiency syndrome. *Clin Exp Immunol* 2000;121:173 [PMID: 10931128].

5. Other Combined Immunodeficiency Disorders

A poorly defined group of infants exists with more severe impairment of antibody and CMI than occurs in common variable immunodeficiency disease but who have more T cells than are usually seen in SCID. These patients have severe and protracted infections, mainly of the respiratory tract and gut. A subgroup with multiple intestinal atresias, hypogammaglobulinemia, and impaired CMI has recently been recognized; the mechanism for this association is unknown. Many have severe herpesviruses infections. Autoimmune neutropenia, anemia, and thrombocytopenia are common, as are allergies. Immune deficiency in some of these patients has been corrected by BMT.

Moore SW et al: Immune deficiency in familial duodenal atresia. *J Pediatr Surg* 1996;31:1733 [PMID: 8987005].

6. Nude/SCID phenotype

Mutations of forkhead/winged helix transcription factor causes thymic aplasia with congenital alopecia—a human equivalent of the nude mouse. One affected child was successfully treated with a marrow transplant from an HLA-matched sibling.

Pignata C: A lesson for unraveling complex aspects of novel immunodeficiencies from the human equivalent of the nude/SCID phenotype. *J Hematotherapy Stem Cell Res* 2002;11:409 [PMID: 11983112].

OTHER DISORDERS ASSOCIATED WITH IMMUNODEFICIENCY

WISKOTT-ALDRICH SYNDROME

Patients with Wiskott–Aldrich syndrome have thrombocytopenia, eczema, and recurrent infection (originally draining ears). The syndrome results from mutation of the *WASP* gene at X11p. Inheritance is X-linked recessive; the incidence is about 4 per million male

births. The mutated gene is for a protein involved in the rearrangement of actin. Common presenting symptoms are bloody diarrhea, cerebral hemorrhage, and septicemia followed by severe infections with polysaccharide-encapsulated bacteria. Symptoms can fluctuate over time so they depend only in part on the domains of the WAS protein that are inactivated by the mutation. The main causes of death in infancy are bleeding and infections, but with time lymphomas become increasingly common. Autoimmune syndromes, particularly thrombocytopenia, hemolysis, and vasculitis, occur in about 50% of patients by 5 years of age. Survival through the teens is rare in patients not receiving treatment, though partial syndromes are sometimes diagnosed in adults. A specific diagnosis should be easier now that the gene has been identified. Routine laboratory findings that suggest the diagnosis are a low platelet count, low or absent isohemagglutinins, and reduced antibody response to polysaccharides. IgM may be low; IgA and IgE are often high. BMT using the best-matched donor offers the best hope for long-term correction of the defect and is generally necessary for patients who develop autoimmune hemolytic anemia. Patients with increased susceptibility to infection are often given IgG replacement and trimethoprim-sulfamethoxazole for *Pneumocystis* prophylaxis. The platelet count generally rises following splenectomy, but this operation must be followed by antibiotic prophylaxis because of the increased risk of septicemia and sudden death.

Dupuis Girod S et al: Autoimmunity in Wiskott-Aldrich syndrome: Risk factors, clinical features, and outcome in a single-center cohort of 55 patients. *Pediatrics* 2003;111:e622 [PMID: 12728121].

Ochs HD: The Wiskott-Aldrich syndrome. *Clin Rev Allergy Immunol* 2001;20:61 [PMID: 11269229].

ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia is characterized by cerebellar ataxia (due to degeneration of Purkinje cells), usually developing between ages 2 and 5 years and followed by the appearance of telangiectasias, particularly on the conjunctiva and over exposed areas (ie, nose, ears, and shoulders). The ataxia-telangiectasia mutated (ATM) protein is kinase, encoded on chromosome 11, and required for cell cycle regulation and DNA repair. The Nijmegen breakage syndrome is probably a variant of ataxia-telangiectasia with more severe clinical features, including microcephaly and bird-like facies. Abnormal findings in ataxia-telangiectasia include raised serum α -fetoprotein levels (useful diagnostically), thymic hypoplasia, low or absent serum IgE, low IgA in 50%, abnormal carbohydrate tolerance, and defective ability to

repair radiation-induced DNA fragmentation. Clinically, the most important symptom is progressive loss of motor coordination, followed by weakness. Respiratory tract infections and many types of malignancy (including carcinomas) are the major causes of death. About 10% of patients develop lymphomas, the majority of which are T-cell-derived. Many of the lymphomas have translocations or inversions at sites where T-cell receptor genes are normally rearranged. Radiotherapy has been followed by skin breakdown, presumably the result of the DNA repair defect. Heterozygotes number 0.5–5%, depending on geographic and ethnic factors, and have a small increase in risk for breast cancer.

Perlman S et al: Ataxia-telangiectasia: Diagnosis and treatment. *Semin Pediatr Neurol* 2003;10:173 [PMID: 14653405].

CHRONIC MUCOCUTANEOUS CANDIDIASIS

This entity consists of chronic candidiasis affecting the skin or nails and mucous membranes not attributable to antibiotic treatment or another defined immunodeficiency disease. Involvement of the scalp and flexural creases is common, usually as erythema and scaling but occasionally as granulomas with skin hypertrophy. The recurrent candidiasis points to an underlying immunodeficiency, but the faulty mechanism has not been identified. Affected patients make anti-*Candida* antibodies, and their in vitro lymphocyte responses may be positive even when *Candida* skin tests are negative. Evidence for the complexity of this form of immunodeficiency includes the frequent association with endocrinopathy, sometimes autoimmune (affecting the parathyroids, thyroid, pituitary, or gonads), and, less commonly, increased susceptibility to staphylococcal infections with defective neutrophil mobility. Some control of the candidiasis can usually be achieved with continuous fluconazole treatment.

de Moraes-Vasconcelos D et al: Characterization of the cellular immune function of patients with chronic mucocutaneous candidiasis. *Clin Exp Immunol* 2001;123:247 [PMID: 11207655].

X-LINKED LYMPHOPROLIFERATIVE SYNDROME

This term is applied to boys who develop bone marrow aplasia, hypogammaglobulinemia, or a lymphoproliferative syndrome following EBV infection. The defective gene encodes a signaling protein used by T lymphocytes and NK cells. Antenatal diagnosis is possible. Affected boys are immunologically normal prior to EBV

infection, and during acute mononucleosis they make some antibody to the EBV. In most instances, the EBV infection results in a lethal lymphoproliferative syndrome characterized by liver failure, disseminated intravascular coagulation, and multiple monoclonal serum IgM bands. Acyclovir is sometimes beneficial, and treatment with IFN α and monoclonal anti-B-cell antibodies is being investigated. Only 10–20% of affected boys who are infected with EBV survive to develop hypogammaglobulinemia.

Benoit L et al: Defective NK cell activation in X-linked lymphoproliferative disease. *J Immunol* 2000;165:3549 [PMID: 11034354].

GRAFT-VERSUS-HOST DISEASE

GVHD follows transfusion of immunocompetent but incompatible lymphocytes into a person incapable of rejecting them. It causes significant morbidity in about 30% of BMT recipients and causes death in infants with SCID. It has been reported in infants receiving transfusions from HLA homozygous donors, so blood products for infants should be irradiated. An erythematous macular and then bullous skin rash is variably followed by diarrhea, hepatitis, nephritis, pulmonary infiltrates, and fever, whereas marrow damage results in neutropenia and then thrombocytopenia. Many patients develop high IgE levels. The diagnosis is suspected on the basis of transplantation and a history of an unirradiated blood or blood product transfusion, usually into an immunodeficient patient, and is confirmed by skin or lip biopsy. Prophylaxis in transplant recipients is with corticosteroids and cyclosporine, and when the disease becomes severe it may be slowed by high-dose corticosteroids or at least temporarily halted by anti-T-cell antibodies (see Table 29–5). Chronic GVHD after allogeneic BMT causes scleroderma and bile duct destruction. The liver damage can be severe enough to require transplantation.

Henslee-Downey PJ: Mismatched bone marrow transplantation. *Curr Opin Oncol* 1995;7:115 [PMID: 7756375].

Takanashi M et al: Graft-versus-host disease associated with transfusions of HLA-matched, HLA-homozygous platelets. *Transfusion* 1995;35:535 [PMID: 7878725].

BIOCHEMICAL DEFECTS SOMETIMES ASSOCIATED WITH IMMUNODEFICIENCY

Several primary errors of metabolism affect immunity adversely. Transcobalamin 2 deficiency causes a megaloblastic anemia with impaired bacterial killing by neutrophils and reduced serum immunoglobulins of all

classes. Biotin-dependent decarboxylase deficiencies may be associated with convulsions, alopecia, candidiasis, low serum IgA, and a reduced number of T cells. Lymphopenia and impaired CMI are reported in hereditary orotic aciduria. Bloom syndrome, in which mutations in a DNA helicase result in excess sister chromatid exchanges, is associated principally with lymphoma and cancer, as well as life-threatening infections. Serum IgA and IgM are sometimes low, and lymphocytes respond abnormally in laboratory tests. A systematic listing of genetic disorders with immunodeficiency is given in the review by Ming and others.

Bloom syndrome:

Ming JE et al: Syndromic immunodeficiencies: Genetic syndromes associated with immune abnormalities. *Crit Rev Clin Lab Sci* 2003;40:587 [PMID: 14708957].

SECONDARY IMMUNODEFICIENCY

Secondary immunodeficiency is a common cause of pediatric illness. The mechanisms that may be impaired are summarized in Table 29–4, and the symptoms are generally those that would be anticipated from the combination of the primary disorder and the complicating immunodeficiency. Whenever possible, treatment should be directed at the primary disorder. Occasionally, immunologic methods may help; for example, postexposure varicella-zoster immune globulin may prevent varicella infection in patients with leukemia, and intravenous immune globulin replacement might provide added protection when antibody production is diminished. IgG replacement is unlikely to help when loss (as in nephrotic syndrome) is responsible for hypogammaglobulinemia.

Lee ML et al: Use of intravenous immunoglobulin to prevent or treat infections in persons with immune deficiency. *Annu Rev Med* 1997;48:93 [PMID: 9046948].

POST-BONE MARROW TRANSPLANT IMMUNODEFICIENCY

In the months following a BMT, patients remain highly susceptible to herpesvirus, *P jiroveci*, and other fungal infections even when their blood leukocyte counts recover. They require prophylaxis with trimethoprim–sulfonamide, acyclovir, and intravenous immune globulin, and pulmonary symptoms (cough, impaired oxygenation) must be investigated promptly.

Table 29–4. Mechanisms of secondary immunodeficiency.

Mechanism	Example
Loss	
Immunoglobulin	Renal, in nephrotic syndrome
Immunoglobulin	Skin, from burns
Immunoglobulin and cells	Gut, in intestinal lymphangiectasia
Phagocytes	Following splenectomy
Malnutrition	Kwashiorkor
Zinc deficiency	Impaired cell-mediated immunity
Copper and iron deficiency	Impaired neutrophil function
Drugs	Steroids, cancer chemotherapy Specific immunosuppressants Phenytoin → IgA deficiency
Infections	HIV, EBV, CMV, measles, rubella, hepatitis, malaria

HIV = human immunodeficiency virus; EBV = Epstein–Barr virus; CMV = cytomegalovirus.

These problems arise partly from immunosuppression by cyclosporine and steroids that reduces GVHD, partly from delay in recovery of the B lymphocytes required for antibody responses, and, under some circumstances, because of cytokines given to boost neutrophil production.

Volpi I et al: Postgrafting administration of granulocyte colony-stimulating factor impairs functional immune recovery in recipients of human leukocyte antigen haplotype-mismatched hematopoietic transplants. *Blood* 2001;97:2514 [PMID: 11290617].

THERAPEUTIC IMMUNOSUPPRESSION

Therapeutic immunosuppression is increasingly used in pediatrics for transplant recipients and for autoimmune disease. Corticosteroids at doses equivalent to 2 mg/kg of prednisolone per day interfere with cytokine production and cause lymphopenia by directing lymphocytes to the marrow; the effects of a single dose last about 24 hours. Much higher doses, equivalent to 20–30 mg/kg of prednisolone per day, are used in 3- to 5-day courses for treatment of life-threatening conditions or to evaluate the potential for more powerful immunosuppressive agents. Corticosteroids are satisfactory anti-inflammatory and immunosuppressive agents when they can be given on alternate days as a single morning dose (as is sometimes the case for systemic lupus erythematosus or autoimmune anemias). The use

of higher doses of corticosteroids is limited by the growth arrest and severe cushingoid changes, which occur even in dosages of 2 mg/kg of prednisolone per day. Transplant recipients require additional powerful immunosuppressives such as cyclosporine or tacrolimus (FK506). Both bind to immunophilins to form a complex that reversibly inhibits calcineurin-dependent signaling in lymphocytes, blocking cytokine production and release. Immunosuppression achievable by both agents is limited by their nephrotoxicity; trough blood levels need to be monitored carefully, and drugs that affect their metabolism (erythromycin, theophylline) tracked. Tacrolimus is increasingly used because rejection episodes tend to be fewer, though a possible increase in post-transplant lymphoproliferative disease (PTLD) is a concern. Preventing organ rejection usually requires two drugs, such as cyclosporine with either mycophenolate mofetil (MMF) or azathioprine. MMF inhibits purine synthesis and is relatively specific for lymphocytes. It is usually taken by mouth, absorption is erratic, and blood levels must be checked. High cost is one reason why MMF has not replaced azathioprine, which causes much more general marrow suppression. Patient compliance with chronic antirejection medicines is a significant problem. Because MMF causes gastrointestinal disturbance, patients may not take it, and teenagers who have received organ transplants sometimes become depressed and stop taking all their medicines.

Sirolimus (rapamycin) inhibits T-cell activation and proliferation as well as antibody production. It is orally active and is generally combined with cyclosporine for treating transplant rejection. It has activity in chronic GVHD: Increases in cholesterol and triglycerides are adverse effects. Animal models suggest that the currently popular combinations of steroids and cyclosporine interfere with the acquisition of tolerance for grafts, and combinations of newer agents (rapamycin with monoclonal antibodies to the IL-2 receptor) are being evaluated clinically.

Severe organ rejection episodes, or GVHD, can be controlled acutely with antibodies to T lymphocytes such as antithymocyte globulin and monoclonal CD3 antibody. Both deplete T cells and clear antigen receptors off the T-cell surface. Some T cells are activated as well, causing a cytokine syndrome of fever, malaise, skin rash, and pulmonary edema. This syndrome is minimized by premedicating patients with an antihistamine, acetaminophen, corticosteroids, and even cyclosporine. Patients generally need to be tested for antihorse, antirabbit, or antimouse antibodies after treatment, and those who test positive should not receive the same preparation again.

Antimitotic agents (eg, cyclophosphamide, chlorambucil) and antimetabolites (methotrexate) that block

lymphocyte proliferation are effective but toxic immunosuppressants. The range of licensed monoclonal antibodies with immunosuppressive or anticancer activities has increased greatly (Table 29–5). Immunosuppressive antibodies carry the risk of reactivation of latent herpesviruses (ie, cytomegalovirus, herpes simplex virus, varicella-zoster virus), although antiviral treatments have made these infections less life-threatening. EBV reactivation is hazardous if it results in a lymphoproliferative disease, which, when severe, is associated with marrow phagocytosis of red and white cells. The appearance of free EBV genome in the plasma probably provides the best advance warning of this dangerous complication. Testing serum for oligoclonal immunoglobulin bands may give some indication of the progression or regression of lymphoproliferative disease. The usual treatment strategy is to reduce the dosage of agents such as cyclosporine and tacrolimus while continuing immunosuppression with steroids. Rituximab may be useful too. Combined immunosuppression with agents having different modes of action tends to be much more potent, with a greater potential for opportunistic infections, than immunosuppression by single agents. The risk of infection is greatest when the neutrophil count is depressed by antimetabolic agents at the

same time that specific immunity is suppressed by corticosteroids and cyclosporine.

INVESTIGATION OF IMMUNODEFICIENCY

Physical and anatomic defects are the most common causes of recurrent infections, and if a single site is af-

Table 29–5. Monoclonal antibodies.

Disorder Treated ^a	Antibody ^b	Comments/Adverse Reactions
Crohn disease, rheumatoid arthritis	Infliximab: tumor necrosis factor alpha	Single-dose infusions at 5 mg/kg. 28% of recipients had DNA antibodies and EBV reactivation. 5% severe infections include Tb reactivation and retropharyngeal abscesses
B-cell lymphomas, autoantibody production	Rituximab: CD20	B-cell lymphopenia, tumor lysis, rare severe infusion reactions
Transplant rejection, graft-versus-host disease.	Daclizumab: IL-2R (Tac)	Appears well tolerated, usually given as 1–2 infusions
Graft-versus-host disease	Visilizumab: CD3	Depletes T cells, EBV reactivation
Graft-versus-host disease.	ABX-CBL: CD147 (mouse IgM)	Myalgias reported
Non-Hodgkin lymphoma, chronic lymphocytic leukemia	Alemtuzumab: CD52	T-cell activation and cytokine syndrome, lymphopenia
Transplant rejection	Muromonab-CD3 (OKT3)	T-cell activation, cytokine syndrome, lymphopenia, EBV reactivation
B-cell lymphomas	Epratuzumab: CD22	Four treatments at weekly intervals, no effect on Ig levels
Psoriasis, asthma	Efalizumab: CD11a	Flu-like syndrome with headache after first injection

^aExperimental treatment included.

^bThese are humanized mouse antibodies unless otherwise indicated.

ected it should be searched for a local abnormality. The age at onset of infections is important because defects of phagocytes, C3, or cellular immunity becomes symptomatic in the first months of life, whereas maternal antibody protects infants with hypogammaglobulinemia for 3–6 months. Antibody, complement, and phagocyte defects predispose mainly to bacterial infections; diarrhea, superficial candidiasis, and severe herpesvirus infections are typical of cellular immunodeficiency. A simple protocol for testing these mechanisms is presented in Table 29–6, and the level of investigation should reflect the frequency and severity of infections. A complete blood count and quantitative immunoglobulin measurement will identify more than 90% of primary immunodeficiency syndromes.

Fleisher TA: Evaluation of the potentially immunodeficient patient. *Adv Intern Med* 1996;41:1 [PMID: 8903585].

PHAGOCYTE FUNCTION

Tests of phagocytic cell function should first rule out neutropenia with white blood cell count and differential. A blood film is useful to exclude the Howell–Jolly bodies of asplenia and to look for normal lysosomal granules in neutrophils. Myeloperoxidase deficiency is excluded by histochemical stains available in most oncology laboratories. The respiratory burst and generation of bactericidal factors can be tested by nitroblue tetrazolium reduction, so this test screens for most types of chronic granulomatous disease (the most common bacterial killing defect) and for leukocyte glucose-6-phosphate dehydrogenase deficiency. Leukocyte adhesion molecules are screened by flow cytometry, although the difference in symptoms of these various phagocyte defects should dictate which tests are used. Chemotaxis can be measured in migration chambers in the laboratory and can also be assessed by migration of cells from abraded skin onto a sterile coverslip. Results of chemotaxis tests must be interpreted cautiously, be-

cause secondary and transient defects in chemotaxis are common. Quantitations of bacterial ingestion and microbicidal activity are mostly research procedures.

COMPLEMENT

Deficiency of a classic pathway component can be excluded by a normal hemolytic complement titer, for which the patient’s serum must be separated and frozen to –70°C within 30 minutes of collection. Alternative pathway function is tested by lysis of rabbit red blood cells. There is little point in measuring individual complement component levels if the hemolytic titer is normal—unless it is done to follow the activity of an immune complex-associated disease in which C4 and C3 may be low. The common form of opsonizing defect of yeast is now known to be due to allelic variants of mannan-binding protein.

Martin P et al: Inherited mannose-binding lectin deficiency as evidenced by genetic and immunologic analyses: Association with severe recurrent infections. *Ann Allergy Asthma Immunol* 2003;91:386 [[PMID: 14582818].

ANTIBODIES & IMMUNOGLOBULINS

In patients who are not blood group AB, isohemagglutinins are the most easily tested naturally occurring antibodies. They are of the IgM class, become detectable by age 6 months, and reach adult levels about 1 year later. Tetanus and diphtheria antibody tests are widely available, as are antibodies to the 23-valent pneumococcal polysaccharide, rubella, and mumps. In practice, it is often easier to measure serum immunoglobulins as a screening procedure than to test for antibodies, but some patients with varied immunodeficiency syndromes and some infants with severely impaired CMI make immunoglobulin that does not have useful antibody activity. Properly performed immunoglobulin estimations are reproducible to ±10% for IgG and IgA

Table 29–6. Hierarchy of tests for investigation of primary immunodeficiency.

Test Level	Complement	Phagocytes	Antibody	CMI
Screening	CH ₅₀	Count, morphology	Ig measurement	Delayed hypersensitivity skin tests
First level		NBT, LFA-1 ^a	IHA, ^b TT	T-cell counts ^c
Second level	Factor assays	Killing and chemotaxis	Immunize	In vitro tests

^bIHA = isohemagglutinins, after age 1; TT = tetanus toxoid.

^cIdentify all T cells with CD3, subsets with CD4, CD8. CD45RO for memory cells.

CMI = cell-mediated immunity.

Table 29–7. Blood lymphocyte phenotyping.

Antigen	Cells Stained	Normal Range and Changes Seen Clinically
CD2	T, NK	70–90%. Falls to 10–20% when T cells absent.
CD3	All T	55–85%. Falls when T-cell number reduced. Increases to 90% when B cells absent.
CD4	HLA-D restricted T cells	35–60%. Selectively reduced in HIV infections. Reduced with other T cells by steroids, defect of cell-mediated immunity.
CD5	T cells, immature B cells	55–85%. Falls when T-cell number reduced. Increased with immature B cells.
CD8	HLA-A/B restricted T cells	25–50%. Selectively increased in response to some viral infections. Reduced with other T-cell defects.
CD11	Monocytes	Lacking in LFA-1 deficiency.
CD16	NK cells	Increased by viral infections.
CD19	B cells	Absent or low in congenital X-linked agammaglobulinemia and common variable immunodeficiency disease. Increased when T cells are lacking.
CD20	B cells	Increased when T cells lacking.
CD25	IL-2 receptor	Activated T cells. Increased in graft-versus-host disease.
CD45RO	T cells	Memory T cells, low in newborns.
CD56	NK cells	Raised in active viral infections.

NK = natural killer; HLA = human leukocyte antigen; LFA1 = leukocyte functional antigen-1.

and $\pm 20\%$ for IgM, so small changes are of no significance. Measurement of serum IgD is not generally of diagnostic value in pediatrics. Immunoglobulin concentrations are lower in infants than in adults, and laboratories may erroneously report normal children's values as low. Patients with very low immunoglobulins of all classes should have blood T- and B-cell counts as most boys with BTK deficiency lack B cells—as do the small number of patients with μ chain deficiency. Protein electrophoresis is valuable for identifying the monoclonal excesses seen in macroglobulinemia, in the oligoclonal gammopathy of EBV infections in X-linked lymphoproliferative syndrome, and in heavy-chain diseases. Serum albumin should be measured at least once in patients with hypogammaglobulinemia to exclude secondary deficiencies due to loss. IgG or IgA subclass measurements may be abnormal in patients with varied immunodeficiency syndromes, but they are rarely helpful.

CELL-MEDIATED IMMUNITY

Positive delayed hypersensitivity skin tests give good evidence for antigen-specific T-cell immunity. Only a

positive response is interpretable—particularly in infancy, when prior immunization may not have been adequate to elicit good skin responses.

Blood T- and B-lymphocyte counts are good screening tests for disorders of CMI. Only small volumes of blood are required, and results are rapidly available. Some of the more useful phenotypes—and common deviations from normal—are summarized in Table 29–7. When abnormalities are suspected, it is important to check absolute numbers of lymphocytes and their subsets. Tests of T-cell proliferation and cytokine production are useful for characterizing immunodeficiency detected by simpler tests, but they are not useful screening tests for children with recurrent infections.

Endocrine Disorders

30

Philip S. Zeitler, MD, PhD, Sharon H. Travers, MD, Jennifer Barker, MD, Kristen Nadeau, MD, & Michael S. Kappy, MD, PhD

■ GENERAL CONCEPTS

One of the major functions of the endocrine system is to regulate enzymatic and other metabolic processes (eg, molecular transport) responsible for maintaining the equilibrium (homeostasis) of the internal environment to ensure survival of the individual. Other critical roles for the endocrine system are regulation of growth (in utero and postnatal), pubertal development and reproduction, energy production, blood pressure, and, to a lesser extent, behavior.

The classic concept that endocrine effects are the result of hormones secreted into the blood to reach a target cell has been updated to account for other ways in which hormonal effects occur. Specifically, some hormone systems involve the stimulation or inhibition (or both) of metabolic processes in neighboring (as opposed to distant) cells (eg, within the pancreatic islets or cartilage). This phenomenon is termed *paracrine*. Other hormone effects reflect the action of particular hormones on the same cells that produced them. This action is termed *autocrine*. The discoveries of local production of insulin, glucagon, atrial natriuretic hormone, and many other hormones in the brain and gut support the concept of paracrine and autocrine processes in these tissues.

Another significant discovery in endocrine physiology was an appreciation of the role of specific hormone receptors in target tissues, without which the hormonal effects could not occur. In the *complete* androgen insensitivity (resistance) syndrome, androgen receptors are absent, and the individual develops normal female external genitalia despite the presence of testes (usually intra-abdominal) and adequate testosterone production. Similarly, in nephrogenic diabetes insipidus or Albright hereditary osteodystrophy (pseudohypoparathyroidism), affected persons have abnormal antidiuretic hormone (ADH) or parathyroid hormone (PTH) receptor function and show the metabolic effects of diabetes insipidus or hypoparathyroidism (low serum calcium and high serum phosphate levels), despite more than adequate hormone secretion. Alternatively, autonomous (abnormal) activation of a hormone receptor

leads to the effects of the hormone without its abnormal secretion. Examples of this phenomenon include McCune–Albright syndrome (precocious puberty and hyperthyroidism) and testotoxicosis (familial male precocious puberty).

HORMONE TYPES

Three main structural types of hormones exist: peptides and proteins, steroids, and amines. The peptide hormones include the releasing factors secreted by the hypothalamus, the hormones of the anterior and posterior pituitary gland, pancreatic islet cells and parathyroid glands, insulin-like growth factor 1 (IGF-1) from the liver and other tissues, angiotensin II, atrial natriuretic hormone, and many local growth factors. Steroid hormones are secreted primarily by the adrenal cortex, the gonads, and the liver and kidney (active vitamin D). The amine hormones are secreted by the adrenal medulla (epinephrine) and the thyroid gland (triiodothyronine [T₃] and thyroxine [T₄]).

As a rule, the peptide hormones and epinephrine act more rapidly than the others and bind to specific receptors on the surface of their target cell. The metabolic effect of these hormones is usually stimulation or inhibition of the activity of pre-existing enzymes or transport proteins (post-translational effects). The steroid hormones and active vitamin D, in contrast, act more slowly and bind to specific cytoplasmic receptors within the target cell and subsequently to specific regions (genes) on nuclear DNA, where they direct a read-out of specific protein(s). Their metabolic effects are generally caused by stimulating or inhibiting the synthesis of new enzymes or transport proteins (transcriptional effects), thereby increasing or decreasing the amount rather than the activity of these proteins in the target cell.

Metabolic processes that must be regulated rapidly (eg, blood glucose or calcium homeostasis) are usually under the control of the peptide hormones and epinephrine, whereas those processes that may be regulated more slowly (eg, pubertal development, metabolic rate) are under the control of the steroid hormones and thyroid hormone (Table 30–1). The control of electrolyte homeostasis is intermediate and is regulated by a

Table 30–1. Hormonal regulation of metabolic processes.

First Level (Most Direct)			
Metabolite or Other Parameter	Abnormality	Endocrine Gland	Hormone
Glucose	Hyperglycemia	Pancreatic beta cell	Insulin

Releasing Hormone	Tropic Hormone	Endocrine Gland	Endocrine Gland Hormone
CRH	ACTH	Adrenal cortex	Cortisol
GHRH	GH	Liver	IGF-1
GnRH	LH	Testis	Testosterone
GnRH	FSH/LH	Ovary	Estradiol/progesterone
TRH	TSH	Thyroid gland	T ₄ (some T ₃)

ACTH = corticotropin; ADH = antidiuretic hormone; ANH = antinatriuretic hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotropin-releasing hormone; IGF = insulin-like growth factor; LH = luteinizing hormone; PTH = parathyroid hormone; T₃ = triiodothyronine; T₄ = thyroxine; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

combination of peptide and steroid hormones (see Table 30–1).

FEEDBACK CONTROL OF HORMONE SECRETION

Hormone secretion is regulated, for the most part, by feedback in response to changes in the internal environment as postulated by Claude Bernard in the nineteenth century (see Table 30–1). When the metabolic imbalance is corrected, stimulation of the hormone's secretion ceases and may even be inhibited. Overcorrection of the imbalance stimulates secretion of a counterbalancing hormone or hormones, so that the circulating concentrations of metabolites are kept within relatively narrow limits.

Hypothalamic–pituitary control of hormonal secretion is also regulated by feedback, so that end-organ

failure (endocrine gland insufficiency) leading to decreased circulating concentrations of endocrine gland hormones results in increased secretion of hypothalamic releasing and pituitary hormones (see Table 30–1; Figure 30–1). If restoration of normal circulating concentrations of endocrine gland hormones occurs, feedback inhibition at the pituitary and hypothalamus results in cessation of the previously stimulated secretion of releasing and pituitary hormones and restoration of their circulating concentrations to normal.

Similarly, if autonomous endocrine gland hyperfunction is present (eg, McCune–Albright syndrome, Graves disease, adrenal tumor), the specific hypothalamic releasing and pituitary hormones are suppressed (see Figure 30–1). An understanding of the basic phenomenon of feedback control of hormonal secretion is fundamental to the understanding of endocrine disorders and their evaluation in children.

Figure 30–1. General scheme of the hypothalamus–pituitary–endocrine gland axis. Releasing hormones synthesized in the hypothalamus are secreted into the hypophysial portal circulation. Trophic hormones are secreted by the pituitary gland in response, and they in turn act on specific endocrine glands to stimulate the secretion of their respective hormones. The endocrine gland hormones exert their respective effects on various target tissues (end organs) and exert an indirect negative feedback (feedback inhibition) on their own secretion by acting at the level of the pituitary and hypothalamus. This system is characteristic of those hormones listed in Table 30–1 (third level).

DISTURBANCES OF GROWTH

Disturbances of growth and development are the most common presenting complaints in the pediatric endocrine clinic. It is critical to distinguish between normal and abnormal growth patterns, because deviation from a normal growth pattern can be the first or only manifestation of a wide variety of diseases. Determination of height velocity is the single most critical factor in evaluating the growth of a child, and a persistent increase or decrease in height percentiles between age 2 years and the onset of puberty should warrant further evaluation. It is a little more difficult to distinguish

normal from abnormal growth in the first 2 years of life, as infants will show catch-up or catch-down growth during this period. It is also important to evaluate a child's growth in the context of normal standards. The National Center for Health Statistics provides standard growth charts derived from growth data of North American children (see Chapter 1). Height and weight measurements should be plotted on these charts. Growth charts are also available for children with specific growth disturbances, such as Turner syndrome and Down syndrome.

TARGET HEIGHT AND SKELETAL MATURATION

The growth and height potential of a child is determined largely by genetic factors. The target (mid-parental) height of a child can be determined by calculating the mean parental height and adding or subtracting 6.5 cm for boys and girls, respectively. Most children will achieve an adult height that is within 8 cm of their target height; consequently, this calculation is very helpful in evaluating a child's genetic growth potential. Another important parameter in determining growth potential is bone age, which is a measure of skeletal maturation. Beyond the neonatal period, a radiograph of the left hand and wrist is obtained and compared with the published standards of Greulich and Pyle. The extent of skeletal maturation can be used to predict a child's ultimate height potential because growth ceases when epiphyseal fusion is complete. A delayed bone age is not diagnostic of a specific disease but indicates that there is residual growth potential.

SHORT STATURE

Short stature has many causes, and it is important to distinguish between normal variants of growth (familial short stature and constitutional growth delay) and pathologic conditions (Table 30–2). Pathologic short stature should be suspected in children who have an abnormal growth velocity (crossing major height percentiles on the growth curve) or in children who are significantly short for their family. Children with chronic illness or nutritional deficiencies may have poor linear growth, but this is typically associated with inadequate weight gain. In contrast, endocrine causes of short stature are usually associated with normal or excessive weight gain.

Familial Short Stature and Constitutional Growth Delay

Children with familial short stature are typically born with normal weight and length. In the first 2 years of

---	---

life, however, they will have a deceleration in linear growth to reach their target percentile, which is determined largely by genetic factors. Once this target percentile is obtained, the child will have normal linear growth parallel to the growth curve. Skeletal maturation and the timing of puberty are consistent with chronologic age. Consequently, the height percentile the child has been following is maintained, and final height is short but appropriate for the family (Figure 30–2). For example, an infant boy of a mother who is 5'0" and father who is 5'5" may have a birth length at the fiftieth percentile. However, this child's length will probably change percentiles downward within the first 2 years of life to reach the fifth percentile. The calculated midparental height of this child is 5'5", which is at the fifth percentile for a full grown male. Consequently, the fifth percentile is an appropriate growth trajectory for this child.

Children with constitutional growth delay do not necessarily have short parents but have a growth pattern similar to those with familial short stature. The difference is that children with constitutional growth delay will have a delay in skeletal maturation and a delay in

the onset of puberty. In these children, growth continues beyond the time the average child has stopped growing, and final height is appropriate for target height (Figure 30–3). There is often a history of other family members being so-called "late bloomers."

Growth Hormone Deficiency

Human growth hormone (GH) is produced by the anterior pituitary gland under the stimulation of growth hormone-releasing hormone (GHRH) and the inhibition of somatostatin. GH is secreted in a pulsatile pattern in response to sleep, exercise, and hypoglycemia and has direct growth-promoting and metabolic effects (Figure 30–4). GH also promotes growth indirectly by stimulating the production of insulin-like growth factors, primarily IGF-1.

Growth hormone deficiency (GHD) is characterized by decreased growth velocity, delay in skeletal maturation, absence of other explanations for poor growth, and laboratory tests indicating subnormal GH secretion. GHD may be isolated or may occur with other pituitary hormone deficiencies. Identifiable causes of

Figure 30-2. Typical pattern of growth in a child with familial short stature. After attaining an appropriate percentile during the first 2 years of life, the child will have normal linear growth parallel to the growth curve. Skeletal maturation and the timing of puberty are consistent with chronological age. The height percentile the child has been following is maintained, and final height is short but appropriate for the family.

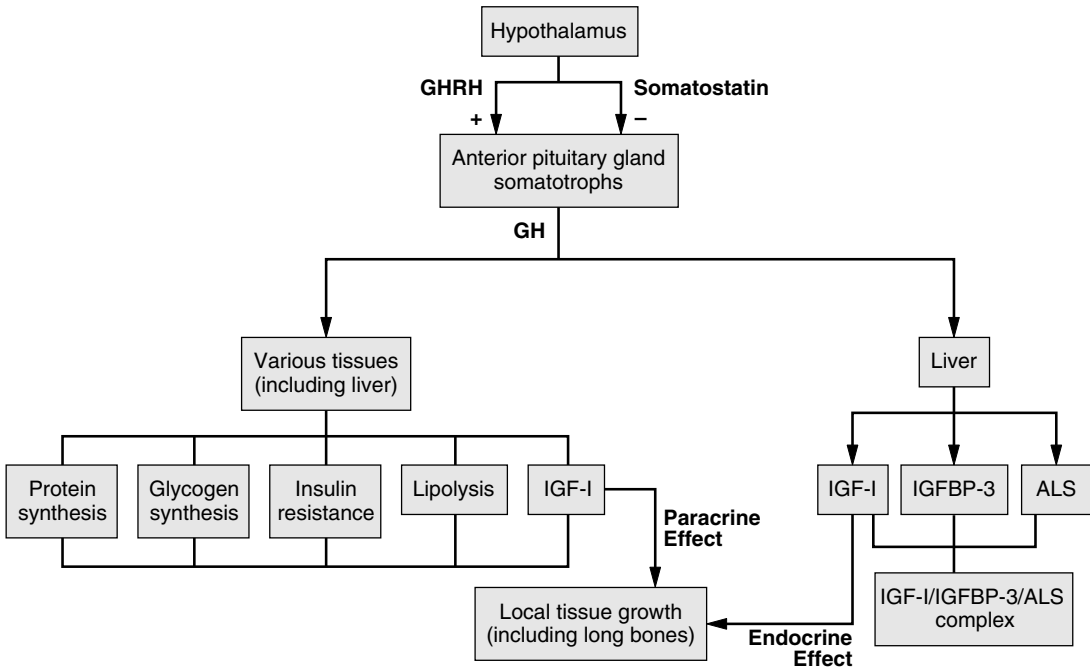

Figure 30–4. The GHRH/GH/IGF-1 system. The effects of growth hormone (GH) on growth are partly due to its direct anabolic effects in muscle, liver, and bone. In addition, GH stimulates many tissues to produce insulin-like growth factor 1 (IGF-1) locally, which stimulates the growth of the tissue itself (paracrine effect of IGF-1). The action of GH on the liver results in the secretion of IGF-1 (circulating IGF-1), which stimulates growth in other tissues (endocrine effect of IGF-1). The action of growth hormone on the liver also enhances the secretion of IGF-binding protein-3 (IGFBP-3) and acid-labile subunit (ALS), which form a high-molecular-weight complex with IGF-1. The function of this complex is to transport IGF-1 to its target tissues, but the complex also serves as a reservoir and possible inhibitor of IGF-1 action. In various chronic illnesses, the direct metabolic effects of growth hormone are inhibited; the secretion of IGF-1 in response to GH is blunted, and in some cases IGFBP-3 synthesis is enhanced, resulting in marked inhibition in the growth of the child. (GHRH = growth hormone-releasing hormone.)

GHD may be congenital (septo-optic dysplasia, empty-sella syndrome), genetic (HGH or GHRH gene mutation), or acquired (craniopharyngioma, germinoma, histiocytosis, cranial irradiation). Idiopathic GHD, however, occurs more commonly than any of these recognized causes, with an incidence of approximately 1:4000 children. The GH insensitivity syndrome (Laron dwarfism) is caused by a mutation in the GH receptor. These children present in a manner similar to those with GHD, but children with Laron dwarfism may have a distinctive facial appearance.

Infants with GHD are of normal birth weight; birth length may be reduced slightly, suggesting that GH is not a major contributor to intrauterine growth. Classic HGH-deficient infants may present initially with hypoglycemia or evidence of other pituitary deficiencies such as central hypothyroidism or adrenal insufficiency. Go-

nadotropin and GH deficiency may be suspected in the newborn male who has a micropenis. Growth retardation may begin in infancy or may be delayed until later childhood. In children with acquired or idiopathic GHD, the primary manifestation is a subnormal growth velocity (Figure 30–5). Because GH promotes lipolysis, many GH-deficient children will also have truncal adiposity.

Laboratory tests to assess GH status may be difficult to interpret. Children with normal and short stature have a broad range of HGH secretion patterns, and significant overlap exists between test results of normal and GH-deficient children. Traditionally, provocative studies are performed using such agents as insulin-induced hypoglycemia, arginine, levodopa, clonidine, or glucagon. Serum concentrations of IGF-1 and IGF-binding protein 3 may give reasonable estimations of

Figure 30-5. Typical pattern of growth in a child with acquired growth hormone deficiency. Children with acquired growth hormone deficiency have an abnormal growth velocity and fail to maintain height percentile during childhood. Other phenotypic features (central adiposity, immaturity of facies) may be present. Children with congenital growth hormone deficiency will cross percentiles during the first 2 years of life, similar to the pattern seen in familial short stature and constitutional delay, but will fail to attain a steady height percentile subsequently.

GH secretion in the adequately nourished child (see Figure 30-4). When results of GH tests are equivocal, a trial of HGH treatment may be useful in determining whether an abnormally short child will benefit from GH. Currently the treatment of choice for GHD is recombinant HGH in a dose of 0.15–0.3 mg/kg/wk administered subcutaneously divided into six or seven equal once-daily doses.

GH therapy is FDA-approved for children with GHD and growth retardation associated with chronic renal failure, for girls with Turner syndrome, children with Prader–Willi syndrome, and children born small for gestational age (SGA) who fail to demonstrate “catch-up” growth by age 4. GH therapy has been recently approved for children with idiopathic short stature whose current height is more than 2.25 SD below the norm for age. Final height improvement may be 5–7 cm in this population. This indication has generated much controversy, and the role of GH in these children remains unclear. GH therapy is expensive, and indications other than these remain controversial. Reported side effects of recombinant GH therapy are uncommon but include benign intracranial hypertension and slipped capital femoral epiphysis. With early diagnosis and treatment, children with GHD reach normal or nearly normal adult height.

Small for Gestational Age/Intrauterine Growth Restriction

Small-for-gestational-age (SGA) infants are those who have birth weights less than the tenth percentile for the population’s birth weight/gestational age relationship. SGA infants include those who are constitutionally small and growing at their potential, as well as those with intrauterine growth retardation (IUGR). IUGR refers to a heterogeneous group of patients who fail to grow at a normal rate in utero. SGA/IUGR occurs secondary to poor maternal environment, intrinsic fetal abnormalities, congenital infections, or other forms of fetal malnutrition. Conditions secondary to intrinsic fetal abnormalities are often referred to as primordial short stature and include the Russell–Silver, Seckel, Noonan, Bloom, and Cockayne syndromes, and progeria. Many children with milder degrees of SGA/IUGR (except those with intrinsic fetal abnormalities) exhibit catch-up growth during their first 3 years of life. However, 15–20% will remain short throughout life, particularly those whose growth restriction in utero occurred over several months rather than just the last 2 or 3 months of gestation, as well as those born preterm with subsequent inadequate postnatal nutrition. Those children who do not show catch-up growth will have a normal growth velocity, although they will follow a lower height percentile than expected for the family. In most instances, skeletal maturation corresponds to

chronologic age or is delayed only mildly—in contrast to the delay occurring in children with constitutional growth delay. GH therapy has been evaluated in SGA children, and short-term studies have shown increases in growth velocity. Consequently, growth hormone has recently been approved for treatment in these children.

Disproportionate Short Stature

Skeletal dysplasias are disorders that result in disproportionate short stature. More than 200 different types of skeletal dysplasias may occur, either sporadically or genetically. Measurements of arm span and upper-to-lower body segment ratio are helpful in determining whether a child has normal body proportions. If disproportionate short stature is found, a skeletal survey may be useful because specific radiographic features characterize certain disorders. Because skeletal dysplasias are individually rare, the effect of GH on most types is largely unknown.

Short Stature Associated with Syndromes

Short stature is associated with many syndromes, including Turner, Down, and Prader–Willi. Girls with Turner syndrome typically have such other typical features as micrognathia, webbed neck, low posterior hairline, edema of hands and feet, multiple pigmented nevi, and an increased carrying angle. In some girls with Turner syndrome, however, short stature is the only clinical manifestation. Consequently, any girl with unexplained short stature should have a chromosomal evaluation. Although girls with Turner syndrome are not classically GH-deficient, GH therapy has been shown to improve final height by an average of 6.0 cm. The duration of GH therapy is a significant predictor of long-term height gain; consequently, it is important that Turner syndrome be diagnosed early and GH started as soon as possible.

GH is also approved for growth failure associated with Prader–Willi syndrome, a syndrome in which many individuals are GH-deficient. GH improves growth as well as body composition and physical activity in these patients. A few fatalities have been reported in Prader–Willi children treated with GH. All of these children were severely obese or had a history of respiratory impairment, sleep apnea, or an unidentified respiratory infection. The role of GH, if any, in contributing to these deaths is unknown. As a precaution, it is recommended that all Prader–Willi patients be evaluated for upper airway obstruction and sleep apnea prior to initiation of GH therapy.

Children with Down syndrome should be evaluated for GHD only if their linear growth is abnormal compared with the Down syndrome growth chart.

Psychosocial Short Stature (Psychosocial Dwarfism)

Psychosocial short stature is characterized by growth retardation in association with emotional deprivation. Undernutrition contributes to the growth retardation of some affected children. In addition to impaired growth, bizarre eating and drinking habits, bowel and bladder incontinence, social withdrawal, and delayed speech may occur. GH secretion in children with psychosocial short stature is diminished, but GH therapy is usually not beneficial. Foster home placement or a change in the psychological environment at home usually results in improved growth and normalization of GH secretion, personality, and eating behaviors.

Diagnostic Approach to Short Stature

Laboratory investigation should be guided by information gained from the history and physical examination. Initial considerations should include size at birth, presence of dysmorphism, pattern of growth since birth, family pattern of growth, pubertal stage, body segment proportion, and psychological problems. In a child who has poor weight gain as the primary disturbance, history of chronic illness and nutritional assessment are indicated. The following laboratory tests may be useful:

1. Radiograph of left hand and wrist for bone age
2. Complete blood count (to detect chronic anemia, infection)
3. Erythrocyte sedimentation rate (often elevated in collagen-vascular disease, cancer, chronic infection, inflammatory bowel disease)
4. Urinalysis, blood urea nitrogen, and serum creatinine (occult renal disease)
5. Serum electrolytes, calcium, and phosphorus (renal tubular disease, metabolic bone disease)
6. Stool examination for fat, serum endomysial antibody (malabsorption, celiac disease)
7. Karyotype (in girls)
8. Thyroid function tests: free thyroxine (FT₄) and thyroid-stimulating hormone (TSH)
9. IGF-1 and IGF-binding protein 3 (IGFBP-3)

TALL STATURE

Although we typically think of growth disturbances in relation to short stature, potentially serious pathologic conditions may be associated with tall stature and excessive growth (Table 30-3). Excessive GH secretion is rare in children and is generally associated with a functioning pituitary adenoma. GH excess leads to gigantism if the epiphyses are open and to acromegaly if the epiphyses are closed. Affected children present with an accelerated growth velocity. The diagnosis is confirmed by demonstrating elevated GH and IGF-1 levels and failure of GH to suppress during a standard oral glucose tolerance test.

Constitutional tall stature may be a concern to adolescent girls. However, the upper limit of acceptable height in both sexes is increasing, and concerns about excessive growth for girls are becoming less frequent. When such concerns arise, the family history, growth curve, pubertal stage, and assessment of skeletal maturation allow assessment of predicted final adult height. Reassurance, counseling, and education may alleviate the family's concerns. In extremely rare instances in which the predicted height appears to be excessive and unacceptable, estrogen therapy may accelerate bone maturation and shorten the growth period.

4. Cerebral gigantism (Soto syndrome)
5. Homocystinuria

■ THE POSTERIOR PITUITARY GLAND

The posterior pituitary (neurohypophysis) is an extension of the ventral hypothalamus. The two principal neurohormones of the posterior pituitary, oxytocin and arginine vasopressin (AVP), are synthesized in the supraoptic and paraventricular nuclei. After synthesis, these neurohormones are packaged in granules with specific neurophysins and transported via the axons to their storage site in the neurohypophysis. AVP is essential for fluid homeostasis; its primary action is on the kidney to cause antidiuresis. Oxytocin is primarily important during parturition and breast-feeding and is not discussed further here.

Arginine Vasopressin (Antidiuretic Hormone)

Osmoreceptors in the anterolateral hypothalamus and baroreceptors in the cardiac atria regulate AVP release. The release of vasopressin is primarily influenced by serum osmolality and vascular volume. Disorders of vasopressin release and action include (1) central (neurogenic) diabetes insipidus (discussed in the following section), (2) nephrogenic diabetes insipidus (see Chapter 22), and (3) the syndrome of inappropriate antidiuretic hormone (SIADH) (see Chapter 42).

CENTRAL DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polydipsia and polyuria ($> 2 \text{ L/m}^2/\text{d}$).
- Urine specific gravity (< 1.010 ; osmolality $< 300 \text{ mOsm/kg}$).
- Inability to concentrate urine after fluid restriction.
- Hyperosmolality of plasma.
- Subnormal plasma AVP concentration.
- Responsiveness to AVP administration.

General Considerations

Central diabetes insipidus, a result of vasopressin deficiency, is caused by defects in hypothalamic vasopressin

synthesis, packaging, or transport along the neurohypophyseal tract to the posterior pituitary gland. Genetic causes of vasopressin deficiency are rare and include inherited mutations in the vasopressin structural gene, defects in the neurophysin protein, and the DID-MOAD syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness). Midline brain abnormalities such as septo-optic dysplasia and holoprosencephaly may also be associated with central diabetes insipidus. Accidental or surgical trauma to the axons of the vasopressin-containing neurons can cause transient or permanent diabetes insipidus. In this situation, a triphasic pattern often results, in which transient diabetes insipidus occurs first as a consequence of edema in the hypothalamic–pituitary area. This is followed in 2–5 days by SIADH, caused by the unregulated release of vasopressin from the dying neurons. The third phase is permanent diabetes insipidus, which results if significant damage to the vasopressin neurons has occurred.

Hypothalamic tumors and infiltrative diseases are found in a significant number of children who present with diabetes insipidus. In patients with craniopharyngiomas, diabetes insipidus usually develops only after surgical intervention. This is in contrast to germinomas in which diabetes insipidus is often the presenting symptom. Germinomas may be undetectable by magnetic resonance imaging (MRI) for several years; consequently, children with unexplained diabetes insipidus should have regularly repeated MRI scans. Infiltrative diseases such as histiocytosis and lymphocytic hypophysitis also cause diabetes insipidus in children. In these conditions, as well as germinomas, MRI scans characteristically show thickening or a mass within the infundibular stalk.

Clinical Findings

The onset of diabetes insipidus is often abrupt and is characterized by polyuria and intense thirst. The affected child typically has nocturia or enuresis and cannot go through the night without drinking water. Cold water is typically the preferred fluid. Dehydration may occur if fluid intake is not sufficient to keep up with urine losses or if concomitant damage has occurred to the normal thirst mechanism. In infants, symptoms may also include failure to thrive, vomiting, constipation, and unexplained fevers. It is especially difficult to recognize polyuria and polydipsia in a young infant on an ordinary feeding regimen, and the infant may present with severe dehydration, circulatory collapse, and convulsions. Familial diabetes insipidus may have a more insidious onset and a slowly progressive course.

Symptoms and signs of AVP deficiency may be absent in patients with panhypopituitarism due to the im-

paired excretion of free water that may accompany adrenal insufficiency. Treating these patients with glucocorticoids may unmask underlying polyuria and polydipsia.

Diagnosis

The diagnosis of diabetes insipidus is confirmed when hypotonic urine accompanies hypertonic serum. Response to vasopressin or desmopressin indicates central rather than nephrogenic diabetes insipidus. In children with symptoms of increased thirst and urination, primary polydipsia must be distinguished from true diabetes insipidus. If the history reveals that the child can go through the night comfortably without drinking, screening tests can be obtained as an out patient. Oral intake of fluid is prohibited after midnight. A first morning void is obtained to determine urine osmolality, and sodium concentration, and a standard urinalysis is performed. A blood sample should be obtained within a few minutes of the urine collection and analyzed for osmolality, sodium, potassium, creatinine, and calcium levels. Children with primary polydipsia will produce appropriately concentrated urine. If screening results are unclear or if symptoms preclude safely withholding fluids at home, a water deprivation test performed in the hospital is indicated. During fluid deprivation, a serum osmolality of greater than 290 mOsm/kg associated with excretion of dilute urine (osmolality < 300 mOsm/kg) is suggestive of diabetes insipidus. Measurement of serum AVP concentration at the end of the test and the administration of parenteral AVP may help distinguish between central neurogenic and nephrogenic forms of diabetes insipidus. When the diagnosis of central diabetes insipidus is made, an MRI scan with contrast should be obtained to look for tumors or infiltrative processes. An absent posterior bright spot on MRI also correlates with AVP deficiency.

Decreased ability to concentrate urine may also occur with hypokalemia (eg, hyperaldosteronism), with various forms of hypercalcemia (including hypervitaminosis D), and with renal tubular abnormalities (eg, Fanconi syndrome).

Treatment

A. MEDICAL TREATMENT

The treatment of choice for partial and total diabetes insipidus is desmopressin acetate (DDAVP) administered orally or intranasally. The aim of therapy is to provide the child with antidiuresis and uninterrupted sleep during the night and allow for approximately 1 hour of diuresis before the next DDAVP dose. Treatment of diabetes insipidus in infants is more difficult

because formula and breast milk have a large amount of free water; consequently, the risk of water overload with DDAVP therapy is great. For this reason, infants are often given extra free water, rather than DDAVP, to maintain normal hydration. Chlorothiazides, as prescribed for nephrogenic diabetes insipidus, may also be helpful in the infant with central diabetes insipidus.

B. OTHER THERAPY

Specific therapy is directed toward specific causative diseases when they are identified. Radiation therapy, chemotherapy, or surgery may be indicated for germiomas, histiocytosis, and craniopharyngiomas.

AUTOIMMUNE POLYGLANDULAR SYNDROMES

Two autoimmune polyglandular syndromes (APS types 1 and 2) causing multiple endocrine deficiencies are distinguished by their clinical, laboratory, and epidemiologic characteristics. APS type 1 is also known as autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED). Inactivating mutations of the autoimmune regulator gene (AIRE) cause the disease. It is inherited as an autosomal recessive trait and therefore affects females and males equally. There is no HLA association. APS-1 typically presents in childhood. It is characterized by chronic mucocutaneous candidiasis, ectodermal dysplasia, and multiple autoimmune diseases: hypoparathyroidism, adrenal and gonadal failure, alopecia, vitiligo, hepatitis, pernicious anemia, and type 1 diabetes mellitus. Autoimmune thyroid disease is rare.

In contrast, APS-2, Schmidt syndrome, is a polygenic disorder highly influenced by HLA. Specifically it is associated with HLA DR3. It is defined by at least two of three autoimmune diseases: type 1 diabetes mellitus, Addison disease, or thyroid disease. Other autoimmune disease such as vitiligo, alopecia, hypogonadism, pernicious anemia, rheumatoid arthritis, celiac disease, and other autoimmune gastroenteropathies can also occur. There is a 2–3:1 female preponderance. Treatment is specific for each complication that occurs, and recognition of the associations of disorders in these syndromes may help to detect them early in their course.

■ THE THYROID GLAND

FETAL DEVELOPMENT OF THE THYROID

The thyroid is capable of hormone synthesis in the fourteenth week of gestation, when TSH is detected in the fetal serum and pituitary gland. TSH does not normally cross the placenta, but T_4 and T_3 cross in limited amounts. The fetal pituitary–thyroid axis functions largely independently of the maternal pituitary–thyroid axis. Antithyroid drugs, including propylthiouracil (PTU) and methimazole, freely cross the placenta, and goitrous hypothyroid newborns may be born to hyperthyroid mothers who undergo treatment during pregnancy.

Mothers who have thyroid-stimulating immunoglobulins (TSI) can transmit these antibodies transplacentally, causing thyrotoxicosis in newborns who may be born with goiter and exophthalmos. Because TSI may be present in the serum of controlled, previously hyperthyroid mothers—or even in women who have had surgical or radioiodine-induced removal of their thyroid glands—the possible transmission of TSI should be considered in all mothers who are or have been hyperthyroid. In addition, thyroid-binding inhibitory immunoglobulins (TBIs) can cross the placenta, so that the newborn is also at risk for hypothyroidism. Both maternal TSI and TBII usually disappear from the infant's circulation by 6–8 weeks.

Physiology

Pituitary TSH stimulates the thyroid gland to take up iodine and synthesize active thyroid hormones (ie, T_3 , T_4). Active hormone produced in excess of physiologic needs is stored within the thyroid follicles as thyroglobulin. The release of active thyroid hormones into the circulation is regulated by a negative feedback mechanism involving pituitary TSH and free thyroid hormone (see Figure 30–1).

Most T_3 and T_4 circulates bound to thyroid hormone-binding globulin (TBG), albumin, and prealbumin, and less than 1% of T_3 and T_4 is free. T_4 is deiodinated in the tissues to either T_3 (active) or reverse T_3 (inactive), and the physiologic activity of thyroid hormone depends primarily on the amount of FT_4 presented to the cells. Receptors for T_3 are present on the

cell surface, in the nucleus, in the cytosol, and on mitochondria.

At birth, the newborn's T_4 approximates that of the mother, but levels increase rapidly during the first 5 days of life in response to a TSH surge immediately following birth. TSH levels subsequently decrease to childhood levels by age 2–4 weeks. This physiologic neonatal TSH surge can cause falsely positive neonatal screens for hypothyroidism (ie, high TSH), because blood specimens for screening may be collected on the first day of life.

The total thyroxine (TT_4) level is low in hypothyroidism and may be reduced in premature infants (particularly those with sepsis or respiratory distress), subacute and chronic thyroiditis, hypopituitarism, nephrosis, cirrhosis, hypoproteinemia, malnutrition, and following therapy with T_3 . Prolonged administration of high doses of adrenocorticosteroids—as well as of sulfonamides, testosterone, phenytoin, and salicylates—may also produce a decrease in the TT_4 level. However, since these effects are primarily on TBG levels, and not on thyroid function per se, TSH and FT_4 levels remain in the normal range. Total T_3 and T_4 levels are high in hyperthyroidism and may be elevated in acute forms of thyroiditis and hepatitis; in some types of inborn errors of thyroid hormone synthesis, release, or binding; following the administration of estrogens or clofibrate or during pregnancy; and following the administration of various iodine-containing globulins.

TBG levels are increased in pregnancy, after estrogen therapy (including oral contraceptives), occasionally as a genetic variation, in certain hepatic disorders, following administration of phenytoin or phenothiazines, and occasionally from an unknown cause. TBG levels are decreased in familial TBG deficiency; following the administration of glucocorticoids, androgens, or anabolic steroids; in nephrotic syndrome with marked hypoproteinemia; in some forms of hepatic disease; or as an idiopathic finding.

Because of the many “nonthyroidal” effects on TT_4 , it is recommended that FT_4 be measured routinely in children suspected of having disorders of thyroid function.

HYPOTHYROIDISM (Congenital & Acquired Hypothyroidism)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Growth retardation, diminished physical activity, impaired tissue perfusion, constipation, thick tongue, poor muscle tone, hoarseness, anemia,

and intellectual retardation. (These findings can arise in the first 2 months of life, but are absent in 75% of newborns with documented hypothyroidism.)

- *Thyroid hormone concentrations low (TT_4 , FT_4 , and T_3 resin uptake [T_3RU]); TSH levels are elevated in primary hypothyroidism.*

Note: Most newborns with congenital hypothyroidism appear normal at birth and gain weight normally, even if not receiving treatment, for the first 3–4 months of life. Because congenital hypothyroidism must be treated as early as possible to avoid intellectual impairment, the diagnosis should be based on the newborn screening test and not on abnormal physical findings.

General Considerations

Thyroid hormone deficiency may be either congenital or acquired (juvenile hypothyroidism). Although hy-

pothyroidism in the newborn has many causes (Table 30–4), most cases are a result of hypoplasia or aplasia of the thyroid gland or failure of the gland to migrate into its normal anatomic location (ie, lingual or sublingual thyroid glands). Juvenile hypothyroidism, particularly if goiter is present, usually results from chronic lymphocytic (Hashimoto) thyroiditis (see later discussion).

Of the genetically determined enzymatic defects causing hypothyroidism (see Table 30–4), only Pendred syndrome (a defect in iodide organification with congenital nerve deafness) has distinguishing clinical features. In children who have enzymatic defects, thyroid enlargement is usually not present in the newborn period but occurs within the first two decades of life. Although thyroid function tests (including radioactive iodide uptake studies) may be helpful in diagnosis, final clarification of the defect generally requires chromatographic fractionation of iodinated compounds in the serum, urine, and thyroid tissue.

Cabbage, soybeans, aminosalicylic acid, thiourea derivatives, resorcinol, phenylbutazone, cobalt, and iodides have been reported to cause goiter and hypothy-

Table 30–4. Causes of hypothyroidism.

A. Congenital (cretinism)

1. Aplasia, hypoplasia, or associated with maldescent of thyroid
 - a. Embryonic defect of development
 - b. Autoimmune disease (?)
2. Familial iodine-induced goiter secondary to metabolic inborn errors
 - a. Iodide transport defect (defect 1)
 - b. Organification defect (defect 2)
 - (1) Lack of iodine peroxidase
 - (2) Lack of iodine transferase: Pendred syndrome, associated with congenital nerve deafness
 - c. Coupling defect (defect 3)
 - d. Iodotyrosine deiodinase defect (defect 4)
 - e. Abnormal iodinated polypeptide (defects 5a and 5b)
 - (1) Resulting from defect in intrathyroidal proteolysis of thyroglobulin
 - (2) Abnormal plasma binding preventing use of T_4 by peripheral cells
 - f. Inability of tissues to convert T_4 to T_3
3. Maternal ingestion of medications during pregnancy
 - a. Maternal radioiodine
 - b. Goitrogens (propylthiouracil, methimazole)
 - c. Iodides
4. Iodide deficiency (endemic cretinism)
5. Idiopathic

B. Acquired (juvenile hypothyroidism)

1. Thyroidectomy or radioiodine therapy for
 - a. Thyrotoxicosis
 - b. Cancer
 - c. Lingual thyroid
 - d. Isolated midline thyroid
2. Destruction by x-ray
3. Thyrotropin deficiency
 - a. Isolated
 - b. Associated with other pituitary tropic hormone deficiencies
4. TRH deficiency due to hypothalamic injury or disease
5. Autoimmune disease (lymphocytic thyroiditis)
6. Chronic infections
7. Medications
 - a. Iodides
 - (1) Prolonged, excessive ingestion
 - (2) Deficiency
 - b. Cobalt
8. Idiopathic

roidism during pregnancy. Because many of these agents cross the placenta freely, they should be used with great caution during pregnancy.

Several hundred patients with clinical and laboratory features of resistance to thyroid hormone have been described. These syndromes are generally familial and are classified on the basis of the site of the resistance (eg, generalized; pituitary or peripheral tissue).

Clinical Findings

The severity of the findings in patients with thyroid deficiency depends on the age at onset and the degree of deficiency.

A. SYMPTOMS AND SIGNS

Even with congenital absence of the thyroid gland, the first finding may not appear for several days or weeks. Consequently, any suspected abnormality in the results of the newborn screen should be investigated promptly. Findings include physical and mental sluggishness; pale, gray, cool, or mottled skin; nonpitting myxedema; constipation; large tongue; poor muscle tone giving rise to a protuberant abdomen, umbilical hernia and lumbar lordosis; hypothermia; bradycardia; diminished sweating (variable); decreased pulse pressure; hoarse voice or cry; delayed transient deafness; and a slow relaxation component of deep tendon reflexes (best appreciated in the ankles). Nasal obstruction and discharge and persistent jaundice may be present in the neonatal period.

The skin may be dry, thick, scaly, and coarse, with a yellowish tinge due to excessive deposition of carotene. The hair is dry, coarse, and brittle (variable) and may be excessive. Lateral thinning of the eyebrows may occur. The axillary and supraclavicular fat pads may be prominent in infants. Muscular hypertrophy (Kocher-Debré-Sémélaigne syndrome) is an unusual association with congenital hypothyroidism.

Growth changes include short stature; infantile skeletal proportions with relatively short extremities; infantile naso-orbital configuration (bridge of nose flat, broad, and underdeveloped; eyes seem to be widely spaced); delayed epiphyseal development; delayed closure of fontanelles; and retarded dental eruption. Treatment of acquired hypothyroidism may not result in the attainment of predicted adult target height. Metromenorrhagia may occur in older girls, and galactorrhoea resulting from the stimulation of prolactin secretion or elevated thyrotropin-releasing hormone (TRH) has been reported.

In hypothyroidism resulting from enzymatic defects, ingestion of goitrogens, or chronic lymphocytic thyroiditis, the thyroid gland may be enlarged. Thyroid enlargement in children is usually symmetrical, and the

gland is moderately firm and without nodularity. In chronic lymphocytic thyroiditis, however, the thyroid frequently has a cobblestone surface; size and shape are readily apparent on inspection in children. Slowing of mental responsiveness and retardation of development of the brain may occur in neonates and infants, and a coincidental congenital malformation of the brain is present in some patients.

B. LABORATORY FINDINGS

TT_4 and FT_4 levels are decreased. Radioiodine uptake is below 10% (normal: 10–30%). The binding of T_3 by erythrocytes or resin in vitro (T_3 RU test) is lowered. With primary hypothyroidism, the serum TSH concentration is elevated. Normocytic anemia is common, but microcytic or macrocytic anemia may occur as a result of decreased iron, folate, and cobalamin absorption. Serum cholesterol and carotene are usually elevated in childhood but may be low or normal in infants. Cessation of therapy in previously treated hypothyroidism produces a marked rise in serum cholesterol levels in 6–8 weeks. Urinary creatinine excretion is decreased, and urinary hydroxyproline is low. Circulating autoantibodies to thyroid constituents may be present. Serum GH may be decreased, with subnormal HGH response to stimulation in children with severe primary hypothyroidism, as well as low IGF-1 or IGF binding protein 3 (or both).

C. IMAGING

Skeletal maturation (bone age) is delayed. Centers of ossification, especially of the hip, may show multiple small centers or a single stippled, porous, or fragmented center (epiphyseal dysgenesis). Vertebrae may show anterior beaking. Coxa vara and coxa plana may occur. Cardiomegaly is common.

Screening Programs for Neonatal Hypothyroidism

Congenital hypothyroidism should be diagnosed by neonatal screening within 10 days of birth. It may be recognized clinically during the first month of life or may be so mild that it is unrecognized clinically for months. Adequate treatment started as soon as possible—but certainly before the end of the first month of life—improves the prognosis for intellectual performance later in life.

Differential Diagnosis

The causes of primary hypothyroidism due to intrinsic defects of the thyroid gland must be differentiated from pituitary and hypothalamic failure with secondary thyroid insufficiency. TSH and FT_4 levels are the most

useful tests and are usually sufficient in directing treatment or the need for further investigations.

Down syndrome, chondrodystrophy, generalized gangliosidosis, I-cell disease, Hurler and Hunter syndromes, and certain other causes of short stature and coarse features can all be readily distinguished from hypothyroidism by their clinical manifestations and by laboratory studies.

Treatment

Levothyroxine is the drug of choice in a dosage of 75–100 $\mu\text{g}/\text{m}^2/\text{d}$ as a single dose. In newborns and infants, the dose is 10–12 $\mu\text{g}/\text{kg}$. The hypothyroid patient may be very responsive to thyroid and may be sensitive to slight excesses of thyroid hormone. A dose of 0.0375 μg (37.5 μg) of levothyroxine is often recommended initially. Serum FT_4 concentrations should be used to monitor the adequacy of therapy initially, because the elevated TSH may not fall into the normal range for several days to weeks. Subsequently, elevations of serum TSH are sensitive early indicators of the need for increased medication (or increased compliance).

In the treatment of neonatal goiter with or without hypothyroidism resulting from drugs and goitrogens taken by the pregnant woman, temporary use of levothyroxine may be helpful in decreasing the size of the goiter.

THYROIDITIS

Chronic lymphocytic (Hashimoto) thyroiditis is perhaps the most common pediatric endocrinopathy, particularly in adolescent girls. Acute and subacute thyroiditis are rare in all age groups.

1. Acute Suppurative Thyroiditis

Acute thyroiditis is rare. Oropharyngeal organisms are thought to reach the thyroid via a patent foramen cecum and thyroglossal duct tract. The most common pathogens are group A streptococci, pneumococci, *Staphylococcus aureus*, and anaerobes. The patient is invariably toxic, and the thyroid gland is exquisitely ten-

der. Pain may radiate to adjacent areas of the neck or to the ear or chest. No endocrine disturbance is consistently associated with this disorder. Specific antibiotic therapy should be administered.

2. Subacute Nonsuppurative Thyroiditis

Subacute thyroiditis (de Quervain thyroiditis) is rare in the United States. In most cases, the cause is a virus (mumps, influenza, echovirus, coxsackievirus, Epstein–Barr virus, or adenovirus). Presenting features are similar to those of acute thyroiditis: fever, malaise, sore throat, dysphagia, pain in the thyroid gland that may radiate to the ears, and mild and transient manifestations of hyperthyroidism. In contrast to acute thyroiditis, the onset of the subacute form is generally insidious. The thyroid gland is firm, and the enlargement may be confined to one lobe. Radioiodine uptake is usually reduced, but thyroid hormone levels in the blood are normal or elevated. The differentiation from bacterial thyroiditis is difficult, and antibiotic therapy is therefore recommended.

3. Chronic Lymphocytic Thyroiditis (Chronic Autoimmune Thyroiditis, Hashimoto Thyroiditis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Firm, freely movable, nontender, and diffusely enlarged goiter.
- Serum FT_4 concentrations are generally normal but may be elevated or decreased depending on the stage of the disease.

General Considerations

Chronic lymphocytic thyroiditis is occurring with increasing frequency in all age groups and currently is the most common cause of goiter and hypothyroidism in childhood. In children and adolescents, the incidence peaks between 8 and 15 years of age and occurs most commonly in females (4:1). The disease is the result of an autoimmune attack on the thyroid. Susceptibility to thyroid autoimmunity (and other endocrine autoimmune disorders) is associated with inheritance of certain histocompatibility alleles in APS type II (described earlier in this chapter).

Clinical Findings

A. SYMPTOMS AND SIGNS

The goiter is characteristically firm, freely movable, nontender, and symmetrical, with a pebbly consistency. Onset is usually insidious, and except for painless goiter, clinical manifestations are unusual. Occasionally a sensation of tracheal compression or fullness, hoarseness, and dysphagia are described by the patient. No local signs of inflammation or evidence of systemic infection are present.

B. LABORATORY FINDINGS

Laboratory findings vary. Serum concentrations of T_4 , FT_4 , and T_3RU are usually normal but may be elevated (hashitoxicosis) or depressed. Thyroid antibodies (antithyroglobulin, antithyroid peroxidase) are usually present, though titers are frequently low. A variety of abnormalities in radioactive iodide uptake studies have been described; thyroid scans usually show a diffuse or patchy pattern, and cold (nonfunctioning) nodules have been reported. Thyroid scans and uptake studies add little to the diagnosis. Surgical or needle biopsy is diagnostic but seldom indicated.

Treatment

The treatment of chronic lymphocytic thyroiditis is controversial. Full therapeutic doses of thyroid hormone (levothyroxine, 75–100 $\mu\text{g}/\text{m}^2/\text{d}$) may decrease the size of the goiter within 3 months, but in controlled trials the efficacy of thyroid hormone therapy is unsupported in the euthyroid child. Hypothyroidism is believed to be a common end result of autoimmune thyroiditis in the second to third decades of life; consequently, patients with adolescent goiter require lifelong surveillance, and children with documented hypothyroidism should receive levothyroxine in full replacement doses.

HYPERTHYROIDISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Nervousness, irritability, emotional lability, tremor, excessive appetite, weight loss; smooth, moist, warm skin; increased perspiration, and heat intolerance.*
- *Goiter, exophthalmos, tachycardia, widened pulse pressure (systolic hypertension).*
- *Thyroid function studies elevated (eg, TT_4 , FT_4 , T_3RU). TSH concentration suppressed.*

General Considerations

Most cases of hyperthyroidism in children have an autoimmune cause. Hyperthyroidism occurs with certain diseases that have an autoimmune basis, and a familial pattern with a predilection for females supports a role for a heritable and autoimmune basis. IgG antibody to thyroid receptors (TSI) stimulates thyroid hormone production in one form of hyperthyroidism accompanied by exophthalmos (Graves disease). Transient congenital hyperthyroidism may occur in infants of thyrotoxic mothers and is potentially life-threatening. Hyperthyroidism may be associated with acute, subacute, or chronic thyroiditis; tumors of the thyroid; other tumors producing thyrotropin-like substances; and exogenous thyroid hormone excess.

Clinical Findings

A. SYMPTOMS AND SIGNS

Hyperthyroidism is four times more common in females than in males. The disease most frequently occurs in childhood between ages 12 and 14 years; only 2% of patients present before age 10 years. The course of hyperthyroidism tends to be cyclic, with spontaneous remissions and exacerbations. A deterioration in school performance is a common historical feature. Findings include weakness, dyspnea, dysphagia, amenorrhea, emotional instability, nervousness, marked variability in mood, personality disturbances, and (rarely) tremors and movements that may simulate chorea. The skin is warm and moist; the face is flushed. Palpitations, tachycardia, and systolic hypertension with increased pulse pressure are common. Proptosis and exophthalmos are common in hyperthyroid children. Goiter is present in more than 90% of cases and is characteristically diffuse and usually firm. A bruit and thrill may be present. Variable degrees of accelerated growth and development occur, and loss of weight is common despite polyphagia. In neonatal hyperthyroidism, hepatosplenomegaly and thrombocytopenia with antiplatelet antibodies are occasionally seen.

B. LABORATORY FINDINGS

TT_4 , FT_4 , and T_3RU are elevated except in rare cases in which only the serum T_3 is elevated (T_3 thyrotoxicosis). Radioiodine uptake is elevated and does not suppress with T_3 (liothyronine). The basal metabolic rate is elevated, and the serum cholesterol level is low. Antibodies to thyroglobulin are found in most patients. Circulating TSH concentrations measured by very sensitive assays are depressed, and TSI is often present in plasma.

C. IMAGING

Skeletal maturation assessed radiographically is advanced in younger children. In newborns, accelerated

bone maturation may be associated with subsequent premature closure of the cranial sutures. Long-standing hyperthyroidism is associated with osteoporosis.

Differential Diagnosis

Although the well-established case of hyperthyroidism seldom presents a problem in diagnosis, the findings in the early stages of the disease may be confused with chorea or, more commonly, with euthyroid goiter. Typically the patient is an adolescent with a recent decline in school performance, nervousness, emotional lability, and increased perspiration. Repeated clinical and laboratory evaluations may be required to make the diagnosis. Disease states associated with hypermetabolism (severe anemia, leukemia, chronic infections, pheochromocytoma, and muscle-wasting disease) may resemble hyperthyroidism clinically but differ in the thyroid function studies.

Treatment

The symptoms of hyperthyroidism can fluctuate and in some mild cases may not require treatment.

A. GENERAL MEASURES

Bed rest is advisable only in severe cases, in preparation for surgery, or at the beginning of a medical regimen. The diet should be high in calories, carbohydrates, and vitamins (particularly vitamin B₁).

B. MEDICAL TREATMENT

It takes 2–3 weeks to see a clinical response, and adequate control may take 2–3 months. The thyroid frequently increases in size as treatment is started but then usually decreases within several months.

1. β -Adrenergic blocking agents—These agents may be helpful in controlling symptoms of nervous instability and tachycardia and are indicated in severe disease with cardiovascular abnormalities (tachycardia, hypertension). In mild cases, β -blockade without other antithyroid treatment may be adequate. β_1 -Specific agents (metoprolol, atenolol) are preferable to nonspecific agents, such as propranolol, due to their lower likelihood of exacerbating pulmonary bronchospasm, greater specificity for tachycardia, and additional effect in decreasing conversion of T₄ to T₃.

2. Antithyroid agents (PTU, methimazole)—These drugs interfere with thyroid hormone synthesis and, in large doses, with the peripheral conversion of T₄ to T₃. The correct dose must always be determined individually. Antithyroid agents are frequently used in the initial treatment of hyperthyroidism in children. Short-term therapy is occasionally successful, but treatment usually must be continued for at least 18–24 months.

The optimal dose of antithyroid agent for maintenance treatment remains somewhat unclear. Recent studies suggest that 10–15 mg/d of methimazole or 100–150 mg/d of PTU provide adequate long-term control in most patients with a minimum of side effects. If T₄ levels rise rapidly with reduction in drug dosage after 18–24 months of therapy, continued or alternative therapy, such as radioablation of the thyroid gland, will be necessary. Relapse occurs in 10–30% of patients, and severe cases may not respond to initial treatment.

a. Initial dosage—Treatment with methimazole is initiated with a dose of 15 mg/d in mild cases, 30 mg/d in moderate cases, and 45 mg/d in patients with severe symptoms and markedly elevated FT₄. Methimazole can be given once a day. PTU dosing is 10 times that for methimazole (150–450 mg/d) given in three divided doses 8 hours apart. Initial dosing is continued until FT₄ or TT₄, measured every 2 weeks, is clearly improving and signs and symptoms have subsided. Larger doses are rarely necessary.

b. Maintenance—Give methimazole 10–15 mg/d as a single dose or PTU 100–150 mg/d in two or three divided doses. Some authors recommend continuing the drug at higher levels until the euthyroid state is approached or reached and then, as the TSH level rises, adding thyroid hormone. This approach can simplify the management of some cases of Graves disease. However, the role of adjunctive thyroxine therapy in preventing recurrence of hyperthyroidism in Graves disease is not proven. Free T₄ and TSH levels should be monitored during antithyroid treatment to determine whether the patient is becoming hypothyroid; thyroid hormone is added when indicated to maintain normal TSH while the patient is receiving maintenance antithyroid therapy.

c. Toxicity—Granulocytopenia, fever, rash, and arthralgia may occur. The drug must be discontinued, and antibiotics and a short course of one of the adrenocorticosteroids should be prescribed if indicated.

3. Iodide—By itself, treatment with orally administered iodide usually produces a rapid but brief response. Because the efficacy of iodide is short-lived, it is generally recommended only for acute management. A progressive increase in dosage is often required for satisfactory control, and toxic reactions to iodide sometimes occur.

C. RADIATION THERAPY

Radioactive iodide (¹³¹I) ablation of the thyroid gland is used as definitive therapy for hyperthyroidism in children and adolescents that does not remit after 2 years or more of medical therapy or in situations in which compliance with medication is poor. Reports do not sup-

port the fear of an increased incidence of thyroid cancer or other neoplasms, particularly when an ablative dose of ^{131}I is used. Therapy with a β -adrenergic antagonist may be necessary for 1–2 months after ablation, until FT_4 is in the normal range. In most cases, thyroid hormone replacement is ultimately necessary.

D. SURGICAL TREATMENT

Thyroidectomy is no longer considered a primary form of treatment. An exception would be in the case of a noncompliant pregnant female in whom radioiodine would be contraindicated because it crosses the placenta. The patient should be prepared first with bed rest, diet, and propranolol (as detailed earlier) and with iodide and PTU as follows: PTU should be given for 2–4 weeks. Iodide (as saturated solution of potassium iodide) is added 10–21 days before surgery is scheduled. Iodides act by blocking the effect of TSH on the thyroid, with a resulting decrease in iodine trapping and reduction of vascularity, and by inhibiting the release of hormone, thus reducing the possibility of thyroid storm. Give 1–10 drops daily for 10–21 days. Continue the drug for 1 week after surgery.

Course & Prognosis

Improvement may rarely occur without therapy, but partial remissions and exacerbations may continue for several years. With medical treatment alone, prolonged remissions may be expected in one half to two thirds of patients in the first 2 years or so.

Kadmon PM et al: Thyroid storm in a child following radioactive iodine therapy. *J Clin Endocrinol Metab* 2001;86:1865 [PMID: 11344172].

Management of Congenital (Transient) Hyperthyroidism

Congenital hyperthyroidism has a significant death rate in the neonatal period, but the eventual prognosis in surviving infants is excellent. Temporary treatment of congenital hyperthyroidism may be necessary, in which case iodides appear to be the initial drug of choice, to be followed by PTU or methimazole. β -adrenergic antagonists may be necessary to control cardiac arrhythmias. Transection of an enlarged thyroid isthmus may be of value if respiratory distress due to tracheal compression is present.

Radetti G et al: Fetal and neonatal thyroid disorders. *Minerva Pediatr* 2002;54:383 [PMID: 12244277].

CARCINOMA OF THE THYROID

Carcinoma of the thyroid is uncommon in childhood. The child usually presents with asymptomatic asymmetrical thyroid enlargement. Neck discomfort, dysphagia, voice changes, and respiratory difficulty are unusual but may occur. Fifty percent of children have metastatic disease, usually to regional lymph nodes, at the time of presentation. Pulmonary metastasis occurs in 5% of patients.

Thyroid function tests are usually normal. A technetium or iodine scan of the thyroid shows a so-called cold nodule and is the most definitive diagnostic test. Pulmonary metastases should be excluded by computed tomography (CT) scan of the chest.

Papillary carcinoma is the most common form in childhood, and the prognosis with treatment is relatively good (survival rate greater than 80% after 10–20 years). The treatment of choice is surgical excision of the entire gland and removal of all involved lymph nodes. If metastatic disease is not identified at surgery or by radioactive iodide scan postoperatively, replacement thyroid hormone is generally the only additional therapy required. Follow-up thyroid scans every 2–5 years are recommended.

Less common malignant tumors of the thyroid are follicular, medullary, and undifferentiated carcinomas, lymphomas, and sarcomas. Medullary carcinoma of the thyroid may be familial (autosomal dominant), usually occurring as a component of type 2 multiple endocrine neoplasia (MEN). This condition may be associated with excessive elaboration of gastrin and calcitonin, with pheochromocytoma, parathyroid hyperplasia, marfanoid habitus, and mucosal neuromas (MEN type 2b). The treatment and prognosis depend on the cell type present, but the outcome is generally less favorable.

DISORDERS OF CALCIUM HOMEOSTASIS

The parathyroid glands, kidney, liver, and small intestine tightly regulate serum calcium concentration. Parathyroid hormone (PTH) acts in concert with dietary vitamin D or with active vitamin D produced in

the course of sun exposure and subsequent hydroxylation of precursors in the liver and kidney. Low calcium levels stimulate PTH release. PTH in turn acts on the bone to cause release of calcium and phosphorus and on the kidney to cause resorption of calcium and activation of the 1-hydroxylation of 25-hydroxylated vitamin D to 1,25-(OH)₂ vitamin D. 1,25-(OH)₂ vitamin D acts in the intestine to promote the absorption of calcium. Deficiencies or excesses of these agents, as well as abnormalities in their receptors or of vitamin D metabolism, lead to clinical disturbances described in the following section. Less important factors contributing to calcium homeostasis include calcitonin, magnesium, pyrophosphate, prostaglandins, and phosphate.

HYPOCALCEMIC DISORDERS

A normal serum calcium concentration is 8.9–10.1 mg/dL or an ionized level of 1.2–1.4 mg/dL. Levels in newborns are slightly lower, whereas premature infants may have levels as low as 7 mg/dL. Because 50–60% of calcium in the serum is protein-bound, determination of an ionized calcium level may be helpful in conditions with low serum protein. Some laboratories report calcium levels in units of mEq/L. Units of mEq/L can be converted to mg/dL by multiplying the value by 2.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Tetany with facial and extremity numbness, tingling, cramps, spontaneous muscle contractures, carpopedal spasm, positive Trousseau and Chvostek signs, loss of consciousness, convulsions.*
- *Diarrhea, photophobia, prolongation of electrical systole (QT interval), and laryngospasm.*
- *In hypoparathyroidism or pseudohypoparathyroidism—Defective nails and teeth, cataracts, and ectopic calcification in the subcutaneous tissues and basal ganglia.*

General Considerations

Hypocalcemia is a consistent feature of conditions such as hypoparathyroidism, pseudohypoparathyroidism, transient tetany of the newborn, and severe vitamin D–deficiency rickets (milder rickets generally has normal calcium level), and may be present in rare disorders of vitamin D action. Hypocalcemia may also occur in

other conditions such as malabsorption syndromes, chronic renal disease, hypophosphatemic rickets, tumor lysis syndrome, or rhabdomyolysis (Table 30–5).

Hypoparathyroidism may be idiopathic or may be a result of autoimmune damage. Table 30–6 summarizes the findings in various disorders of parathyroid hormone secretion or action. Autoimmune parathyroid destruction with subsequent hypoparathyroidism may be isolated, or associated with other autoimmune disorders in the APECED syndrome (APS-1).

Hypoparathyroidism may also result from congenital absence of the parathyroid glands, which can occur in DiGeorge syndrome. Other features of this disorder include congenital absence of the thymus (with resultant thymus-dependent immunologic deficiency) and cardiovascular anomalies. A monosomy in the q11 region of chromosome 22 is responsible for the majority of DiGeorge syndrome cases.

Autosomal dominant hypocalcemia is associated with a gain of function mutation in the calcium receptor. This causes a low PTH in the face of hypocalcemia and excessive loss of urinary calcium. Affected individuals present in childhood. A family history of hypocalcemia may provide a clue to differentiate this condition from other forms of hypoparathyroidism.

Hypoparathyroidism may develop following thyroidectomy, with either acute or insidious onset, and may be transient or permanent. Parathyroid deficiency following irradiation of the neck or the administration of therapeutic doses of radioactive iodine for carcinoma of the thyroid has been reported.

Transient neonatal hypoparathyroidism, also known as transient tetany of the newborn, is caused by a relative deficiency of PTH or hormone action (see Table 30–6). There are two forms of this condition. The early form occurs within the first 2 weeks of life in newborns with a history of birth asphyxia or in those born to mothers with diabetes mellitus or hyperparathyroidism. Hypomagnesemia may occur in the early form and augments the severity of hypocalcemia. The late form occurs after 2 weeks and has been associated with infant formulas high in phosphate.

Both tumor lysis syndrome and rhabdomyolysis can cause hypocalcemia. These conditions involve cellular destruction with liberation of large amounts of intracellular phosphate that subsequently complex with serum calcium.

Malabsorption states result in hypocalcemia by impairing absorption of calcium, vitamin D, and magnesium (see Table 30–6). Hypomagnesemia may cause or augment the severity of hypocalcemia by impairing the release of PTH. Magnesium may be lost from either the gastrointestinal tract or the kidney.

Rickets describes a characteristic radiographic picture. Radiographic evidence of rickets includes meta-

Table 30–5. Hypocalcemia associated with rickets and other disorders.

Condition	Pathogenesis	Disease States/ Inheritance	Clinical Features	Biochemical Findings			
				Serum Calcium	Serum Phosphorus	Serum Alkaline Phosphatase	Other
Malabsorption	Impairment in intestinal absorption in any or all of the following: calcium, vitamin D, and magnesium	Cystic fibrosis, celiac disease, sprue, Shwachman syndrome	Failure to thrive, poor weight gain, steatorrhea, superimposed vitamin D deficiency rickets.	Low or normal	Low or normal	Variable, may be low with concomitant zinc deficiency	Potentially low magnesium levels, potentially low 25-OH vitamin D
Chronic renal insufficiency	Decreased renal phosphate excretion, decreased 1-hydroxylase activity	Obstruction, glomerulonephritis, dysplastic kidneys	Uremia, growth failure, acidosis	Low or normal	Elevated	Elevated or normal	Elevated PTH levels in longstanding cases, low 1,25-OH vitamin D
Rhabdomyolysis	Muscle damage with liberation of large amounts of intracellular phosphate	Crush injuries of muscles, Pompe disease, carnitine deficiency	Hypocalcemic tetany, cardiac arrhythmia, risk of renal failure	Low	Elevated	Normal	Myoglobinuria
Tumor lysis syndrome	Release of intracellular phosphate and potassium	Initiation of chemotherapy for ALL, Burkitt's lymphoma, or other malignancies	Hypocalcemic tetany, cardiac arrhythmia, risk of renal failure	Low	Elevated	Normal	Hyperkalemia, elevated uric acid
Vitamin D deficiency rickets	Deficient dietary vitamin D intake, vitamin D malabsorption, other risk factors include dark skin and lack of sunlight exposure	May cluster in families due to various risk factors	Characteristic skeletal changes appear early, poor growth, symptomatic hypocalcemia is a late finding	Normal until late in course	Low or normal	Elevated	Elevated PTH levels, low 25-OH vitamin D
Vitamin D refractory rickets-type I	Mutation in 1-hydroxylase enzyme required for synthesis of fully active 1,25-OH vitamin D	Autosomal recessive inheritance	Skeletal changes of rickets, symptomatic hypocalcemia	Low	Low or normal	Elevated	Elevated PTH, low 1,25-OH vitamin D
Vitamin D refractory rickets-type II	Mutation in 1,25-OH vitamin D receptor	Autosomal recessive inheritance	Severe skeletal changes of rickets, total alopecia, symptomatic hypocalcemia	Low	Low or normal	Elevated	Elevated PTH, elevated 1,25-OH vitamin D
Hypophosphatemic rickets	Excessive loss of phosphate in the urine, ? abnormal humoral factor	X-linked dominant	Skeletal changes primarily in the lower extremities— genu varum or valgus, short stature	Normal or low	Very low	Usually normal	Normal PTH levels, abnormally high urinary phosphate excretion

PTH = parathyroid hormone; ALL = acute lymphoblastic leukemia.

Table 30–6. Disorders of parathyroid hormone secretion or action.

Condition	Pathogenesis	Inheritance Pattern	Clinical Features	Biochemical Findings			
				Serum Calcium	Serum Phosphorus	Serum Alkaline Phosphatase	Serum PTH
Isolated hypoparathyroidism	Trauma, surgical destruction, isolated autoimmune destruction, rare familial forms	None; reports in familial forms of inheritance as X-linked recessive, autosomal recessive, or autosomal dominant	Symptoms of hypocalcemia	Low	High	Normal/Low	Low
DiGeorge syndrome	Deletion in chromosome 22	Majority represent new mutations	Symptoms of hypocalcemia, cardiac anomalies, immune disorder	Low	High	Normal/Low	Low
APS type I	Autoimmune destruction	Autosomal recessive	Mucocutaneous candidiasis, Addison disease, potential for autoimmune destruction in other endocrine glands	Low	High	Normal/Low	Low
PHP type IA	Mutation in stimulatory G protein; resistance to PTH action	Autosomal dominant	AHO phenotype, variable hypocalcemia, may have resistance to other hormones using G protein signaling	Low or normal	Elevated or normal	Variable	Elevated
PPHP	Mutation in stimulatory G protein	Autosomal dominant—frequently found within same families with PHP type IA	AHO phenotype, biochemical parameters are normal	Normal	Normal	Normal	Normal
Transient tetany of the newborn—early onset	Deficiency in PTH secretion and/or action	Sporadic—associated with difficult deliveries, infants of diabetic mothers, or maternal hyperparathyroidism	Onset of symptoms of hypocalcemia within 2 wk of birth	Low	Normal or low	Normal or low	Normal or low
Transient tetany of the newborn—late onset	Deficiency in PTH secretion and/or action	Sporadic—associated with infant formulas that had a high phosphate content	Onset of symptoms of hypocalcemia after 2 wk of age	Low	Normal or low	Normal or low	Normal or low
Autosomal dominant hypocalcemia	Gain of function mutation of calcium receptor	Autosomal dominant	Symptoms of hypocalcemia family history	Low	High	Normal/Low	Low

PTH = parathyroid hormone; APS = autoimmune polyglandular syndrome; PHP = pseudohypoparathyroidism; PPHP = pseudopseudohypoparathyroidism; AHO = Albright hereditary osteodystrophy.

physical cupping and irregularity. Vitamin D deficiency caused by lack of sunlight exposure or dietary deficiency is the most common cause of rickets. It is classically described in dark-skinned, breast-fed infants born in the winter months. However, occult vitamin D deficiency may be more common than initially recognized. This concern forms the basis for the recommendation by the American Association of Pediatrics that breast-fed infants receive vitamin D supplementation of 200 IU/d. Rickets can be caused by several defects in the metabolism of vitamin D (see Table 30–6). Less common causes of rickets include defects in vitamin D metabolism including liver disease (with impaired 25-hydroxylation of vitamin D), kidney disease (with impaired 1-hydroxylation of 25-(OH) vitamin D), an inherited deficiency of 1 α -hydroxylase (vitamin D-dependent rickets type 1) or end-organ resistance to vitamin D (vitamin D-dependent rickets type 2).

Familial hypophosphatemic rickets (vitamin D-resistant rickets) has skeletal findings similar to those of vitamin D-related rickets; however, the basic defect in this condition is abnormal renal phosphate loss. Dietary deficiency of calcium may also be an important cause of rickets.

DeLucia MC et al: Nutritional rickets with normal circulating 25-hydroxyvitamin D: A call for reexamining the role of dietary calcium intake in North American infants. *J Clin Endocrinol Metab* 2003;88:3539 [PMID: 12915633].

Clinical Findings

A. SYMPTOMS AND SIGNS

Prolonged hypocalcemia causes tetany, photophobia, blepharospasm, and diarrhea. The symptoms of tetany include numbness, cramps, and twitchings of the extremities; carpopedal spasm and laryngospasm; a positive Chvostek sign (tapping of the face in front of the ear produces spasm of the facial muscles); unexplained bizarre behavior; irritability; loss of consciousness; convulsions; and retarded physical and mental development. Headache, vomiting, increased intracranial pres-

sure, and papilledema may occur. In early infancy, respiratory distress may be the presenting finding.

B. LABORATORY FINDINGS

Calcium levels may be low or normal (see Tables 30–5 and 30–6). Phosphate levels may be low, normal, or high depending on the cause of the hypocalcemia. Magnesium levels may also be low. PTH levels are elevated in the hypocalcemic conditions, with the notable exception of hypoparathyroidism. Markedly elevated serum PTH may be associated with pseudohypoparathyroidism (see following discussion). Measurement of urinary excretion of calcium and phosphate can assist in diagnosis and monitoring of therapy.

C. IMAGING

Soft tissue and basal ganglia calcification may occur in idiopathic hypoparathyroidism and pseudohypoparathyroidism. A variety of skeletal changes are associated with rickets, including cupped and irregular appearance at the metaphysis of the long bones. Torsional deformities can result in genu varum (bowleg). Accentuation of the costochondral junction gives the rachitic rosary appearance seen on the chest wall.

Differential Diagnosis

Tables 30–5 and 30–6 outline the features of disorders associated with hypocalcemia. An artifactually low total serum calcium level may be seen with low serum albumin, and measurement of ionized calcium is advised in these cases.

Treatment

A. ACUTE OR SEVERE TETANY

The objective of treatment is to correct hypocalcemia immediately by the administration of intravenous calcium. Calcium gluconate and calcium chloride 10 mg/kg are generally used for acute treatment. To avoid cardiac arrhythmia, intravenous calcium infusions should not exceed 50 mg/min. Cardiac monitoring should be performed during the infusion.

B. MAINTENANCE MANAGEMENT OF HYPOPARATHYROIDISM OR CHRONIC HYPOCALCEMIA

The objective of treatment is to maintain the serum calcium and serum phosphate at approximately normal levels without excessive urinary calcium excretion.

1. Diet—In addition to a diet high in calcium, calcium supplements are generally required. A starting dosage of 50–75 mg of elemental calcium per kilogram of body weight per day divided in three to four doses is used as initial management and should be titrated based on serum calcium levels and urinary calcium excretion.

Therapy should be monitored to prevent hypercalcemia and its complications (see Monitoring section). Often, supplemental calcium can be decreased or discontinued after vitamin D therapy has reached its peak effect. Supplemental phosphate and activated vitamin D (calcitriol) are required in the treatment of hypophosphatemic rickets.

2. Vitamin D supplementation—A variety of vitamin D preparations are available for treatment. Ergocalciferol (vitamin D₂) and calcitriol (1,25-dihydroxyvitamin D₃) are used in the majority of cases. Ergocalciferol is the preferred agent for the treatment of vitamin D deficiency. Impaired metabolism of vitamin D to its active end product 1,25-(OH)₂ vitamin D or impaired function of PTH requires supplementation with calcitriol. Selection and dosage of a vitamin D supplement vary with the condition to be treated and the patient's response to therapy. As with calcium supplementation, monitoring of therapy is essential to avoid toxicity.

3. Monitoring—Dosages of calcium and vitamin D must be tailored for each patient. Monitoring serum calcium, urine calcium, and serum alkaline phosphatase levels at 1- to 3-month intervals is necessary to ensure adequacy of therapy and to prevent hypercalcemia and nephrocalcinosis.

Basic goals in monitoring therapy include the following: (1) maintenance of serum calcium and phosphorous concentrations within normal ranges; (2) normalization of alkaline phosphatase concentrations for age; (3) regression of skeletal changes, if present; and (4) maintenance of spot urine calcium to creatinine ratio between 0.1 and 0.3 (0.05–0.15 if calcium is measured in mEq/L).

Hypophosphatemic rickets is an exception, since the monitoring goals are somewhat different. Serum calcium and alkaline phosphatase should be maintained within normal limits; however, phosphorus levels should be corrected only to the low normal range. Monitoring of serum PTH level is necessary to ensure that secondary hyperparathyroidism does not develop from excessive phosphate treatment or inadequate calcitriol replacement.

Singh J et al: The investigation of hypocalcaemia and rickets. *Arch Dis Child* 2003;88:403 [PMID: 12716711].

PSEUDOHYPOPARATHYROIDISM (Resistance to Parathyroid Hormone Action)

In pseudohypoparathyroidism (PHP), PTH production is adequate; however, target organs (renal tubule, bone, or both) fail to respond. This receptor resistance to PTH action is due to a heterozygous inactivating mutation in the stimulatory G protein subunit associated with the PTH receptor, which leads to impaired signal-

ing. Resistance to other G protein-dependent hormones may also be present.

Several types of PHP have been identified, with variable biochemical and phenotypic features (see Table 30–6). PHP has biochemical abnormalities similar to hypoparathyroidism with hypocalcemia and hyperphosphatemia. However, PTH levels are elevated, suggesting resistance to the action of the hormone. It may be accompanied by a characteristic phenotype known as Albright osteodystrophy (AHO). The AHO phenotype includes short stature; round, full facies; irregularly shortened fourth metacarpal; a short, thick-set body; delayed and defective dentition; and mild mental retardation. Corneal and lenticular opacities and ectopic calcification of the basal ganglia and subcutaneous tissues may occur with or without abnormal serum calcium levels. Treatment is the same as that for hypoparathyroidism.

Pseudopseudohypoparathyroidism (PPHP) describes individuals with the AHO phenotype, but normal calcium homeostasis. PHP and PPHP can occur in the same cohort. Genomic imprinting is thought to be responsible for the differential phenotypic expression of disease. With heterozygous loss of maternal allele associated with PHP and heterozygous loss of paternal allele associated with PPHP.

HYPERCALCEMIC STATES

Hypercalcemia is defined as a serum level greater than 11 mg/dL. Severe hypercalcemia is defined as a level above 13.5 mg/dL. Some laboratories report calcium levels in units of mEq/L. Units of mEq/L can be converted to mg/dL by multiplying the value by 2.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Abdominal pain, polyuria, polydipsia, hypertension, nephrocalcinosis, failure to thrive, renal stones, intractable peptic ulcer, constipation, uremia, and pancreatitis.*
- *Bone pain and, rarely, pathologic fractures. Radiograph shows subperiosteal resorption, loss of the lamina dura of the teeth, renal parenchymal calcification or stones, and osteitis fibrosa cystica (brown tumors).*

- *Vague psychiatric symptoms, impaired concentration, altered mental status, mood swings, coma.*
- *Transient or mild hypercalcemia may be entirely asymptomatic; hypercalcemia and mild hyperparathyroidism noted frequently as incidental findings in routine laboratory screening.*

General Considerations

More than 80% of hypercalcemic children or adolescents have either hyperparathyroidism or a malignant tumor as the underlying cause. Table 30–7 summarizes the differential diagnosis of childhood hypercalcemia.

Hyperparathyroidism is rare in childhood and may be primary or secondary. The most common cause of primary hyperparathyroidism is a parathyroid adenoma. Diffuse parathyroid hyperplasia or multiple adenomas have also been described in families.

Table 30–7. Hypercalcemic states.

nomas have also been described in families. Familial hyperparathyroidism may be an isolated disease, or it may be associated with multiple endocrine neoplasia (MEN), usually type 1 and, rarely, type 2A. Hypercalcemia of malignancy can be associated with both solid and hematologic malignancies. Hypercalcemia of malignancy is caused by local destruction of bone by tumor infiltration. Another cause is the secretion of PTH-related protein (PTH-RP). PTH-RP is responsible for parathyroid hormone-like actions. With PTH-RP as the causative agent, calcium is elevated, PTH is suppressed, and PTH-RP is high. Chronic renal disease with impaired phosphate excretion is the most common secondary cause of hyperparathyroidism.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Due to hypercalcemia—Findings include hypotonicity and weakness of muscles; apathy, mood swings, and bizarre behavior; nausea, vomiting, abdominal pain, constipation, and weight loss; hyperextensibility of joints; and hypertension, cardiac irregularities, bradycardia, and shortening of the QT interval. Coma occurs rarely. Calcium deposits in the cornea or conjunctiva (band keratopathy) may occur and are detected by slit-lamp examination of the eye. Intractable peptic ulcer and pancreatitis occur in adults but rarely in children.

2. Due to increased calcium and phosphate excretion—Findings include loss of renal concentrating ability with polyuria, polydipsia, precipitation of calcium phosphate in the renal parenchyma or as urinary calculi, and progressive renal damage.

3. Due to changes in the skeleton—Findings may include bone pain, osteitis fibrosa cystica, subperiosteal absorption of the distal clavicles and phalanges, absence of lamina dura around the teeth, spontaneous fractures, and a moth-eaten appearance of the skull on radiograph. Later, there is generalized demineralization with a predilection for subperiosteal cortical bone.

B. IMAGING

Bone changes may be subtle in children even when radiography shows nephrocalcinosis. Technetium-99m scintigraphy is now shown to be more promising than conventional procedures such as ultrasonography, CT, and MRI for localizing parathyroid tumors.

Treatment

A. SYMPTOMATIC

Initial management consists of vigorous hydration with normal saline and forced calcium diuresis using a loop diuretic such as furosemide (1 mg/kg given every 6 hours). In cases of inadequate response to initial intervention, interventions with glucocorticoids or calcitonin have been used. Bisphosphonates, standard agents for the management of acute hypercalcemia in adults, are being used with increasing frequency for cases of refractory pediatric hypercalcemia.

B. CHRONIC

Treatment options vary depending on the condition. Removal of a parathyroid adenoma or subtotal removal of hyperplastic parathyroid glands will treat hyperparathyroidism. Postoperatively, hypocalcemia due to the rapid remineralization of chronically calcium-depleted bones may occur. A diet high in calcium and vitamin D is recommended immediately postoperatively and is continued until serum calcium concentrations are normal and stable. Treatment of secondary hyperparathyroidism from chronic renal disease is primarily directed at controlling serum phosphorus levels with phosphate binders. Pharmacologic doses of calcitriol are used to suppress PTH secretion.

Long-term therapy for hypercalcemia of malignancy is the treatment of the underlying disorder.

Course & Prognosis

The prognosis following removal of a single adenoma is excellent. The prognosis following subtotal parathyroidectomy for diffuse hyperplasia or removal of multiple adenomas is usually good and depends on correction of the underlying defect. In patients with multiple sites of parathyroid adenoma or hyperplasia, MEN is likely, and other family members may be at risk. Genetic counseling and DNA analysis to determine the specific gene defect are indicated.

Allgrove J: Use of bisphosphonates in children and adolescents. *J Pediatr Endocrinol Metab* 2002;15(Suppl 3):921 [PMID: 12199351].

Mathur M et al: Treatment of acute lymphoblastic leukemia-induced extreme hypercalcemia with pamidronate and calcitonin. *Pediatr Crit Care Med* 2003;4(2):252 [PMID: 12749663].

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA (Familial Benign Hypercalcemia)

Familial hypocalciuric hypercalcemia is distinguished by low to normal urinary calcium excretion as a result

of high renal reabsorption of calcium. PTH is normal or slightly elevated.

In most cases, the gene defect has been identified as a mutation in the membrane-bound calcium-sensing receptor expressed on parathyroid and renal tubule cells. It is inherited as an autosomal dominant trait with high penetrance. There is a low rate of new mutations. The majority of patients are asymptomatic, and treatment is unnecessary. A severe form of symptomatic neonatal hyperparathyroidism may occur in infants homozygous for the receptor mutation.

Heath DA: Familial hypocalciuric hypercalcemia. *Rev Endocr Metab Disord* 2000;1:291 [PMID: 11706743].

HYPERVITAMINOSIS D

Vitamin D intoxication is almost always the result of ingestion of excessive amounts of vitamin D, some forms of which may be stored for months in adipose tissue.

Signs, symptoms, and treatment of vitamin D-induced hypercalcemia are the same as those in other hypercalcemic conditions.

Treatment depends on the stage of hypercalcemia. Severe hypercalcemia requires hospitalization and aggressive intervention. Due to the storage of vitamin D in the adipose tissue, several months of a low-calcium, low-vitamin D diet may be required.

IDIOPATHIC HYPERCALCEMIA OF INFANCY (Williams Syndrome)

Williams syndrome is an uncommon disorder of infancy characterized in its classic form by elfin-appearing facies and hypercalcemia in infancy. Other features include failure to thrive, mental and motor retardation, cardiovascular abnormalities (primarily supravalvular aortic stenosis), irritability, purposeless movements, constipation, hypotonia, polyuria, polydipsia, and hypertension. A gregarious and affectionate personality is the rule in older children with the syndrome. Hypercalcemia may not appear until several months after birth. Treatment consists of rigid restriction of dietary calcium and vitamin D, and, in severe cases, moderate doses of glucocorticoids.

A defect in the metabolism of, or responsiveness to, vitamin D is postulated as the cause of Williams syndrome. Elastin deletions localized to chromosome 7 have been identified in over 90% of patients; thus, fluorescent in situ hybridization analysis may be the best initial diagnostic tool. The risk of hypercalcemia generally resolves by age 4, and dietary restrictions can be relaxed.

Morris CA, Mervis CB: Williams syndrome and related disorders. *Annu Rev Genomics Hum Genet.* 2000;1:461 [PMID: 11701637].

IMMOBILIZATION HYPERCALCEMIA

Abrupt immobilization, particularly in a rapidly growing adolescent, is a risk factor for hypercalcemia. Hypercalcemia and hypercalciuria often appear 1–3 weeks after immobilization. Medical or dietary intervention may be required in severe cases.

HYPOPHOSPHATASIA

Hypophosphatasia is an uncommon autosomal recessive condition characterized by a deficiency of alkaline phosphatase activity in serum, bone, and tissues. The deficiency of this enzyme leads to inadequate skeletal mineralization with clinical and radiographic features similar to rickets. Six different clinical forms have been identified. The perinatal form is characterized by severe skeletal deformity and death that occurs within a few days. The infantile form includes failure to thrive, hypotonia, and craniosynostosis. The childhood form has variable skeletal findings, reduced bone mineral density, and is associated with premature loss of deciduous teeth. Serum calcium levels may be elevated. The diagnosis of hypophosphatasia is made by demonstrating elevated levels of urinary phosphoethanolamine associated with low serum alkaline phosphatase.

Therapy is generally supportive. Children who survive the neonatal period may experience an improvement in severity of disease. Calcitonin may be of value for the temporary treatment of hypercalcemia.

Table 30–8. Sexual differentiation in the female and male.

Internal Duct Derivatives		
Müllerian Duct Derivatives	Wolffian Duct Derivatives ^a	
Fallopian tubes (oviducts) and fimbriae	Epididymis	Vas deferens
Uterus	Seminal vesicles	
Cervix	Ejaculatory duct	
Vagina (posterior two thirds)	Prostatic urethra	
External Genitalia Homologues		
Primitive Structure	Female Genitalia	Male Genitalia ^b
Undifferentiated gonad	Ovary	Testis
Genital tubercle	Clitoris	Glans penis
Genital swelling	Labia majora	Scrotum
Genital/urethral fold	Labia minora	Penile urethra/corpora

^aNormal wolffian duct development is dependent on the local production of testosterone by Leydig cells of the adjacent testis and on testosterone's diffusion into the surrounding embryonic tissues. Thus females with congenital adrenal hyperplasia who are virilized as the result of circulating androgens do not have wolffian duct development. Normal male development is also dependent on regression of müllerian duct derivatives through the local action of müllerian inhibiting factor elaborated by the Sertoli cells of the adjacent testis.

^bThe normal development of male external genitalia is dependent on an adequate circulating concentration of testosterone, which is then further converted to dihydrotestosterone in the target tissues through the action of the enzyme 5 α -reductase. Significantly elevated circulating concentrations of other (adrenal) androgens, as in females with congenital adrenal hyperplasia, can virilize the genital tubercle, genital swelling, and genital/urethral folds along the lines of their male homologues, resulting in varying degrees of female pseudohermaphroditism (ambiguity) (see text).

THE GONADS (Ovaries & Testes)

DEVELOPMENT & PHYSIOLOGY

The fetal gonads develop from bipotential anlagen in the genital ridge. In addition to gonadal tissue, both müllerian and wolffian structures are present and have the potential to differentiate into components of the internal reproductive structures. Table 30–8 summarizes the male and female structures arising from müllerian and wolffian ducts. The Y chromosome, specifically the

SRY gene region of the chromosome, promotes testicular differentiation of the bipotential gonads. Once testicular differentiation has been determined, the fetal testis produces two substances critical for further male differentiation. Antimüllerian hormone (AMH) promotes the regression of müllerian structures, and the rising concentrations of testosterone stimulate growth of wolffian derivatives into male internal structures. Dihydrotestosterone (DHT), formed by 1 α -reductase action on testosterone, is primarily responsible for virilization of the external genitalia. In the absence of both AMH and testosterone, differentiation into female internal and external genitalia occurs.

AMBIGUOUS GENITALIA IN THE NEWBORN

A variety of abnormalities in chromosomal allocation, gonadal differentiation, gonadal function, testosterone synthesis and action, or adrenal function can lead to aberrant development of internal and external genital structures. These abnormalities can be divided into four categories.

A. ABNORMALITIES IN NORMAL GONADAL DIFFERENTIATION

These abnormalities usually result from an abnormality in the number of sex chromosomes. Klinefelter syndrome (see Chapter 32), with a 47,XXY karyotype, is associated with a male phenotype but with poorly functioning testes. Turner syndrome with a 45,XO karyotype (see Chapter 32) is associated with a female phenotype but with streak ovaries (gonadal dysgenesis) or premature ovarian failure. The phenotype is less severe if mosaicism or only partial absence of an X chromosome occurs. Mosaic forms of gonadal dysgenesis that contain a Y-bearing cell line have variable ambiguous internal and external phenotypes. Idiopathic testicular failure prior to completion of sexual differentiation results in ambiguous genitalia (incomplete virilization). True hermaphroditism, with the presence of both testicular and ovarian tissue, is rare and associated with external genitalia that range from fully masculine to almost completely feminine.

B. ABNORMALITIES IN TESTOSTERONE SYNTHESIS OR ACTION

These disorders generally present as micropenis, genital ambiguity, or complete absence of male external genitalia in an XY individual (Figure 30–6). Testicular tissue is present and produces AMH; therefore, internal structures are wolffian. Disorders in this category include enzymatic defects in testosterone synthesis (such as 12-ketoreductase deficiency) or defects in conversion of testosterone to DHT (5 α -reductase deficiency). If the enzyme defect is incomplete, the external genitalia may masculinize at puberty when testosterone production increases. Since the gonads and adrenal gland share common enzymes of steroid hormone production, some of the enzymatic defects associated with male genital ambiguity may also affect production of cortisol and aldosterone, leading to cortisol deficiency and salt wasting. Defects in testosterone action result from absent or defective androgen receptors (androgen insensitivity) and, depending on the resultant degree of defect in androgen binding, the genital phenotype can range from relatively mild male ambiguity to complete female external development.

C. DISORDERS OF ADRENAL ANDROGEN PRODUCTION

These disorders can cause genital ambiguity in both XY and XX individuals. Excessive adrenal androgen production secondary to an enzyme defect in cortisol synthesis (ie, congenital adrenal hyperplasia, described in a later section) is the cause of 95% of inappropriate virilization in 46,XX newborns. An enzyme defect in adrenal androgen, cortisol, and aldosterone production (3 β HSD deficiency) is a rare cause of genital ambiguity in XY individuals.

D. MISCELLANEOUS SYNDROMES

Various syndromes, such as VATER, WAGR, Denys–Drash, and Smith–Lemli–Opitz, have a wide variety of congenital anomalies, including genital ambiguity. Maternal exposure to androgens or androgen antagonists is a rare cause of genital ambiguity in newborns.

ABNORMALITIES IN FEMALE PUBERTAL DEVELOPMENT AND OVARIAN FUNCTION

1. Precocious Puberty in Girls

Puberty is considered precocious in girls if the onset of secondary sexual characteristics occurs before 7–8 years of age. Precocious puberty is thought to be more common in girls than in boys, but this may be the result of the inclusion, in published studies, of a large group of 6- to 8-year-old girls who have a benign, slowly progressing form that is probably a normal variant. The age of pubertal onset may also be advanced by obesity.

True (gonadotropin-releasing hormone [GnRH]-dependent) precocious puberty refers to early sexual maturation in response to hypothalamic–pituitary stimulation (GnRH, FSH, LH). In pseudoprecocity (ie, GnRH-independent precocity), the cause is elsewhere (eg, adrenal gland or ovary, or the result of exogenous estrogen). GnRH-dependent precocious puberty is always isosexual and may progress to the production of mature ova. In pseudoprecocity, sexual characteristics may be isosexual or heterosexual; secondary sexual characteristics develop, but the hypothalamic–pituitary gonadal axis (see Figure 30–1) does not mature, unless the

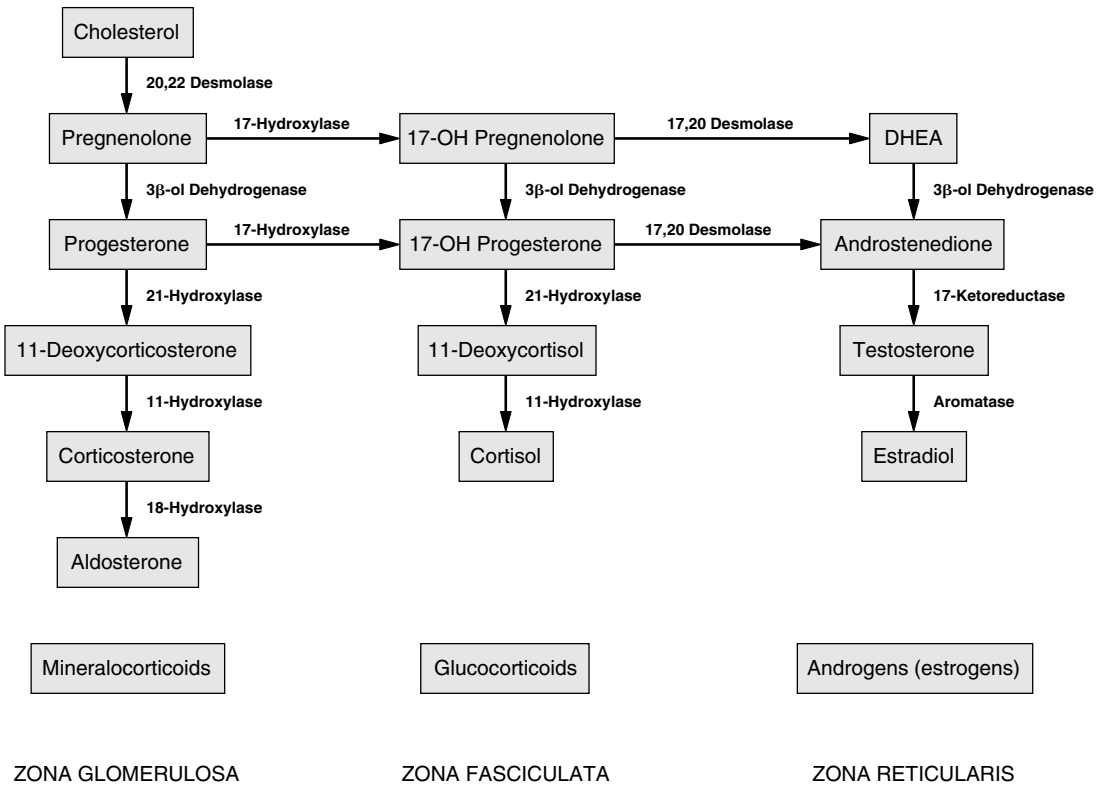

Figure 30–6. The corticosteroid hormone synthetic pathway. The pathways illustrated are present in differing amounts in the steroid-producing tissues: adrenal glands, ovaries, and testes. In the adrenal glands, mineralocorticoids from the zona glomerulosa, glucocorticoids from the zona fasciculata, and androgens (and estrogens) from the zona reticularis are produced. The major adrenal androgen is androstenedione, because the activity of 17-ketoreductase is relatively low. The adrenal gland does secrete some testosterone and estrogen, however. The pathways leading to the synthesis of mineralocorticoids and glucocorticoids are not present to any significant degree in the gonads; however, the testes and ovaries each produce both androgens and estrogens. Further metabolism of testosterone to dihydrotestosterone occurs in target tissues of the action of the enzyme 5 α -reductase.

bone age is advanced sufficiently to stimulate central (GnRH-dependent) puberty.

Clinical Findings

A. SYMPTOMS AND SIGNS

Sexual development in girls usually starts with breast development, followed by pubic hair growth and menarche, but the order may vary. The interval between breast development and menarche can range from 1 to 6 years but is usually about 2 years. Girls with ovarian or adrenal tumors may have a palpable abdominal mass, also visualized by ultrasonography. A history of excessive mood changes and emotional lability is common. Children with precocious puberty usu-

ally have accelerated growth and may appear tall during childhood. However, because skeletal maturation (bone age) advances at a more rapid rate than linear growth (particularly in the female), final adult stature may be short.

B. LABORATORY FINDINGS

In true precocious puberty, the basal serum concentrations of FSH and LH may still be in the prepubertal range. Thus documentation of the maturity of the hypothalamic-pituitary axis depends on demonstrating a pubertal LH response 30–40 minutes after stimulation with GnRH. In pseudoprecocity, basal serum FSH and LH are low, and the LH response to GnRH stimulation is suppressed as a result of feedback inhibition of

the hypothalamic–pituitary axis by the autonomously secreted gonadal steroids (see Figure 30–1).

C. IMAGING

Determination of skeletal maturation at onset and then every 6–12 months is helpful in predicting the effect of precocity on adult height and may be used as one of several criteria to determine if treatment is warranted.

Abdominal and pelvic ultrasonography can usually identify an ovarian mass, follicular cyst, or adrenal mass greater than 5 mm in diameter. Serial examinations are useful in demonstrating significant changes. An MRI of the hypothalamic and pituitary regions can identify mass lesions and other structural abnormalities of the CNS. Because some of these lesions produce no clinical manifestations for prolonged periods, examinations should be performed periodically.

Differential Diagnosis

In girls with precocious puberty, 90% have true precocious puberty (Table 30–9). Definable abnormalities on MRI scans are seen more commonly in younger children. With newer scanning techniques, static (presumably congenital) mass lesions in the hypothalamus,

including benign hypothalamic hamartomas, can be seen. The most common cause of pseudoprecocious puberty is McCune–Albright syndrome. Clinical manifestations of this disorder include polyostotic fibrous dysplasia, café au lait lesions with irregular borders, and autonomous hyperfunction of several endocrine glands, resulting in sexual precocity and other findings (eg, hyperthyroidism). Laboratory and radiographic findings helpful in differentiating true and pseudoprecocious puberty are discussed earlier.

Premature thelarche—benign early breast development—occurs most commonly between ages 12 and 36 months. It is often bilateral but may begin or remain as unilateral breast enlargement. In the absence of other signs of pubertal development (eg, accelerated growth rate or skeletal maturation, pubic hair, or vaginal mucosal maturation), no laboratory evaluation is necessary. Treatment consists of reassurance regarding the self-limited nature of this condition, but observation of the child at regular intervals (eg, twice a year) is also useful. Onset of thelarche after age 3 or in association with other signs of puberty requires more evaluation.

Premature adrenarche—benign early adrenal maturation—is manifested by gradual increase in pubic hair and body odor and, less commonly, axillary hair and acne. The average age at onset is 5–6 years. It is seen more commonly in obese girls. No increase in growth rate or skeletal maturation occurs, and no abnormal virilization (eg, clitoromegaly) is present. No treatment is required, though the possibility that premature adrenarche is a risk factor for later development of syndrome X is currently an area of investigation. Early adrenarche can also occur with undiagnosed CAH and may be associated with other signs of virilization.

Table 30–9. Causes of isosexual precocious pubertal development.

A. True (GnRH-dependent) precocious puberty

1. Constitutional (idiopathic)
2. Hypothalamic lesions (hamartomas, tumors, congenital malformations)
3. Dysgerminomas
4. Hydrocephalus
5. CNS infections
6. CNS trauma, irradiation
7. Pineal tumors (rare)
8. Neurofibromatosis with CNS involvement
9. Tuberous sclerosis
10. HCG-secreting tumors (eg, hepatoblastomas, choriocarcinomas)

B. Pseudo (GnRH-independent)-precocious puberty

1. CAH in males
2. Adrenal tumors
3. McCune–Albright syndrome (polyostotic fibrous dysplasia)
4. Familial Leydig cell hyperplasia (testotoxicosis)—males
5. Gonadal tumors
6. Exogenous estrogen—oral (contraceptive pills) or topical

CAH = congenital adrenal hyperplasia; CNS = central nervous system; GnRH = gonadotropin-releasing hormone; HCG = human chorionic gonadotropin.

Treatment

In pseudoprecocious puberty, removal of the adrenal or ovarian tumor or correction of the adrenal enzyme disorder usually halts abnormal pubertal development. True precocious puberty can be treated with an analog of GnRH when bone age advancement indicates that adult height will be reduced or when precocious development is causing psychosocial stress. Some long-term outcomes (eg, fertility rate) have not been established. The analogs—given as a depot sustained-release preparation—interrupts the physiologic pulsatile effect of native GnRH on the pituitary. Down-regulation of the pituitary GnRH receptor also occurs, resulting in inhibition of pituitary LH secretion and release and the return of plasma estrogen concentrations to prepubertal values. If present initially, menses cease, secondary sexual development stabilizes or regresses, and linear growth and skeletal maturation slow to normal prepubertal rates.

In McCune–Albright syndrome, analogs of GnRH are not initially helpful. Therapy with antiestrogens (eg, tamoxifen) or agents that block estrogen synthesis (eg, ketoconazole or testolactone), or both, may be effective. Regardless of the cause of precocious puberty or the medical therapy selected, attention to the psychological needs of the patient and family is essential.

2. Amenorrhea

Primary amenorrhea is the absence of menarche in a female age 14 years or older or in a female of any age who is more than 3 years postpubertal maturation (Table 30–10). Secondary amenorrhea is cessation of established menses after an interval of time equal to at least 6 months postmenarche or three menstrual cycles. A history and physical examination (including pelvic examination) often identify possible causes of amenorrhea. The term “pseudoamenorrhea” is used when the patient is menstruating but has a genital tract obstruction that prevents release of menstrual blood. Sexual development is usually at Tanner state III or IV, and cyclic abdominal pain without menstruation is noted.

Primary Amenorrhea

The most common cause of primary amenorrhea is physiologic or constitutional delay. However, Turner syndrome, chronic illness, and severe undernutrition or strenuous exercise also can lead to delay in onset of menses.

Turner syndrome (45,XO syndrome and its variants) should be considered in patients with short stature and sexual infantilism or adrenarche without normal pubertal progression. This is a form of hypergonadotropic hypogonadism in which serum concentrations of FSH and LH are elevated but plasma estrogen concentration is low after attainment of pubertal age owing to a total or relative lack of ovarian tissue. Skeletal maturation is usually delayed. The phenotypic

Table 30–10. Causes of amenorrhea.

A. With obstruction of outflow tract

1. Fusion or stenosis of labia, hymen (imperforate), vagina, or cervix
2. Müllerian agenesis (Mayer–Rokitansky–Küster–Hauser syndrome)
3. Postabortion infection, cesarean section, hysterectomy
4. Complete androgen resistance syndrome (46,XY female)

B. Estrogen deficiency

1. Primary ovarian insufficiency
 - a. Gonadal agenesis
 - b. Gonadal dysgenesis (Turner syndrome variants, true gonadal dysgenesis)
 - c. Ovarian steroid biosynthesis deficiency (enzyme defects)
 - d. Premature ovarian failure
 - (1) Autoimmune disease
 - (2) Infection, surgery, radiation, chemotherapy
2. Secondary/tertiary ovarian insufficiency
 - a. Hypothalamic or pituitary tumor, infection, irradiation
 - b. Kallman syndrome (GnRH/FSH/LH deficiency associated with anosmia)
 - c. Eating disorders (eg, anorexia nervosa, bulimia)
 - d. Excessive exercise (swimmers, runners, gymnasts)
 - e. Chronic illness, malnutrition

C. Androgen excess

1. Polycystic ovary syndrome
2. Adrenal androgen excess (CAH, Cushing disease or syndrome)

D. Ovarian tumors—granulosa-theca cell, and others

CAH = congenital adrenal hyperplasia; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone.

features of Turner syndrome (described in Chapter 32) may be absent in 40–50% of girls with the syndrome. Current treatment for short stature includes HGH with or without anabolic steroids. Low doses of estrogens are added to the treatment regimen when breast development is desired, but usually at a later age than the average girl, to ensure that maximal height will be achieved. After 2–3 years of estrogen therapy, a combination of estrogen and progesterone in physiologic doses is indicated.

Mayer–Rokitansky–Küster–Hauser syndrome is characterized by congenital müllerian agenesis with normal ovaries, normal ovarian function, and normal breast development. Pelvic examination reveals an absent vagina and various uterine abnormalities with or without additional renal and skeletal anomalies. Full evaluation is necessary, including karyotype, renal ul-

trasonography, and laparoscopy. Therapy for this syndrome is surgical vaginoplasty.

Androgen insensitivity syndrome (androgen receptor defect) may be manifested as primary amenorrhea because the affected individual (46,XY) has functioning testes that produce müllerian-inhibiting hormone during fetal life. Thus no müllerian duct (oviduct, uterus) development occurs, but external sexual characteristics appear female.

The history should include whether and when puberty commenced, level of exercise, nutritional intake, presence of stressors, and the age of menarche for female relatives. A careful physical examination should note the percentage of ideal body weight for height and age, Tanner stage, vaginal patency, presence of a uterus (assessed through pelvic examination or ultrasonography), signs of virilization, excess body hair, or stigmata of Turner syndrome.

A bone age radiograph should be obtained. If the patient has not attained an age consistent with pubertal onset, further evaluation should focus on determining the cause of the delay. Laboratory studies should include a complete blood count, erythrocyte sedimentation rate, chemistry panel, and renal and liver function tests to screen for undiagnosed chronic medical illness. Tests for FT_4 and TSH can exclude hypothyroidism. Measurement of FSH and LH will not be helpful in this setting since prepubertal levels are normally low. Determination of a karyotype should be considered if short stature, stigmata of Turner syndrome, or genital abnormalities noted on exam or ultrasonography are present.

If the patient has attained a skeletal age consistent with onset of puberty and there are minimal or no signs of puberty on physical exam, determination of FSH and LH will distinguish between hypergonadotropic states (gonadal dysgenesis, Turner syndrome, premature ovarian failure) and hypogonadotropic states (anorexia, chronic disease, severe stress). If significant pubertal signs are present, the patient should be given a course of medroxyprogesterone, 10 mg/day orally for 10 days. If withdrawal bleeding occurs within 7 days of completion of the course, normal anatomy and adequate estrogen effect can be assumed. If the patient is obese, a work-up for the metabolic syndrome is indicated, and weight loss or insulin-sensitizing medications may restore menses. If no bleeding occurs, FSH, LH, and prolactin levels should be drawn.

Secondary Amenorrhea (See Chapter 3, Adolescence.)

OVARIAN TUMORS

Ovarian tumors are not rare in children. They may occur at any age and are usually large, benign, and uni-

lateral. They may be estrogen-producing. Ovarian tumors account for about 1% of cases of female sexual precocity. The most common estrogen-producing tumor is the granulosa cell tumor. Other tumors causing sexual precocity include thecomas, luteomas, mixed types, theca-lutein and follicular cysts, and ovarian tumors (teratomas, choriocarcinomas, and dysgerminomas). Ovarian tumors are usually palpated on rectal examination and are seen readily by ovarian ultrasonography. Treatment is surgical removal. Recurrences are uncommon.

ABNORMALITIES IN MALE PUBERTAL DEVELOPMENT AND TESTICULAR FUNCTION

1. Precocious Puberty in Boys

Puberty is considered precocious in boys if secondary sexual characteristics appear before age 9 years. Precocious puberty appears to be much less common in boys than in girls. In boys presenting with sexual precocity, pseudoprecocious puberty is as common as true GnRH-dependent, precocious puberty. In addition, boys with true precocious puberty are more likely to have an identifiable pathologic process (eg, CNS abnormality) than are girls.

Two primary GnRH-independent forms of precocious puberty have been described in boys: McCune–Albright syndrome (described previously) and familial Leydig cell hyperplasia, or testotoxicosis, a condition in which a mutated LH receptor on the Leydig cell is autonomously activated, resulting in testicular production of testosterone despite prepubertal LH concentrations.

Clinical Findings

A. SYMPTOMS AND SIGNS

In precocious development, increases in growth rate and growth of pubic hair are the common presenting signs. Testicular size may differentiate true precocity, in which the testes enlarge, from pseudoprecocity (most commonly due to congenital adrenal hyperplasia), in which the testes usually remain small. Some exceptions do occur—for example, testicular enlargement may occur in pseudoprecocity of long-standing due to secondary activation of central precocity from prolonged elevation of androgen levels. Tumors of the testis are associated with asymmetrical testicular enlargement.

B. LABORATORY FINDINGS

Basal serum LH and FSH concentrations are usually not in the pubertal range in boys with true sexual precocity, but the LH response to GnRH stimulation testing is pubertal (> 10 IU/L). Sexual precocity caused by congeni-

tal adrenal hyperplasia is usually associated with abnormal plasma concentrations of dehydroepiandrosterone (DHEA), androstenedione, 17-hydroxyprogesterone (in congenital adrenal hyperplasia due to 21-hydroxylase deficiency), 11-deoxycortisol (in congenital adrenal hyperplasia due to 11-hydroxylase deficiency), or a combination of these steroids (see Adrenal Cortex section). Serum HCG concentrations can identify the presence of an HCG-producing tumor (eg, CNS dysgerminoma, hepatoma) in boys who present with apparent true sexual precocity (ie, accompanied by testicular enlargement) but suppressed gonadotropins following LHRH.

C. IMAGING

Diagnostic studies are similar to those used to evaluate sexual precocity in girls. Ultrasonography may be useful in detecting hepatic, presacral, and testicular tumors.

Differential Diagnosis

The causes of isosexual precocity are outlined in Table 30–9. In boys, it is particularly important to differentiate pseudoprecocity from true sexual precocity. Seventy percent of boys with pseudoprecocious puberty have an adrenal enzyme abnormality (congenital adrenal hyperplasia). Of boys with true precocious puberty, 70% have benign CNS mass lesions. Premature adrenarche (described earlier) may occur in males as well as females.

Treatment

Specific therapy should be provided whenever possible. Treatment of idiopathic true precocious puberty in boys is similar to that in girls (see previous discussion). Treatment of McCune–Albright syndrome or familial Leydig cell hyperplasia with agents that block steroid synthesis (eg, ketoconazole), with an antiandrogen (eg, spironolactone), or a combination of both has been successful.

2. Delayed Puberty (Primary & Secondary Testicular Failure)

Lack of development of secondary sexual characteristics after age 15 years suggests abnormal testicular maturation.

Although delay of puberty until age 15 years may be physiologically normal, boys generally become concerned if pubertal changes do not occur by then, and evaluation should be initiated at that time. Hypogonadism may be difficult to differentiate from constitutionally delayed adolescence. Although the latter may be associated with a delay in testicular function, normal puberty occurs at a later date.

Testicular failure or insufficiency may be primary, resulting from the absence, malfunction, or destruction of testicular tissue, or secondary, due to pituitary (or hypothalamic) insufficiency. Primary testicular failure may be due to anorchia, surgical castration, Klinefelter syndrome or other sex chromosome abnormalities, enzymatic defects in testosterone synthesis or action, or inflammation and destruction of the testes following infection (eg, mumps), autoimmune disorders, radiation, trauma, or tumor.

Secondary testicular failure may accompany panhypopituitarism, empty-sella syndrome, Kallmann syndrome (gonadotropin deficiency accompanied by anosmia), or isolated LH or FSH deficiencies. Destructive lesions in or near the anterior pituitary, especially craniopharyngiomas, gliomas, or infection, may also result in hypothalamic or pituitary dysfunction. Prader–Willi syndrome and Laurence–Moon syndrome (Bardet–Biedl syndrome) are frequently associated with LH and FSH deficiency secondary to GnRH deficiency. Miscellaneous causes of secondary testicular failure include chronic debilitating disease and hypothyroidism.

Clinical Findings

A. SYMPTOMS AND SIGNS

Physical examination may not be helpful in differentiating primary from secondary testicular insufficiency. Whereas cryptorchidism suggests primary testicular failure, hypothalamic or pituitary insufficiency as well as anatomic abnormalities may also lead to failure of testicular descent.

B. LABORATORY FINDINGS

In primary testicular failure, the plasma testosterone concentration is low, whereas LH and FSH values are elevated into the castrate range in children who have attained a pubertal skeletal age. In secondary testicular failure, circulating concentrations of all three hormones are below the normal adult range. To establish the presence of the testes and their ability to respond to stimulation, chorionic gonadotropin (1500 units) is given intramuscularly on days 1, 3, and 5. The plasma testosterone should rise to above 200 mg/dL 24 hours after the final dose. A karyotype should be determined in primary testicular failure of unknown cause.

C. IMAGING

Skeletal (epiphyseal) maturation is usually delayed. A cranial CT scan or MRI should be performed in cases of secondary testicular failure.

Treatment

Specific therapy is indicated when the cause of testicular failure is known. Treatment with depot testosterone (eg, testosterone enanthate), beginning with 75–100 mg intramuscularly and increasing to 200 mg every 3–4 weeks, may be continued indefinitely. Specific therapy (pulsatile subcutaneous delivery of GnRH) may result in fertility in patients with hypothalamic–pituitary insufficiency.

3. Cryptorchidism

Cryptorchidism (undescended testis) is a common disorder in children. It may be unilateral or bilateral and may be classified as ectopic or true cryptorchidism. Approximately 3% of full-term male newborns have an undescended testis at birth, with a higher proportion among premature infants. In over 50% of these patients, the testes descend by the third month; by age 1 year, 80% of all undescended testes are in the scrotum. Further descent may occur through puberty, the latter perhaps stimulated by endogenous gonadotropins.

Infertility and testicular malignancy risk must be considered in cases of cryptorchidism. The exact incidence of impairment in fertility is unknown and incidence figures vary in reported studies. However, histologic changes clearly occur as early as age 6 months in children with undescended testes. The reported malignancy rate in cryptorchidism is 48.9 per 100,000, which is 22 times higher than in the general population. In addition, 25% of tumors develop in the contralateral testis, indicating that abnormality of testicular development (dysgenesis) may be bilateral in unilateral cryptorchidism.

Ectopic testes are presumed to develop normally but are diverted as they descend through the inguinal canal. True cryptorchidism is thought in most cases to be the result of dysgenesis. Cryptorchid testes frequently have a short spermatic artery, poor blood supply, or both. Although early scrotal positioning of these testes will obviate further damage related to intra-abdominal loca-

tion, the testes generally remain abnormal, spermatogenesis is rare, and the risk of malignant neoplasm is increased. These testes should probably be removed if spermatogenesis does not occur after a reasonable period of observation.

Cryptorchidism can occur in an isolated fashion or may be associated with other findings. Abnormalities in the hypothalamic–pituitary–gonadal axis predispose to cryptorchidism. Androgen biosynthesis or receptor defects may also predispose to cryptorchidism and under-virilization.

The diagnosis of bilateral cryptorchidism in an apparently male newborn should never be made until ruling out the possibility that the child is actually a fully virilized female with potentially fatal salt-losing congenital adrenal hyperplasia. (see Adrenal Cortex section).

Clinical Findings

Plasma testosterone concentrations may be obtained after HCG stimulation to confirm the presence or absence of abdominal testes (see preceding section).

Differential Diagnosis

In palpating the testis, the cremasteric reflex may be elicited, causing the testis to be retracted into the inguinal canal or abdomen (pseudocryptorchidism). To prevent retraction, the fingers first should be placed across the abdominal ring and the upper portion of the inguinal canal, obstructing ascent. Examination while the child is in the squatting position or in a warm bath is also helpful. No treatment for retractile testes is necessary, and the prognosis for testicular descent and competence is excellent.

Treatment

A. SURGICAL TREATMENT

The current recommendation for treatment of cryptorchidism is that surgical orchidopexy be performed by an experienced surgeon if no descent has occurred by 1 year of age.

B. HORMONAL TREATMENT

Various treatment regimens have been used, ranging from 250 to 1000 IU given twice weekly for 5 weeks. Such therapy will generally cause descent of retractile testes, but is generally not successful in treating cryptorchidism. Androgen treatment (eg, depot testosterone) is indicated as replacement therapy in the male child who lacks functional testes beyond the normal age of puberty.

4. Gynecomastia

Adolescent gynecomastia is a common, self-limited finding in boys that can occur in up to 75% of normal boys during puberty. Adolescent gynecomastia typically resolves within 2 years. Gynecomastia may sometimes occur as part of Klinefelter syndrome, or it may occur in boys who are taking drugs such as antidepressants or marijuana. Therapy, either medical (antiestrogens, aromatase inhibitors) or surgical, should be considered in cases that are prolonged or severe. This topic is discussed in more detail in Chapter 3.

TESTICULAR TUMORS

The major primary malignant tumors of the testis are seminomas and teratomas. Seminomas are rare in childhood; they may be hormone-producing. The major hormone-producing tumor of the testis is the Leydig cell tumor. It is frequently associated with sexual precocity. Other testicular tumors (choriocarcinomas and dysgerminomas) have been reported in association with sexual precocity.

Treatment of testicular tumors is surgical removal; chemotherapy and radiation therapy are not used in childhood unless a high-grade malignancy or metastasis is present. The prognosis in patients with Leydig cell tumors is generally good.

ADRENAL CORTEX

The adult adrenal cortex displays relative regional specificity of terminal steroid production. The outermost zona glomerulosa is the predominant source of aldosterone, whereas the zona fasciculata makes cortisol, the major glucocorticoid, as well as small amounts of mineralocorticoids. The innermost zona reticularis produces mainly adrenal androgens and estrogens. During fetal life, a fetal zone, or provisional cortex, predominates. This fetal zone produces glucocorticoids, mineralocorticoids, androgens, and estrogens but is relatively deficient in β -ol dehydrogenase (see Figure 30–6). Therefore, placentally produced progesterone serves as the major precursor for the fetal adrenal production of cortisol and aldosterone.

The adrenal cortex produces cortisol under the control of pituitary corticotropin (ACTH) (see Figure 30–1 and Table 30–1), which is, in turn, regulated by corticotropin-releasing hormone (CRH), a hypothalamic peptide. The complex interaction of CNS influences on CRH secretion coupled with negative feedback of serum cortisol leads to a marked diurnal pattern of ACTH and cortisol release. ACTH concentrations

are greatest during the early morning hours, display a smaller peak in the late afternoon, and are lowest during the night. The pattern of serum cortisol concentration closely follows this diurnal pattern with a lag of a few hours. In the absence of cortisol feedback, both CRH and ACTH display dramatic hypersecretion.

At the cellular level, glucocorticoids are critical for normal gene expression in a wide variety of cells. In excess, glucocorticoids are both catabolic and antianabolic; that is, they promote the release of amino acids from muscle and increase gluconeogenesis while decreasing incorporation of amino acids into muscle protein. They also antagonize insulin action and facilitate lipolysis. Glucocorticoids help maintain blood pressure through their supportive effect on peripheral vascular tone and by promoting sodium and water retention.

Mineralocorticoids (primarily aldosterone in humans) promote sodium retention and stimulate potassium excretion in the distal tubule. Although ACTH can stimulate aldosterone production, the predominant regulator of aldosterone secretion is the volume- and sodium-sensitive renin–angiotensin–aldosterone system. Elevations of serum potassium concentrations also directly influence aldosterone release from the cortex.

Androgen (DHEA and androstenedione) production by the zona reticularis is insignificant in prepubertal children. At the onset of puberty, androgen production increases and may be an important factor in the dynamics of puberty in both sexes. The adrenal gland is a major source of androgen in the pubertal and adult female.

ADRENOCORTICAL INSUFFICIENCY (Adrenal Crisis, Addison Disease)

The leading causes of adrenal insufficiency today are hereditary enzymatic defects (congenital adrenal hyperplasia), loss of adrenal function due to autoimmune destruction of the glands (Addison disease), and central adrenal insufficiency following an intracranial neoplasm or its treatment, or congenital midline defects in association with optic nerve hypoplasia (Septo-optic dysplasia). A rare form of familial adrenal insufficiency can occur in association with cerebral sclerosis and spastic paraplegia (adrenoleukodystrophy). Autoimmune Addison disease may be familial and has been described in association with hypoparathyroidism, candidiasis, hypothyroidism, pernicious anemia, hypogonadism, and diabetes mellitus as one of the polyglandular autoimmune syndromes. The finding of circulating antibodies to adrenal tissue and other tissues involved in these conditions suggests that an autoimmune mechanism is the cause. Less commonly, the gland is destroyed by tumor, calcification, or hemorrhage (Waterhouse–Friderichsen syndrome). Adrenal disease

secondary to opportunistic infections (fungal, tuberculous) is again being reported in adults who have acquired immunodeficiency syndrome. A similar relationship is likely in children. In children, central adrenal insufficiency due to a primary anterior pituitary tumor is rare. A temporary salt-losing disorder due to partial mineralocorticoid deficiency or renal underresponsiveness (pseudohypoaldosteronism) may occur during infancy or with pyelonephritis.

Any acute illness, surgery, trauma, or exposure to excessive heat may precipitate an adrenal crisis in patients with adrenal insufficiency. Patients with primary adrenal insufficiency are generally at greater risk for life-threatening crisis than patients with central ACTH deficiency. This is a consequence of intact mineralocorticoid secretion and low-level autonomous cortisol secretion in central ACTH deficiency.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Acute form (adrenal crisis)—Manifestations include nausea and vomiting, diarrhea, abdominal pain, dehydration, fever (which may be followed by hypothermia), weakness, hypotension, circulatory collapse, and confusion or coma. Increased pigmentation may be associated with primary adrenal insufficiency as a result of the melanocyte-stimulating activity of the hypersecreted parent molecule of ACTH.

2. Chronic form—Manifestations include fatigue, hypotension, weakness, failure to gain or loss of weight, increased appetite for salt (primary insufficiency), vomiting (which may become forceful and sometimes projectile), and dehydration. Diffuse tanning with increased pigmentation over pressure points, scars, and mucous membranes may be present in primary adrenal insufficiency. A small heart may be seen on chest radiograph.

B. LABORATORY FINDINGS

1. Suggestive of adrenocortical insufficiency—In primary adrenal insufficiency, serum sodium and bicarbonate levels, PaCO_2 , blood pH, and blood volume are decreased. Serum potassium and urea nitrogen levels are increased. Urinary sodium levels and the ratio of sodium to potassium are elevated for the degree of hyponatremia. In central adrenal insufficiency, serum sodium levels may be mildly decreased as a result of impaired water excretion. Eosinophilia and moderate lymphopenia may be present in either form of insufficiency.

2. Confirmatory tests—The following tests measure the functional capacity of the adrenal cortex:

a. The ACTH (cosyntropin) stimulation test—This is the most direct test of adrenal gland function. In primary adrenal insufficiency (ie, originating in the gland itself), plasma cortisol and aldosterone concentrations fail to increase significantly over baseline 60 minutes after an intravenous dose of ACTH (250 μg). To diagnose central adrenal insufficiency, a low dose of ACT is given (1 μg).

b. Baseline serum ACTH concentrations—These are elevated in primary adrenal failure and are low in central adrenal insufficiency.

c. Urinary free cortisol and 17-hydroxycorticosteroid excretion—These values are decreased.

d. The CRH test—This recently introduced test can be used to assess responsiveness of the entire hypothalamic–pituitary–adrenal axis. After administration of ovine CRH, serum concentrations of ACTH and cortisol can be measured over a period of 2 hours. Verification of the presence of an intact axis or localization of the site of impairment is possible with careful interpretation of these results.

Differential Diagnosis

Acute adrenal insufficiency must be differentiated from severe acute infections, diabetic coma, various disturbances of the CNS, and acute poisoning. In the neonatal period, adrenal insufficiency may be clinically indistinguishable from respiratory distress, intracranial hemorrhage, or sepsis.

Chronic adrenocortical insufficiency must be differentiated from anorexia nervosa, certain muscular disorders (eg, myasthenia gravis), salt-losing nephritis, and chronic debilitating infections (eg, tuberculosis) and must be considered in cases of recurrent spontaneous hypoglycemia.

Treatment

A. ACUTE (ADRENAL CRISIS)

1. Hydrocortisone sodium succinate—Hydrocortisone sodium succinate, initially 50 mg/m^2 intravenously over 2–5 minutes or intramuscularly; thereafter, it is given intravenously, 12.5 mg/m^2 , every 4–6 hours until stabilization is achieved and oral therapy can be tolerated.

2. Fluids and electrolytes—In primary adrenal insufficiency, 5–10% glucose in normal saline, 10–20 mL/kg intravenously, is given over the first hour and repeated if necessary to reestablish vascular volume. Normal saline is continued thereafter at one and one-half to two times the maintenance fluid requirements. In addition, intravenous boluses of glucose (10% glu-

cose, 2 mL/kg) may be needed every 4–6 hours for hypoglycemia. In central adrenal insufficiency, routine fluid management is generally adequate following reinstatement of vascular volume and institution of cortisol replacement.

3. Fludrocortisone—When oral intake is tolerated, fludrocortisone, 0.05–0.15 mg daily, is started and continued as necessary every 12–24 hours for primary adrenal insufficiency.

4. Inotropic agents—Rarely, inotropic agents such as dopamine and dobutamine are needed. However, adequate cortisol replacement is critical because pressor agents may be ineffective in adrenal insufficiency.

5. Waterhouse–Friderichsen syndrome with fulminant infections—The use of adrenocorticosteroids and norepinephrine in the treatment or prophylaxis of fulminant infections remains controversial; corticosteroids may augment the generalized Shwartzman reaction in fatal cases of meningococcemia. However, corticosteroids should be considered in the presence of possible adrenal insufficiency, particularly with hypotension and circulatory collapse.

B. MAINTENANCE THERAPY

Following initial stabilization, the most effective substitution therapy is hydrocortisone, combined with fludrocortisone in primary adrenal insufficiency. Over-treatment should be avoided because it may result in obesity, growth retardation, and other cushingoid features. Additional hydrocortisone, fludrocortisone, or sodium chloride, singly or in combination, may be necessary with acute illness, surgery, trauma, or other stress reactions.

Supportive adrenocortical therapy should be given whenever surgical operations are performed in patients who have at some time received prolonged therapy with adrenocorticosteroids (see below).

1. Glucocorticoids—A maintenance dosage of 8–10 mg/m²/d of hydrocortisone (or equivalent) is given orally in two or three divided doses. For adrenal enzyme defects (see following section), this dosage may need to be increased to 18–22 mg/m²/d to obtain adequate suppression of the adrenal axis, with two thirds given at night (the time of greatest axis suppressibility). The dosage of all glucocorticoids is increased to 30–50 mg/m²/d during intercurrent illnesses or other times of stress.

2. Mineralocorticoids—In primary adrenal insufficiency, give fludrocortisone, 0.05–0.15 mg orally daily as a single dose or in two divided doses. Periodic monitoring of blood pressure is recommended to avoid overdosing.

3. Salt—The child should be given ready access to table salt. Frequent blood pressure determinations in the recumbent position should be made to ensure that hypertension is avoided. In the infant, supplementation of 3–5 mEq Na⁺/kg/d by adding the injectable solution (4 mg/mL) to formula or breast milk is generally required until table foods are introduced.

C. CORTICOSTEROIDS IN PATIENTS WITH ADRENOCORTICAL INSUFFICIENCY WHO UNDERGO SURGERY

1. Before operation—Hydrocortisone sodium succinate, 30–50 mg/m²/d intravenously, is given 1 hour before surgery.

2. During operation—Hydrocortisone sodium succinate, 25–100 mg intravenously, is administered with 5–10% glucose in saline throughout surgery.

3. During recovery—Hydrocortisone sodium succinate, 12.5 mg/m² intravenously, is given every 4–6 hours until oral doses are tolerated. The oral dose of three to five times the maintenance dose is continued until the acute stress is over, at which time the patient can be returned to the maintenance dose.

Course & Prognosis

A. ACUTE ADRENAL INSUFFICIENCY

The course of acute adrenal insufficiency is rapid, and death may occur within a few hours, particularly in infants, unless adequate treatment is given. Spontaneous recovery is unlikely. Patients who have received long-term treatment with adrenocorticosteroids may exhibit adrenal collapse if they undergo surgery or other acute stress. Pharmacologic doses of glucocorticoids during these episodes may be needed throughout life.

In all forms of acute adrenal insufficiency, the patient should be observed carefully once the crisis has passed and evaluated with laboratory tests to assess the degree of permanent adrenal insufficiency.

B. CHRONIC ADRENAL INSUFFICIENCY

Adequately treated, chronic adrenocortical insufficiency is consistent with a relatively normal life.

CONGENITAL ADRENAL HYPERPLASIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Pseudohermaphroditism in females, with urogenital sinus, enlargement of the clitoris, or other evidence of virilization.*
- *Salt-losing crisis in infant males or isosexual precocity in older males with infantile testes.*
- *Increased linear growth in young children; advancement of skeletal maturation.*
- *Urinary and plasma androgen elevation; plasma 17-hydroxyprogesterone and urinary pregnanetriol concentrations increased in the common form; may be associated with electrolyte and water disturbances (hyponatremia, hyperkalemia, and metabolic acidosis), particularly in the newborn period.*

General Considerations

Autosomal recessive enzyme defects involved in adrenal steroidogenesis have in common a defect in cortisol biosynthesis with resultant increased ACTH secretion during fetal life. ACTH excess subsequently results in adrenal hyperplasia with increased production of various adrenal hormone precursors, including androgens, and increased urinary excretion of their metabolites. Increased pigmentation, especially of the scrotum, labia majora, and nipples, frequently results from excessive ACTH secretion. Congenital adrenal hyperplasia (CAH) is most commonly (in > 80% of patients) the result of homozygous 21-hydroxylase (P450c21) deficiency (see Figure 30–6), an autosomal recessive disorder. In its severe form, excess adrenal androgen production beginning in the first trimester of fetal development results in virilization of the female infant and life-threatening hypovolemic, hyponatremic shock (adrenal crisis) in the newborn. Other enzyme defects that less commonly result in congenital adrenal hyperplasia include 20,22-desmolase, 3 β -ol dehydrogenases, 18-hydroxylase-17,22-desmolase, and 11-hydroxylase deficiencies. The clinical syndromes associated with each of these defects can be predicted from Figure 30–6 and Table 30–11. All of these enzymes except 3 β -ol dehydrogenase have been shown to be associated with the cy-

Table 30–11. Clinical and laboratory findings in adrenal enzyme defects resulting in CAH.

Enzyme Deficiency ^a	Urinary 17-Ketosteroids	Elevated Plasma Metabolite	Plasma Androgens	Aldosterone	Hypertension/ Salt Loss	External Genitalia
20,22-Desmolase	↓↓↓	—	↓↓↓	↓↓↓	-/+	Males: ambiguous Females: normal
3 β -ol Dehydrogenase	↑↑ (DHEA)	17-OH pregnenolone (DHEA)	↑ (DHEA)	↓↓↓	-/+	Males: ambiguous Females: possibly virilized

11-Hydroxylase	↑↑	11-Deoxycortisol	↑↑	↓↓ (↑ Deoxycorticosterone)	+/-	Males: normal Females: virilized
17,20-Desmolase	↓↓↓	17-Hydroxysteroids (?)	↓↓	Normal	-/-	Males: ambiguous Females: normal

^aChildren with “simple virilizing (non-salt-wasting)” forms of 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH) may have normal aldosterone production and serum electrolytes, but some children have normal aldosterone production and serum electrolytes at the expense of elevated plasma renin activity and are, by definition, compensated salt-wasters. These children usually receive mineralocorticoid as well as glucocorticoid treatment. Children with 21-hydroxylase deficiency CAH should therefore have documented normal plasma renin activity in addition to normal serum electrolytes before they are considered non-salt-wasters.

tochrome P-450 complex. A new enzyme nomenclature has been established, and it is given along with the older, more familiar nomenclature in Figure 30–6.

Studies of patients with 21-hydroxylase deficiency indicate that the clinical type (salt-wasting versus non-salt-wasting) is usually consistent within a family and that a close genetic linkage exists between the 21-hydroxylase gene and the HLA complex on chromosome 6. The latter finding has allowed more precise heterozygote detection and prenatal diagnosis. Population studies indicate that the defective gene is present in 1:250–1:100 people and that the incidence of the disorder is 1:15,000–1:5000. Evaluation of the hormone responses of unaffected family members following ACTH stimulation allows detection of the heterozygote with a certainty of 80–90%, and a combination of hormonal and HLA studies can increase the number of cases detected. HLA typing in combination with the measurement of 17-hydroxyprogesterone and androstenedione in amniotic fluid has been used in the prenatal diagnosis of 21-hydroxylase deficiency. Mass screening for this enzyme defect, using a microfilter paper technique to measure 17-hydroxyprogesterone, has been established in some US states.

Nonclassic presentations of 21-hydroxylase deficiency have been reported with increasing frequency. Affected persons have a normal phenotype at birth and develop evidence of virilization during later childhood, adolescence, or early adulthood. In these cases, previously referred to as late-onset or acquired enzyme deficiency, results of hormonal studies are characteristic of 21-hydroxylase deficiency. An asymptomatic form has also been identified in which individuals have none of the phenotypic features of the disorder but have hormonal study results identical to those of patients with nonclassic 21-hydroxylase deficiency. The nonclassic form appears to be less severe than the classic form. Because members of the same family may have classic, nonclassic, and asymptomatic forms, the disorders may be due to allelic variations of the same enzyme.

Male pseudohermaphroditism may occur in children with 17,20-desmolase deficiency because that enzyme is necessary for normal androgen biosynthesis (see Table 30–11).

Clinical Findings

A. SYMPTOMS AND SIGNS

1. In females—In the female with potentially normal ovaries and uterus, virilization occurs, and sexual development is therefore along heterosexual lines. The abnormality of the external genitalia may vary from mild enlargement of the clitoris to complete fusion of the labioscrotal folds, forming a scrotum, a penile urethra,

a penile shaft, and enlargement of the clitoris to form a normal-sized glans (see Table 30–8). Signs of adrenal insufficiency (salt loss) may be present during the first days of life (typically in the first or second week). In rare cases, adrenal insufficiency does not occur for months or years. When the enzyme defect is milder, salt loss may not occur, and virilization predominates (simple virilizing form). In untreated, non-salt-losing 21-hydroxylase or 11-hydroxylase deficiency, growth rate and skeletal maturation are accelerated, and patients may become muscular. Pubic hair appears early (often before the second birthday); acne may be excessive; and the voice may deepen. Excessive pigmentation may develop. Final adult height is often compromised.

2. In males—In males, sexual development proceeds normally. The male infant usually appears normal at birth but may present with a salt-losing crisis in the first 2–4 weeks of life. In milder forms, salt-losing crises may not occur. In this circumstance, enlargement of the penis and increased pigmentation may be noted during the first few months. Other symptoms and signs are similar to those seen in females. The testes are soft and not enlarged except in the rare male in whom aberrant adrenal cells (adrenal rests) are present in the testes and produce unilateral or bilateral enlargement, often asymmetrical. In the rare isolated defect of 17,20-desmolase activity, ambiguous genitalia may be present because of the compromise in androgen production (see Figure 30–6).

B. LABORATORY FINDINGS

1. Blood and urine—Hormonal studies are essential for accurate diagnosis. Findings characteristic of the enzyme deficiencies are shown in Table 30–11. With adrenal tumor, secretion of DHEA is greatly elevated, and determining plasma concentrations of DHEA sulfate may be useful in the differential diagnosis.

2. Genetic studies—Rapid chromosomal diagnosis should be obtained in any newborn with ambiguous genitalia.

C. IMAGING

Adrenal ultrasonography, CT scanning, and MRI may be useful in defining pelvic anatomy or enlarged adrenals or in localizing an adrenal tumor. Vaginograms using contrast material and pelvic ultrasonography may be helpful in delineating the internal anatomy in a newborn with ambiguous genitalia.

Treatment

A. MEDICAL TREATMENT

Treatment goals in congenital adrenal hyperplasia consist of normalizing growth velocity and skeletal maturation.

tion using the smallest dose of glucocorticoid that will suppress adrenal function. The use of excessive amounts of glucocorticoids results in the undesirable side effects of Cushing syndrome. Mineralocorticoid replacement helps to sustain normal electrolyte homeostasis, although excessive mineralocorticoid dosing results in hypertension. (See Uses of Glucocorticoids & ACTH in Treatment of Nonendocrine Diseases section for a more complete discussion of the effects of pharmacologic glucocorticoid therapy.)

1. Glucocorticoids—Initially hydrocortisone given in a dosage of 30–50 mg/m²/d parenterally or orally suppresses abnormal adrenal steroidogenesis within 2 weeks. When adrenal suppression has been accomplished, as evidenced by normalization of serum 17-hydroxyprogesterone, the patients are placed on maintenance doses of 15–20 mg/m²/d in two or three divided doses. Between 50% and 60% of the daily dose should be given in the late evening to suppress the early morning ACTH rise. Dosage is adjusted to maintain normal growth rate and skeletal maturation. A variety of serum and urine androgens have been used to monitor adequacy of therapy, including 17-hydroxyprogesterone, androstenedione, and urinary pregnanetriol. However, none of these has been universally accepted. In adolescent females, normal menses are a sensitive index of the adequacy of therapy. Therapy should be continued throughout life in both males and females because of the possibility of malignant degeneration of the hyperplastic adrenal gland. In pregnant females who have congenital adrenal hyperplasia, adequate suppression of adrenal androgen secretion is critical to avoid virilization of the fetus, particularly a female fetus.

2. Mineralocorticoids—Fludrocortisone in a dose of 0.05–0.15 mg is given orally once a day or in two divided doses. Periodic monitoring of blood pressure and plasma renin is recommended to adjust dosing.

B. SURGICAL TREATMENT

Consultation with a urologist experienced with female genital reconstruction is indicated in affected females as soon as possible during infancy.

Course & Prognosis

When therapy is initiated in early infancy, abnormal metabolic effects and progression of masculinization can be avoided. Treatment with glucocorticoids permits normal growth, development, and sexual maturation. However, if not adequately controlled, congenital adrenal hyperplasia results in sexual precocity and masculinization throughout childhood. Affected individuals will be tall as children but short as adults because the rate of skeletal maturation is rapid with resultant pre-

mature closure of the epiphyses. If treatment is delayed or inadequate until somatic development is over 12–14 years as determined by skeletal maturation (bone age), true central sexual precocity may occur in males and females.

Patient education stressing lifelong therapy is important to ensure compliance in adolescence and later life.

Virilization and multiple surgical genital reconstructions are associated with a high risk of psychosexual disturbances in female patients. Ongoing psychological evaluation and support is a critical component of care.

When virilization of the patient (male or female) is caused by a tumor, the progression of signs and symptoms ceases after surgical removal; however, evidence of masculinization, particularly deepening of the voice, may persist.

Prenatal treatment of the mother with dexamethasone can eliminate or reduce virilization of female infants. However, this requires treatment of seven eighths of fetuses unnecessarily (only one quarter of offspring are affected with CAH and only half of these are females) and causes maternal side effects as well. Therefore, such treatment is still under investigation.

ADRENOCORTICAL HYPERFUNCTION (Cushing Disease, Cushing Syndrome)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Truncal adiposity with thin extremities, moon facies, muscle wasting, weakness, plethora, easy bruising, purplish striae, decreased growth rate, delayed skeletal maturation.*
- *Hypertension, osteoporosis, glycosuria.*
- *Elevated serum and urine adrenocorticosteroids; low serum potassium levels; eosinopenia, lymphopenia.*

General Considerations

Cushing syndrome is nonspecific. It may result from excessive secretion of adrenal steroids autonomously (adenoma or carcinoma), from excessive ACTH secretion from the pituitary (Cushing disease) or from ectopic sources, or from chronic exposure to pharmacologic doses of glucocorticoids.

In children younger than age 12 years, Cushing syndrome is usually iatrogenic (secondary to pharmacologic doses of ACTH or one of the glucocorticoids). It may rarely be due to an adrenal tumor, adrenal hyperplasia, an adenoma of the pituitary gland, or, even more rarely, an extrapituitary (ectopic) ACTH-producing tumor.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Excess glucocorticoid—Adiposity, most marked on the face, neck, and trunk (a fat pad in the interscapular area is characteristic); easy fatigability and weakness; plethoric facies; purplish striae; easy bruising; ecchymoses; hirsutism; osteoporosis; hypertension; diabetes mellitus (usually latent); pain in the back; muscle wasting and weakness; and marked retardation of growth and skeletal maturation.

2. Excess mineralocorticoid—Hypokalemia, mild hypernatremia with water retention, increased blood volume, edema, and hypertension.

3. Excess androgen—Hirsutism, acne, and varying degrees of virilization. Menstrual irregularities occur during puberty in older girls.

B. LABORATORY FINDINGS

1. Blood—

a. Plasma cortisol concentrations—These are elevated, with loss of the normal diurnal variation in cortisol secretion. Determination of cortisol level between midnight and 2 AM may be a sensitive indicator of loss of variation.

b. Serum chloride and potassium concentrations—These values may be lowered. Serum sodium and bicarbonate concentrations may be elevated (metabolic alkalosis).

c. Serum ACTH concentrations—ACTH concentrations are slightly elevated with adrenal hyperplasia (Cushing disease), decreased in cases of adrenal tumor, and greatly increased with ACTH-producing pituitary or extrapituitary tumors.

d. The leukocyte count—This measurement shows polymorphonuclear leukocytosis with lymphopenia,

and the eosinophil count is low. The erythrocyte count may be elevated.

2. Saliva

a. Salivary cortisol—This value is elevated and is a less invasive means by which to measure several samples (may be performed at home). A salivary cortisol obtained at midnight is a highly specific and sensitive test in adults, but has not yet been studied in children.

3. Urine—

a. Urinary free cortisol excretion—This value is elevated. This is currently considered the most useful initial diagnostic test.

b. Urinary 17-hydroxycorticosteroid excretion (excretion products of the glucocorticoids)—This value is elevated.

c. Urinary 17-ketosteroid excretion—This is usually elevated in association with adrenal tumors.

d. Glycosuria—This finding may be present.

3. Response to dexamethasone suppression test—Adrenal function suppression is diminished after a small dose (0.5 mg) of dexamethasone; larger doses of dexamethasone cause suppression of adrenal activity when the disease is due to adrenal hyperplasia. Adenomas and adrenal carcinomas may rarely be suppressed by large doses of dexamethasone (4–16 mg/d in four divided doses).

4. CRH test—The CRH stimulation test may replace the high-dose dexamethasone test for differentiating pituitary and ectopic sources of ACTH excess.

C. IMAGING

Pituitary imaging may demonstrate a pituitary adenoma. This can be used in conjunction with petrosal sinus blood sampling for localization of ACTH-secreting adenomas. Adrenal imaging (eg, CT scan) may demonstrate adenoma or bilateral hyperplasia. Radionuclide studies of the adrenals may be useful in complex cases. Osteoporosis (evident first in the spine and pelvis) with compression fractures may occur in advanced cases, and skeletal maturation is usually delayed.

Differential Diagnosis

Children with exogenous obesity, particularly when accompanied by striae and hypertension, are frequently suspected of having Cushing syndrome. The child's height, growth rate, and skeletal maturation are helpful in differentiating the two, because children with Cushing syndrome have a poor growth rate, relatively short stature, and delayed skeletal maturation, whereas those with exogenous obesity usually have a normal or slightly increased growth rate, normal to tall stature,

and advanced skeletal maturation. In addition, the color of the striae (purplish in Cushing syndrome, pink in obesity) and the distribution of the obesity assist in the differentiation. The urinary free cortisol excretion (mg/g creatinine) and salivary cortisol are normal in obesity.

Treatment

In all cases of primary adrenal hyperfunction due to tumor, surgical removal, if possible, is indicated. ACTH should be given preoperatively and postoperatively to stimulate the nontumorous contralateral adrenal cortex, which is generally atrophied. Glucocorticoids should be administered parenterally in pharmacologic doses during and after surgery until the patient is stable. Supplemental oral glucocorticoids, potassium, salt, and mineralocorticoids may be necessary until the suppressed contralateral adrenal gland has recovered, sometimes over a period of several months. (See earlier discussion of corticosteroid administration in surgical patients.)

The use of mitotane, a DDT derivative that is toxic to the adrenal cortex, and aminoglutethimide, an inhibitor of steroid synthesis, has been suggested, but the efficacy of these agents in children with adrenal tumors has not been determined.

Adrenal hyperplasia resulting from a pituitary microadenoma may respond to pituitary surgery or irradiation.

Prognosis

If the tumor is malignant, the prognosis is poor if it cannot be completely removed. If it is benign, cure is to be expected following proper preparation and surgery.

PRIMARY HYPERALDOSTERONISM

Primary hyperaldosteronism may be caused by a benign adrenal tumor or by adrenal hyperplasia. It is characterized by paresthesias, tetany, weakness, polyuria (nocturnal enuresis is common in young children), periodic

paralysis, low serum potassium and elevated serum sodium levels, hypertension, metabolic alkalosis, and production of a large volume of alkaline urine with a low fixed specific gravity; the latter does not respond to vasopressin. Edema is rare. The glucose tolerance test is frequently abnormal. Plasma and urinary aldosterone are elevated, but other steroid levels are variable. Plasma renin activity is suppressed, in contrast to the secondary hyperaldosteronism due to renal vascular disease and Bartter syndrome. In patients with adrenal tumor, the administration of ACTH may further increase the excretion of aldosterone. Marked decrease of aldosterone-induced hypokalemia, alkalosis, hypochloremia, or hyponatremia after the administration of an aldosterone antagonist such as spironolactone may be of diagnostic value.

Treatment is with glucocorticoids or spironolactone, subtotal or total adrenalectomy for hyperplasia, and surgical removal if a tumor is present.

USES OF GLUCOCORTICOIDS & ACTH IN TREATMENT OF NONENDOCRINE DISEASES

Glucocorticoids are used for their anti-inflammatory and immunosuppressive properties in a variety of conditions in childhood. Pharmacologic doses are necessary to achieve these effects, and side effects are common. Numerous synthetic preparations possessing variable ratios of glucocorticoid to mineralocorticoid activity are available (Table 30–12).

Actions

Glucocorticoids exert a direct or permissive effect on virtually every tissue of the body; major known effects include the following:

1. Gluconeogenesis in the liver
2. Stimulation of fat breakdown (lipolysis) and redistribution of body fat
3. Catabolism of protein with an increase in nitrogen and phosphorus excretion
4. Decrease in lymphoid and thymic tissue and a decreased cellular response to inflammation and hypersensitivity
5. Alteration of CNS excitation

Table 30–12. Potency equivalents for adrenocorticosteroids.

Adrenocorticosteroid	Trade Names	Potency/mg Compared with Cortisol (Glucocorticoid Effect)	Potency/mg Compared with Cortisol (Sodium-Retaining Effect)
Glucocorticoids			
Hydrocortisone (cortisol)	Cortef	1	1
Cortisone	Cortone Acetate	0.8	1
Prednisone	Meticorten, others	4–5	0.4
Methylprednisolone	Medrol, Meprolone	5–6	Minimal
Triamcinolone	Aristocort, Kenalog Kenacort, Atolone	5–6	Minimal
Dexamethasone	Decadron, others	25–40	Minimal
Betamethasone	Celestone	25	Minimal
Mineralocorticoid			
Fludrocortisone	Florinef	15–20	300–400

- Retardation of connective tissue mitosis and migration, decreased wound healing
- Improved capillary tone and increased vascular compartment volume and pressure

Uses

Glucocorticoids are used in physiologic doses to treat adrenal insufficiency (eg, Addison disease and congenital adrenal hyperplasia) and in pharmacologic doses to treat a wide variety of inflammatory and autoimmune malignant conditions in childhood. Corticosteroid use is contraindicated in active, questionably healed, or suspected tuberculosis. Corticosteroids should be used with extreme caution in the presence of herpes simplex infection of the eye, osteoporosis, peptic ulcer, active systemic infections, emotional instability, and thrombophlebitis.

Side Effects of Therapy

When prolonged use of pharmacologic doses of glucocorticoids is necessary, clinical manifestations of Cushing syndrome are common. Side effects may occur with the use of synthetic exogenous agents by any route, including inhalation and topical administration (inflamed skin), or with the use of ACTH, which stimulates excessive production of endogenous corticosteroids. Use of a larger dose of glucocorticoids given once every 48 hours (alternate-day therapy) lessens the incidence and severity of some of the side effects (Table 30–13).

Tapering of Pharmacologic Doses of Steroids

Prolonged use of pharmacologic doses of glucocorticoids results in suppression of ACTH secretion and consequent adrenal atrophy. Thus the abrupt discontinuation of glucocorticoids may result in adrenal insufficiency. Furthermore, ACTH secretion generally does not occur until the administered steroid has been given in sub-physiologic doses (< 8 mg/m²/d orally) for several weeks.

If pharmacologic glucocorticoid therapy has been given for less than 10–14 days, the drug can be discontinued abruptly (if the condition for which it was prescribed allows) because adrenal suppression will be short-lived. However, it is advisable to educate the patient and family about the signs and symptoms of adrenal insufficiency in case problems arise.

If tapering is necessary in treating the condition for which the glucocorticoid is prescribed, a reduction of 25–50% every 2–7 days is sufficiently rapid to permit observation of clinical symptomatology. Moreover, the use of an alternate-day schedule (ie, a single dose given every 48 hours) will allow for a 50% decrease in the total 2 days' dosage while providing the desired pharmacologic effect. If tapering is not necessary for the underlying disease, the dosage can be decreased safely to the physiologic range. However, although a rapid decrease in dose to the physiologic range will not lead to frank adrenal insufficiency (because adequate exogenous cortisol is being provided), some patients may experience a steroid withdrawal syndrome, characterized by malaise, fatigue, and loss of appetite. These symp-

Table 30–13. Side effects of glucocorticoid use.**A. Endocrine and metabolic effects**

1. Hyperglycemia and glycosuria (chemical diabetes).
2. Cushing syndrome.
3. Persistent suppression of pituitary-adrenal responsiveness to stress with resultant hypoadrenocorticism.

B. Effects on electrolytes and minerals

1. Marked retention of sodium and water, producing edema, increased blood volume, and hypertension (more common in endogenous hyperadrenal states).
2. Potassium loss with symptoms of hypokalemia.
3. Hypocalcemia, tetany.

C. Effects on protein metabolism and skeletal maturation

1. Negative nitrogen balance, with loss of body protein and bone protein, resulting in osteoporosis, pathologic fractures, and aseptic bone necrosis.
2. Suppression of growth, retarded skeletal maturation.
3. Muscular weakness and wasting.
4. Osteoporosis.

D. Effects on the gastrointestinal tract

1. Excessive appetite and intake of food.
2. Activation or production of peptic ulcer.
3. Gastrointestinal bleeding from ulceration or from unknown cause (particularly in children with hepatic disease).
4. Fatty liver with embolism, pancreatitis, nodular panniculitis.

E. Lowering of resistance to infectious agents; silent infection; decreased inflammatory reaction

1. Susceptibility to fungal infections; intestinal parasitic infections.
2. Activation of tuberculosis; false-negative tuberculin reaction.
3. Stimulation of activity of herpes simplex virus.

F. Neuropsychiatric effects

1. Euphoria, excitability, psychotic behavior, and status epilepticus with electroencephalographic changes.
2. Increased intracranial pressure with pseudotumor cerebri syndrome.

G. Hematologic and vascular effects

1. Bleeding into the skin as a result of increased capillary fragility.
2. Thrombosis, thrombophlebitis, cerebral hemorrhage.

H. Miscellaneous effects

1. Myocarditis, pleuritis, and arteritis following abrupt cessation of therapy.
2. Cardiomegaly.
3. Nephrosclerosis, proteinuria.
4. Acne (in older children), hirsutism, amenorrhea, irregular menses.
5. Posterior subcapsular cataracts; glaucoma.

toms may necessitate a two- or three-step decrease in dose to the physiologic range.

Once a physiologic equivalent dose (8–10 mg/m²/d hydrocortisone or equivalent) is achieved and the patient's underlying disease is stable, the dose can be decreased to 4–5 mg/m²/d given only in the morning. This will allow the adrenal axis to recover. After this dose has been given for 4–6 weeks, assessment of endogenous adrenal activity can be estimated by obtaining fasting plasma cortisol concentrations between 7 and 8 AM prior to the morning steroid dose or by a low-dose ACTH stimulation test (1 µg cosyntropin with cortisol measured 30 minutes after). When an alternate-day schedule is followed, plasma cortisol is measured the morning prior to treatment. A plasma cortisol concentration within the physiologic range (> 10 mg/dL) demonstrates return of basal physiologic adrenal rhythm. Exogenous steroids may then be discontinued safely, although it is advisable to continue to give the patient stress doses of glucocorticoids when appropriate until recovery of the response to stress has been documented.

After basal physiologic adrenal function returns, the adrenal reserve or capacity to respond to stress and infection can be estimated by the low-dose ACTH stimulation test, in which 1 µg of synthetic ACTH (cosyntropin) is administered intravenously. Plasma cortisol is measured prior to (zero time) and at 45–60 minutes after the infusion. A plasma cortisol concentration of greater than 18 mg/dL at 60 minutes indicates a satisfactory adrenal reserve.

Even if the results of testing are normal, patients who have received prolonged treatment with glucocorticoids may exhibit signs and symptoms of adrenal insufficiency during acute stress, infection, or surgery for months to years after treatment has been stopped. Careful monitoring and, when necessary, the use of stress doses of glucocorticoids should be considered during severe illnesses and surgery.

ADRENAL MEDULLA PHEOCHROMOCYTOMA

Pheochromocytoma is an uncommon tumor in childhood. Only 10% of the reported cases occur in pediatric

patients. The tumor may be located wherever chromaffin tissue (eg, adrenal medulla, sympathetic ganglia, carotid body) is present. It may be multiple, familial (autosomal dominant, in which case a high prevalence of MEN exists), recurrent, and sometimes malignant.

Although the symptoms of pheochromocytoma may result from physical expansion of lesions into surrounding tissue (eg, spinal cord), they are generally caused by excessive secretion of epinephrine or norepinephrine. Attacks of anxiety, unexplained perspiration, and headaches should arouse suspicion. Other findings are palpitation and tachycardia, dizziness, weakness, nausea and vomiting, diarrhea, dilated pupils with blurring of vision, abdominal and precordial pain, hypertension (usually persistent), heat intolerance, and vasomotor instability (flushing, postural hypotension). The symptoms may be sustained, producing all of the previously mentioned findings plus papilledema, retinopathy, and enlargement of the heart. There is an increased incidence of pheochromocytomas in patients and families with neurofibromatosis and MEN type 2 (described earlier). Neuroblastomas, ganglioneuromas, and other neural tumors may secrete pressor amines and may occasionally simulate the symptoms and signs of pheochromocytoma. Carcinoid tumors may produce cardiovascular changes similar to those associated with pheochromocytoma.

Laboratory diagnosis is possible in over 90% of cases. Serum catecholamines are elevated, particularly while the patient is symptomatic, and urinary excretion of catecholamines parallels this elevation. Catecholamine levels are characteristically high enough to be diagnostic but may be limited to the period of a paroxysm. The 24-hour urine excretion of metanephrines and vanillylmandelic acid is increased. Testing of plasma free metanephrine levels is the gold standard for

diagnosis. Provocative tests using histamine, tyramine, or glucagon and the phentolamine tests may be abnormal but are dangerous and are rarely necessary for diagnosis. Displacement of the kidney may be shown by intravenous urography, and the tumor may be identified by CT scans or MRI. Angiocatheterization with localized measurement of circulating concentrations of catecholamines may be helpful in localizing the tumor prior to surgery.

Surgical removal of the tumor is the treatment of choice; however, the procedure must be undertaken with great caution and with the patient properly stabilized because manipulation of the tumor may cause sudden, profound, potentially fatal changes in blood pressure. Oral phenoxybenzamine or intravenous phentolamine is used preoperatively. Profound hypotension may occur as the tumor is removed but may be controlled with an infusion of norepinephrine, which may have to be continued for 1–2 days.

Unless irreversible secondary vascular changes have occurred, complete relief of symptoms is to be expected after recovery from removal of a benign tumor. Without treatment, severe cardiac, renal, and cerebral damage may result.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polyuria, polydipsia, and weight loss.
- Hyperglycemia and glucosuria with or without ketonuria.

General Considerations

Type 1 diabetes or immune-mediated diabetes (previously called juvenile diabetes or insulin-dependent diabetes mellitus [IDDM]) is the most common type of diabetes in people younger than age 40 years. It is associated with islet cell antibodies (immunologic markers), diminished insulin production, and being ketosis-prone.

Type 2 diabetes (non-insulin-dependent diabetes mellitus [NIDDM], non-immune-mediated) is the most common type in persons older than age 40 years; it is associated with being overweight, insensitivity to insulin, and not being prone to ketosis. Type 2 diabetes is increasing in frequency in children and is found in up to half of black and Hispanic children and in over two thirds of American Indian children who develop diabetes. It occurs most frequently in overweight teenagers.

Maturity-onset diabetes of youth (MODY) is much less common and comprises several forms of diabetes in children with identified genetic mutations (eg, mutations of glucokinase and hepatic nuclear factor 1 and 2 genes).

Etiology

A. TYPE 1 DIABETES

Type 1 diabetes results from immunologic damage to the insulin-producing β -cells of the pancreatic islets. This damage occurs gradually—over months or years in most people—and symptoms do not appear until about 90% of the pancreatic islets have been destroyed. The immunologic damage requires a genetic predisposition and is probably influenced by environmental factors.

The importance of genetics is shown by the fact that 35–50% of second identical twins develop diabetes after the first twin develops the disease. About 6% of siblings or offspring of persons with type 1 diabetes also develop diabetes (compared with a prevalence in the general population of 0.2–0.3%). The condition is more common in white children but occurs in all racial groups. There is an association with HLA-DR3 and HLA-DR4, and about 95% of white diabetic children have at least one of these HLA types. Forty percent have both HLA-DR3 and HLA-DR4 (one from each parent), compared with only 3% of the general population.

The importance of environmental factors is suggested because not all second identical twins develop diabetes. If the condition were purely genetic and had no random factors, the second twin would always develop the disease. Important environmental factors may be viral infections or factors in the diet. For example, 40% of infants with congenital rubella develop diabetes or an abnormal glucose tolerance test by age 20 years, and the incidence of diabetes is high in individuals after eating foods accidentally preserved with excessive nitrates. The early introduction of cow's milk has also been suggested as an environmental factor, but recent prospective studies have failed to confirm this association.

The immunologic basis of diabetes is demonstrated by the ability of cyclosporine, a potent immunosuppressive agent, to preserve islet tissue for 1–2 years when given to newly diagnosed patients. However, renal damage from cyclosporine precludes its use. White blood cells are found in the islets of newly diagnosed patients and may release toxic products (free radicals, interleukin-1, tumor necrosis factor) that injure the islets. Antibodies to islet cells (ICA), insulin, "64 K" or glutamic acid decarboxylase (GAD), ICA512 (IA-2), and other antibodies are present for months to years prior to diagnosis in the serum of over 90% of patients who will develop type 1 diabetes. These antibodies are probably the effect and not the cause of islet β -cell destruction.

B. TYPE 2 DIABETES

Type 2 diabetes has a strong genetic component, although the defects inherited in different families vary. Obesity (particularly central) and lack of exercise are

often major environmental contributing factors. Insulin insensitivity results from all of the above-mentioned circumstances. The prevalence is increased among females, which may be related to the association with polycystic ovary syndrome (PCOS). Acanthosis nigricans, a thickening and darkening of the skin over the posterior neck, armpits or elbows, may aid in the diagnosis of type 2 diabetes.

Prevention

A. TYPE 1 DIABETES

Many centers now screen for prediabetes using the previously mentioned antibody tests. Intervention trials on antibody-positive first-degree relatives have begun in an effort to try to prevent type 1 diabetes. European investigators conducted a double-blind study of nicotinamide, which did not show an effect. United States centers conducted randomized trials of both oral and injected insulin. Unfortunately, neither had an effect in preventing or delaying the onset of type 1 diabetes.

B. TYPE 2 DIABETES

The prevention of type 2 diabetes was evaluated in a large study, the Diabetes Prevention Program (DPP). The study found that 30 minutes of exercise per day (5 days/week) and a low-fat diet reduced the risk for diabetes by 58%. Taking metformin (Glucophage) also reduced the risk for getting type 2 diabetes by 31%.

Diagnosis

The classic symptoms of polyuria, polydipsia, and weight loss are now so well recognized that friends or family members often suspect the diagnosis of type 1 diabetes in affected individuals. Other cases may be detected by finding glucosuria on routine office urinalysis. Up to 50% of new cases of diabetes used to be diagnosed in patients presenting in coma, but most are now diagnosed before the individuals develop severe ketonuria, ketonemia, and secondary acidosis. Children often have a preceding minor illness, such as a flu-like episode. The check of a blood or urine glucose can be done in a few seconds and could be life-saving. No disease other than diabetes (mellitus or insipidus) presents with continued frequent urination in spite of a dry tongue. An oral glucose tolerance test is rarely necessary in children. A random blood glucose level above 300 mg/dL (16.6 mmol/L) or a fasting blood glucose above 200 mg/dL (11 mmol/L) is sufficient to make the diagnosis of diabetes. The 1997 revised guidelines for the diagnosis of diabetes (see references) are a fasting plasma glucose level over 126 mg/dL (7 mmol/L) or a plasma glucose level above 200 mg/dL (11.1 mmol/L) taken randomly (with symptoms of diabetes) or 2 hours

after an oral glucose load (1.75 g glucose/kg up to a maximum of 75 g). Confirmation of such abnormalities on more than one occasion is recommended as transient hyperglycemia can occur, particularly with illness. Impaired (not yet diabetic) fasting glucose values are 110–125 mg/dL (6.1–6.9 mmol/L) and impaired 2-hour values are 140–200 mg/dL (7.8–11.1 mmol/L). If the presentation is mild, hospitalization is usually not necessary.

Education about diabetes for all family members is essential for the home management of diabetes. The use of an educational book (see References *Understanding Diabetes*) can be very helpful to the family. All caregivers need to learn about diabetes, how to give insulin injections, perform home blood glucose monitoring, and handle acute complications. The stress imposed on the family around the time of initial diagnosis may lead to feelings of shock, denial, sadness, anger, fear, and guilt. Meeting with a counselor to express these feelings at the time of diagnosis helps with long-term adaptation.

Treatment

Most children have type 1 diabetes. The five major variables in treatment are (1) insulin type and dosage, (2) diet, (3) exercise, (4) stress management, and (5) blood glucose and ketone monitoring. All must be considered to obtain safe and effective metabolic control. Although teenagers can be taught to perform many of the tasks of diabetes management, they do better when supportive—not overbearing—parents continue to be involved in management of their disease. Children younger than age 10 or 11 years cannot reliably administer insulin without adult supervision because they lack fine motor control and may not understand the importance of accurate dosage.

A. INSULIN

Insulin functions (1) to allow glucose to pass into the cell, (2) to decrease the physiologic production of glucose, particularly in the liver, and (3) to turn off ketone production.

1. Treatment of new-onset diabetes—The greater the acidemia and ketone production, the greater the amount of insulin needed. If ketonemia is significant, the venous blood pH low (< 7.30), and the patient dehydrated, intravenous insulin and fluid therapy should be given (see Ketonuria, Ketonemia, and Ketoacidosis section). If the child is adequately hydrated and has a normal venous blood pH, one or two intramuscular or subcutaneous injections of 0.1–0.2 unit/kg of regular insulin—or preferably of insulin lispro (Humalog, [H]), or insulin aspart (NovoLog, [NL]) 1 hour apart will help shut down ketone production. If ketone pro-

duction is insignificant or absent, this regimen is not necessary, and routine subcutaneous injections can be started.

When ketones are not present, the child is usually more sensitive to insulin, and a total daily dosage of 0.25–0.5 unit/kg/24 h (by subcutaneous injection) can be used. If ketones are or were present, the child usually does not produce as much insulin and will require 0.5–1 unit/kg of total insulin per 24 hours.

Children usually receive mixtures of a short-acting insulin (to cover food intake or high blood sugars) and a longer-acting insulin (to suppress endogenous hepatic glucose production). This is achieved by combining insulins of different formulations with the desired properties (Table 31–1). The dosages are adjusted with each injection during the first week. Most physicians begin newly diagnosed children with two injections per day of an intermediate-acting insulin (eg, NPH) and a short-acting insulin such as Humalog or NovoLog (H or NL). About two-thirds of the total dosage is usually given before breakfast and the remainder before dinner. If human regular insulin is used, the injections are given 30–60 minutes before meals; when using H or NL as the short-acting insulin, the injections are given just before eating. In young children who eat irregular amounts of food, it is often helpful to wait until after the meal to give the injection and decide on the appropriate dose of H or NL. Children younger than age 4 years usually need 1 or 2 units of short-acting insulin

to cover meals, and the remainder of the dosage is NPH insulin. Children age 4–10 years may require up to 4 units of short-acting insulin to cover breakfast and dinner, whereas proportionately higher doses (usually 4–10 units) of H or NL or regular insulin are used for older children.

The onset of activity for H or NL is 10–15 minutes rather than the 30–60 minutes associated with regular insulin (see Table 31–1). It is not necessary to wait 30–60 minutes to eat after injection of H or NL. These insulins also peak sooner than regular insulin, and activity is gone within 4 hours. The shorter duration reduces the risk of later hypoglycemia.

A new 24-hour basal insulin, insulin glargine (Lantus), is now available, and many physicians initiate therapy with this insulin. It has an acidic pH and must be given alone in the syringe. It is given once daily in the morning, at dinner, or at bedtime depending on patient and family wishes. The Lantus dose is adjusted up or down depending on the morning fasting glucose levels. The most physiologic insulin regimen is then to add H/NL prior to each meal/snack. Children who are unable to consistently get H or NL at lunch can receive H/NL with NPH at breakfast. The main advantage of Lantus over two injections of NPH daily is that severe hypoglycemic episodes (particularly at night) are greatly reduced with its use.

2. Continuing insulin dosage—The total daily insulin dosage may need to be increased gradually to 1 unit/kg (especially if ketones are present at onset). When gluconeogenesis and glycolysis are suppressed by insulin, a honeymoon or grace period is a common phenomenon. This often occurs 1–4 weeks after diagnosis in over 50% of children and tends to last longer in older children.

In helping families with day-to-day dosing of regular insulin or H or NL, some physicians initially use sliding scales, more recently referred to as “thinking” scales, to emphasize that the family must always be thinking about food recently eaten, or to be eaten, and recent or forthcoming exercise in addition to the blood glucose level. Examples of thinking scales are given in *Understanding Diabetes* (see references).

After the appropriate dosage of intermediate (eg, NPH) or long-acting (Lantus) insulin is achieved, daily adjustments usually are not needed. However, small decreases may be made for heavy activity (eg, afternoon sports or overnight events). Many families gradually learn to make small (0.5–1 unit) weekly adjustments in insulin dosage based on home blood glucose testing. Understanding the onset, peak, and duration of insulin activity is essential (see Table 31–1).

Most children receive two to four injections of insulin daily. The most common combinations are mix-

Table 31–1. Kinetics of insulin action.

Type of Insulin	Begins Working	Main Effect	All Gone
Short-acting			
Regular	½ h	2–4 h	6–9 h
Humalog or Novolog	10–15 min	30–80 min	4 h
Intermediate-acting			
NPH	2–4 h	6–8 h	12–15 h
Ultralente	4–6 h	8–15 h	15–18 h
Long-acting			
Lantus	1–2 h	2–23 h	24–26 h
Premixed			
Lente ^a	1–2 h	6–12 h	15–18 h
NPH/Regular	½ h	Variable ^b	12–15 h
75/25 ^c	15 min	1–8 h	12–15 h

^a30% Semilente and 70% Ultralente.

^bAvailable in various combinations to fit individual needs.

^cA mixture of 75% NPH and 25% Humalog.

NPH = neutral protamine Hagedorn insulin.

tures of either H or NL or regular insulin and NPH insulin twice daily (see Table 31-1) or H or NL (or regular) insulin and NPH insulin in the morning and H/NL at dinner and NPH insulin at bedtime.

As noted earlier, when the more physiologic (closer to human insulin output) basal insulin, Lantus, is used, it must be given alone in the syringe or pen. When changing a patient from two shots/day of NPH insulin to Lantus, the total 24-hour dose of NPH is divided in half to use as the initial dose of Lantus. The Lantus dose is then increased or decreased 1 or 2 units every few days based on the fasting morning blood sugars. Common glucose level goals are 70–180 mg/dL (3.9–10 mmol/L) for preteens and 70–150 mg/dL (3.9–8.3 mmol/L) for teens. A short-acting insulin (H or NL) is then given prior to meals/snacks or a mixture of H or NL and NPH is given in the morning and H or NL at dinner. The dosages of H or NL may initially be based on a “thinking” scale (see previous discussion), and may later be based on carbohydrate-counting as the family becomes more knowledgeable (see Diet section).

Continuous subcutaneous insulin (insulin pump) therapy is now being used more often in children, particularly for emotionally mature teens who are willing to do frequent blood glucose monitoring and to count carbohydrates. Basal insulin doses (usually H/NL) to use are chosen by the physician, with bolus doses prior to meals selected by the patient (or an appropriate adult) depending on the carbohydrate content of the food to be eaten. Insulin pump therapy is discussed in depth in Chapter 26 of *Understanding Diabetes*.

The following constitutes intensive diabetes management: (1) three or more insulin injections per day, or insulin pump therapy; (2) four or more blood glucose determinations per day; (3) careful attention to dietary intake; and (4) frequent contact with the health care provider. This was shown in the Diabetes Control and Complications Trial (DCCT; see Diet section) to result in improved glucose control and to reduce the risk for retinal, renal, and neurologic complications of diabetes. All teenagers with suboptimal glucose control who are willing to comply should be considered for intensive diabetes management.

3. Treatment of type 2 diabetes—The treatment of type 2 diabetes in children varies with the severity of the disease. If the glycosylated hemoglobin (HbA_{1c}) is still normal (or near normal) and ketone levels are not moderately or significantly increased, modification of lifestyle (preferably for the entire family) is the first line of therapy. This must include reducing caloric intake and increasing exercise. If the HbA_{1c} is mildly elevated (6.2–9.0%) and ketone levels are not moderately or significantly increased, an oral hypoglycemia agent can be tried. Metformin is usually tried along with modifica-

tion of lifestyle, starting with a dose of 250–500 mg once daily. If needed, and if gastrointestinal adaptation has occurred, the dose can be gradually increased to 1 g bid. If the presentation is more severe, with moderately or significantly increased urine ketone levels, or blood β -hydroxybutyrate (β OHB) > 1.0 mmol/L, the initial treatment is similar to that of type 1 diabetes (including intravenous or subcutaneous insulin). Oral hypoglycemic agents may be tried at a later date, particularly if weight loss has been successful.

B. DIET

The mainstays of dietary treatment are discussed in detail in *Understanding Diabetes* (see References). The American Diabetes Association (ADA) no longer recommends any one diabetic diet or ADA diet. Instead, nutrition therapy for diabetics should be individualized, with consideration given to the patient’s customary cultural eating habits and other lifestyle circumstances. Some families and children (particularly those with weight problems) find exchange diets helpful initially while they are learning food categories. Most centers now just use exchanges of carbohydrates, referred to below as carbohydrate-counting or “carb-counting.”

The DCCT found that four nutrition factors contributed to better sugar control (lower HbA_{1c} levels). These factors are (1) adherence to a meal plan, (2) avoidance of extra snacks, (3) avoidance of over-treatment of low blood sugars (hypoglycemia), and (4) prompt treatment of high blood sugars. Two other nutritional factors include adjusting insulin levels for meals and maintaining a consistent schedule of nighttime snacks. The DCCT popularized the carb-counting dietary plan in which the dosage of H/NL or regular insulin is altered with each injection to adjust for the amount of carbohydrate to be eaten and the amount of exercise contemplated. One carbohydrate choice is 15 g of glucose in the United States (10 g in Canada and the United Kingdom). A common formula is to use 1 unit of H/NL for each 15 g of carbohydrate eaten, although this ratio must be adjusted (using blood glucose levels 2 hours after meals) for each person.

C. EXERCISE

Regular aerobic exercise—at least 30 minutes a day—is important for children with diabetes. Exercise fosters a sense of well-being; helps increase insulin sensitivity; and helps maintain proper weight, blood pressure, and blood fat levels. Exercise may also help maintain normal peripheral circulation in later years. It is particularly important for children with type 2 diabetes.

Hypoglycemia during exercise or in the 2–8 hours after exercise (delayed hypoglycemia) can be prevented by careful monitoring of blood sugar before, during, and after exercise; sometimes by reducing the dosage of

the insulin active at the time of the exercise; and by providing extra snacks. Children using insulin pumps should reduce pre-exercise bolus insulin dosages as well as the basal dosages during the exercise. In general, the longer and more vigorous the activity, the greater the reduction in insulin dose before exercising. Extra snacks should also be eaten. Fifteen grams of glucose usually covers about 30 minutes of exercise. The use of drinks containing 5–10% dextrose, such as Gatorade, during the period of exercise is often beneficial.

D. STRESS MANAGEMENT

Management of stress is important on a short-term basis because stress hormones increase blood glucose levels. Chronic emotional upsets may lead to missed injections or other compliance problems. When this happens, counseling for the family and child becomes an important part of diabetes management.

E. BLOOD GLUCOSE MEASUREMENTS

All families must be able to monitor blood glucose levels three or four times daily—and more frequently in small infants or patients who have glucose control problems or intercurrent illnesses. Blood glucose levels can be monitored using any of the available meters, which generally have an accuracy of 90% or better. Target levels when no food has been eaten for 2 or more hours vary according to age (Table 31–2).

Blood glucose results should be recorded even if the meter has a memory feature. This allows the family to look for patterns and make changes in insulin dosage. If more than 50% of the values are above the desired range for age or more than 12% below the desired range, the insulin dosage usually needs to be adjusted. Some families are able to make these changes independently (particularly after the first year), whereas others need help from the health care provider. Children with diabetes should have clinic visits every 3 months. This provides an opportunity to adjust insulin dosages according to changes in growth and blood glucose levels

Table 31–2. Ideal glucose levels after 2 or more hours of fasting.^a

Age (years)	Glucose Level
≤ 4	80–200 mg/dL (4.6–11 mmol/L)
5–11	70–180 mg/dL (3.9–10 mmol/L)
≥ 12	70–150 mg/dL (3.9–8.3 mmol/L)

^aAt least half of the values must be below the upper limit to have a good HbA_{1c} value. The values should also be below the upper limits for age when tested 2 h after a meal.

as well as to check for changes noted on physical examination (eg., eyes, thyroid). Continuous subcutaneous glucose monitoring using the Continuous Glucose Monitoring System (CGMS) by MiniMed or the GlucoWatch by Cygnus may also be helpful in monitoring glucose trends.

Laboratory Evaluations

In addition to home measurements of blood glucose and blood or urine ketone levels, HbA_{1c} should be measured every 3 months. This test reflects the frequency of elevated blood glucose levels over the previous 3 months. Normal values vary among laboratories but are usually below 6.2% (HbA_{1c}) or below 8% (total glycosylated hemoglobin). The desired ranges are based on age. For the HbA_{1c} method, these ranges are as follows: 12 years or older, less than 7.8%; 5–11 years, less than 8.0%; and younger than 5 years, 7.5–9%. Higher levels are allowed in younger children to reduce the risk of hypoglycemia because their brains are still developing and they may not relate symptoms of hypoglycemia to a need for treatment. Low HbA_{1c} values are generally associated with a greater risk for hypoglycemia (see following section). Using either method, researchers found that longitudinal averages more than 33% above the upper limit of normal are associated with a higher risk for later renal and retinal complications. In the intensive treatment group of the DCCT, the lower HbA_{1c} values resulted in a greater than 50% reductions in the retinal, renal, and neurologic complications of diabetes in pubertal patients.

Since atherosclerosis is the major cause of death in older patients with diabetes it is important to measure serum cholesterol, LDL, and HDL levels once yearly. Cholesterol levels should be below 200 mg/dL and LDL levels below 100 mg/dL in post-pubertal people with diabetes.

When puberty is reached and the individual has had diabetes for 3 years or longer, the urinary excretion of albumin should be measured (as microalbumin) in two separate urine samples once yearly (see Chronic Complications section). This can be done using timed overnight urine collections as teens are less likely to collect 24-hour specimens. Normal values differ with the methodology of the laboratory but are generally below 20 µg/min. People with type 2 diabetes should have this test done soon after diagnosis and then annually.

If the thyroid is enlarged (about 20% of patients with type 1 diabetes), the thyroid-stimulating hormone (TSH) level should be measured yearly. This is usually the first test to become abnormal in the autoimmune thyroiditis commonly associated with type 1 diabetes.

In recent years antiendomysial and transglutaminase antibodies, reliable predictors of celiac disease, have

been shown to be more common in children with diabetes as well as in their siblings. Risk of celiac disease is associated with HLA-DR3 and is more frequent in children with diabetes (celiac disease occurring in about 5%). The celiac antibodies should be checked in diabetic children with poor growth (especially when not related to poor glucose control) or those who present with gastrointestinal symptoms. The 21-hydroxylase autoantibody, a marker of increased risk of Addison disease, is present in approximately 1.3% of patients with type 1 diabetes, although Addison disease is found in only 1 in 200.

Type 2 diabetes is not an autoimmune disease, and the islet antibody tests are negative. An elevated insulin or C-peptide level is also helpful, indicating that insulin production is normal or elevated.

A checklist of the physician's contributions to good diabetes care is presented in Table 31–3.

Acute Complications

A. HYPOGLYCEMIA

Hypoglycemia (or insulin reaction) is defined as a blood glucose level below 60 mg/dL (or 3.3 mmol/L). For preschool children, values below 70 mg/dL (3.9 mmol/L) should be cause for concern. The common symptoms of hypoglycemia are hunger, weakness,

shakiness, sweating, drowsiness (at an unusual time), headache, and behavioral changes. Children learn to recognize hypoglycemia at different ages but can often report “feeling funny” as young as age 4–5 years. If low blood sugar is not treated immediately with simple sugar, the hypoglycemia may result in loss of consciousness or convulsions. If hypoglycemia is left untreated for several hours, brain damage or death can occur.

Consistency in daily routine, correct insulin dosage, regular blood glucose monitoring, controlled snacking, compliance of patients and parents, and good education are all important in preventing severe hypoglycemia. In addition, insulin should not be injected prior to getting into a hot tub, bath, or shower. The heat will increase circulation to the skin and cause more rapid insulin uptake. The use of H/NL insulin and of Lantus insulin has also helped to reduce the occurrence of hypoglycemia.

The treatment of mild hypoglycemia involves giving 4 oz of juice, a sugar-containing soda drink, or milk, and waiting 10 minutes. If the blood glucose level is still below 60 mg/dL (3.3 mmol/L), the liquids are repeated. If the glucose level is above 60 mg/dL, solid foods are given. Moderate hypoglycemia, in which the person is conscious but incoherent, is treated by squeezing one-half tube of concentrated glucose (eg., Insta-Glucose or cake frosting) between the gums and lips and stroking the throat to encourage swallowing.

In the DCCT study, 10% of patients with standard management and 25% of those with intensive insulin management—insulin pumps or three or more insulin shots per day—had one or more severe hypoglycemic reactions each year. Families are advised to have glucagon in the home and to treat hypoglycemia by giving subcutaneous or intramuscular injections of 0.3 mL (30 units in an insulin syringe) for children younger than age 5 years and 0.5 mL (50 units) to those older than age 5 years. Some patients (usually those who have had diabetes for more than 10 years) fail to recognize the symptoms of low blood sugar (hypoglycemic unawareness). For these individuals, glucose control must be liberalized to prevent severe hypoglycemic reactions. School personnel, sports coaches, and baby-sitters must be trained to recognize and treat hypoglycemia.

B. KETONURIA, KETONEMIA, AND KETOACIDOSIS

Families must be educated to check blood or urine ketone levels during any illness (including vomiting even once) or any time a fasting blood glucose level is above 240 mg/dL (13.3 mmol/L), or a randomly measured glucose level is above 300 mg/dL (16.6 mmol/L). If moderate or significant ketonuria is detected, or the blood ketone (β OHB—using the Precision Xtra meter) is above 1.0 mmol/L, the health care provider must be called. Usually 10–20% of the total daily insulin dosage

Table 31–3. Physician's checklist of good diabetes management.

Variable	Frequency of Measurement	Tests and Values
Blood sugars	3–4 times daily	See age-appropriate values.
Hemoglobin A _{1c}	Every 3 mos	See age-appropriate values.
Urine micro-albumin	Annually after 3 y of diabetes (pubertal patients)	< 20 μ g/min
Ophthalmology referral	Annually after 3 y of diabetes (10 y old or greater)	Retinal photographs
Signs of other endocrinopathy	Evaluate at least annually (eg, thyroid enlargement)	(eg: TSH: 0.5–5.0 IU/mL)
Blood lipid panel	Annually	eg: Cholesterol = <200 mg/dL; LDL = <100

TSH = thyroid-stimulating hormone.

is given subcutaneously as H or NL (or regular) insulin every 2–3 hours until the elevated ketones are gone. This prevents ketonuria/ketonemia from progressing to ketoacidosis and allows most patients to receive treatment at home by telephone management. Juices and other fluids to help wash out the ketones and to prevent dehydration are encouraged, and suppositories of promethazine to prevent vomiting may be indicated. If deep breathing (Kussmaul respirations) or excessive weakness occurs, the patient should be evaluated promptly by a physician.

Acidosis (venous blood pH < 7.30) is now present in fewer than 25% of newly diagnosed children. Acidosis may also occur in those with known diabetes who do not check blood or urine ketone levels or fail to call the health care provider when ketones levels are elevated. Repeated episodes of ketoacidosis usually result from missed insulin injections and signify that counseling may be indicated, and that a responsible adult must take over the diabetes management. If, for any reason this is not possible, a change in the child's living situation may be necessary.

Treatment of diabetic ketoacidosis (DKA) is based on four physiologic principles: (1) restoration of fluid volume, (2) inhibition of lipolysis and return to glucose utilization, (3) replacement of body salts, and (4) correction of acidosis. Laboratory tests at the start of treatment should include venous blood pH, blood glucose, and an electrolyte panel. Mild DKA is defined as a venous blood pH of 7.2–7.3; moderate DKA, a pH of 7.10–7.19; and severe DKA, a pH below 7.10. Patients with severe DKA should be hospitalized in a pediatric intensive care unit, if available in the area. More severe cases may benefit from determination of osmolality, calcium and phosphorus, and blood urea nitrogen levels. Severe and moderate episodes of DKA generally require hourly determinations of serum glucose, electrolytes, and venous pH levels, whereas these parameters can be measured every 2 hours if the pH level is 7.20–7.30.

1. Restoration of fluid volume—Dehydration is judged by (1) acute loss of body weight (if a recent weight is known), (2) dryness of oral mucous membranes, (3) low blood pressure, and (4) tachycardia. Initial treatment is with physiologic saline (0.9%), 10–20 mL/kg during the first hour. If indicated by continued signs of dehydration, this is repeated during the second hour. The total volume of fluid in the first 4 hours of treatment should not exceed 40 mL/kg because of the danger of cerebral edema (see Management of Cerebral Edema section). Human albumin, 10 mL/kg of 5% solution, can be given over 30 minutes if the patient is in shock. After initial reexpansion, half-physiologic (0.45%) saline usually is given at

1.5 times maintenance. Maintenance fluids are as shown in Chapter 42.

2. Inhibition of lipolysis and return to glucose utilization—Insulin turns off fat breakdown and ketone formation. Regular insulin is usually given intravenously at a rate of 0.1 unit/kg/h. The insulin solution should be administered by pump and can be made by diluting 30 units of regular insulin in 150 mL of 0.9% saline (1 unit/5 mL). If the glucose level falls below 250 mg/dL (13.9 mmol/L), 5% dextrose is added to the intravenous fluids. If the glucose level continues to decrease below 120 mg/dL (6.6 mmol/L), 10% dextrose can be added. If necessary, the insulin dosage can be reduced to 0.05 unit/kg/h, but it should not be discontinued before the venous blood pH reaches 7.30. The half-life of intravenous insulin when discontinued is 6 minutes, whereas subcutaneous H or NL insulin takes 10–15 minutes, and regular insulin takes 30–60 minutes, to begin activity. Thus it is often better to continue intravenous insulin until subcutaneous insulin can begin acting.

3. Replacement of body salts—In patients with DKA, both sodium and potassium pass into the urine with the ketones and are depleted. Serum sodium concentrations may be falsely lowered by hyperglycemia, causing water to be drawn into the intravenous space, and by hyperlipidemia if fat replaces some of the water in the serum used for electrolyte analysis. Sodium is usually replaced adequately by the use of physiologic and half-physiologic saline in the rehydration fluids as discussed earlier.

Serum potassium levels may be elevated initially because of inability of potassium to stay in the cell in the presence of acidosis (even though total body potassium is low). Potassium should not be given until the serum potassium level is known to be low or normal and the pH is above 7.10. It is then usually given at a concentration of 40 mEq/L, with one half of the potassium (20 mEq/L) either as potassium acetate or potassium chloride and the other half as potassium phosphate (20 mEq/L). Hypocalcemia can occur if all of the potassium is given as the phosphate salt; hypophosphatemia occurs if none of the potassium is of the phosphate salt.

4. Correction of acidosis—Acidosis is corrected as the fluid volume and aerobic glycolysis are restored and as insulin is administered to inhibit ketogenesis. As noted earlier, measurement of the venous blood pH (identical to arterial blood pH) reveals the severity of acidosis. Bicarbonate is usually not given, even with severe DKA.

5. Management of cerebral edema—Some degree of cerebral edema has been shown by computed tomogra-

phy scan to be common in DKA. Associated clinical symptoms are rare, unpredictable, and often associated with demise. Cerebral edema may be related to overhydration with hypotonic fluids, although the cause is not well understood. It is now recommended that no more than 40 mL/kg of fluids be given in the first 4 hours of treatment. Cerebral edema is more common with a pH lower than 7.1, a PCO₂ lower than 20 mm Hg, or when the serum sodium is noted to be falling rather than rising. Early neurologic signs may include headache, excessive drowsiness, and dilated pupils. Prompt initiation of therapy should include elevation of the head of the bed, hyperventilation, mannitol (1 g/kg over 30 minutes), and fluid restriction. If the cerebral edema is not recognized and treated early, over 50% of patients will die or have permanent brain damage.

Chronic Complications

In the past, about 30–40% of persons with type 1 diabetes eventually developed renal failure or loss of vision. Factors that greatly reduce this likelihood are longitudinal HbA_{1c} levels in a good range, maintenance of blood pressure below the 90th percentile for age, and abstinence from smoking or chewing tobacco. Annual retinal examinations and urine microalbumin measurements are important for children age 10 years or older who have had diabetes for 3 years or longer (see Laboratory Evaluations section). Data now show that the use of angiotensin-converting enzyme inhibitors may reverse or delay kidney damage when it is detected in the microalbuminuria stage (20–300 µg/min). Similarly, laser treatment to coagulate proliferating capillaries prevents bleeding and leakage of blood into the vitreous fluid or behind the retina. This treatment helps to prevent retinal detachment and to preserve useful vision for many people with proliferative diabetic retinopathy.

Carol L. Greene, MD, Janet A. Thomas, MD, & Stephen I. Goodman, MD

Disorders in which defects of single genes cause clinically significant blocks in metabolic pathways are called inborn errors of metabolism. For many years after Garrod first described them in 1908, these conditions were thought rare. Because the number of recognized inborn errors has increased, they are now acknowledged to be important causes of disease in children. Many of these disorders can now be treated effectively. Even when treatment is not available, correct diagnosis permits parents to make informed decisions about future offspring.

The pathology is almost always due either to accumulation of enzyme substrate behind the metabolic block or to deficiency of the reaction product. In some cases, the accumulated enzyme substrate is diffusible and has an adverse effect on distant organs; in other cases, as in lysosomal storage diseases, the substrate primarily accumulates locally.

The clinical manifestations of inborn errors vary widely; both mild and severe forms of virtually every disorder occur, and many patients do not match the classic phenotype. Often this is because the mutations in different patients, even though in the same gene, are not identical.

Strategies used to treat inborn errors include avoiding enzyme substrate in the diet (eg, low-phenylalanine diet for phenylketonuria), removing accumulated substrate by pharmacologic means (eg, glycine therapy for isovaleric acidemia), supplementing an inadequately produced metabolite (eg, arginine administration for urea cycle disorders), providing additional coenzyme (eg, vitamin B₁₂ therapy for methylmalonic acidemia), and providing normal enzyme (eg, enzyme infusion in Gaucher disease or liver transplantation for Wilson disease). Gene replacement is a long-term goal, and various gene therapy trials are in progress. However, problems of delivery to target organs and control of gene action make this an unrealistic option at present for treating most of these disorders.

Inborn errors can become manifest at any time, affect virtually any organ system, and cause all but the most common pediatric problems. This chapter focuses first on when these conditions should be considered in the differential diagnosis of common pediatric problems. A few of the more important disorders are then discussed in greater detail.

■ DIAGNOSIS

SUSPECTING INBORN ERRORS

In general, inborn errors must be considered in the differential diagnosis of the critically ill newborn and of the child with seizures, mental retardation or developmental delay, recurrent vomiting, Reye-like syndromes, parenchymal liver disease, unusual odor, unexplained acidosis, hyperammonemia, and hypoglycemia. Inborn errors should be strongly suspected when (1) symptoms accompany changes in diet, (2) the child is developmentally slow or regresses, (3) the child has a history of food preferences or aversions, or (4) the family has a history of parental consanguinity or of problems that could be due to an inborn error, such as retardation or unexplained deaths in siblings, cousins, or other relatives.

Physical findings that should always arouse suspicion of an inborn error include alopecia or abnormal hair, retinal cherry-red spot or retinitis pigmentosa, cataracts or corneal opacity, hepatomegaly or splenomegaly, coarse features, skeletal changes (including gibbus), and ataxia. Features that may be important, in combination with a suspicious history, include failure to thrive, microcephaly, rash, jaundice, hypotonia, and hypertonia.

Finding an immediate cause of symptoms does not rule out an underlying inborn error. For example, renal tubular acidosis and cirrhosis may be due to an underlying inborn error. Some inborn errors predispose to infection, for example, gram-negative septicemia in patients with galactosemia. In other inborn errors, acute crises may be brought on by intercurrent infections. Manifestation of some inborn errors has been mistaken for nonaccidental trauma (eg, glutaric acidemia type I) or poisoning (eg, methylmalonic acidemia); in addition, children with inborn errors of metabolism may be at higher risk for child abuse or neglect because of the much greater irritability that some of these children often demonstrate.

LABORATORY STUDIES

Table 32-1 lists common clinical and laboratory features of different groups of inborn errors. Table

^cIncludes maple syrup urine disease and disorders of pyruvate oxidation.

32–2 lists the most common laboratory tests used to diagnose these diseases and offers some comments about their use.

Laboratory studies are almost always needed for the diagnosis of inborn errors. Serum electrolytes and pH should be used to estimate anion gap as well as acid–base status. Analysis of serum lactate, pyruvate, and ammonia levels may be available in large hospitals. Amino acid and organic acid studies must be performed at specialized facilities to ensure adequate analysis and interpretation. An increasing number of inborn errors are diagnosed with DNA probes, although this method may require an extensive genealogic chart or knowledge of the precise mutation carried in the family.

The physician should know what conditions a test will detect and when it will detect them. For example, urine organic acids may be normal in patients with medium-chain acyl-CoA dehydrogenase deficiency or biotinidase deficiency; glycine may be elevated only in cerebrospinal fluid (CSF) in patients with glycine encephalopathy; and a result that is normal in one physiologic state may be abnormal in another. For instance, the urine of a hypoglycemic child should be positive for ketones; in such a child, a ketone-negative urine test may suggest the presence of a defect in fatty acid oxidation.

Samples used to diagnose metabolic disease may be obtained at autopsy. They may be analyzed directly or stored frozen until a particular analysis is justified by

the results of postmortem examination, new clinical information, or new developments in the field. Studies of other family members may also help to establish the diagnosis in a deceased patient; these include demonstrating that the parents are heterozygous carriers of a particular disorder or showing that another sibling has the condition.

COMMON CLINICAL SITUATIONS

Mental Retardation

Many inborn errors can cause mental retardation without other distinguishing characteristics. Laboratory studies of serum and urine amino acids should be obtained for every patient who has nonspecific mental retardation. Urine screens for mucopolysacchariduria are useful because some mucopolysaccharidoses do not have specific physical findings. The presence of a high anion gap or renal tubular acidosis significantly increases the chance of finding an underlying inborn error.

Acute Presentation in the Neonate

Acute metabolic disease in the newborn may be clinically indistinguishable from sepsis and is most often caused by disorders of protein or carbohydrate metabolism. Initial symptoms may be poor feeding or vomit-

Table 32–2. Obtaining and handling samples to diagnose inborn errors.

Test	Comments
Acid-base status	Accurate estimation of anion gap must be possible. Samples for blood gases should be kept on ice and analyzed immediately.
Blood ammonia	Sample should be collected without a tourniquet, kept on ice, and analyzed immediately.
Blood lactic acid and pyruvic acid	Sample should be collected without a tourniquet, kept on ice, and analyzed immediately. Reduction of pyruvic acid to lactic acid must be prevented. Normal literature values are for the fasting, rested state.
Amino acids	Blood and urine should be examined. CSF glycine should be measured if non-ketotic hyperglycinemia is to be ruled out. Normal literature values are for the fasting state. Growth of bacteria in urine should be prevented. At autopsy: liver, kidney, or aqueous humor may be analyzed if urine is not available.
Organic acids	Urine preferred for analysis. At autopsy: liver, kidney, or aqueous humor may be analyzed if urine is not available.
Carnitine and acylcarnitine profile	Blood (plasma) may be analyzed for total, free, and esterified carnitine; normal values are for the healthy, nonfasted state. Acylcarnitine profile in blood may identify compounds esterified to carnitine, and urine and tissue studies may be needed for certain conditions.
Urine mucopolysaccharides	Variations in urine concentration may cause errors in screening tests. Diagnosis requires knowing which mucopolysaccharides are increased. Some patients with Morquio disease do not have abnormal mucopolysacchariduria.
Enzyme assays	Specific assays must be requested. Exposure to heat may cause loss of enzyme activity. Enzyme activity in whole blood may become normal after transfusion or vitamin therapy. Leukocyte or fibroblast pellets should be kept frozen prior to assays. Fibroblasts may be grown from skin biopsies taken up to 72 h after death. Tissues such as liver and kidney should be taken as soon as possible after death, frozen immediately, and kept at -70°C until assayed.

CSF = cerebrospinal fluid.

ing, altered mental status or tone, jitteriness or seizures, and jaundice. Acidosis or altered mental status out of proportion to systemic symptoms should increase suspicion of a metabolic disorder. Laboratory measurements should include the following: electrolytes, ammonia, glucose, urine pH, and urine ketones. Glycine in CSF should be measured if glycine encephalopathy is suspected. Serum and urine to be used for amino acid and organic acid analysis should be collected, before oral intake is stopped, and sent for analysis if indicated by the results of initial studies.

Vomiting & Encephalopathy in the Infant or Older Child

Electrolytes, ammonia, glucose, urine pH, urine-reducing substances, and urine ketones should be measured in all patients who exhibit vomiting and encephalopathy, before any treatment affects the results. Samples for amino and organic acid analysis should be obtained early and frozen pending the results of initial studies. An inborn error is even more likely when the presentation is judged typical of Reye syndrome (ie, vomiting, encephalopathy, hepatomegaly), and amino acids and organic acids should be studied immediately. If hypoglycemia with inappropriately low urine or serum ketones is present, disorders of fatty acid oxidation should be considered.

Hypoglycemia

Electrolytes, ammonia, uric acid, urine-reducing substances, and urine ketones should be measured, along with urinary organic acids. Ketone body production is usually not efficient in the neonate, and ketonuria in a hypoglycemic or acidotic neonate suggests an inborn error. In the older child, inappropriately low urine ketone levels suggest an inborn error of fatty acid oxidation.

Hyperammonemia

Symptoms of hyperammonemia may appear and progress rapidly or insidiously. Decreased appetite and irritability usually appear first, with vomiting, lethargy, seizures, and coma appearing as ammonia levels increase. Tachypnea is caused by a direct effect on respiratory drive. Physical examination cannot exclude the presence of hyperammonemia, and serum ammonia should be measured whenever hyperammonemia is possible.

Severe hyperammonemia may be due to urea cycle disorders, organic acidemias, or carnitine–acylcarnitine translocase deficiency or, in the neonate, to transient hyperammonemia of the newborn. The cause can usu-

ally be ascertained by measuring citrulline, electrolytes, and carnitine and acylcarnitine esters in serum and measuring amino acids, organic acids, and orotic acid in urine. Respiratory alkalosis is usually present in transient hyperammonemia of the newborn and hyperammonemia due to a urea cycle defect, whereas metabolic acidosis is usually associated with hyperammonemia due to organic acidemia. Urine organic acid analysis will identify organic acidemia. Serum citrulline is usually low or undetectable in early urea cycle defects, normal or slightly high in transient hyperammonemia of the newborn, and very high in citrullinemia and argininosuccinic acidemia. Argininosuccinic acid is found in urine only in the last case. Of infants with early urea cycle defects, only those with hyperammonemia due to ornithine transcarbamoylase deficiency have increased urine orotic acid levels and (often) a family history of male newborn deaths consistent with X-linked inheritance. Infants with carnitine–acylcarnitine translocase deficiency often have low serum carnitine and elevated palmitoylecarnitine.

Acidosis

Inborn errors may cause chronic or acute acidosis at any age and with or without an increased anion gap. Inborn errors are in the differential diagnosis of acidosis occurring with recurrent vomiting or hyperammonemia and when acidosis is out of proportion to the clinical status. Acidosis due to an inborn error is usually difficult to correct. The presence of renal tubular acidosis does not exclude an underlying inborn error.

Serum glucose and ammonia levels and urine pH and ketone levels should always be examined. Samples for amino acids and organic acids should be obtained at once and sent to the laboratory or saved in the freezer, depending on how strongly an inborn error is suspected. It is useful to test blood lactate and pyruvate levels in the chronically acidotic patient even if urine organic acid levels are normal. Lactate and pyruvate levels are difficult to interpret in the acutely ill patient, but in the absence of shock, high levels of lactic acid suggest primary lactic acidosis.

MANAGEMENT OF METABOLIC EMERGENCIES

Patients with severe acidosis, hypoglycemia, and hyperammonemia may be very ill; initially mild symptoms may worsen quickly, and coma and death may ensue within hours. With prompt and vigorous treatment, however, patients can recover completely, even from

deep coma. All oral intake should be stopped. Sufficient glucose should be given intravenously to avoid or minimize catabolism in a patient with a known inborn error who is at risk for crisis. Most conditions respond favorably to glucose administration, and few (eg, primary lactic acidosis due to pyruvate dehydrogenase deficiency) do not. Severe or increasing hyperammonemia should be treated pharmacologically or with dialysis, and severe acidosis should be treated with bicarbonate. More specific measures can be instituted when a diagnosis is established.

NEWBORN SCREENING

Criteria used to decide whether to screen newborns for a disorder include the disorder's frequency, the significance of consequences if it is not treated, the ability to avert or mitigate those consequences with therapy, the cost of screening and diagnostic tests, and the cost of treatment. All states in the United States screen newborns for phenylketonuria and hypothyroidism, and in most states newborns are screened for galactosemia. Other metabolic disorders for which newborns are frequently screened include maple syrup urine disease, homocystinuria due to cystathionine synthase deficiency, biotinidase deficiency, and, using tandem mass spectrometry, several disorders of amino acid, organic acid, and fatty acid metabolism.

Some screening tests measure a metabolite (eg, phenylalanine) that becomes abnormal only with time and exposure to diet, and in such instances the disease cannot be detected reliably until intake of the enzyme substrate has become established. Other tests (eg, for biotinidase deficiency) assay an enzyme and can be performed at any time; however, transfusions may cause false-negative results, and exposure of the sample to heat may cause false-positive results. Technologic advances extend the power of newborn screening but sometimes bring additional challenges. For example, although tandem mass spectrometry (MS-MS) is capable of detecting many more disorders in the newborn period, wider application is controversial because of the cost and the limitations of some treatments.

Screening tests are not diagnostic, and diagnostic tests must be undertaken when an abnormal screening result is obtained. Furthermore, because false-negative results occur, a normal newborn screening test does not rule out a condition.

The timing of newborn screening recommended by the American Academy of Pediatrics (AAP) is appropriate for the detection of phenylketonuria, but hypothyroidism, for instance, can be missed when screening is

carried out at the same time. Early discharge of neonates causes significant problems with newborn screening, with both false-negative and false-positive results. Nevertheless, all babies should be screened before discharge from the hospital.

The appropriate response to an abnormal screening test depends on the condition for which screening is conducted and the predictive value of the screening test. For example, when screening for galactosemia using enzyme assay, complete absence of enzyme activity is highly predictive of classic galactosemia, and failure to treat may rapidly lead to death. In that case, treatment must be initiated immediately while diagnostic studies are pending. In PKU, however, a diet restricted in phenylalanine is harmful to the baby who proves to have had a false-positive screen, but an excellent outcome of therapy in the affected baby is well demonstrated so long as treatment is established within the first weeks of life. Therefore, initiation of treatment for PKU is contraindicated until diagnosis is confirmed. Physicians should combine current AAP recommendations and state laws and regulations to arrive at appropriate strategies for each hospital and practice.

DISORDERS OF CARBOHYDRATE METABOLISM

GLYCOGEN STORAGE DISEASES

Glycogen is a highly branched polymer of glucose that is stored in liver and muscle. Different enzyme defects affect its biosynthesis and degradation. The most common glycogenoses cause growth failure, hepatomegaly, and fasting hypoglycemia. The so-called hepatic forms of the disease include glucose-6-phosphatase (type I; von Gierke disease), debrancher enzyme (type III), hepatic phosphorylase (type VI), and phosphorylase kinase (type IX), which normally regulates hepatic phosphorylase activity. There are two forms of glucose-6-phosphatase deficiency: In one, the enzyme defect can be demonstrated in fresh or frozen liver; in the other, the defect can be demonstrated only in fresh tissue.

Forms of the disease affecting primarily muscle include acid maltase deficiency (type II; Pompe disease), which may occur in infancy and is associated with cardiomegaly and macroglossia, and muscle phosphorylase (type V) and phosphofructokinase (type VII) deficiencies, in which the most striking features are easy fatigability and muscle weakness and stiffness.

Diagnosis

Precise diagnosis is by biochemical tests, such as responsiveness of blood glucose to fasting and glucagon, and enzyme assays on leukocytes, liver, or muscle. Disorders that can be diagnosed using red or white blood cells include deficiencies of debrancher enzyme (type III) and phosphorylase kinase (IX). Pompe disease can usually be diagnosed by assaying acid maltase in fibroblasts.

Treatment

Treatment is designed to prevent hypoglycemia while avoiding storage of even more glycogen in the liver. In the most severe hepatic forms, this requires careful monitoring of specific diets, using restriction of free sugars and measured amounts of cornstarch, and good results have been reported following continuous nighttime carbohydrate feeding.

GALACTOSEMIA

Classic galactosemia is caused by almost total deficiency of galactose-1-phosphate uridylyltransferase. Accumulation of galactose-1-phosphate in liver, brain, and renal tubules causes hepatic parenchymal disease, mental retardation, and renal Fanconi syndrome. Accumulation of galactitol (dulcitol) in the lens produces cataracts. With prompt institution of a galactose-free diet, the prognosis for survival without severe mental retardation and liver disease is excellent.

Onset of the severe form of the disease is accompanied by vomiting, jaundice, and hepatomegaly in the newborn period after milk feeding. Without treatment, death frequently occurs in the first month of life, often from *Escherichia coli* sepsis. Cataracts usually develop within 2 months in untreated cases, and hepatic cirrhosis is progressive. Survival is possible, but mental retardation is irreversible. Even when dietary restrictions are instituted early, patients with galactosemia are at increased risk for speech and language deficits and ovarian failure, and some patients develop progressive delay, tremor, and ataxia. Milder variants of galactosemia with better prognosis exist in all populations.

The disorder is inherited as an autosomal recessive trait with an incidence of approximately 1:40,000 live

births. Because disease in infancy may be severe and diagnosed late, newborn screening is common. Screening is accomplished by demonstrating enzyme deficiency in red cells with the Beutler test or by demonstrating increased serum galactose. Prenatal diagnosis is possible if a specific DNA mutation in a family is known.

Diagnosis

In infants receiving foods containing galactose, laboratory findings include galactosuria and hypergalactosemia together with proteinuria and aminoaciduria. Absence of urine-reducing substances does not exclude the diagnosis. When the diagnosis is suspected, galactose-1-phosphate uridylyltransferase should be assayed in erythrocytes. Blood transfusions give false-negative results and sample deterioration false-positive results.

Treatment

A galactose-free diet should be instituted as soon as the diagnosis is made. Compliance with the diet must be monitored because it is not a simple exclusion of milk and requires extensive knowledge about the galactose content of foods. Avoidance of galactose should be lifelong in severe cases, with appropriate calcium replacement. Heterozygous mothers may be advised to maintain a galactose-free diet during pregnancy.

HEREDITARY FRUCTOSE INTOLERANCE

Hereditary fructose intolerance is an autosomal recessive disorder in which deficient activity of fructose-

1-phosphate aldolase causes hypoglycemia and tissue accumulation of fructose-1-phosphate on fructose ingestion. Other abnormalities include failure to thrive, vomiting, jaundice, hepatomegaly, proteinuria, and generalized aminoaciduria. The untreated condition can progress to death as a result of liver failure.

Diagnosis

The diagnosis is supported by the demonstration of fructosuria following an in-patient, closely monitored fructose load. The appearance of hypoglycemia and hypophosphatemia after fructose loading (200 mg/kg) is diagnostic, as is reduced activity of fructose-1-phosphate aldolase in the liver. Some patients may be diagnosed by identification of one of the common mutations on DNA analysis.

Treatment

Treatment consists of eliminating fructose from the diet and is complicated by the fact that many proprietary drugs and vitamins are in a sucrose base. If the diet is relaxed, physical growth retardation may occur, but growth will resume when more stringent dietary restrictions are instituted. If the disorder is recognized early, the prospects for normal development are good. As affected individuals grow up, they may recognize the association of nausea and vomiting with fructose-containing foods and selectively avoid them.

Ali M et al: Hereditary fructose intolerance. *J Med Genet* 1998; 35:353 [PMID: 9610797].

PRIMARY LACTIC ACIDEMIAS & OTHER DISORDERS OF ENERGY METABOLISM

Primary lactic acidemia is a diagnosis being made with increasing frequency and may be one of the more common causes of static, progressive, or self-limited neurodevelopmental problems in children. The range of severity and prognosis in these disorders is illustrated by extremes. For example, defects in the mitochondrial respiratory chain, including complex IV deficiency, may cause Leigh disease, a fatal neurodegenerative disorder, whereas another manifestation of complex IV deficiency is benign-resolving congenital hypotonia. Lactic acidemia is said to be primary when it is due to a defect in the metabolism of pyruvic acid and secondary when a change in cellular redox potential favors the reduction of pyruvate to lactate (as in shock). Table

Table 32-3. Causes of primary lactic acidosis in childhood.

Defects of the pyruvate dehydrogenase complex

- E₁ (pyruvate decarboxylase) deficiency
- E₂ (dihydrolipoyl transacetylase) deficiency
- E₃ (lipoamide dehydrogenase) deficiency
- Pyruvate decarboxylase phosphate phosphatase deficiency

Abnormalities of gluconeogenesis

- Pyruvate carboxylase deficiency
 - Isolated
 - Biotinidase deficiency
 - Holocarboxylase synthetase deficiency
- Fructose-1,6-diphosphatase deficiency
- Glucose-6-phosphatase deficiency (von Gierke disease)

Defects in mitochondrial respiratory chain

- Complex I deficiency
- Complex IV deficiency (cytochrome C oxidase deficiency; frequent cause of Leigh disease)
- ATPase deficiency (frequent cause of Leigh disease)
- Other respiratory chain disorders

32-3 lists some causes of primary lactic acidosis. In general, such disorders may present at any age with neurologic findings and, when the defect is in gluconeogenesis, with hypoglycemia. Patients with a defect in the E₁ component of the pyruvate dehydrogenase complex often have central nervous system (CNS) malformations or mild facial dysmorphism. Recurrent altered mental status, recurrent ataxia, and recurrent acidosis are typical of many disturbances of pyruvate metabolism.

Patients with defects in the mitochondrial respiratory chain also may present with nonspecific findings such as hypotonia, failure to thrive, or renal tubular acidosis or with more specific features such as ophthalmoplegia or cardiomyopathy. Ragged red fibers and mitochondrial abnormalities may be noted on histologic examination of muscle. Thirteen of the more than 100 genes that control activity of the respiratory chain are part of the mitochondrial genome. Therefore, inheritance of defects in the respiratory chain may be mendelian or maternal.

Diagnosis

Diagnosis of primary lactic acidemia may be based on (1) demonstration of significant elevations of lactic or pyruvic acid concentrations in the blood (in a fasting, resting, free-flowing sample) with absence of causes of secondary lactic acidemia; (2) elevated lactic or pyruvic acid in spinal fluid; or (3) demonstration of classic features of mitochondrial disorder, such as ragged red

fibers in skeletal muscle biopsy. Primary lactic acidemia may be present even if the blood lactic acid concentration is normal, because lactate levels may vary according to the state of the patient (eg, resting versus active; fasting versus fed). Carefully controlled and monitored provocative testing such as fasting, challenge with carbohydrates, or exercise may identify affected individuals, and the specific responses to challenge may suggest both a diagnosis and possible treatment. Diagnostic tests of blood samples for enzyme activity (eg, biotinidase, pyruvate carboxylase) may be diagnostic, but enzyme analysis of fibroblasts or skeletal muscle is often required. For some clinical presentations, mitochondrial DNA analysis of blood or tissue may identify a diagnostic mutation. With many patients, the cause of lactic acidemia cannot yet be defined. In some instances, the genetics and prognosis may be clear, but in many cases neither prognosis nor genetic risk can be predicted.

Treatment

In some patients, defects in gluconeogenesis can be treated with glucose administration, fructose avoidance, or administration of pharmacologic amounts of biotin. Modified ketogenic diet has been reported to be useful in some cases of proved or presumed pyruvate dehydrogenase deficiency. Other treatments are of theoretical value, with little data on efficacy. Thiamine and lipoic acid have been tried in patients who have pyruvate dehydrogenase complex deficiencies, and coenzyme Q and riboflavin have been reported to be helpful in some patients with respiratory chain defects. Dichloroacetic acid has been tried in pyruvate dehydrogenase complex deficiencies and in respiratory chain disorders, with variable clinical responses and adverse effects.

DISORDERS OF AMINO ACID METABOLISM

DISORDERS OF THE UREA CYCLE

Ammonia is converted to an amino group in urea by enzymes of the urea cycle. Patients with defects in early urea cycle enzymes, such as carbamoyl phosphate synthetase or ornithine transcarbamoylase, usually present in infancy with severe and rapidly fatal hyperammonemia, vomiting, and encephalopathy, but the course may also be milder, with vomiting and encephalopathy following protein ingestion or infections. Although defects in argininosuccinic acid synthetase (citrullinemia) and argininosuccinic acid lyase (argininosuccinic acidemia) may also cause severe hyperammonemia in infancy, a chronic course with mental retardation is more usual in these conditions.

Except for ornithine transcarbamoylase deficiency, which is X-linked, urea cycle disorders are inherited as autosomal recessive traits. Citrullinemia and argininosuccinic acidemia can be diagnosed in utero by appropriate enzyme assays, but carbamoyl phosphate synthetase and ornithine transcarbamoylase deficiency can be diagnosed in utero only by using specific gene probes, and then only in certain families.

Diagnosis

Blood ammonia levels should be measured in any newborn who is acutely ill without obvious cause. A urea cycle defect should be suspected when severe hyperammonemia is associated with respiratory alkalosis. Serum citrulline is low or undetectable in carbamoyl phosphate synthetase and ornithine transcarbamoylase deficiency, high in argininosuccinic acidemia, and very high in citrullinemia. Large amounts of argininosuccinic acid are found in the urine of patients with argininosuccinic acidemia. Urine orotic acid is increased in infants with ornithine transcarbamoylase deficiency, and there may also be a family history of male newborn deaths consistent with an X-linked genetic trait.

Age at onset of symptoms varies with residual enzyme activity, protein intake, growth, and stress such as infection. Even within a family, affected males may differ by decades in their age at onset of symptoms. Many female carriers of ornithine transcarbamoylase deficiency exhibit protein intolerance; some develop migraine-like symptoms after protein loads, and others develop potentially fatal episodes of vomiting and encephalopathy after protein ingestion, certain infections, or labor and delivery. Trichorrhexis nodosa is common in patients with the chronic form of argininosuccinic acidemia.

Treatment

In the newborn, measures to reduce serum ammonia by hemodialysis, peritoneal dialysis, or double-volume exchange transfusion should be instituted as soon as hyperammonemia is documented. Protein intake should be stopped, and glucose should be given to reduce endogenous protein breakdown. Arginine should be given intravenously, both because it is an essential amino acid for patients with urea cycle defects and because it increases the excretion of waste nitrogen in patients with citrullinemia and argininosuccinic acidemia. Sodium benzoate, either alone or with sodium phenylacetate, can be given intravenously to treat hyperammonemic coma.

Long-term treatment includes oral administration of arginine (or citrulline), adherence to a low-protein diet, and administration of sodium benzoate and sodium phenylacetate or sodium phenylbutyrate to increase excretion of nitrogen as hippuric acid and phenylacetylglutamine. Females who are heterozygous for ornithine transcarbamoylase deficiency and who develop hyperammonemia should also receive such treatment. Liver transplantation may improve outcome.

The outcome of argininosuccinic acidemia and citrullinemia is better than that of ornithine transcarbamoylase and carbamoyl phosphate synthetase defi-

ciency. Most patients with urea cycle defects, no matter what the enzyme defect, develop permanent neurologic and intellectual impairments, with cortical atrophy and ventricular dilation seen on CT scan. The prognosis may be improved if the initial hyperammonemic episode is rapidly identified and treated.

PHENYLKETONURIA & THE HYPERPHENYLALANINEMIAS

Probably the best-known disorder of amino acid metabolism is the classic form of phenylketonuria caused by decreased activity of phenylalanine hydroxylase, the enzyme that converts phenylalanine to tyrosine. Phenylketonuria is inherited as an autosomal recessive trait, with an incidence in whites of approximately 1:10,000 live births. On normal phenylalanine intake, affected patients develop hyperphenylalaninemia and produce and excrete phenylpyruvic, phenyllactic, phenylacetic, and 2-hydroxyphenylacetic acid. The patient with untreated phenylketonuria exhibits severe mental retardation, hyperactivity, seizures, a light complexion, and eczema. The patient's urine has a "mouse-like" odor.

Success in preventing severe mental retardation in phenylketonuric children by restricting phenylalanine from the diet starting in early infancy led to screening programs to detect the disease early. Because the outcome is best when treatment is begun in the first month of life, infants should be screened during the first few days. A second test is necessary when newborn screening is done before 24 hours of age, and in such cases the second test should be completed by the third week of life. Infants receiving hyperalimentation and premature infants should be screened at or near 7 days and rescreened if they were transfused or not fed at the time of the initial test.

Enzymes involved with the interconversion of phenylalanine and tyrosine and whose deficiencies can produce hyperphenylalaninemia are shown in Figure 32-1. In classic phenylketonuria, little or no phenylalanine hydroxylase activity is present, but in the less severe hyperphenylalaninemias significant residual activity does occur. Rare variants (also with autosomal recessive inheritance) can be due to deficiency of dihydropterin reductase or to defects in biopterin synthesis.

Prenatal diagnosis of phenylketonuria is possible using DNA probes. Molecular approaches are replacing serum measurements of phenylalanine and tyrosine to determine carrier status. Prenatal diagnosis of defects in pterin metabolism can often be made.

Diagnosis & Treatment

The diagnosis of phenylketonuria in a severely mentally retarded older child with typical biochemical and physi-

Figure 32-1. Oxidation of phenylalanine to tyrosine. 1: Phenylalanine hydroxylase. 2: Dihydropterin reductase. 3: Enzymes of biopterin biosynthesis.

cal characteristics is straightforward, but in the newborn period, especially when there is no family history, the condition must be differentiated from other forms of hyperphenylalaninemia. This is usually done by determining serum phenylalanine and tyrosine levels on a normal diet and by examining pterins in blood and urine.

A. CLASSIC PHENYLKETONURIA

Findings include persistently elevated serum levels of phenylalanine (> 20 mg/dL on a regular diet), normal or low serum levels of tyrosine, urinary excretion of phenylpyruvic and 2-hydroxyphenylacetic acids, and normal pterins. Poor phenylalanine tolerance persists throughout life. Restriction of dietary phenylalanine intake (see Treatment section) is indicated, and a favorable outcome is the rule.

B. PERSISTENT HYPERPHENYLALANINEMIA

In infants receiving a normal protein intake, serum phenylalanine levels are usually 4–20 mg/dL, and pterins are normal. Phenylalanine restriction may or may not be indicated, depending on the patient's phenylalanine tolerance.

C. TRANSIENT HYPERPHENYLALANINEMIA

Serum phenylalanine levels are elevated early but progressively decline toward normal. Dietary restriction is only temporary, if required at all.

D. DIHYDROPTERIDINE REDUCTASE DEFICIENCY

Serum phenylalanine levels vary. The pattern of pterin metabolites is abnormal. Seizures and psychomotor regression occur even with diet therapy, probably because the enzyme defect also causes neuronal deficiency of serotonin and dopamine. These deficiencies require treatment with levodopa, carbidopa, and 5-hydroxytryptophan, and possibly also with tetrahydrobiopterin.

E. DEFECTS IN BIOPTERIN BIOSYNTHESIS

Serum phenylalanine levels vary. Total pterins are low, and their pattern may suggest the specific defect, which can be at one of several steps in the biosynthetic pathway. Clinical findings include myoclonus, tetraplegia, and other movement disorders. Treatment is the same as for dihydropterin reductase deficiency but in general is not as effective.

F. TYROSINEMIA OF THE NEWBORN

Serum phenylalanine levels are lower than those associated with phenylketonuria and are accompanied by marked hypertyrosinemia. Tyrosinemia of the newborn usually occurs in premature infants and is due to immaturity of 4-hydroxyphenylpyruvic acid oxidase. The

condition resolves spontaneously within 3 months, almost always without sequelae. If necessary, oral administration of 50–200 mg ascorbic acid per day for 1–2 weeks will normalize serum tyrosine (and phenylalanine) levels.

G. MATERNAL PHENYLKETONURIA

Offspring of phenylketonuric mothers may have transient hyperphenylalaninemia at birth. Elevated maternal phenylalanine causes mental retardation, microcephaly, growth retardation, and often congenital heart disease or other malformations. The risk to the fetus is lessened considerably if phenylalanine restriction is begun before conception and maintained throughout pregnancy.

Treatment of Classic Phenylketonuria

Treatment of classic phenylketonuria is to limit dietary phenylalanine intake to amounts that permit normal growth and development. Metabolic formulas, deficient in phenylalanine, are available but must be supplemented with normal milk and other foods to supply enough phenylalanine to permit normal growth and development. Serum phenylalanine concentrations must be monitored frequently while ensuring that growth, development, and nutrition are adequate. This monitoring is best done in clinics experienced in dealing with such problems. Although dietary treatment is most effective when initiated during the first months of life, it may also be of benefit in reversing behaviors such as hyperactivity, irritability, and distractibility when started later in life.

Phenylalanine restriction should continue throughout life, both because of subtle changes in intellect and behavior in persons receiving treatment early who later stop the diet and because of the risk of late development of potentially irreversible neurologic damage after stopping the diet. Phenylketonuric females merit special attention during the childbearing years. Counseling should be given during adolescence, and the woman's diet should be monitored closely prior to conception and throughout pregnancy.

Children with classic phenylketonuria who receive treatment promptly after birth and achieve phenylalanine and tyrosine homeostasis will develop well physically and can be expected to have normal or nearly normal intellectual development.

HEREDITARY TYROSINEMIA

Type 1 hereditary tyrosinemia is caused by deficiency of fumarylacetoacetase and is characterized by progressive hepatic parenchymal damage, renal tubular dystrophy with generalized aminoaciduria, hypophosphatemic rickets, hypermethioninemia, and the tyrosine metabolites, succinylacetone, and aminolevulinic acid in the urine. Liver failure may be rapidly fatal in infancy or somewhat more chronic, with liver cell carcinoma almost invariable in long-term survivors. The condition is inherited as an autosomal recessive trait and is especially common in Scandinavia and in the Chicoutimi–Lac St. Jean region of Quebec. Prenatal diagnosis can be established.

Diagnosis

Similar clinical and biochemical findings may occur in galactosemia and hereditary fructose intolerance, but

increased succinylacetone occurs only in fumarylacetoacetase deficiency, and diagnosis is based on demonstrating succinylacetone in urine.

Treatment

A diet low in phenylalanine and tyrosine is indicated but not usually successful in preventing or reversing liver disease. Liver transplantation appears to be the only effective therapy for these children. Pharmacologic therapy to inhibit 4-hydroxyphenylpyruvate dehydrogenase using 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) decreases the production of toxic metabolites maleylacetoacetate and fumarylacetoacetate and improves the hepatic biochemical profile and clinical status. Studies are in progress to determine to what extent the risk of hepatocellular carcinoma is altered.

MAPLE SYRUP URINE DISEASE (Branched-Chain Ketoaciduria)

Maple syrup urine disease is due to deficiency of the enzyme that catalyzes oxidative decarboxylation of the branched-chain keto acid derivatives of leucine, isoleucine, and valine. The accumulated keto acids of leucine and isoleucine cause the characteristic odor, whereas only the keto acid of leucine has been implicated in causing CNS dysfunction. Many variants of this disorder have been described, including mild, intermittent, and thiamin-dependent forms, and all are inherited as autosomal recessive traits.

Patients with classic maple syrup urine disease are normal at birth but soon develop the characteristic odor, lethargy, feeding difficulties, coma, and seizures. Unless diagnosis is made and dietary restriction of branched-chain amino acids is begun, most will die in the first month of life, but nearly normal growth and development may be achieved if treatment is begun before about age 10 days.

Diagnosis

Marked elevations of branched-chain amino acids (including alloisoleucine) in serum and urine are charac-

teristic. Alloisoleucine, a transamination product of the keto acid of isoleucine, is almost pathognomonic. The magnitude and consistency of amino acid and organic acid changes are altered in mild and intermittent forms of the disease. Prenatal diagnosis is possible.

Treatment

Metabolic formulas, deficient in branched-chain amino acids, are available but must be supplemented with normal milk and other foods to supply enough branched-chain amino acids to permit normal growth and development. Serum levels of branched-chain amino acids must be monitored frequently—even at intervals of 1 or 2 days—in the first months of life to deal with changing protein requirements. Acute episodes must be aggressively treated to prevent catabolism and negative nitrogen balance.

HOMOCYSTINURIA

Homocystinuria is most often due to deficiency of cystathionine synthase, but it may also be due to deficiency of methylenetetrahydrofolate reductase (MTHFR) or to defects in the biosynthesis of methyl-B₁₂, which is the coenzyme for N⁵-methyltetrahydrofolate methyltransferase. All known inherited forms of homocystinuria are transmitted as autosomal recessive traits and can be diagnosed in the fetus.

About half of patients with untreated cystathionine synthase deficiency are mentally retarded, and most have arachnodactyly, osteoporosis, and a tendency to develop dislocated lenses and thromboembolic phenomena. Milder elevations of homocystine are increasingly recognized to be a factor in the etiology of vascular disease leading to myocardial infarction and stroke. These mild elevations are often caused by mutations leading to heat-sensitive defects in MTHR. Patients with remethylation defects usually exhibit failure to thrive and a variety of neurologic symptoms, including microcephaly and seizures in infancy and early childhood.

Diagnosis

Diagnosis is made by demonstrating homocystinuria in a patient who is not severely deficient in vitamin B₁₂. Serum methionine levels are usually high in patients with cystathionine synthase deficiency and often low in

patients with remethylation defects. When the remethylation defect is due to deficiency of methyl-B₁₂, megaloblastic anemia may be present, and an associated deficiency of adenosyl-B₁₂ may cause methylmalonic aciduria. Studies of cultured fibroblasts may be necessary to make a specific diagnosis.

Treatment

About 50% of patients with cystathionine synthase deficiency respond to large oral doses of pyridoxine. Early treatment of pyridoxine nonresponders by dietary methionine restriction may prevent mental retardation and delay lens dislocations, perhaps justifying screening of newborn infants for the condition. Oral administration of betaine will increase methylation of homocystine to methionine in patients with remethylation defects and may also improve neurologic function. Large doses of vitamin B₁₂ (eg, 1 mg hydroxocobalamin administered intramuscularly) are indicated in some patients.

NONKETOTIC HYPERGLYCINEMIA

Inherited deficiency of various subunits of the glycine cleavage enzyme causes nonketotic hyperglycinemia. Glycine accumulation in the brain is thought to cause excessive stimulation of the *N*-methyl-D-aspartate (NMDA) receptor. In its most severe form, also termed glycine encephalopathy, the condition manifests in the newborn period as unremitting seizures, hypotonia, hiccups, a burst suppression pattern on electroencephalography, and (usually) death in infancy. Some patients with this disorder present with seizures later in infancy or with developmental delay in childhood. All forms of the condition are inherited as autosomal recessive traits.

Diagnosis

Nonketotic hyperglycinemia should be suspected in any infant with intractable seizures, especially when

hiccupping, and is confirmed by demonstrating a large increase in glycine in CSF, with the ratio of CSF glycine to serum glycine being abnormally high. Demonstration of the specific enzyme defect by liver biopsy is necessary only if the parents are contemplating having more children, because prenatal diagnosis is possible only by assaying the enzyme in chorionic villus samples.

Treatment

Treatment is generally unsuccessful. Early efforts to use sodium benzoate therapy were thought to be without effect on long-term outcome, but recent studies suggest that this drug may be useful in seizure control. Dextromethorphan has also been advocated in the treatment of nonketotic hyperglycinemia with some evidence of improved seizure control and improved developmental progress.

ORGANIC ACIDEMIAS

Organic acidemias are disorders of amino and fatty acid metabolism in which nonamino organic acids accumulate in serum and urine. These conditions are usually diagnosed by examining organic acids in urine, a complex procedure that requires considerable interpretive expertise and is usually performed only in specialized laboratories. Table 32-4 lists the clinical features of organic acidemias, together with the urine organic acid patterns typical of each. Additional details about some of the more important organic acidemias are provided in the sections that follow.

KETOTIC HYPERGLYCINEMIAS (Propionic & Methylmalonic Acidemia)

Idiopathic hyperglycinemia was first reported in 1961 as a syndrome of mental retardation and episodic ketoacidosis, neutropenia, thrombocytopenia, osteoporosis, and hyperglycinemia induced by protein intake or infection. It was then renamed ketotic hyperglycinemia to distinguish it from nonketotic hyperglycinemia,

Table 32–4. Clinical and laboratory features of organic acidemias.

Disorder	Enzyme Defect	Clinical and Laboratory Features
Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Acidosis and odor of sweaty feet in infancy, or growth retardation and episodes of vomiting, lethargy, acidosis, and odor. Isovalerylglycine always present in urine, with 3-hydroxyisovaleric acid during acute episodes.
3-Methylcrotonyl-CoA carboxylase deficiency	3-Methylcrotonyl-CoA carboxylase	Acidosis and feeding problems in infancy, or Reye-like episodes in older child. 3-Methylcrotonylglycine in urine, usually with 3-hydroxyisovaleric acid.
Combined carboxylase deficiency	Holocarboxylase synthetase	Hypotonia and lactic acidosis in infancy. 3-Hydroxyisovaleric acid in urine, often with small amounts of 3-hydroxypropionic and methylcitric acids. Often biotin-responsive.
	Biotinidase	Alopecia, seborrheic rash, and ataxia in infancy or childhood. Urine organic acids as above. Usually biotin-responsive.
3-Hydroxy-3-methylglutaric acidemia	Hydroxymethylglutaryl-CoA lyase	Hypoglycemia and acidosis in infancy; Reye-like episodes with non-ketotic hypoglycemia in older children. 3-Hydroxy-3-methylglutaric, 3-methylglutaconic, and 3-hydroxyisovaleric acids in urine.
3-Ketothiolase deficiency	3-Ketothiolase	Ketotic hyperglycinemia syndrome in infancy, or developmental and growth retardation with episodes of vomiting, acidosis, and encephalopathy. 2-Methyl-3-hydroxybutyric and 2-methylacetoacetic acids and tiglylglycine in urine, especially after isoleucine load.
Propionic acidemia	Propionyl-CoA carboxylase	Hyperammonemia and metabolic acidosis in infancy; ketotic hyperglycinemia syndrome later. 3-Hydroxypropionic and methylcitric acids in urine, with 3-hydroxy- and 3-ketovaleric acids during ketotic episodes.
Methylmalonic acidemia	Methylmalonyl-CoA mutase	Clinical features same as in propionic acidemia. Methylmalonic acid in urine, often with 3-hydroxypropionic and methylcitric acids.
	Defects in B ₁₂ biosynthesis	Clinical features same as above when only adenosyl-B ₁₂ synthesis is decreased: early neurologic features prominent when accompanied by decreased synthesis of methyl-B ₁₂ . In latter instance, hypomethioninemia and homocystinuria accompany methylmalonic aciduria.
Pyroglutamic acidemia	Glutathione synthetase	Acidosis and hemolytic anemia in infancy; chronic acidosis later. Pyroglutamic acid in urine.
Glutaric acidemia type I	Glutaryl-CoA dehydrogenase	Progressive extrapyramidal movement disorder in childhood, with episodes of acidosis, vomiting, and encephalopathy. Glutaric acid in urine, usually with 3-hydroxyglutaric acid.
Glutaric acidemia type II	Electron transfer flavoprotein (ETF) ETF:ubiquinone oxidoreductase (ETF dehydrogenase)	Hypoglycemia, acidosis, hyperammonemia, and odor of sweaty feet in infancy, often with polycystic and dysplastic kidneys. Later onset may be with episodes of hypoketotic hypoglycemia or slowly progressive skeletal myopathy. Glutaric, ethylmalonic, 3-hydroxyisovaleric, isovalerylglycine, and 2-hydroxyglutaric acids in urine, often with sarcosine in serum and urine.
4-Hydroxybutyric acidemia	Succinic semialdehyde dehydrogenase	Seizures and developmental retardation. 4-Hydroxybutyric acid in urine.

CoA = coenzyme A.

described in the preceding section. It is now known that the syndrome is almost always due to propionic or methylmalonic acidemia.

The oxidation of threonine, valine, methionine, and isoleucine through propionyl- and L-methylmalonyl-CoA is diagrammed in Figure 32-2. Propionic acidemia is due to a defect in the biotin-containing enzyme propionyl-CoA carboxylase, and methylmalonic acidemia is due to a defect in methylmalonyl-CoA mutase. In most cases the latter is due to a defect in the mutase apoenzyme, but in others it is due to a defect in the biosynthesis of its adenosyl-B₁₂ coenzyme. In some of these defects, only the synthesis of adenosyl-B₁₂ is blocked; in others, the synthesis of methyl-B₁₂ is also blocked.

Clinical symptoms in propionic and methylmalonic acidemia vary according to the location and severity of the enzyme block. Children with severe blocks present with acute, life-threatening metabolic acidemia and hyperammonemia early in infancy or with metabolic acidemia, vomiting, and failure to thrive during the first few months of life. Children with less severe blocks may present later with only mild or moderate mental retardation.

All known forms of propionic and methylmalonic acidemia are transmitted as autosomal recessive traits and can be diagnosed in utero.

Diagnosis

Laboratory findings include hyperglycinemia and hyperglycinuria, increases in certain urinary organic acids (see Table 32-4), and, in some forms of abnormal B₁₂ metabolism, hypomethioninemic homocystinuria.

Treatment

Patients with enzyme blocks in B₁₂ metabolism usually respond to massive doses of vitamin B₁₂ given intramuscularly, whereas nonresponders require amino acid restriction and correction of their rather constant metabolic acidemia. Secondary carnitine deficiency has been reported, and blood carnitine should be measured and

supplemented if required. Liver transplantation may improve outcome.

www.oaane.org

ISOVALERIC ACIDEMIA

Isovaleric acidemia, due to deficiency of isovaleryl-CoA dehydrogenase in the leucine oxidative pathway, was the first organic acidemia to be described in humans. Patients with this disorder usually present with poor feeding, metabolic acidosis, seizures, and an odor of sweaty feet during the first few days of life, with coma and death occurring if the condition is not recognized and appropriate therapy started quickly. Other patients show a more chronic course, with episodes of vomiting, lethargy, and urine (and body) odor precipitated by intercurrent infections or increased protein intake. The condition is inherited as an autosomal recessive trait and can be diagnosed in utero.

Diagnosis

Isovaleric acidemia and glutaric acidemia type II are the only conditions in which the characteristic odor of sweaty feet occurs. Isovalerylglycine is consistently detected in the urine by organic acid chromatography.

Treatment

Providing a low-protein diet or diets low in leucine or all three branched-chain amino acids is effective. Oral administration of glycine appears to prevent complications during acute infections but poses a risk of neuro-

Figure 32-2. Oxidation of propionyl-CoA to succinyl-CoA. **1:** Propionyl-CoA carboxylase. **2:** Methylmalonyl-CoA mutase.

toxicity due to severe hyperglycinemia. Oral administration of L-carnitine may also be indicated.

COMBINED CARBOXYLASE DEFICIENCY

Holocarboxylase synthetase and biotinidase are two enzymes of biotin metabolism in mammals. Holocarboxylase synthetase covalently binds biotin to the apocarboxylases for pyruvate, 3-methylcrotonyl-CoA, and propionyl-CoA; and biotinidase releases biotin from these proteins and from proteins in the diet. Recessively inherited deficiency of either enzyme causes deficiency of all three carboxylases (ie, multiple carboxylase deficiency). Patients with holocarboxylase synthetase deficiency usually present in the neonatal period with hypotonia; those with biotinidase deficiency more often present somewhat later with a syndrome of ataxia, seborrhea, and alopecia. Because many patients with biotinidase deficiency do not have typical symptoms but do develop neurologic sequelae, newborn screening for the condition is justified.

Diagnosis

This diagnosis should be considered in patients with typical symptoms or in those with primary lactic acidosis. Urine organic acids are usually but not always abnormal (see Table 32-4). Diagnosis is usually by enzyme assay. Biotinidase can be assayed in serum; holocarboxylase synthetase, in leukocytes or fibroblasts.

Treatment

Oral administration of biotin in large doses often reverses the organic aciduria within days and the clinical symptoms within days to weeks. The incidence of hearing loss is high even in patients receiving treatment.

GLUTARIC ACIDEMIA TYPE I

Glutaric acidemia type I is due to deficiency of glutaryl-CoA dehydrogenase and causes a progressive extrapyramidal movement disorder in childhood, with dystonia and athetosis and neuronal degeneration in the caudate and putamen. Macrocephaly at birth is common. Death often occurs during the first decade, but the clinical course is highly variable, and several patients have had only mild neurologic abnormalities. Children with glutaric acidemia type I may present with retinal hemorrhages and intracranial bleeding, strongly resembling shaken baby syndrome. The condition is inherited as an autosomal recessive trait and prenatal diagnosis is possible.

Diagnosis

Glutaric acidemia type I should be suspected in any patient with progressive dystonia or athetosis. The diagnosis is supported by demonstration of glutaric and 3-hydroxyglutaric acids in urine by organic acid analysis. Deficiency of glutaryl-CoA dehydrogenase can be demonstrated in fibroblasts, leukocytes, and, for prenatal diagnosis, amniotic cells.

Treatment

Restriction of dietary lysine and tryptophan is indicated, but neurologic symptoms, once present, may not resolve. A variety of drugs that alter neurotransmitter levels, especially those of γ -aminobutyric acid, may be used to control dystonia. Studies suggest that early dietary treatment and aggressive management of intercurrent illness may prevent neurologic deterioration in some patients.

DISORDERS OF FATTY ACID OXIDATION & CARNITINE

FATTY ACID OXIDATION DISORDERS

Deficiencies of very-long-chain and medium-chain acyl-CoA dehydrogenase (VLCAD, MCAD) and long-

chain hydroxyacyl-CoA dehydrogenase (LCHAD), three enzymes of fatty acid β -oxidation, usually cause Reye-like episodes of hypoketotic hypoglycemia, mild hyperammonemia, hepatomegaly and encephalopathy, or, less often, sudden death in infancy. The long- and medium-chain defects can usually be distinguished clinically; the long-chain defects often cause early severe hypotonia and cardiomyopathy. MCAD deficiency is common, occurring in perhaps 1:9000 live births, and recent studies suggest that LCHAD deficiency may also be common. Although Reye-like episodes may be fatal, they tend to become less frequent and severe with time, and prolonged survival is typical of MCAD deficiency, with few deaths after diagnosis is made and treatment instituted. In VLCAD and LCHAD deficiencies, cardiomyopathy is the direct result of the defect in the oxidation of long-chain fatty acids, and progressive liver disease and renal tubular acidosis may also be present.

Short-chain acyl-CoA dehydrogenase (SCAD) deficiency is characterized by the presence of ethylmalonic acid in the urine, and although some patients have symptoms similar to those seen in MCAD deficiency, many remain asymptomatic. Glutaric acidemia type II results from defects in the transfer of electrons from fatty acid oxidation and some amino acid oxidation into the respiratory chain. Some patients with glutaric acidemia type II have a clinical presentation resembling MCAD deficiency. Other patients with glutaric acidemia type II, especially those with severe neonatal presentation, also have renal cystic disease and dysmorphic features.

These conditions are inherited as autosomal recessive traits. LCHAD deficiency is an example of a condition in which a heterozygous individual may manifest symptoms of disease. The pregnancies of mothers with LCHAD-deficient fetuses may be complicated by acute fatty liver of pregnancy (AFLP) or HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome.

Diagnosis

Suspicion should be increased by the lack of an appropriate ketone response to fasting. Patients with MCAD deficiency may excrete phenylpropionylglycine and hexanoylglycine in the urine and have increased octanoylcarnitine in blood; urine and blood findings in glutaric acidemia type II and SCAD deficiency are often diagnostic, but are highly variable in VLCAD and LCHAD deficiencies. A common mutation has been found in MCAD deficiency, which may be useful in confirming the diagnosis; a common mutation in LCHAD deficiency may be similarly used. Assays of MCAD activity in fibroblasts are necessary only when typical biochemistry is not found. Fibroblast studies may be required for diagnosis of VLCAD, LCHAD, or

SCAD deficiencies. The finding of normal urine organic acids does not exclude these conditions, because excretion of dicarboxylic acids and other products of microsomal and peroxisomal oxidation of fatty acids can be intermittent.

Treatment

Acute management is directed toward preventing or reversing catabolism and hypoglycemia. Long-term measures include providing carbohydrate snacks before bedtime and vigorous treatment of intercurrent infections. Because cardiomyopathy and muscle weakness in MCAD deficiency may be due to secondary carnitine deficiency, oral administration of carnitine is typically prescribed; carnitine use in VLCAD and LCHAD is controversial. Restriction of dietary long-chain fats is controversial in MCAD deficiency, but is required for VLCAD and LCHAD deficiencies. Medium-chain triglycerides are contraindicated in MCAD deficiency because they may cause serum octanoic acid to rise to neurotoxic concentrations, but are an essential energy source for patients with VLCAD and LCHAD deficiencies. Riboflavin may be very beneficial in some patients with glutaric acidemia type II.

CARNITINE

Carnitine is an essential nutrient found in highest concentrations in red meats. Its primary function is to transport long-chain fatty acids into mitochondria for oxidation. Primary defects of carnitine biosynthesis and transport (related to defects of carnitine palmitoyl transport protein I or II, or carnitine translocase) may manifest as Reye syndrome, myoglobinuria, hypotonia, or cardiomyopathy. These disorders are exceedingly rare compared with secondary carnitine deficiency or insufficiency, which may be due to diet (especially intravenous alimentation), renal losses, drug therapy (especially valproic acid), and other metabolic disorders (especially disorders of fatty acid oxidation and organic acidemias). The prognosis depends on the cause of the carnitine abnormality.

Carnitine can be measured in blood. Unless the purpose is solely to monitor dietary deficiency, amounts of free and esterified carnitine should be determined. In some situations, muscle carnitine may be low despite normal blood levels. Free and esterified carnitine also can be measured in urine, and specialized laboratories can identify the specific ester present. If carnitine insufficiency is suspected, the patient should be evaluated to rule out disorders that might cause secondary carnitine deficiency.

Oral levocarnitine is used in carnitine deficiency or insufficiency in doses of 25–100 mg/kg/d or higher. Levocarnitine may be added to intravenous alimentation solutions, and high-dose intravenous levocarnitine is available. Treatment is aimed at maintaining normal free carnitine levels. Carnitine supplementation in patients with some disorders of fatty acid oxidation and organic acidosis may also augment excretion of accumulated metabolites in addition to ameliorating carnitine insufficiency. Supplementation may not prevent metabolic crises in such patients, however, even when serum carnitine has been normalized.

HYPOXANTHINE–GUANINE PHOSPHORIBOSYLTRANSFERASE DEFICIENCY (Lesch–Nyhan Syndrome)

Hypoxanthine–guanine phosphoribosyltransferase (HPRT) is the enzyme that converts the purine bases hypoxanthine and guanine to inosine monophosphate (IMP) and guanosine monophosphate (GMP), respectively. The X-linked recessive disorder with complete deficiency is characterized by CNS dysfunction and purine overproduction with hyperuricemia and hyperuricuria. Depending on the residual activity of the mutant enzyme, male hemizygous individuals may be severely disabled and show choreoathetosis, spasticity, and compulsive, mutilating lip and finger biting, or they may present with only gouty arthritis and urate urolithiasis. The enzyme deficiency can be demonstrated in erythrocytes, fibroblasts, and cultured amniotic cells; this disorder can thus be diagnosed in utero.

Although the cause of the CNS dysfunction in Lesch–Nyhan syndrome remains obscure, the absent or less severe CNS manifestations of purine nucleoside phosphorylase deficiency suggest that the problem relates to accumulation of substrate behind the block.

Diagnosis

Diagnosis is made by demonstrating an elevated uric acid:creatinine ratio in urine, followed by demonstration of enzyme deficiency in red blood cells or fibroblasts.

Treatment

Allopurinol and probenecid may be given to reduce hyperuricemia but do not affect the neurologic status. Insertion of the HPRT gene into cultured cells from affected patients and into experimental animals has been effective, and such experiments offer promise as models for human gene therapy in the future.

■ LYSOSOMAL DISEASES

Lysosomes are cellular organelles in which complex macromolecules are degraded by specific acid hydrolases. Deficiency of a lysosomal enzyme causes its substrate to accumulate in lysosomes of tissues that degrade it, creating a characteristic clinical picture. These so-called storage disorders are classified as mucopolysaccharidoses, lipidoses, or mucolipidoses depending on the nature of the stored material. Two additional disorders, cystinosis and Salla disease, are caused by defects in lysosomal proteins that normally transport material from the lysosome to the cytoplasm. Table 32–5 lists clinical and laboratory features of these conditions. Most are inherited as autosomal recessive traits, and all can be diagnosed in utero.

The diagnosis of mucopolysaccharidosis is suggested by certain clinical and radiologic findings and urine screening tests. Further tests are needed to determine which mucopolysaccharides are present. Diagnosis should be confirmed by enzyme assays of cultured fibroblasts or leukocytes; this is especially important when the parents are contemplating having more children.

When a lipidosis or mucolipidosis is suspected, diagnosis is made by appropriate enzyme assays of biopsy specimens, cultured skin fibroblasts, and peripheral leukocytes.

Most of these conditions cannot be treated effectively, although increasing evidence indicates that hematopoietic stem cell transplantation may affect the course of some lysosomal diseases. Gaucher disease is treated effectively with infusions of natural enzyme modified to allow uptake of the enzyme by lysosomes. Enzyme replacement products have been developed to treat other lysosomal storage disorders, such as Pompe disease, Fabry disease, and several mucopolysaccharidoses, but data on long-term efficacy is not yet available.

■ PEROXISOMAL DISEASES

Peroxisomes are intracellular organelles that contain a large number of enzymes, many of which are oxidases linked to catalase or peroxidase. Among the enzyme systems in peroxisomes is one for β -oxidation of very-long-chain fatty acids (which is analogous in many ways to the system for fatty acid oxidation in mitochondria) and another for plasmalogen biosynthesis. In addition, peroxisomes contain oxidases for D- and L-amino acids, pipercolic acid and phytanic acid, and an enzyme (alanine-glyoxylate aminotransferase) that effects transamination of glyoxylate to glycine.

In some peroxisomal diseases, many enzymes are deficient. Zellweger (cerebrohepato-renal) syndrome, the best known among these, can be caused by several defects in organelle assembly. Patients present in infancy with seizures, hypotonia, characteristic facies with a large forehead, and hepatomegaly; at autopsy renal cysts and absent peroxisomes are found. Neonatal adrenoleukodystrophy and hyperpipercolic acidemia have similar clinical and laboratory findings and multiple enzyme deficiencies in cultured fibroblasts, but peroxisomes are usually detected in tissues.

In other peroxisomal diseases, only a single enzyme is deficient. Primary hyperoxaluria (alanine-glyoxylate aminotransferase deficiency), X-linked adrenoleukodystrophy and adrenomyeloneuropathy (very-long-chain acyl-CoA ligase deficiency), and adult Refsum disease (phytanic acid oxidase deficiency) are disorders caused by deficiency of single peroxisomal enzymes.

Except for childhood adrenoleukodystrophy, which is X-linked, all peroxisomal diseases are transmitted as autosomal recessive traits and can be diagnosed in

Table 32–5. Clinical and laboratory features of lysosomal storage diseases.

Disorder	Enzyme Defect	Clinical and Laboratory Features
I. Mucopolysaccharidoses		
Hurler syndrome	α -Iduronidase	Autosomal-recessive. Mental retardation, hepatosplenomegaly, umbilical hernia, coarse facies, corneal clouding, dorsolumbar gibbus, severe heart disease. Heparan sulfate and dermatan sulfate in urine.
Scheie syndrome	α -Iduronidase (incomplete)	Autosomal-recessive. Corneal clouding, stiff joints, normal intellect. Clinical types intermediate between Hurler and Scheie common. Heparan sulfate and dermatan sulfate in urine.
Hunter syndrome	Sulfoiduronate sulfatase	X-linked recessive. Coarse facies, hepatosplenomegaly, mental retardation variable. Corneal clouding and gibbus not present. Heparan sulfate and dermatan sulfate in urine.
Sanfilippo syndrome: Type A Type B Type C Type D	Sulfamidase α -N-Acetylglucosaminidase Acetyl-CoA: α -glucosaminide-N-acetyltransferase α -N-acetylglucosamine-6-sulfatase	Autosomal-recessive. Severe mental retardation with comparatively mild skeletal changes, visceromegaly, and facial coarseness. Types cannot be differentiated clinically. Heparan sulfate in urine.
Morquio syndrome	N-Acetylgalactosamine-6-sulfatase	Autosomal-recessive. Severe skeletal changes, platyspondylisis, corneal clouding. Keratan sulfate in urine.
Maroteaux–Lamy syndrome	N-Acetylgalactosamine-4-sulfatase	Autosomal-recessive. Coarse facies, growth retardation, dorsolumbar gibbus, corneal clouding, hepatosplenomegaly, normal intellect. Dermatan sulfate in urine.
β -Glucuronidase deficiency	β -Glucuronidase	Autosomal-recessive. Varies from mental retardation, dorsolumbar gibbus, corneal clouding, and hepatosplenomegaly to mild facial coarseness, retardation, and loose joints. Hearing loss common. Dermatan sulfate or heparan sulfate in urine.
II. Mucopolipidoses		
Mannosidosis	α -Mannosidase	Autosomal-recessive. Varies from severe mental retardation, coarse facies, short stature, skeletal changes, and hepatosplenomegaly to mild facial coarseness and loose joints. Hearing loss common. Abnormal oligosaccharides in urine.
Fucosidosis	α -Fucosidase	Autosomal-recessive. Variable: coarse facies, skeletal changes, hepatosplenomegaly, occasional angiokeratoma corporis diffusum. Abnormal oligosaccharides in urine.
I-cell disease (mucopolipidosis II)	N-Acetylglucosaminyl-phosphotransferase	Autosomal-recessive; severe and mild forms known. Very short stature, mental retardation, early facial coarsening, clear cornea, stiffness of joints. Increased lysosomal enzymes in serum. Abnormal sialyl oligosaccharides in urine.
Sialidosis	N-Acetylneuraminidase (sialidase)	Autosomal-recessive. Mental retardation, coarse facies, skeletal dysplasia, myoclonic seizures, macular cherry-red spot. Abnormal sialyl oligosaccharides in urine.

(continued)

Table 32–5. Clinical and laboratory features of lysosomal storage diseases. (continued)

Disorder	Enzyme Defect	Clinical and Laboratory Features
III. Lipidoses		
Niemann–Pick disease	Sphingomyelinase	Autosomal recessive. Acute and chronic forms known. Acute neuronopathic form common in eastern European Jews. Accumulation of sphingomyelin in lysosomes of RE system and CNS. Hepatosplenomegaly, developmental retardation, macular cherry-red spot. Death by 1–4 y.
Metachromatic leuko-dystrophy	Arylsulfatase A	Autosomal recessive. Late infantile form, with onset at 1–4 y, most common. Accumulation of sulfatide in white matter. Gait disturbances (ataxia), motor incoordination, and dementia. Death usually in first decade.
Krabbe disease (globoid cell leukodystrophy)	Galactocerebrosidase β -galactosidase	Autosomal recessive. Globoid cells in white matter. Onset at 3–6 mos with seizures, irritability, and retardation. Death by 1–2 y. Juvenile and adult forms are rare.
Fabry disease	α -Galactosidase A	X-linked recessive. Storage of trihexosylceramide in endothelial cells. Pain in extremities, angiokeratoma corporis diffusum and (later) poor vision, hypertension, and renal failure.
Farber disease	Ceramidase	Autosomal recessive. Storage of ceramide in tissues. Subcutaneous nodules, arthropathy with deformed and painful joints, and poor growth and development. Death within first year.
Gaucher disease	Glucocerebrosidase β -glucosidase	Autosomal recessive. Acute neuronopathic form: Accumulation of glucocerebrosidase in lysosomes of RE system and CNS. Retardation, hepatosplenomegaly, macular cherry-red spot, and Gaucher cells in bone marrow. Death by 1–2 y. Chronic form common in eastern European Jews. Accumulation of sphingomyelin in lysosomes of RE system. Hepatosplenomegaly and flask-shaped osteolytic bone lesions. Consistent with normal life expectancy.
G_{M1} gangliosidosis	G_{M1} ganglioside β -galactosidase	Autosomal recessive. Accumulation of G_{M1} ganglioside in lysosomes of RE system and CNS. Infantile form: Abnormalities at birth with dysostosis multiplex, hepatosplenomegaly, macular cherry-red spot, and death by 2 years. Juvenile form: Normal development to 1 year of age, then ataxia, weakness, dementia, and death by 4–5 y. Occasional inferior beaking of vertebral bodies of L1 and L2.
G_{M2} gangliosidosis Tay–Sachs disease Sandhoff disease	β -N-Acetylhexos-aminidase A β -N-Acetylhexos-aminidase A & B	Autosomal recessive. Tay–Sachs disease common in eastern European Jews; Sandhoff disease is panethnic. Clinical phenotypes are identical, with accumulation of G_{M2} ganglioside in lysosomes of CNS. Onset at age 3–6 months, with hypotonia, hyperacusis, retardation, and macular cherry-red spot. Death by 2–3 years. Juvenile and adult onset forms of Tay–Sachs disease are rare.
Wolman disease	Acid lipase	Autosomal recessive. Accumulation of cholesterol esters and triglycerides in lysosomes of reticuloendothelial system. Onset in infancy with gastrointestinal symptoms and hepatosplenomegaly, and death by 3–6 mos. Adrenals commonly enlarged and calcified.

CNS = central nervous system.

utero. Bone marrow transplantation may be effective treatment for some patients with adrenoleukodystrophy. Dietary treatment may have some promise for female carriers of X-linked adrenomyeloneuropathy, and diet therapy is being attempted in other peroxisomal disorders.

Diagnosis

The best screening test for Zellweger syndrome, hyper-pipelic acidemia, X-linked adrenoleukodystrophy, neonatal adrenoleukodystrophy, and infantile Refsum disease is determination of very-long-chain fatty acids in serum or plasma; the levels of these acids are increased in all of these conditions. Urine bile acids are abnormal in other peroxisomal disorders; together, these studies identify most peroxisomal diseases. Tissue biopsy and appropriate enzyme assays are needed for confirmation, especially when the parents plan further pregnancies.

■ CARBOHYDRATE-DEFICIENT GLYCOPROTEIN SYNDROMES

A variety of proteins, including many enzymes, require glycosylation with various carbohydrate moieties for normal function. The carbohydrate-deficient glycoprotein syndromes are a family of disorders that result from failures of glycosylation. Children with type I disease usually present with prenatal growth disturbance, often with abnormal fat distribution, cerebellar hypoplasia, typical facial dysmorphic features, and mental retardation. The typical course is remarkable for chronic liver

disease, peripheral neuropathy, endocrinopathies, retinopathy, and, in some patients, acute life-threatening events. Biochemical differences and variations in clinical course (eg, the absence of peripheral neuropathy) characterize the other types. Pathophysiology probably relates to defects of those biochemical pathways that require glycosylated proteins. The syndromes appear so far to be inherited in an autosomal recessive manner, and frequency was initially estimated to be as high as 1:20,000 in northern Europe.

Diagnosis

Diagnosis is supported by finding altered levels of glycosylated enzymes or other proteins such as transferrin, thyroxine-binding globulin, lysosomal enzymes, and clotting factors, but these levels may be normal in carbohydrate-deficient glycoprotein syndromes or altered in other conditions. Diagnosis is confirmed by demonstration of typical patterns of altered isoelectric focusing of selected proteins, with most diagnostic laboratories examining serum transferrin. Some patients with type I carbohydrate-deficient glycoprotein syndrome may exhibit deficient activity of phosphomannomutase in fibroblasts.

Treatment

Treatment is supportive, with opportunity to monitor and provide early treatment for expected clinical features. Mannose supplementation has been beneficial in the treatment of patients with type 1b deficiency.

■ SMITH-LEMLI-OPITZ SYNDROME AND DISORDERS OF CHOLESTEROL SYNTHESIS

Several defects of cholesterol synthesis are associated with malformations and neurodevelopmental disability. For example, Smith-Lemli-Opitz (SLO) syndrome is

an autosomal recessive disorder caused by a deficiency of the enzyme 7-dehydrocholesterol Δ^7 -reductase and is characterized by microcephaly, poor growth, mental retardation, typical dysmorphic features of face and extremities, and frequent malformations of the heart and genitourinary system. Severity ranges from survival with moderate to severe mental retardation to early death. Although deficient synthesis of cholesterol leads directly to deficiency of some hormones and bile acids, the pathophysiology of the malformations remains unclear. Frequency is estimated to be between 1:40,000 and 1:20,000.

Diagnosis

Presence of abnormal cholesterol metabolites leads to diagnosis. In SLO, elevated 7- and 8-dehydrocholesterol in serum or other tissues, including amniotic fluid, is diagnostic. Serum cholesterol levels may be low, but may be in the normal range. Enzymes of cholesterol synthesis may be assayed in cultured fibroblasts or amniocytes.

Treatment

Although postnatal treatment does not resolve prenatal injury, supplementation with cholesterol in SLO improves growth and behavior. The role of supplemental bile acids is controversial.

DISORDERS OF NEUROTRANSMITTER METABOLISM

Abnormalities of neurotransmitter metabolism are increasingly recognized as causes of significant neurodevelopmental disabilities, including in patients presenting with movement disorders (especially dystonia), seizures, abnormal tone, or mental retardation. Presentation ranges from mild (eg, adult onset dopa-responsive dystonia) to severe (eg, intractable seizures with profound mental retardation). In the most severe examples, the newborn has brain dysgenesis as a result of neurotransmitter deficiency in utero.

Diagnosis

Although some disorders can be diagnosed by examining amino acids or neurotransmitter metabolites in blood or urine, in most cases, diagnosis requires analysis of CSF. Spinal fluid samples for neurotransmitter analysis require special collection and handling as the neurotransmitter levels are graduated along the axis of the CNS and are highly unstable once the sample is collected.

Treatment

For some conditions, such as pyridoxine-responsive seizures or dopa-responsive dystonia, response to treatment can be dramatic. For others, response to therapy is less satisfactory, likely, in part, because of poor penetration of the blood–brain barrier.

Genetics is a postmodern science, the applications of which are critical to all stages of life and to all manner of diseases. Many new technologies in molecular biology and biochemistry are allowing better understanding of the mechanisms inherent in genetic disorders and have led to new and better diagnostic tests and management options. However, some of these technologies and terms are unfamiliar to the clinician in practice. To best cover this complex and varied subject, this chapter contains two major parts. The first part serves as an introductory key, which reviews the basic principles of genetics. It starts from foundations of genetic diagnosis, and outlines basic knowledge of cytogenetics and molecular biology. It is then followed by a review of the principles of inherited human disorders, including different causes of genetic disorders, and finally a discussion of dysmorphology and teratology. The second part introduces common clinical disorders and includes descriptions of the diseases, with discussion of pathogenesis, diagnosis, and management.

■ PRINCIPLES OF GENETICS

FOUNDATIONS OF GENETIC DIAGNOSIS

CYTOGENETICS

Cytogenetics is the study of genetics at the chromosome level. Chromosomal anomalies occur in 0.4% of all live births and are a prevalent cause of mental retardation and congenital anomalies or birth defects. The prevalence of chromosomal anomalies is much higher among spontaneous abortions and stillbirths.

Chromosomes

Human chromosomes consist of DNA (the blueprint of genetic material), specific proteins forming the backbone of the chromosome (called histones), and other chromatin structural and interactive proteins. Chromosomes contain most of the genetic information necessary for growth and differentiation. The nuclei of all normal human cells, with the exception of gametes, contain 46 chromosomes, consisting of 23 pairs (Figure

33–1). Of these, 22 pairs are called autosomes. They are numbered according to their size; chromosome 1 is the largest and chromosome 22 the smallest. In addition, there are two sex chromosomes: two X chromosomes in females and one X and one Y chromosome in males. The two members of a chromosome pair are called homologous chromosomes. One homolog of each chromosome pair is maternal in origin (from the egg); the second is paternal (from the sperm). The egg and sperm each contain 23 chromosomes (haploid cells). During formation of the zygote, they fuse into a cell with 46 chromosomes (diploid cell).

Cell Division

Cells undergo cycles of growth and division that are controlled according to their needs and functions.

Mitosis is a kind of cell division, occurring in stages, during which DNA replication takes place and two daughter cells, genetically identical to the original parent cells, are formed. This cell division is typical for all somatic cells (cells other than the sperm or egg, which are called germline cells). There are four phases of mitosis: interphase, prophase, metaphase, and anaphase (Figure 33–2). In interphase, chromosomes are long, thin, and nonvisible. At this time, the genetic material is replicated. In prophase, the chromosomes are more condensed. During metaphase (the phase following DNA replication but preceding cell division), individual chromosomes can be visualized. Each arm consists of two identical parts, called chromatids. Chromatids of the same chromosome are called sister chromatids. In anaphase, the genetic material is separated into two cells.

Meiosis (Figure 33–3), during which eggs and sperm are formed, is cell division limited to gametes. During meiosis, three unique processes take place:

1. Crossing over of genetic material between two homologous chromosomes. This is preceded by the pairing of both members of each chromosome pair, which facilitates the physical exchange of homologous genetic material.
2. Random assortment of maternally and paternally derived homologous chromosomes into the daughter cells. The distribution of maternal or paternal chromosomes to a particular daughter cell occurs independently in each cell.

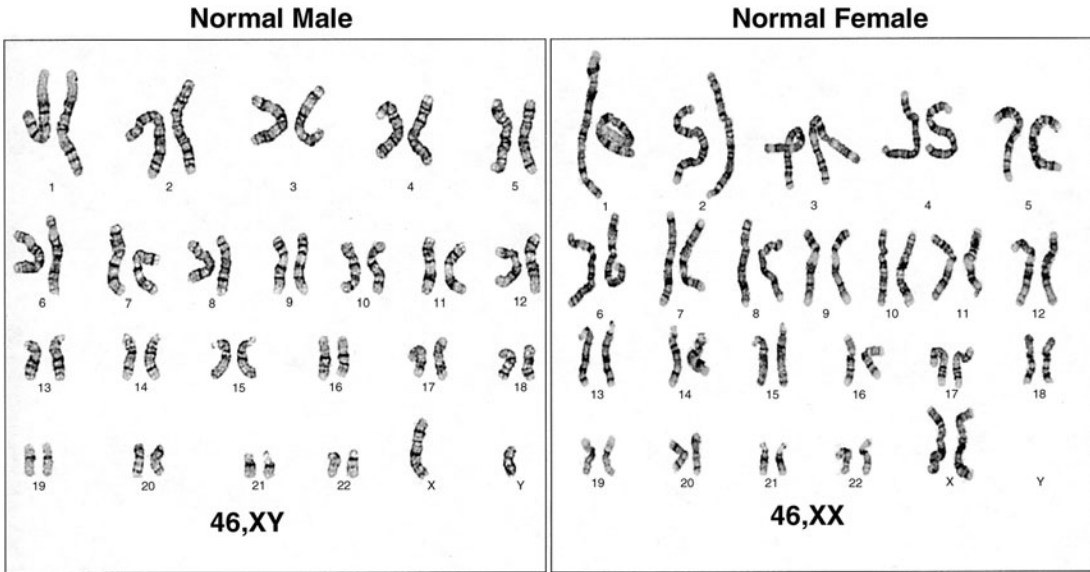

Figure 33-1. Normal male and female human karyotype. (Courtesy of Billie Carstens at CGL.)

- Two cell divisions, the first of which is a reduction division—that is, separation between the homologous chromosomes. The second meiotic division is like mitosis, separating two sister chromatids into two genetically identical daughter cells.

Other tissues used for this purpose include skin, products of conception, cartilage, and bone marrow. Chorionic villi or amniocytes are used for prenatal diagnosis. Spontaneously dividing cells without a mitogen are present in bone marrow, and historically, bone marrow biopsy was done when immediate identification of a pa-

Chromosome Preparation & Analysis

Chromosome structure is visible only during mitosis, most often achieved in the laboratory by stimulating a blood lymphocyte culture with a mitogen for 3 days.

Figure 33-2. Stages of the mitotic cycle.

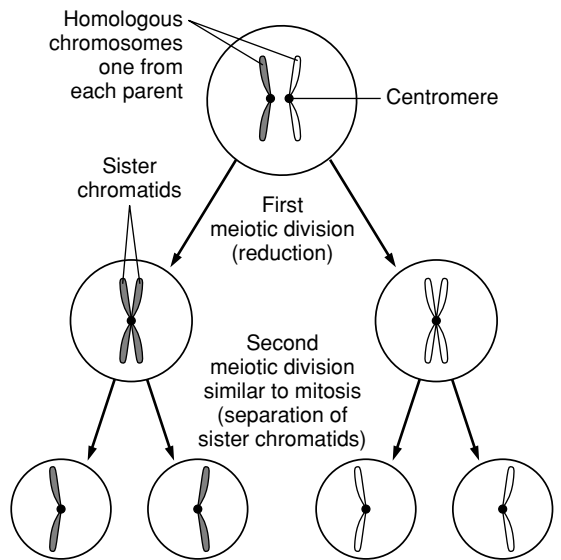

Figure 33-3. Meiosis—demonstrating conversion from the diploid somatic cell to the haploid gamete.

tient's chromosome constitution was necessary for appropriate management (eg, to rule out trisomy 13 in a newborn with a complex congenital heart disease). However, this invasive test has been replaced by the availability of the FISH technique (see following discussion).

Cells processed for routine chromosome analysis are stained on glass slides to yield a light-and-dark band pattern across the arms of the chromosomes (see Figure 33–1). This band pattern is characteristic and reproducible for each chromosome, allowing the chromosomes to be identified. Using different staining techniques, different banding patterns result: G, Q, and R banding. The most commonly used is G banding. The layout of chromosomes on a sheet of paper in a predetermined order is called a karyotype. High-resolution chromosome analysis is the study of more elongated chromosomes in prometaphase. In such an analysis, the bands can be visualized in greater detail, allowing detection of smaller, more subtle chromosomal rearrangements.

Fluorescent in situ hybridization (FISH) is a powerful technique that labels a known chromosome sequence with DNA probes attached to fluorescent dyes, thus enabling visualization of specific regions of chromosomes by fluorescent microscopy. There are many different kinds of probes, including paint probes (a mixture of sequences throughout one chromosome), sequence-specific probes, centromere probes, and telomere probes. A cocktail of differently colored probes, one color for each chromosome, called multicolor FISH, or M-FISH, can detect complex rearrangements between chromosomes. FISH can detect submicroscopic structural rearrangements undetectable by classic cytogenetic techniques and can identify marker chromosomes. For pictures of FISH studies see www.kumc.edu/gec/prof/cytogene.html

FISH also allows interphase cells (lymphocytes, amniocytes) to be screened for numerical abnormalities such as trisomy 13, 18, or 21, and sex chromosome anomalies. However, because of the possible background or contamination of the signal, the abnormality must be confirmed by conventional chromosome analysis.

Assessment of chromosome breaks and sister chromatid exchanges requires special techniques that lead to enhancement of the breaks, or special staining that allows visualization of the exchanged chromatids.

Chromosome Nomenclature

Visible under the microscope is a constriction site on the chromosome called the centromere, which separates

the chromosome into two arms: p, for petite, refers to the short arm, and q, the letter following p, refers to the long arm. Each arm is further subdivided into numbered bands visible using different staining techniques. Centromeres are positioned at different sites on different chromosomes and are used to differentiate the chromosome structures seen during mitosis as **metacentric** (p arm and q arm of almost equal size), **submetacentric** (p arm shorter than q arm), and **acrocentric** (almost no p arm). The use of named chromosome arms and bands provides a universal method of chromosome description. Common symbols include *del* (deletion), *dup* (duplication), *inv* (inversion), *ish* (in situ hybridization), *i* (isochromosome), *pat* (paternal origin), *mat* (maternal origin), and *r* (ring chromosome). See the next section for definitions of these terms.

Chromosomal Abnormalities

There are two types of chromosomal anomalies: numerical and structural.

A. ABNORMALITIES OF CHROMOSOMAL NUMBER

When a human cell has 23 chromosomes, such as human ova or sperm, it is in the haploid state (n). After conception, in cells other than the reproductive cells, 46 chromosomes are present in the diploid state ($2n$). Any number that is an exact multiple of the haploid number [eg, $46(2n)$, $69(3n)$, or $92(4n)$] is referred to as euploid. Polyploid cells are those that contain any number other than the usual diploid number of chromosomes. Polyploid conceptions are usually not viable except in a "mosaic state," with the presence of more than one cell line in the body. (See later text for details.)

Cells deviating from the multiple of the haploid number are called aneuploid, meaning not euploid, indicating an abnormal number of chromosomes. Trisomy, an example of aneuploidy, is the presence of three of a particular chromosome rather than two. It results from unequal division, called nondisjunction, of chromosomes into daughter cells. Trisomies are the most common numerical chromosomal anomalies found in humans [eg, trisomy 21 (Down syndrome), trisomy 18, and trisomy 13]. Monosomies, the presence of only one member of a chromosome pair, may be complete or partial. Complete monosomies may result from nondisjunction or anaphase lag. All complete autosomal monosomies appear to be lethal early in development and only survive in mosaic forms. Sex chromosome monosomy, however, can be viable.

B. ABNORMALITIES OF CHROMOSOMAL STRUCTURE

Many different types of structural chromosomal anomalies exist. Figure 33–4 displays the formal

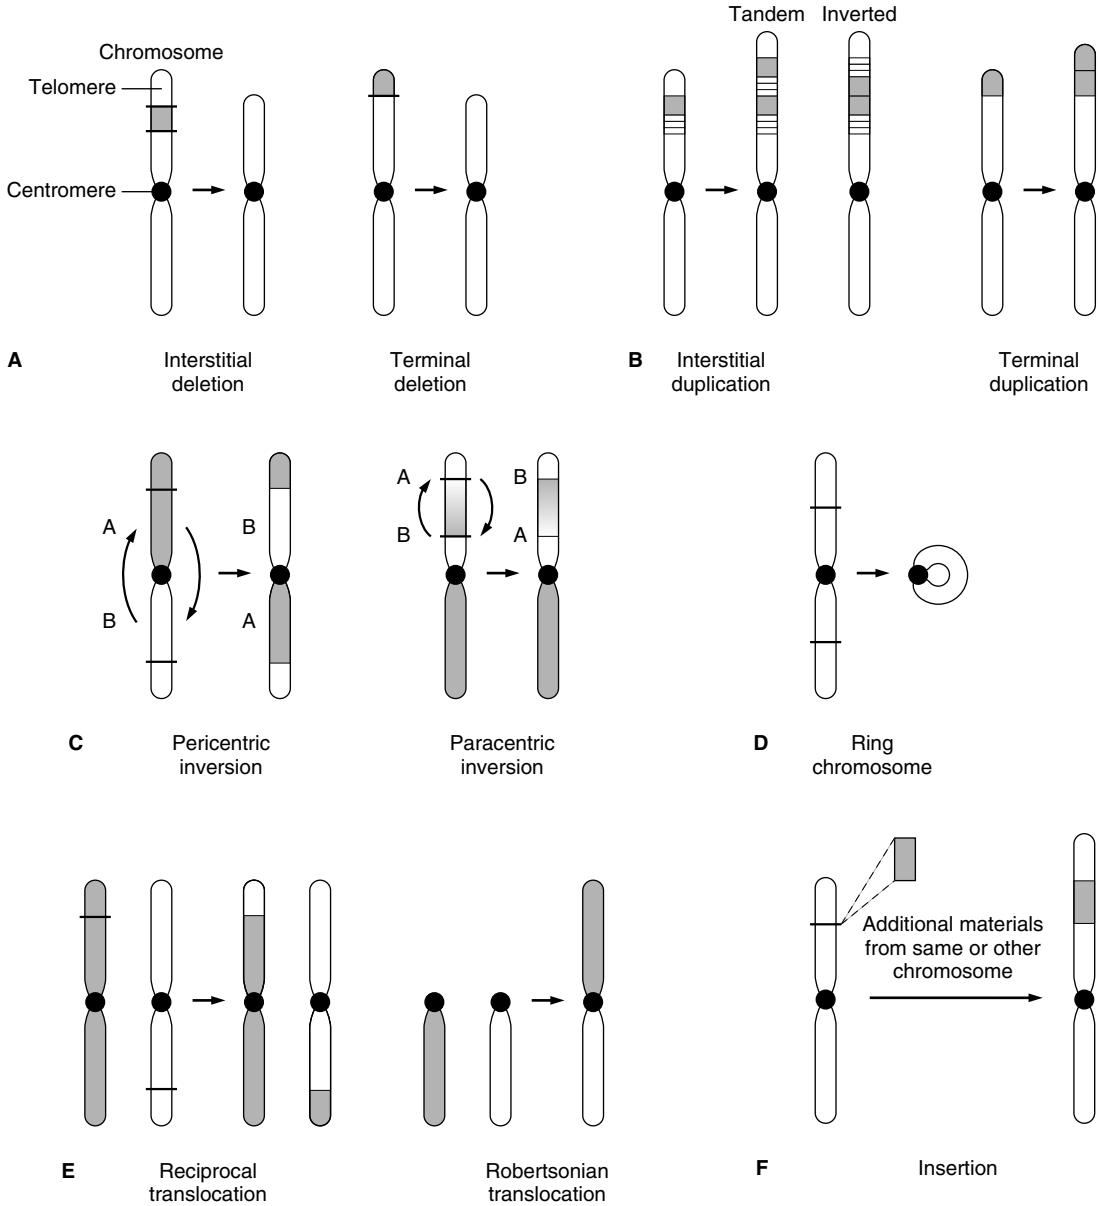

Figure 33-4. Examples of structural chromosomal abnormalities: deletion, duplication, inversion, ring chromosome, translocation, and insertion.

nomenclature as well as the ideogram demonstrating chromosomal anomalies. In clinical context, the sign (+) or (-) preceding the chromosome number indicates increased or decreased number, respectively, of that particular whole chromosome in a cell. For example, 47,XY+21 designates a male with three copies of chromosome 21. The sign (+) or (-) after the chromosome

number signifies extra material or missing material, respectively, on one of the arms of the chromosome. For example, 46,XX,8q- denotes a deletion on the long arm of chromosome 8. Detailed nomenclature, such as 8q11, is required to further demonstrate a specific missing region so that genetic counseling can be provided.

1. Deletion (del) (see Figure 33–4A)—This refers to an absence of normal chromosomal material. It may be terminal (at the end of a chromosome) or interstitial (within a chromosome). The missing part is described using the code “del,” followed by the number of the chromosome involved in parentheses, and a description of the missing region of that chromosome, also in parentheses, for example, 46,XX,del(1)(p36.3). This chromosome nomenclature describes the loss of genetic material from band 36.3 of the short arm of chromosome 1, which results in 1p36.3 deletion syndrome. Some more common deletions result in clinically recognizable conditions associated with mental handicaps and characteristic facial features. For example, Wolf–Hirschhorn syndrome, del(4p), results in an unusual face with “Greek-helmet” appearance; Cri-du-chat syndrome, del(5p), is typified by an unusual high-pitched cry and dysmorphic features.

2. Duplication (dup) (see Figure 33–4B)—An extra copy of a chromosomal segment can be tandem (genetic material present in the original direction) or inverted (genetic material present in the opposite direction). A well-described duplication of chromosome 22q11 causes Cat eye syndrome, resulting in iris coloboma and anal or ear anomalies.

3. Inversion (inv) (see Figure 33–4C)—In this aberration, a rearranged section of a chromosome is inverted. It can be paracentric (not involving the centromere) or pericentric (involving the centromere).

4. Ring chromosome (r) (see Figure 33–4D)—Deletion of the normal telomeres (and possibly other subtelomeric sequences) leads to subsequent fusion of both ends to form a circular chromosome. Ring chromosomal anomalies often cause growth retardation and mental handicap.

5. Translocation (trans) (see Figure 33–4E)—This describes the interchromosomal rearrangement of genetic material. These may be balanced (the cell has a normal content of genetic material arranged in a structurally abnormal way) or unbalanced (the cell has gained or lost genetic material as a result of chromosomal interchange). Balanced translocations may further be described as reciprocal, the exchange of genetic material between two nonhomologous chromosomes, or robertsonian, the fusion of two acrocentric chromosomes.

6. Insertion (ins) (see Figure 33–4F)—Breakage within a chromosome at two points and incorporation of another piece of chromosomal material is called insertion. This requires three breakpoints and may occur between two chromosomes or within the same chromosome. The clinical presentation or phenotype depends on the origin of the inserted materials.

C. SEX CHROMOSOMAL ANOMALIES

Abnormalities involving sex chromosomes, including aneuploidy and mosaicism, are relatively common in the general population. The most common sex chromosome anomalies include 45,X (Turner syndrome), 47,XXX, 47,XXY (Klinefelter syndrome), 47,XYY, and different mosaic states. (Please see later text for clinical discussion.)

D. MOSAICISM

Mosaicism is the presence of two or more different chromosome constitutions in different cells of the same individual. For example, a patient may have some cells with 47 chromosomes and others with 46 chromosomes (46,XX/47,XX,+21 indicates mosaicism for trisomy 21; similarly, 45,X/46,XX/47,XXX indicates mosaicism for a monosomy and a trisomy X). Mosaicism should be suspected if clinical symptoms are milder than expected in a nonmosaic patient with the same chromosomal abnormality, or if the patient’s skin shows patchy or streaky hyper- or hypopigmentation. The prognosis is frequently better for a patient with mosaicism than for one with a corresponding chromosomal abnormality without mosaicism. In general, the smaller the proportion of the abnormal cell line, the better the prognosis. In the same patient, however, the proportion of normal and abnormal cells in various tissues, such as skin and peripheral blood, may be significantly different. The prognosis can seldom be assessed reliably based on the karyotype in one tissue alone, such as peripheral blood. Therefore, any prognosis should be made cautiously or even be deferred.

E. UNIPARENTAL DISOMY

Under normal circumstances, one member of each homologous pair of chromosomes is of maternal origin from the egg and the other is of paternal origin from the sperm (Figure 33–5A). In uniparental disomy (UPD), both copies of a particular chromosome pair originate from the same parent. If UPD is caused by chromosome error in the first meiotic division, both homologous chromosomes of that parent will be present in the gamete—a phenomenon called heterodisomy (see Figure 33–5B). If the disomy is caused by an error in the second meiotic division, two copies of the same chromosome will be present through the mechanism of rescue, duplication, and complementation (see Figure 33–5C–E)—a phenomenon called isodisomy. Isodisomy may also occur as a postfertilization error (see Figure 33–5F).

A chromosomal analysis would not reveal any abnormality, but DNA analysis would reveal that the child inherited two copies of DNA of a particular chromosome from one parent without the contribution

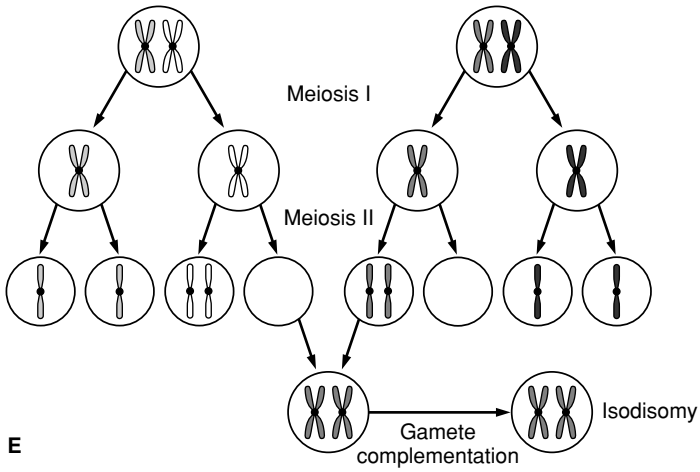

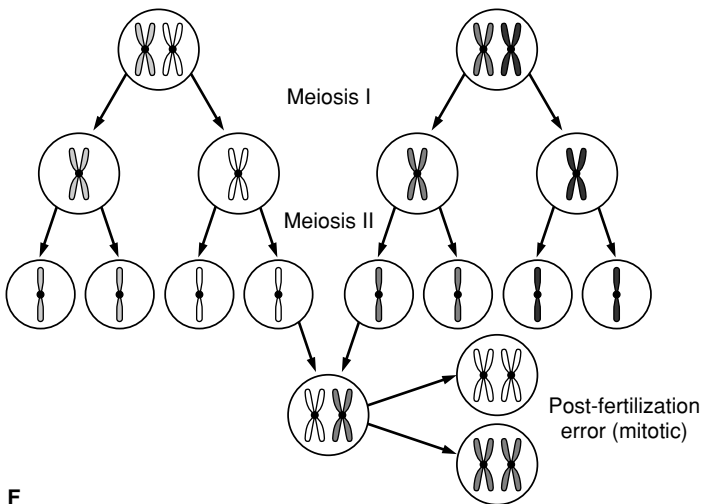

Figure 33-5. The assortment of homologous chromosomes during normal gametogenesis and uniparental disomy. **A:** Fertilization of normal gametes. **B:** Heterodisomy by trisomy rescue. **C:** Isodisomy by trisomy rescue.

D

E

F

from the other parent. UPD has been documented for human chromosomes, including chromosomes 7, 11, 15, and X. It has been found in patients with Prader–Willi, Angelman, and Beckwith–Wiedemann syndromes. In addition, cystic fibrosis with only one carrier parent (caused by maternal isodisomy) has been reported. UPD may cause severe prenatal and postnatal growth retardation. Furthermore, it is suspected that UPD of some chromosomes is lethal. The possible mechanisms for the adverse effects of UPD include possible homozygosity for deleterious recessive genes and the consequences of imprinting. (See principles of imprinting in the Imprinting section.)

F. CONTIGUOUS GENE SYNDROMES

Contiguous gene syndromes result when a deletion causes the loss of genes adjacent to each other on a chromosome. Although many genes may be missing, the deletion may still be too small to be detected by routine karyotype. Therefore, contiguous gene syndromes are sometimes called “microdeletion syndromes.” The genes involved in these syndromes are related only through their linear placement on the same chromosome segments and do not influence each other’s functions directly. Table 33–1 lists examples of some currently known contiguous gene syndromes and their associated chromosomal abnormalities. In some of these syndromes, which usually occur sporadically but, in rare instances, are familial, high-resolution chromosome analysis can lead to identification of small interstitial deletions in affected individuals. In some patients with normal karyotypes, the deletion is submicroscopic and can be detected only with FISH or DNA analysis.

Table 33–1. Examples of contiguous gene syndromes.

Syndrome	Abnormal Chromosome Segment
Prader–Willi/Angelman syndrome	del 15q11
Shprintzen/DiGeorge spectrum	del 22q11
Langer–Giedion syndrome	del 8q24
Miller–Dieker syndrome	del 17p13
Retinoblastoma/mental retardation	del 13q14
Beckwith–Wiedemann syndrome	11p15
Wilms tumor with aniridia, genitourinary malformations, and mental retardation	del 11p13

G. CHROMOSOME FRAGILITY

It is well known that environmental factors such as exposure to radiation, certain chemicals, and viruses contribute to chromosome breaks and rearrangements. However, some well-defined autosomal recessive syndromes with DNA repair defects are associated with a greatly increased risk of chromosome aberrations and are called chromosome instability or breakage syndromes. An example is Bloom syndrome, characterized clinically by small stature and development of telangiectasias on exposure to sunlight. It is caused by a defect in a DNA helicase that leads to increased somatic recombination and sister chromatid exchange. Other syndromes include the following:

- Fanconi anemia, often associated with radial ray defect, pigmentary changes, mild mental retardation, and development of pancytopenia
- Ataxia–telangiectasia (Louis–Bar syndrome), characterized by telangiectasia of the skin and eyes, immunodeficiency, and progressive ataxia, a DNA repair defect
- ICF syndrome, characterized by immunodeficiency, centromeric instability, and facial anomaly
- Roberts syndrome, characterized by growth retardation, developmental delay, and limb and craniofacial anomalies
- Xeroderma pigmentosum, resulting in formation of skin lesions secondary to sun exposure
- Werner syndrome, which is associated with premature senility.

The knowledge that specific chromosome aberrations are associated with these syndromes is often the basis for cytogenetic confirmation of their diagnosis. For example, in Fanconi anemia, after diepoxybutane (DEB) treatment, translocations between nonhomologous so-called quadriradii and chromosomal breakage increase, which confirms the diagnosis.

H. CHROMOSOMAL ABNORMALITIES IN CANCER

Numerical and structural chromosomal abnormalities are often identified in hematopoietic and solid-tumor neoplasms in individuals with otherwise normal chromosomes. These cytogenetic abnormalities have been categorized as primary and secondary. In primary abnormalities, their presence is necessary for initiation of the cancer (eg, 13q– in retinoblastoma). Secondary abnormalities appear in somatic cells de novo only after the cancer has developed (eg, Philadelphia chromosome, t[9;22][q34;q11], in acute and chronic myeloid leukemia). “Cytogenetic noise” is the term used to denote a variety of random chromosomal abnormalities.

The primary and secondary chromosomal abnormalities are specific for particular neoplasms and can be

used for diagnosis or prognosis. For example, the presence of the Philadelphia chromosome is a good prognostic sign in chronic myelogenous leukemia and indicates a poor prognosis in acute lymphoblastic leukemia. The sites of chromosome breaks coincide with the known loci of oncogenes and antioncogenes.

Jones KL: *Smith's Recognizable Patterns of Human Malformation*, 5th ed. WB Saunders, 1996.

MOLECULAR GENETICS

The advances of molecular biology have been a major breakthrough for human genetics, because they allow for the localization, isolation, and characterization of the genes that encode protein sequences. As the Human Genome Project has moved into a postcloning era, the function of the gene products and their interaction with one another has become the main theme of molecular genetics. Also, molecular genetics can help explain the complex underlying biology involved in human diseases.

Recombinant DNA Technology

Recombinant DNA technology was developed using restriction endonucleases, which cleave DNA at specific nucleotide sequences. A difference in DNA sequence caused by a normal variation of DNA or by a gene mutation either produces or eliminates an endonuclease recognition site, resulting in a DNA fragment of different size. Thus the number and arrangement of restriction sites (called a restriction map) are characteristic of a given DNA sequence.

Before a DNA fragment of interest can be analyzed, multiple copies of it must be produced. This can be achieved by incorporating the human DNA fragment into a vector (ie, a DNA segment containing the means of replication and selection in bacteria). The vector-containing human DNA insert is replicated, thus producing multiple copies of the segment of interest. The source of inserts can be genomic DNA, obtained directly from cleaving of the target organism, or complementary DNA (cDNA), obtained by copying messenger RNA (mRNA) into DNA by reverse transcription.

A genomic library can be assembled by fragmenting human genomic DNA with restriction enzymes and then inserting the fragments into a vector. Such a library contains large numbers of different DNA sequences. Some of these specific DNA fragments are used to manufacture human proteins (eg, insulin, growth hormone, interferon, and blood clotting factors) for pharmacologic applications; others are used as probes, which may be thought of as DNA segment-specific, radioactively labeled reagents for mapping and diagnosis.

Molecular genetic techniques are most commonly used to look for changes in genomic DNA detected by Southern blot analysis. But a similar technique with Northern blot analysis is being used increasingly to look for RNA abnormalities. Southern blot analysis relies on the use of restriction endonucleases to cleave human genomic DNA at specific nucleotide sequences and to produce DNA fragments of different lengths. These DNA fragments are then separated by agarose gel electrophoresis, transferred to a membrane, and overlaid with a radioactive probe. This fragment is identified by autoradiography, and its size is determined. Recently, non-radioisotope-based hybridization became available as an alternative to radioisotopes.

The **polymerase chain reaction (PCR)** replicates fragments of DNA between predetermined primers so that sufficient DNA is obtained for characterization or sequencing in the space of a few hours. For example, 20 cycles of synthesis will amplify DNA 1 millionfold. The disadvantage of PCR is that a small contamination with foreign DNA can result in an incorrect diagnosis.

Application of Molecular Biology in Clinical Genetics and Genetic Diagnosis

Genetic diagnosis can be performed by direct detection of a mutant gene or by indirect methods. Direct detection is possible only when the gene causing the disease and the nature of the mutation are known. The advantage of a diagnostic study using the direct detection of the mutant gene is that it requires the affected individual only and need not involve the testing of other family members. Indirect detection of abnormal genes is used when the gene is known but there is extensive heterogeneity of the molecular defect between families, or when the gene responsible for a disease is unknown but its chromosome location is known.

The methods of direct DNA diagnosis include restriction analysis, single strand conformational polymorphism (SSCP) analysis, direct sequencing with assistance of PCR, heteroduplex assay, and protein truncation assay. The molecular mechanisms causing human diseases include point mutations, deletions, and insertions, and the unstable expansion of trinucleotide repeats, which leads to genetic anticipation (see previous sections and later discussion). Congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency, Duchenne muscular dystrophy, hemophilias A and B, Lesch-Nyhan syndrome, fibroblast growth factor receptor (FGFR)-related craniosynostosis, cystic fibrosis, and fragile X syndrome are common examples of diseases caused by these mechanisms, for which direct DNA testing is available.

If the sequence or product of an abnormal gene cannot be studied, then the linkage analysis method may be applicable. Linkage traces the inheritance of the abnormal

gene between members of a kindred. This method requires that the affected individual be studied, with parents and perhaps other relatives, both affected and unaffected.

Neurofibromatosis is an example of a disorder in which both the direct and indirect assay may be used. Because of the size and the heterogenous mutation pattern of the neurofibromin gene (*NFI*), the first step usually is the protein truncation assay, which is done via *in vitro* translation followed by analyzing the size of the protein. However, this method detects only two thirds of affected patients, in whom a nonsense mutation exists that truncates the gene message. All other cases must rely on linkage analysis, by using markers such as a restriction fragment length polymorphism (RFLP) or, increasingly, flanking microsatellite polymorphisms. The increase in density of polymorphisms discovered over the past few years means that the presence or absence of an abnormal copy of a gene in an individual can be predicted with a high degree of confidence, if the relatives have informative polymorphisms. Microsatellite polymorphisms are being used in sibling research studies to identify the multiple genes that contribute to polygenic traits such as diabetes and obesity. They are also used increasingly to identify gene changes in tumors.

Application of Molecular Biology in Prevention of Human Diseases

Recombinant DNA technology has the potential for preventing genetic disease by facilitating the detection of carriers of defective genes and permitting prenatal diagnosis. Family studies can also clarify the mode of inheritance, thus allowing more accurate determination of recurrence risks and appropriate options. For example, differentiation of gonadal mosaicism from decreased penetrance of a dominant gene has important implications for genetic counseling. In the past, the diagnosis of a genetic disease characterized by late onset of symptoms (eg, Huntington disease) could not be made prior to the appearance of clinical symptoms. In some inborn errors of metabolism, diagnostic tests (eg, measurement of enzyme activities) could be conducted only on inaccessible tissues. Gene identification techniques can enormously enhance the ability to diagnose both symptomatic and presymptomatic individuals, as well as heterozygous carriers of the gene, and conduct prenatal diagnosis. However, presymptomatic DNA testing is associated with psychological, ethical, and legal implications and therefore should be used only with informed consent.

Application of Molecular Biology in Treatment of Human Diseases

A normal gene introduced into an individual affected with a serious inherited disorder during embryonic life

(germline therapy) in principle has the potential to be transmitted to future generations, whereas its introduction into somatic cells (somatic therapy) affects only the recipient. Experimental gene therapy by bone marrow transplantation is being tried for adenosine deaminase deficiency. Recombinant enzyme replacement has been successfully applied in treating the nonneurologic form of Gaucher disease and some types of lysosomal storage disease.

PRINCIPLES OF INHERITED HUMAN DISORDERS

MENDELIAN DISORDERS

Traditionally, autosomal single gene disorders follow the principles explained by Mendel's observations. To summarize, the inheritance of genetic traits through generations relies on segregation and independent assortment. **Segregation** is the process through which gene pairs are separated during gamete formation. Each gamete receives only one copy of each gene (allele). **Independent assortment** refers to the idea that the segregation of different alleles occurs independently.

Victor McKusick's catalog, *Mendelian Inheritance in Man*, lists more than 10,000 entries in which the mode of inheritance is presumed to be autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked. Single genes at specific loci on one or a pair of chromosomes cause these disorders. An understanding of inheritance terminology is helpful in approaching mendelian disorders. Analysis of the pedigree and the pattern of transmission in the family, identification of a specific condition, and knowledge of that condition's mode of inheritance usually allows for explanation of the inheritance pattern.

Terminology

The following terms are important in understanding heredity patterns.

Dominant and Recessive—As defined by Mendel, concepts for dominant and recessive refer to the **phenotypic expression** of alleles and are not intrinsic characteristics of gene loci. Therefore, it is inappropriate to discuss "a dominant locus."

Genotype—Genotype means the genetic status—that is, the alleles an individual carries.

Phenotype—Phenotype is the expression of an individual's genotype and may be modified by environment, that is, the structural or functional nature of an individual (appearance, physical features, organ structure, biochemical, physiologic nature).

Pleiotropy—Pleiotropy refers to the phenomenon whereby a single mutant allele can have widespread effects or expression in different tissues or organ systems. In other words, an allele may produce more than one effect on the phenotype. For example, Marfan syndrome has findings in different organ systems (skeletal, cardiac, ophthalmologic, etc) due to a single mutation within the *fibrillin* gene.

Penetrance—Penetrance refers to the proportion of individuals with a particular genotype that express the same phenotype. Penetrance is a proportion that ranges between 0 and 1.0 (or 0 and 100%). When 100% of mutant individuals express the phenotype, penetrance is **complete**. If some mutant individuals do not express the phenotype, penetrance is said to be **incomplete**, or **reduced**. Dominant conditions with incomplete penetrance, therefore, are characterized by “skipped” generations with unaffected, obligate gene carriers.

Expressivity—Expressivity refers to the variability in degree of phenotypic expression (severity) seen in different individuals with the same mutant genotype. Expressivity may be extremely variable or fairly consistent, both within and between families. Intrafamilial variability of expression may be due to factors such as epistasis, environment, true anticipation, presence of phenocopies, mosaicism, and chance (stochastic factors). Interfamilial variability of expression may be due to the previously mentioned factors as well, but may also be due to allelic or locus genetic heterogeneity.

Genetic Heterogeneity—A number of different genetic mutations may produce phenotypes that are identical or similar enough to have been traditionally considered as one diagnosis. The conditions of “anemia” and “mental retardation” are examples of this. There are two types of genetic heterogeneity, **allelic heterogeneity** and **locus heterogeneity**.

Locus heterogeneity—This describes a phenotype caused by mutations at more than one genetic locus; that is, mutations at different loci cause the same phenotype or a group of phenotypes that appear similar enough to have been previously classified as a single disease, clinical “entity,” or diagnostic spectrum. An example would be Sanfilippo syndrome (mucopolysaccharidosis III A, B, C, and D), in which the same phenotype is produced by four different enzyme deficiencies.

Allelic heterogeneity—This term is applied to a phenotype caused by more than one genetic mutation at the same gene locus, that is, different mutations at a single gene locus. As an example, cystic fibrosis may be caused by many different genetic changes, such as homozygosity for the common $\Delta F 508$ mutation, or $\Delta F 508$ and a *R117H* mutation. The latter example represents compound heterozygosity.

Phenotypic Heterogeneity or “Clinical Heterogeneity”—This term describes the situation in which

more than one phenotype is caused by different allelic mutations at a single locus. An example of phenotypic heterogeneity includes different mutations within the *Collagen II* gene, causing hypochondrogenesis, Kniest dysplasia, spondyloepiphyseal dysplasia congenita, and some cases of Stickler syndrome. Furthermore, different mutations in the *FGFR2* gene can cause different craniosynostosis disorders, including Crouzon syndrome, Jackson–Weiss syndrome, Pfeiffer syndrome, and Apert syndrome. These syndromes are clinically distinguishable and are due to the presence of a variety of genetic mutations within single genes.

Homozygous—A cell or organism that has identical alleles at a particular locus is said to be homozygous. For example, in an autosomal recessive disorder, the gene copies from both parents have to be inactivated to manifest the disease.

Heterozygous—A cell or organism that has non-identical alleles at a genetic locus is said to be heterozygous. In autosomal dominant conditions, one copy of the gene pair is inactivated while the other is functional, resulting in a disease state. An individual who is heterozygous for a recessive disorder will not manifest symptoms.

1. Hereditary Patterns

Autosomal Dominant Inheritance

Autosomal dominant inheritance has the following characteristics:

1. Affected individuals in the same family may experience variable expressivity.
2. Nonpenetrance is common, and the penetrance rate varies for each dominantly inherited condition.
3. Both males and females can pass on the abnormal gene to children of either sex, although the manifestations may vary according to sex. For example, pattern baldness is a dominant trait but affects only males. In this case, the trait is said to be sex-limited.
4. Dominant inheritance is typically said to be vertical, that is, the condition passes from one generation to the next in a vertical fashion (Figure 33–6).
5. In some cases, the family history seems to be completely negative, and the patient appears to be the first affected individual. This spontaneous appearance may be caused by a new mutation. In some disorders, which tend to be more severe (eg,

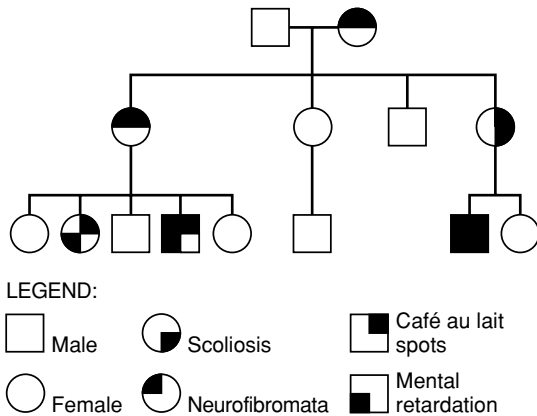

Figure 33–6. Autosomal dominant inheritance. Variable expressivity in NF-1

achondroplasia) and therefore may decrease the reproductive fitness, there is a high rate of new mutations. The mutation rate varies with each dominant condition, and in some cases the mutation rate increases with advancing paternal age. Several other explanations for a negative family history are possible, however:

- Nonpaternity.
 - Decreased penetrance or mild manifestations in one of the parents.
 - Germline mosaicism (ie, mosaicism in the germ cell line of either parent), in which case the risk of recurrence increases. Germline mosaicism may mimic autosomal recessive inheritance, because it leads to situations in which two children of completely normal parents are affected with a genetic disorder. The best example of this is osteogenesis imperfecta type II. Laboratory studies have documented germline mosaicism by finding that only one allele of the paired collagen genes is abnormal in the severe form instead of both, as would be expected in a recessive disease. The recurrence risk in this form of osteogenesis imperfecta is 7%.
 - The abnormality present in the patient may be a phenocopy, or it may be a similar but genetically different abnormality with a different mode of inheritance.
- As a general rule, dominant traits are more often related to structural abnormalities of protein, as for example in Marfan syndrome.
 - For a parent who is affected, the risk of each offspring to inherit the abnormal dominant gene is

50%, or 1:2. This is true whether the gene is penetrant or not in the parent, and the severity of the condition in the offspring is not related to the severity in the affected parent. In some disorders, it may be related to the sex of the parent transmitting the gene. For example, if the gene for myotonic dystrophy is passed through the mother, there is a 10–20% chance that the child (regardless of sex) may have a severe congenital form of the disease. Conversely, if the gene for Huntington disease is passed through the father, the probability is 5–10% that the offspring may have the severe, rigid juvenile form. This has been attributed to imprinting, although we know in these two conditions that it is associated with expansion of the triplet repeats (see Genetic Anticipation section). If an abnormality represents a new mutation of a dominant trait, the parents of the affected individual run a low risk during subsequent pregnancies, but the risk for the offspring of the affected individual is 50%.

- Prevention options available for future pregnancies include prenatal diagnosis, artificial insemination, and egg donation, depending on which parent has the abnormal gene.

Autosomal Recessive Inheritance

Autosomal recessive inheritance also has some distinctive characteristics:

- There is less variability among affected persons. Parents are carriers and are clinically normal. (There are exceptions to this rule, however. For example, sickle cell disease is considered recessive. Under normal circumstances, carriers—those with the sickle cell trait—are normal but may become symptomatic if they become hypoxic.)
- Males and females are affected equally.
- Inheritance is horizontal; siblings may be affected (Figure 33–7).
- Recessive conditions are usually rare; the rarer the condition, the more likely it is that consanguinity is present. Conversely, if a child whose parents are related presents with an unrecognized abnormality, a recessive condition must be suspected.
- The family history is usually negative, with the exception of siblings. However, in common conditions such as cystic fibrosis, a second- or third-degree relative may be affected.
- Recessive conditions are frequently associated with enzyme defects.
- The recurrence risk for parents of an affected child is 25%, or 1:4 for each pregnancy. The gene

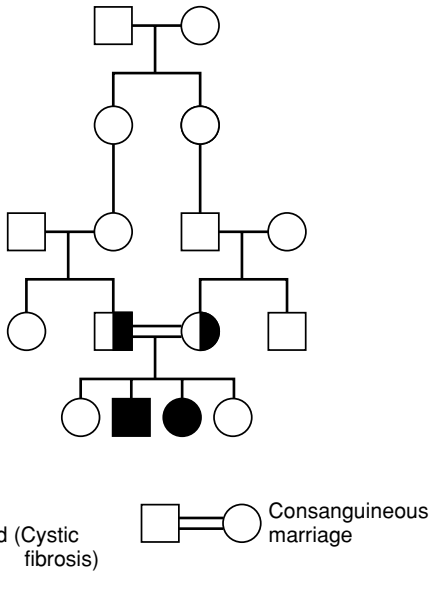

Figure 33-7. Autosomal recessive inheritance: cystic fibrosis.

carrier frequency in the general population can be used to assess the risk of having an affected child with a new partner, for unaffected siblings, and for the affected individuals themselves.

8. In rare instances, a child with a recessive disorder and a normal karyotype may have inherited both copies of the abnormal gene from one parent and none from the other. This uniparental disomy was first described in a girl with cystic fibrosis and growth retardation. This phenomenon is of unknown frequency, but it is more likely to be present in a child with several autosomal recessive conditions or in a patient with unexpected and seemingly unrelated abnormalities or severe growth retardation. Molecular testing can confirm the presence of uniparental disomy. The recurrence risk is obviously lower in such a situation, although the factors predisposing to uniparental disomy are unknown. Maternal age may play a role in these situations.
9. Options available for future pregnancies include prenatal diagnosis in many cases and artificial insemination.

X-Linked Inheritance

When a gene for a specific disorder is on the X chromosome, the condition is said to be X-linked, or sex-

linked. Females may be either homozygous or heterozygous, because they have two X chromosomes. Males, by contrast, have only one X, and a male is said to be hemizygous for any gene on his X chromosome. The severity of any disorder is greater in males than in females (within a specific family). According to the Lyon hypothesis, because one of the two X chromosomes in each cell is inactivated, and because this inactivation is random, the clinical picture in females depends on the percentage of mutant versus normal alleles inactivated. The X chromosome is not inactivated until about 14 days of gestation, and parts of the short arm remain active throughout life.

X-Linked Recessive Inheritance

The following features are characteristic of X-linked recessive inheritance:

1. Males are affected, and heterozygous females are either normal or have mild manifestations.
2. Inheritance is diagonal through the maternal side of the family (Figure 33-8A).
3. A female carrier has a 50% chance that each daughter will be a carrier and a 50% chance that each son will be affected.
4. All of the daughters of an affected male are carriers, and none of his sons are affected. Because a father can give only his Y chromosome to his sons, male-to-male transmission excludes X-linked inheritance except in the rare case of uniparental disomy, in which a son receives both the X and the Y from his father.
5. The mutation rate is high in some X-linked disorders, particularly when the affected male dies or is so incapacitated by the disorder that reproduction is unlikely. In such instances, the mutation is thought to occur in the proband in one third of cases, in the mother in one third of cases, and in earlier generations in one third of cases. For this reason, genetic counseling may be difficult in families with an isolated case.
6. On rare occasions, a female may be fully affected. Several possible mechanisms may account for a fully affected female: (a) unfavorable lyonization; (b) 45,X karyotype; (c) homozygosity for the abnormal gene; (d) an X-autosome translocation, or other structural abnormality of one X chromosome, in which the X chromosome of normal structure is preferentially inactivated; (e) uniparental disomy; and (f) nonrandom inactivation, which may be controlled by an autosomal gene.

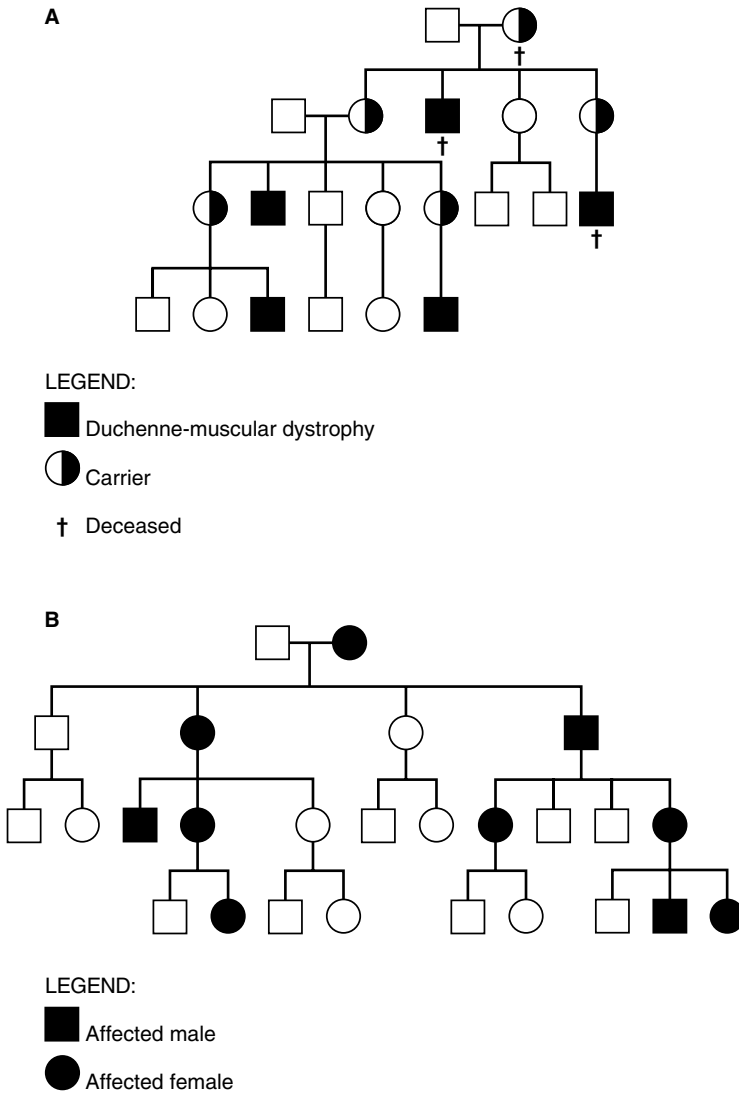

Figure 33–8. A: X-linked recessive inheritance. **B:** X-linked dominant inheritance.

X-Linked Dominant Inheritance

The X-linked dominant inheritance pattern is much less common than the X-linked recessive type. Examples include incontinentia pigmenti and hypophosphatemic or vitamin D-resistant rickets.

1. The heterozygous female is symptomatic, and the disease is twice as common in females because they have two X chromosomes that can have the mutation.
2. Clinical manifestations are more variable in females than in males.
3. The risk for the offspring of heterozygous females to be affected is 50% regardless of sex.
4. All of the daughters but none of the sons of affected males will have the disorder. (see Figure 33–8B)
5. Although a homozygous female is possible (particularly in an inbred population), she would be severely involved. All of her children would also be affected but more mildly.
6. Some disorders (eg, incontinentia pigmenti) are lethal in males (and in homozygous females). Affected women have twice as many daughters as sons and an increased incidence of miscarriages,

because affected males will be spontaneously aborted. A 47,XXY karyotype has allowed affected males to survive.

Y-Linked Inheritance

Also known as “holandric” inheritance, these conditions are caused by genes located on the Y chromosome. These conditions are relatively rare with only about 40 entries listed in McKusick’s catalog. Male-to-male transmission is seen in this category, with all sons of affected males being affected and no daughters or females being affected. Figure 33–9 shows a typical Y-linked inheritance pedigree.

MULTIFACTORIAL INHERITANCE

Many common attributes, such as height, are familial, and are the result of the actions of multiple rather than single genes. Inheritance of these traits is described as **polygenic** or **multifactorial**. The latter term recognizes that environmental factors such as diet also contribute to these traits. As they begin to dissect the genetics of these traits in humans, geneticists are finding that multiple genes are often expressed in hierarchies in which the action of a small number of genes, two or three, explains much of the variation observed within affected populations.

Studies of twins have proven useful in determining the relative importance of genetic versus environmental factors in the expression of polygenic traits. If genetic factors are of little or no importance, then the concordance between monozygotic and dizygotic twins should be the same. (Dizygotic twins are no more genetically similar to each other than to other siblings.) If an abnormality is completely genetic, the concordance between identical twins should be 100%. In polygenic conditions, the concordance rate for identical twins is higher than that seen in dizygotic twins but still not

100%, indicating both genetic and environmental factors.

Many disorders and congenital abnormalities that are clearly familial but do not segregate as mendelian traits (eg, autosomal dominant, recessive, etc) show polygenic inheritance. For the most part, these conditions become manifest when thresholds of additive gene actions or contributing environmental factors are exceeded. Many common disorders ranging from hypertension, stroke, and thrombophlebitis to behavioral traits such as alcoholism demonstrate multifactorial (polygenic) inheritance. Some common birth defects, including isolated congenital heart disease, cleft lip and palate, and neural tube defects, also demonstrate polygenic inheritance. Neural tube defects provide a good model for how identification of both environmental and genetic contributions to multifactorial traits can lead to preventive measures.

Polygenic or multifactorial inheritance has several distinctive characteristics:

1. The risk for relatives of affected persons is increased, and the risk is higher for first-degree relatives (those who have 50% of their genes in common) and lower for more distant relations, although the risk for the latter is higher than for the general population (Table 33–2).
2. The recurrence risk varies with the number of affected family members. For example, after one child is born with a neural tube defect, the recurrence risk is 2–3%. If a second affected child is born, the risk for any future child increases to 10–12%. This is in contrast to single gene disorders, in which the risk is the same no matter how many family members are affected.
3. The risk is higher if the defect is more severe. In Hirschsprung disease, another polygenic condition, the longer the aganglionic segment, the higher the recurrence risk.

LEGEND:
 ■ Affected male

Figure 33–9. Y-linked inheritance.

Table 33–2. Empiric risks for some congenital disorders.**Anencephaly and spina bifida:** Incidence (average) 1:1000

- One affected child: 2–3%
- Two affected children: 10–12%
- One affected parent: 4–5%

Hydrocephalus: Incidence 1:2000 newborns

- Occasional X-linked recessive
- Often associated with neural tube defect
- Some environmental etiologies (eg, toxoplasmosis)
- Recurrence risk, one affected child
- Hydrocephalus: 1%
- Some central nervous system abnormality: 3%

Nonsyndromic cleft lip and/or palate: Incidence (average) 1:1000

- One affected child: 2–4%
- One affected parent: 2–4%
- Two affected children: 10%
- One affected parent, one affected child: 10–20%

Nonsyndromic cleft palate: Incidence 1:2000

- One affected child: 2%
- Two affected children: 6–8%
- One affected parent: 4–6%
- One affected parent, one affected child: 15–20%

Congenital heart disease: Incidence 8:1000

- One affected child: 2–3%
- One affected parent, one affected child: 10%

Clubfoot: Incidence 1:1000 (male:female = 2:1)

- One affected child: 2–3%

Congenital dislocated hip: Incidence 1:1000 (female > male) with marked regional variation

- One child affected: 2–14%

Pyloric stenosis: Incidence, males: 1:200; females: 1:1000

Male index parent

Brothers	3.2%
Sons	6.8%
Sisters	3.0%
Daughters	1.2%

Female index parent

Brothers	13.2%
Sons	20.5%
Sisters	2.5%
Daughters	11.1%

4. Sex ratios may not be equal. If a marked discrepancy exists, the recurrence risk is higher if a child of the less commonly affected sex has the disorder. This assumes that more genetic factors are required to raise the more resistant sex above the threshold. For example, pyloric stenosis is more common in males. If the first affected child is a female, the recurrence risk is higher than if the child is a male.

5. The risk for the offspring of an affected person is approximately the same as the risk for siblings, assuming that the spouse of the affected person has a negative family history. For many conditions, however, assortative mating, “like marrying like,” adds to risks in offspring.

NONMENDELIAN INHERITANCE**Imprinting**

Although the homologs of chromosome pairs may appear identical on routine karyotype analysis, it is now known that the parental origin of each homolog can effect which genes are actually transcribed and which are inactivated. The term “imprinting” refers to the process by which preferential transcription of certain genes takes place, depending on the parental origin, that is, which homolog (maternal or paternal) the gene is located on. Certain chromosomes, particularly chromosome X, and the autosomes 15, 11, and 7, have imprinted regions where certain genes are only read from one homolog (ie, either the maternal or paternal allele) under normal circumstances, and the gene on the other homolog is normally inactivated. Errors in imprinting may arise because of uniparental disomy (in which a copy from one parent is missing), by a chromosomal deletion causing loss of the gene normally transcribed, or by mutations in the imprinting genes that normally code for transcription or inactivation of other genes downstream. A good example of how imprinting may affect human disease is Beckwith–Wiedemann syndrome (BWS), the gene for which is located on chromosome 11p15.

Cohen MM et al: *Overgrowth Syndromes*. Oxford University Press, 2002.

Genetic Anticipation

Geneticists coined the term “anticipation” to describe an unusual pattern of inheritance in which symptoms became manifest at earlier ages and with increasing severity as traits are passed to subsequent generations. Mapping of the genes responsible for these disorders led to the discovery that certain repeat sequences of DNA at disease loci were not stable when passed through meiosis. Repeated DNA sequences, in particular triplets (eg CCG, CAG), tended to increase their copy number. As these runs of triplets expanded they eventually affected the expression of genes and produced symptoms. Curiously, all the disorders undergoing triplet repeat expansion so far detected produce neurologic symptoms. Most are progressive. In general, the size of the triplet expansion is roughly correlated with the timing and severity of symptoms. The reasons for the meiotic

instability of these sequences are not yet understood. The mechanisms appear to involve interactions between DNA structure (eg, formation of hairpin loops) and replication enzymes (DNA polymerase complexes) during meiosis.

Triplet repeat instability can modify the inheritance of autosomal dominant, autosomal recessive, and X-linked traits. Autosomal dominant disorders include several spinal cerebellar atrophies, Huntington disease, and myotonic dystrophy. Unstable triplet repeat expansion contributes to at least one autosomal recessive disorder, Friedreich ataxia. The most common X-linked disorder demonstrating triplet repeat instability and expansion is fragile X syndrome.

Mitochondrial Inheritance

Mitochondrial DNA is double-stranded, circular, and smaller than nuclear DNA, and is found in the cytoplasm. It codes for enzymes involved in oxidative phosphorylation, which generates adenosine triphosphate (ATP). During the last decade of the twentieth century, enormous advances in technology and improved clinical documentation have led to a better understanding of the interesting disorders caused by mutations in mitochondrial DNA (mtDNA). It was initially appreciated that these unusual disorders seemed to be transmitted only by female members of a family and affected a high proportion of offspring, both male and female. Mitochondrial disorders have the following characteristics:

1. They show remarkable phenotypic variability.
2. They are maternally inherited, because only the egg has any cytoplasmic material.
3. In most mitochondrial disorders, cells are heteroplasmic. That is, all cells contain both normal and mutated or abnormal mtDNA. The proportion of normal to abnormal mtDNA in the mother's egg seems to determine the severity of the offspring's disease and the age at onset in most cases.
4. Those tissues with the highest ATP requirements—specifically, central nervous system (CNS) and skeletal muscle—seem to be most susceptible to mutations in mtDNA.
5. Somatic cells show an increase in mtDNA mutations and a decline in oxidative phosphorylation function with age. This explains the later onset of some of these disorders and may indeed be a clue to the whole aging process.

Mitochondrial disorders have been associated with deletions or duplications in mitochondrial DNA. Large deletions are usually sporadic, but smaller deletions may be secondary events due to defects in dominantly

inherited nuclear genes. Mitochondrial dysfunction may also be caused by mutations in nuclear genes encoding mitochondrial proteins and can be inherited as dominant, recessive, or X-linked traits. Because of the difficulty in diagnosing mitochondrial disorders and the variability of the clinical course, it is often difficult to calculate specific recurrence risks.

FAMILY HISTORY AND PEDIGREE

The first step in the collection of information regarding the genetics of a syndromic diagnosis is the construction of a family tree or pedigree. Underused by most medical personnel, the pedigree is a valuable record of genetic and medical information, which is much more useful in visual form than in list form. Tips for pedigree preparation include the following:

- Give simple instructions to the patient regarding the information desired.
- Use clearly defined symbols with a key for interpretation.
- Identify the informant, the historian, and the date of the interview.
- Start in the middle of the page to allow enough room for expansion.
- Start with the proband—the patient's siblings and parents.
- Always ask about consanguinity. Sometimes the question "Are you (the parents) related by blood?" will result in laughter but often yields potentially useful clues suggesting autosomal recessive inheritance. Ask for details such as place of birth, size of towns, and the presence of consanguinity. (These help to define recessive conditions and may increase suspicion of certain diseases that occur more frequently in particular ethnic backgrounds.)
- Obtain the maiden names of women in the family (particularly helpful for X-linked conditions).
- Obtain data from both sides of the family.
- Ask about spontaneous abortions, stillbirths, infertility, children relinquished for adoption, and deceased individuals. Such details are essential for understanding conditions that are lethal or are associated with reproductive losses.
- Even if the disease in question appears to be coming from one side of the family, always get the basic facts about the other side of the family as well. Sometimes unrelated data may be very important in interpreting the family's overall situation. In addition, obtaining data from both sides may avoid an inference of blame being placed on one family member.

In the course of taking the family history, one may find information that is not relevant in elucidating the cause of the patients' problem but may indicate a risk for other important health concerns. Such information should be appropriately followed and addressed. Such conditions that may arise are an overwhelming family history of early-onset breast and ovarian cancer, multiple pregnancy losses necessitating chromosome analyses, or symptoms of hemochromatosis, the common treatable disorder of iron metabolism.

DYSMORPHOLOGY AND HUMAN EMBRYOLOGY

With advances in perinatal medicine and treatment of infectious diseases, birth defects have now become the leading cause of death in the neonatal period and first year of life. Birth defects are evident in 2–3% of newborns and will be detected in 7% of the adult population. The scientific investigation of the origins of birth defects is called teratology. Dysmorphology is its clinical arm.

MECHANISMS

Developmental Genetics

Most birth defects are multifactorial: They result from miscommunication between genetic processes and the environments in which they unfold. Specific causes of maldevelopment can be identified in about 30% of cases, but advances in developmental biology and human genetics promise better understanding. Single gene mutations and chromosomal abnormalities cause approximately 25% of birth defects. Specific genes or chromosome loci have now been identified for many recurring phenotypes, or syndromes.

Among the most fundamental genetic programs in cells are those that regulate cell division, proliferation, and those that program cell death, or apoptosis. Both proliferation and apoptosis are very active in embryogenesis. The balance between these processes is easily disrupted, and imbalances in regulation of cell cycles are an important determinant of birth defects.

Morphogenic processes and the genes that regulate them have been highly conserved through evolution. Thus experiments in lower organisms such as *Drosophila* (fruit flies) can be highly relevant to humans, because mutations producing abnormal development in less complex organisms identify candidate genes for human birth defects. Among the better examples of this connection are *pax* genes, involved in eye development in *Drosophila*. Mutations in one of these

genes, *Pax 6*, produces “small eye” in mice, and aniridia and other abnormalities of the anterior chamber of the eye in humans.

Developmental biology is also taking advantage of two powerful technical advances: *in situ* hybridization for visualizing the expression of genes in embryos, and the production of transgenic animals in which genes of interest can be “knocked out” in order to determine their contributions to development. These techniques have uncovered, for example, very important regulatory pathways, such as the Hedgehog signaling pathway, which affects morphogenesis in organs as diverse as limbs, the heart, and the CNS. Human mutations in one of these evolutionarily conserved genes, sonic Hedgehog (*Shh*), can result in holoprosencephaly, a severe birth defect in which the CNS fails to complete hemispheric division.

Cellular Interactions

The picture emerging from genetic studies of morphogenesis is one of a hierarchy of gene expression during development. Morphogenesis begins with expression of genes encoding transcription factors. These proteins bind to DNA in undifferentiated embryonic cells and recruit them into developmental fields, groups of cells primed to respond to specific signals later in development. This recruitment also establishes spatial relationships and orients cells with respect to their neighbors. As fields differentiate into identifiable tissues (eg, ectoderm, mesoderm, endoderm), cellular proliferation, migration, and further differentiation are mediated through genes encoding proteins that send signals through interactions with other proteins (receptors).

Products of these genes include growth factors and their receptors, cellular adhesion molecules, and extracellular matrix proteins that both provide structure and localize signals for further differentiation. Patterns in which fields of primed cells proliferate, migrate, and then interact through locally expressed growth factors and receptors occur repeatedly in mammalian development. Within these interactions are clues to understanding not only many human birth defects but also cancer. The genes that organize cell proliferation and differentiation during development are often precisely those that are knocked out or amplified by carcinogenic mutations.

Epigenetic Regulation

Although development is regulated by genes, it is initiated and sustained by nongenetic processes. Epigenetic events are points of interaction between developmental programs and the physicochemical environments in dif-

ferentiating cells. Genetic imprinting and DNA methylation are examples of epigenetic processes that affect development. Certain genes important in regulation of growth and differentiation are themselves regulated by chemical modification that occurs in specific patterns in gametes. For example, genes that are methylated are “turned off” and not transcribed. The pattern of which genes are methylated may be determined or affected by the sex of the parent of origin (see Imprinting section). Expression of imprinted genes may sometimes be limited to specific organs (eg, the brain), and imprinting may be relaxed and methyl groups lost as development progresses. Disruption of imprinting is now recognized as contributing to birth defect syndromes (described later in this chapter).

Environmental Factors

The effects of exogenous agents during development are also mediated through genetically regulated pathways. At the cellular level, environmental effects occur because xenobiotics (compounds foreign to nature) either interact with signaling pathways or receptors and misdirect morphologically important cellular functions, or they are cytotoxic and lead to cell death in excess of the usual developmental program.

In general, drug receptors expressed in embryos and fetuses are the same molecules that mediate effects in adults. However, because differentiation pathways are active, and embryonic and fetal physiology differs from that of mature organisms, pharmacologic effector systems may be different.

To affect human embryonic and fetal tissues, xenobiotics must traverse the placenta. The human placenta is a relatively good barrier against microorganisms, but it is substantially less effective at excluding drugs and chemicals. The physicochemical properties (eg, molecular size, solubility, charge) that allow foreign chemicals to be absorbed into the maternal circulation also allow them to cross the placenta. Xenobiotic metabolism occurs in the human placenta, but the placenta is better able to metabolize steroid hormones and low-level environmental contaminants than drugs.

The timing of xenobiotic exposure is an important determinant of its effects. Individual organs express so-called critical periods of development, during which they are particularly susceptible to maldevelopment, if their programs for differentiation are disrupted or unbalanced. Figure 33–10 shows critical periods of development for several organs. These periods are not confined to early gestation. Note, for instance, that the developing brain is susceptible to toxicity throughout pregnancy.

Prescribed and over-the-counter drugs that reach pharmacologically active levels in maternal blood will,

in general, equilibrate to the same levels across the placenta. Agents known to produce cytotoxicity in adults are therefore likely to be teratogenic. Abused substances achieve pharmacologically and toxicologically active levels on both sides of the placenta. Because they are frequently toxic to adults, they will be predictably toxic to embryos and fetuses. Drugs generally safe in adults will be generally safe for fetuses, but depending on specific drug-effector actions, some risk for abnormal development must always be considered. Risk assessment requires continuous monitoring of populations exposed to drugs during pregnancy.

Effects of environmental contaminants on the embryo and fetus are also dose-dependent. Thus the level of exposure frequently becomes the primary determinant of risk. In general, exposures producing symptoms in mothers can be assumed to be potentially toxic to the fetus.

Mutagens in the environment may be a special problem. Experiments at high levels of exposure indicate that mutagenic agents are also teratogenic. Specific phenotypes, however, are difficult to predict. Mutations induced in embryonic tissues result in mosaicism. These changes may not be visible but can contribute to diseases such as cancer later in life. DNA damage in developing cells can switch them into apoptotic pathways and may therefore have more immediate effects. The extent of this problem for humans is incompletely understood. Maternal exposure to mutagenic chemotherapy is predictably associated with abnormalities of fetal growth or birth defects. Evidence is also accumulating that transplacental exposures to environmental mutagens may affect brain growth. Not all transplacental pharmacologic effects are toxic. There is increasing potential for therapeutic transplacental uses of drugs in pregnancy. For example, folic acid supplementation can lower risks for birth defects such as spina bifida, and maternally administered corticosteroids induce fetal synthesis and secretion of surfactants prior to delivery.

MECHANICAL FACTORS

Much of embryonic development and all of fetal growth occur normally with the conceptus surrounded by amniotic fluid. The low pressure and the space provided by this fluid are critical for the development of most organs. Disruption of the formation or integrity of placental membranes for whatever reason can lead to major, usually lethal, distortion of the embryo (early amnion disruption sequence) or to deformation or even amputation of fetal extremities (amniotic band sequence).

Fetal movement is also important for morphogenesis. Normal movement is necessary for normal development of joints and is the principal determinant of folds

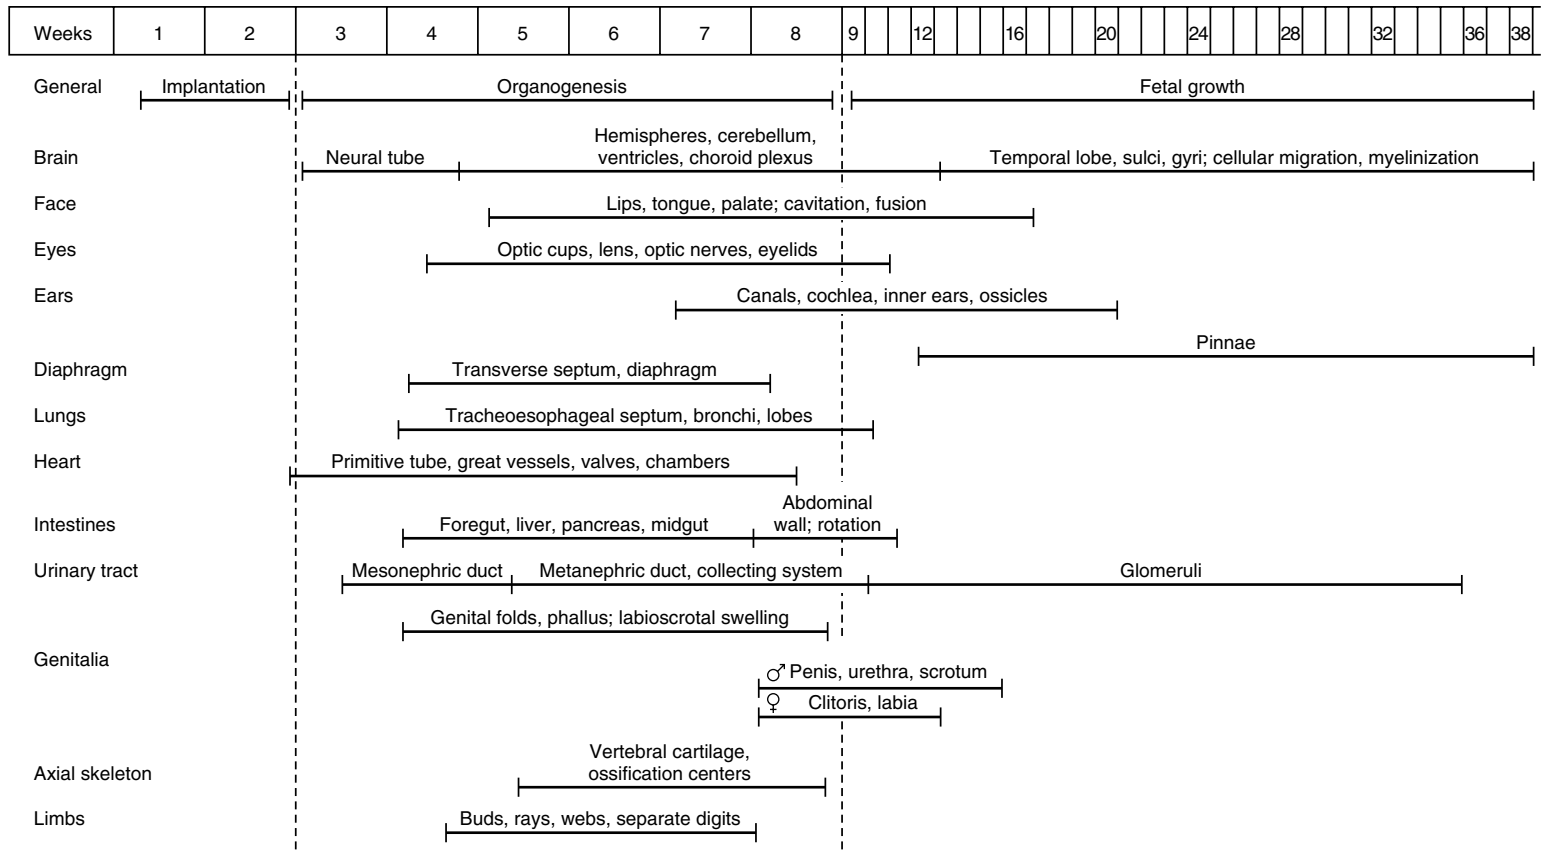

Figure 33–10. Critical periods in human gestation.

and creases present at birth in the face, hands, feet, and other areas of the body. In the presence of fetal muscle weakness, for instance, developing joints conform to fetal position and shape of the uterus. Clubfoot, an etiologically heterogeneous condition in which the foot is malpositioned at birth, more often results from mechanical constraint secondary to intrauterine crowding, decreased muscle strength or tone, or abnormal neurologic function than from primary skeletal maldevelopment.

Lung and kidney development are particularly sensitive to mechanical forces. Constriction of the chest through maldevelopment of the ribs, lack of surrounding amniotic fluid, or lack of movement (fetal breathing) leads to varying degrees of pulmonary hypoplasia in which lungs are smaller than normal and develop fewer alveoli. Mechanically induced pulmonary hypoplasia is a common cause of respiratory distress at birth and may be lethal. Cystic renal dysplasia commonly accompanies birth defects that obstruct ureters or outflow from the bladder. In such cases, as the kidneys become functional, urinary pressure within obstructed collecting systems increases and is propagated back into developing tissues. This is a good example of how distortion of cell surface interactions and malalignment of extracellular matrix may lead to abnormal histogenesis. Developing kidneys exposed for long periods to increased internal pressures eventually become non-functional.

PRENATAL DIAGNOSIS

To investigate fetal growth and development, prenatal visits should be noted and, with the aid of the obstetric wheel, a record should be made of the patterns of fetal growth, the onset of fetal movement (usually at 16 weeks), and the mother's perceptions of fetal movements. Normal fetal movement is usually strong enough to discomfort the mother and be visible to the father. Abnormal fetal movement may indicate neuromuscular dysfunction or fetal constraint. A history of decreased fetal movement will often distinguish neuromuscular abnormalities (which result in a low Apgar score) from intrapartum events (which depress the infant).

Abnormal patterns of uterine growth may also provide clues to fetal function. Increased uterine size may indicate accumulation of amniotic fluid (hydramnios). Fluid may accumulate if the fetus fails to swallow as a result of a neuromuscular disorder, obstruction of the fetal esophagus or proximal small bowel, or fetal heart failure. Hydramnios is also associated with diabetes and high-output renal failure in the fetus. Lack or delay of uterine growth may reflect fetal growth directly or may be a sign of too little amniotic fluid (oligohydramnios).

Amniotic fluid may be lost through premature rupture of membranes with or without formation of amniotic bands, or it may be the result of compromised function of fetal kidneys. The mother should be questioned about loss or leakage of amniotic fluid, which may have been mistaken for a vaginal discharge.

The history should also include details about the onset and progression of labor. Breech presentation at term may indicate a uterine anomaly or abnormality of the fetal CNS. Placental pathology should also be reviewed.

CLINICAL DYSMORPHOLOGY

Classification of dysmorphic features is beginning to reflect better understanding of the mechanisms of maldevelopment. However, much of the nomenclature used to describe abnormal development remains historical, and reflects the fact that many patterns of birth defects were recognized prior to any understanding of their molecular biology.

Birth defects are referred to as **malformations** when they result from altered genetic or developmental processes. When physical forces interrupt or distort morphogenesis, their effects are termed **disruptions** and **deformations**, respectively. The term **dysplasia** is used to denote abnormal histogenesis. Malformations occurring together more frequently than would be expected by chance alone, whether within a currently recognized developmental field or not, may be classified as belonging to **associations**. Those in which the order of maldevelopment is understood may be referred to as **sequences**. For example, Robin sequence (Pierre Robin syndrome) is used to describe cleft palate that has occurred because poor growth of the jaw (retrognathia) has displaced the tongue and prevented posterior closure of the palate. **Syndromes** are simply recurrent patterns of maldevelopment.

Evaluation of the Dysmorphic Infant

Physicians caring for infants with birth defects must frequently provide care and make accurate diagnoses under conditions of great stress. The extent of an infant's abnormalities may not be immediately apparent, and parents who feel grief and guilt are often desperate for information. As with any medical problem, however, the history and physical examination provide most of the clues to diagnosis. Special aspects of these procedures are outlined in the following sections.

A. HISTORY

Environmental, family, and pregnancy histories may contain important clues to the diagnosis. Parental recall after delivery of an infant with an anomaly is better

than recall after a normal birth. An obstetric wheel can help document gestational age and events of the first trimester: the last menstrual period, the onset of symptoms of pregnancy, the date of diagnosis of the pregnancy, the date of the first prenatal visit, and the physician's impressions of fetal growth at that time.

Family histories should always be included and may provide important clues to genetic cause of the infant's issues. Finally, an environmental history that includes descriptions of parental habits, their work, and the home should be obtained.

B. PHYSICAL EXAMINATION

Meticulous physical examination is crucial for accurate diagnosis in dysmorphic infants and children. In addition to the routine procedures described in Chapter 1, special attention should be paid to the neonate's physical measurements (Figure 33–11). Photographs are helpful and should include a scale of measurements for reference.

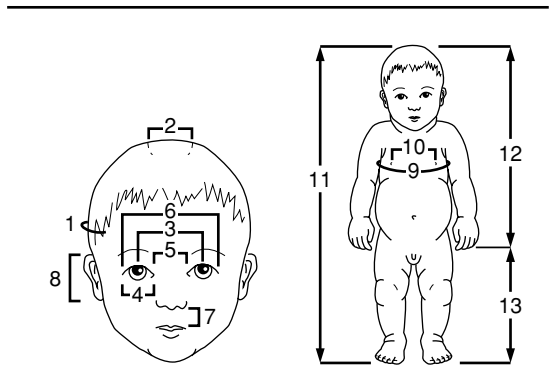

C. IMAGING & LABORATORY STUDIES

Radiologic and ultrasonographic examinations can be extremely helpful in the evaluation of dysmorphic infants. In general, films of infants with apparent limb or skeletal anomalies should include views of the skull and all of the long bones in addition to frontal and lateral views of the axial skeleton. Chest and abdominal films should be obtained when indicated. The pediatrician should consult a radiologist for further work-up. Nuclear scans and imaging by computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography are all useful diagnostic tools, but their interpretation in the presence of birth defects may require considerable experience.

Cytogenetic analysis provides specific diagnoses in approximately 5% of dysmorphic infants who survive the newborn period. Chromosomal abnormalities are recognized in 10–15% of infants who die. Karyotypes can be determined rapidly through use of FISH. These allow limited interpretation and should always be accompanied by complete analysis of cultured cells. Any case requiring rapid diagnosis should be discussed with an experienced dysmorphologist. A normal karyotype does not rule out the presence of significant genetic disease.

D. PERINATAL AUTOPSY

When a dysmorphic infant dies, postmortem examination can provide important diagnostic information and should include sampling of tissue for cytogenetic analysis. The pediatrician and the pathologist should consider whether samples of blood, urine, or tissue should be obtained for metabolic analyses.

Measurement	Range (cm)	
	Term (38–40 weeks)	Preterm (32–33 weeks)
1 Head circumference	32–37	27–32
2 Anterior fontanelle ($\frac{L-W}{2}$)	0.7–3.7	...
3 Interpupillary distance	3.3–4.5	3.1–3.9
4 Palpebral fissure	1.5–2.1	1.3–1.6
5 Inner canthal distance	1.5–2.5	1.4–2.1
6 Outer canthal distance	5.3–7.3	3.9–5.1
7 Philtrum	0.6–1.2	0.5–0.9
8 Ear length	3–4.3	2.4–3.5
9 Chest circumference	28–38	23–29
10 Internipple distance*	6.5–10	5–6.5
11 Height	47–55	39–47
12 Ratio Upper body segment	1.7	...
13 Ratio Lower body segment		
14 Hand (palm to middle finger)	5.3–7.8	4.1–5.5
15 Ratio of middle finger to hand	0.38–0.48	0.38–0.5
16 Penis (pubic bone to tip of glans)	2.7–4.3	1.8–3.2

*Internipple distance should not exceed 25% of chest circumference.

Figure 33–11. Neonatal measurements.

Radiologic studies should be done whenever limb anomalies or disproportionate growth is present. Placental as well as fetal tissue can be used for viral culture. The pediatrician should discuss the case thoroughly with the pathologist, and photographs should always be taken.

CLINICAL FEATURES OF COMMON GENETIC DISORDERS

CHROMOSOMAL DISORDERS: ABNORMAL NUMBER

ANEUPLOIDY

Trisomy 21 (Down Syndrome)

Down syndrome occurs in about 1:600 newborns; however, the incidence is greater among children of mothers older than age 35 years. Mental retardation is characteristic of Down syndrome, with typical intelligence quotients (IQs) between 20 and 80 (mostly between 45 and 55). The principal physical findings include a small, brachycephalic head, characteristic facies (up-slanting palpebral fissures, epicanthal folds, mid-face hypoplasia, and small, dysplastic pinnae), and other dysmorphic features. About one third to one half of children with Down syndrome have congenital heart disease, most often an endocardial cushion defect or other septal defect. Anomalies of the gastrointestinal (GI) tract are seen in about 15% of cases, including esophageal and duodenal atresias. Generalized hypotonia is common. Sexual development is retarded, especially in males, who are usually sterile. The affected newborn may have prolonged physiologic jaundice, polycythemia, and a transient leukemoid reaction. Later, there is an increased tendency for thyroid dysfunction, hearing loss, celiac disease, and atlanto-occipital instability. Leukemia is 12–20 times more common in Down syndrome patients than in unaffected children.

Trisomy 18 Syndrome

The incidence of trisomy 18 syndrome is about 1:4000 live births, and the ratio of affected males to females is approximately 1:3. Trisomy 18 is characterized by prenatal and postnatal growth retardation that is often severe; hypertonicity; dysmorphic features, including a characteristic face (see the following website for clinical pictures:

medgen.genetics.utah.edu/photographs/pages/trisomy_18.htm

and extremities [overlapping fingers and rockerbottom feet]; and congenital heart disease [often ventricular septal defect or patent ductus arteriosus]). Complications are related to associated birth defects. Death is often caused by heart failure or pneumonia and usually occurs in infancy or early childhood, although a small

percentage of patients reach adulthood. Surviving children show significant developmental delay and mental retardation.

Trisomy 13 Syndrome

The incidence of trisomy 13 is about 1:12,000 live births, and 60% of affected individuals are female. The mean maternal age is increased. The symptoms and signs include prenatal and postnatal growth deficiency (although, unlike trisomy 18, infants may have a normal birth weight), CNS malformations, arrhinencephaly, eye malformations (anophthalmia, colobomas), cleft lip and palate, polydactyly or syndactyly, and congenital heart disease (usually ventricular septal defect). The facies of an infant with trisomy 13 can be viewed on the following website:

medgen.genetics.utah.edu/photographs/pages/trisomy_13.htm

Surviving children demonstrate failure to thrive, developmental retardation, apneic spells, seizures, and deafness. Death usually occurs in early infancy or by the second year of life, commonly as a result of heart failure or infection.

Treatment for Aneuploidies

There is no convincing documentation of the merit of any of the forms of specific therapy that have been attempted in Down syndrome, ranging from megadoses of vitamins to exercise programs proposed to overcome the physical and developmental abnormalities of the syndrome. Therapy is for specific problems: surgery or drugs for heart problems, antibiotics for infections and thyroid function tests, infant stimulation programs, special education, and occupational training as required. The goal of treatment is to help affected children develop to their full potential. Parents' participation in support groups such as the local chapter of the National Down Syndrome Congress should be encouraged. See the following website:

<http://www.ndss.org/>

There is no treatment, other than general supportive care, for trisomy 13 or 18. Because it is sometimes necessary to decide immediately after birth how extensive therapy should be for a severely malformed infant, trisomy 13 and 18 can be screened for in interphase nuclei of blood lymphocytes by FISH and confirmed by direct chromosome analysis of blood or bone marrow mitoses. A support group for families of children with trisomies 13 and 18 who survive beyond infancy is called SOFT. See the following website:

www.trisomy.org/

Genetic Counseling

Most parents of trisomic babies have normal karyotypes. The risk of having a child affected with a trisomy varies with maternal age. For trisomy 21, age-specific risks are 1:2000 for mothers younger than age 25 years; 1:200 for mothers age 35 years; 1:100 for mothers age 40; and 1:10 for mothers older than age 45 years. The recurrence risk for trisomy in future pregnancies is equal to 1:100 plus the age-specific maternal risk (for example, a 40-year-old mother with a prior child with Down syndrome would have a risk of 1:100 for her age, plus 1:100 for her prior history, or 1:50). If the child has a trisomy resulting from a translocation, and the parent has an abnormal karyotype, the risks are increased.

When the mother is the carrier of a balanced 14/21 translocation, there is a 10–15% chance that the child will be affected and a 33% chance that the child will be a balanced translocation carrier. When the father is the carrier, there is a smaller than 0.5% chance of having another affected child. If the child has a 21/21 translocation and one parent has the translocation, the recurrence risk is 100%.

The recurrence risks in other trisomies are analogous to those for Down syndrome. The mother's age at the time of conception and the nature of the chromosomal abnormality are important in genetic counseling, which is indicated for prevention of all chromosomal abnormalities. Prenatal diagnosis is available.

SEX CHROMOSOMES

Turner Syndrome (Monosomy X, Gonadal Dysgenesis)

The incidence of Turner syndrome is 1:10,000 females. However, it is estimated that 95% of conceptuses with monosomy X are miscarried and only 5% are liveborn. Newborns with Turner syndrome may have webbed neck, edema of the hands and feet, coarctation of the aorta, and a characteristic triangular facies. Later symptoms include short stature, a shield chest with wide-set nipples, streak ovaries, amenorrhea, absence of secondary sex characteristics, and infertility. Some affected girls, particularly those with mosaicism, have only short stature and amenorrhea, without dysmorphic features. Complications relate primarily to coarctation of the aorta, when present. Rarely, the dysgenetic gonads may become neoplastic (gonadoblastoma). The incidence of malformations of the urinary tract is increased. Learning disabilities are common, secondary to difficulties in perceptual motor integration. Patients with pseudohy-

poparathyroidism and Noonan syndrome have a similar phenotype to patients with Turner syndrome, but have normal chromosomes.

In Turner syndrome the identification and treatment of perceptual difficulties before they become problematic is very important. Teenage patients need counseling to cope with the stigma of their condition and to understand the need for hormone therapy. Estrogen replacement therapy will permit development of secondary sex characteristics and normal menstruation and prevent osteoporosis. Growth hormone therapy has been used to increase the height of affected girls. Females with 45,X or 45,X mosaicism have a low fertility rate, and those who become pregnant have a high risk of fetal wastage (spontaneous miscarriage, approximately 30%; stillbirth, 6–10%). Furthermore, their liveborn offspring have an increased frequency of chromosomal abnormalities involving either sex chromosomes or autosomes, and congenital malformations. Thus prenatal ultrasonography and chromosome analysis are indicated for the offspring of females with sex chromosome abnormalities.

Klinefelter Syndrome (XXY)

The incidence of Klinefelter syndrome in the newborn population is roughly 1:1000, but it is about 1% among mentally retarded males and about 3% among males seen at infertility clinics. The maternal age at birth is often advanced. Unlike Turner syndrome, Klinefelter syndrome is rarely the cause of spontaneous abortions. The diagnosis is rarely made before puberty except as a result of prenatal diagnosis, because prepubertal boys have a normal phenotype. The characteristic findings after puberty include micro-orchidism associated with otherwise normal external genitalia, azoospermia, sterility, gynecomastia, normal to borderline IQ, diminished facial hair, lack of libido and potency, and a tall, eunuchoid build. In chromosome variants with three or four X chromosomes (XXXY and XXXXY), mental retardation may be severe, and radioulnar synostosis may be present as well as anomalies of the external genitalia and cryptorchidism. In the XXXXY cases, these findings are especially prominent, and microcephaly, short stature, and dysmorphic features also occur. In general, the physical and mental abnormalities associated with Klinefelter syndrome increase as the number of sex chromosomes increases. Males with Klinefelter syndrome require testosterone replacement therapy.

XYY Syndrome

Newborns in general are normal. Affected individuals may on occasion exhibit an abnormal behavior pattern

from early childhood and may have mild retardation. Fertility may be normal. Many males with an XYY karyotype are normal. There is no treatment. Long-term problems may relate to low IQ and environmental stress.

XXX Syndrome

The incidence of females with an XXX karyotype is approximately 1:1000. Females with XXX are phenotypically normal. However, they tend to be taller than usual and to have lower IQs than their normal siblings. Learning and behavioral issues are relatively common. This is in contrast to individuals with XXXX, a much rarer condition causing more severe developmental issues, and a dysmorphic phenotype reminiscent of Down syndrome.

Gorlin RJ et al: *Syndromes of the Head and Neck*, 4th ed, Chapter 3. Oxford University Press, 2001.

Jones KL: *Smith's Recognizable Patterns of Human Malformation*, 5th ed. WB Saunders, 1996.

MOSAICISM

Although most cases of severe chromosomal abnormality such as trisomy are lethal, some individuals may survive if the abnormality exists in mosaic form (ie, the patient has a mixture of trisomic and normal cells). Two disorders with this condition include trisomy 8 and Cat-eye syndromes.

Trisomy 8 Syndrome

More than 100 cases of this condition have been reported. The phenotype is variable, but includes mildly dysmorphic features (deep-set eyes, hypertelorism, prominent pinnae, high arched or cleft palate), skeletal, cardiac, and renal malformations. Cognitively, the individuals have limitations ranging from mild to severe.

Cat-Eye Syndrome

Cat-eye syndrome is caused by an extra chromosome, which is derived from a portion of chromosome 22 (the short arm, centromere, and a small piece of the long arm). The phenotype consists of iris coloboma (causing the appearance of the eye lending its name to the syndrome), dysmorphic features (down-slanting palpebral fissures, malformed pinnae), and anal atresia. Other common anomalies include those of the heart, kidneys, and GI tract. Intelligence is usually mildly impaired, but may be normal.

CHROMOSOMAL ABNORMALITIES: STRUCTURAL

Chromosomal abnormalities are most often present in newborns as multiple congenital anomalies in association with intrauterine growth retardation. Common aneuploid syndromes (trisomies 13, 18, and 21) were described earlier in this chapter. Several common chromosomal deletions produce contiguous gene syndromes recognizable in newborns. In the presence of apparently normal chromosomes, each of these conditions can be detected by FISH.

Wolf-Hirschhorn Syndrome

Also known as 4p- (deletion of 4p16), this syndrome is characterized by microcephaly and unusual development of the nose and orbits that produces an appearance suggesting an ancient Greek warrior's helmet. Association with cleft lip and palate and other major organ anomalies, such as heart and renal structural anomalies and seizure disorders, are common. The majority of the patients have severe developmental delay and mental retardation. However, higher functioning individuals have been reported. A critical region defines the facial features of this syndrome and is detectable by FISH.

Cri Du Chat Syndrome

Also known as 5p- (deletion of terminal chromosome 5p), this disorder is characterized by unique facial features, growth retardation, and microcephaly. Patients have an unusual cat-like cry. Most patients have major organ anomalies and significant developmental delay.

Williams Syndrome

This, a contiguous gene disorder involving the elastin gene and other neighboring genes at 7q11.2, is characterized by short stature, congenital heart disease (supravalvular aortic stenosis), coarse, elfin-like facies with prominent lips, hypercalcemia or hypercalciuria in infancy, developmental delay, and neonatal irritability evolving into an overly friendly personality. Microdeletions of the elastin gene are diagnostic through FISH testing. However, individuals with smaller deletions require more specific probes to confirm the diagnosis. Calcium restriction may be necessary in early childhood to prevent nephrocalcinosis. Calcium determination is recommended in early infancy, and the hypercalcemia often resolves during the first year of life. The natural history includes progression of cardiac disease and pre-

disposition to hypertension and spinal osteoarthritis in adults. Most patients have mild to moderate intellectual deficits.

Langer–Giedion Syndrome

This syndrome, also known as trichorhinophalangeal syndrome type II, is caused by a deletion on the long arm of chromosome 8 (8q24.11–q24.13). Individuals with Langer–Giedion syndrome show unusual facial features (large, bulbous nose, large ears), and develop bony abnormalities including cone-shaped epiphyses and multiple bony exostoses. The skin may be loose and redundant, resembling the connective tissue disorder Ehlers–Danlos syndrome. Intelligence is impaired and hearing loss is common.

Aniridia–Wilms Tumor Association (WAGR)

WAGR syndrome, which stands for **W**ilms tumor, **a**niridia, **g**enitourinary anomalies, and **r**etardation, is caused by a deletion of the short arm of chromosome 11 (11p13). In addition to the aniridia, other common eye defects include cataracts and ptosis. Many patients have visual impairment. About one half of patients develop Wilms tumor. Other anomalies include facial dysmorphism and genitourinary abnormalities.

Miller–Dieker Syndrome

A contiguous gene syndrome involving 17p13, this abnormality is characterized by microcephaly and severe CNS dysgenesis. The most commonly seen CNS malformation is termed **lissencephaly** (“smooth brain” as the brain is lacking its normal convolutions and gyri). An unusually developed face and forehead reflect abnormal migration of neuronal germinal matrix cells. When the affected individuals cry, characteristic longitudinal grooves appear in the forehead. Mutations in the gene *MDS1*, which is located in the critical region, can cause isolated lissencephaly, without the full picture of Miller–Dieker. Severe cognitive and developmental delay and seizure disorders are common. In the presence of apparently normal chromosomes, FISH can detect this condition.

Smith–Magenis Syndrome

This syndrome is associated with microdeletion of 17p11 and is characterized by prominent forehead, deep-set eyes, cupid-shaped upper lip, self-mutilating behavior (pulling nails and hair, putting objects into body orifices), sleep disturbance, and developmental delay. Some patients also have seizure disorders. Melatonin has proven helpful in improving the abnormal sleep patterns and controlling the behavior. Some indi-

viduals with larger deletions involving *PMP22* can present with peripheral neuropathy.

Del 22q11 Syndrome

Also known as DiGeorge syndrome, this abnormality was originally described in newborns presenting with cyanotic congenital heart disease, usually involving great vessel abnormalities; thymic hypoplasia leading to immunodeficiency; and hypocalcemia due to absent parathyroid glands. The disorder is now known to result most often from deletions of chromosome 22q11 and to be phenotypically highly variable. The less severe phenotypes include velocardiofacial syndrome (VCFS), Shprintzen syndrome, Cayler cardiofacial syndrome, and a subset of Opitz G and BBB syndromes. Characteristics include mild microcephaly; palatal clefting or incompetence; speech and language delays; congenital heart disease (ventricular or atrial septal defect); build-up of tissue lateral to the nose; long, tapering fingers; and emotional lability. Midline defects such as umbilical hernia and hypospadias can be associated anomalies. In some cases, individuals have an apparent predisposition to psychosis.

MENDELIAN DISORDERS

AUTOSOMAL DOMINANT INHERITANCE

1. Neurofibromatosis Type 1

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Minimal diagnostic criteria require two or more of the following:

- Six or more café au lait macules, at least 15 mm in diameter in postpubertal and 5 mm in prepubertal individuals.
- Two or more neurofibromas of any type or one plexiform neurofibroma.
- Axillary or inguinal freckling.
- Two or more Lisch nodules (iris hamartomas)
- Optic glioma
- Distinctive bony lesions such as sphenoid dysplasia or pseudarthrosis.
- An affected first-degree relative.

General Considerations

Neurofibromatosis 1 (NF-1) is one of the most common autosomal dominant disorders, occurring in 1:3000 births and seen in all races and ethnic groups. It has a wide range of clinical manifestations. In general, the disorder is progressive, and new manifestations appear over time. Neurofibromatosis 2, characterized by bilateral acoustic neuromas, with minimal or no skin manifestations, is a different disease caused by a different gene.

Clinical Findings

Café au lait macules may be present at birth, and about 80% of individuals with neurofibromatosis 1 will have more than six by age 1 year. The typical skin lesion is 10–30 mm, ovoid, and smooth-bordered, but there is great variation. Neurofibromas are benign tumors consisting of Schwann cells, nerve fibers, and fibroblasts; they may be discrete or plexiform. Discrete tumors are more common and can occur at any age. They are well demarcated and can present in cutaneous, subcutaneous, or internal tissues. Plexiform neurofibromas are more diffuse and can invade normal tissue. They are congenital and are frequently detected during periods of rapid growth. If the face or a limb is involved, there may be associated hypertrophy or overgrowth. The incidence of Lisch nodules, which can be seen with a slitlamp, also increases with age.

Common features of affected individuals include a large head (though only a small percentage have true hydrocephalus), bony abnormalities on radiographic studies, scoliosis, and a wide spectrum of developmental problems. The most common problems in childhood are secondary to plexiform neurofibromas and learning disabilities. Although the average IQ is within the normal range, it is lower than in unaffected family members. The common learning disabilities seen in patients with NF include dyslexia, dysgraphia, and disorders of visual perception.

Differential Diagnosis

Areas of hyperpigmentation can occur in other conditions (eg, Albright, Noonan, and Leopard syndromes), but the lesions are either single or different in character. Isolated neurofibromas and familial café au lait spots as an autosomal dominant trait (fewer than six and with no other manifestations of NF) have been described. The relationship of such cases to classic NF-1 is uncertain.

Complications

It is difficult to differentiate a complication from a rare manifestation of the underlying disorder. Seizures,

deafness, short stature, early puberty, and hypertension occur in less than 25% of persons with NF. Optic glioma seems to occur in about 15% of individuals with NF-1. Although the tumor may be apparent at an early age, it rarely causes functional problems and is usually nonprogressive. Patients have a slightly increased risk (5% life risk) for a variety of malignancies. Other tumors may be benign but may cause significant morbidity and mortality because of their size and location in a vital or enclosed space.

Treatment

The therapy is symptomatic. Neurofibromas can be removed if they cause discomfort or are a cosmetic problem. The most important part of therapy is close, ongoing follow-up. Because this disorder is progressive, affected individuals should be seen at regular intervals and have regular monitoring of height, head circumference, blood pressure, and scoliosis. Additionally, eye examinations are necessary for early detection of changes associated with aggressive optic glioma. Developmental screening as well as other evaluations (eg, MRI scans) are done as indicated according to symptoms. Follow-up is best done in a multidisciplinary neurocutaneous clinic.

Prognosis

Because NF varies so widely in its progress, assessing prognosis is difficult. However, most affected children have only skin lesions and few other problems. Severely affected individuals are rare in the pediatric age range, and close follow-up and early intervention may ameliorate some complications.

Genetic Counseling

The gene for NF-1 is on the long arm of chromosome 17 and seems to code for a protein similar to a tumor suppressor factor. NF results from many different mutations of this gene. Approximately 50% of all cases of NF are caused by new mutations. Before attributing an individual case to a new mutation, however, both parents must be evaluated carefully, including a thorough examination of the skin and a slitlamp examination to look for Lisch nodules. Recent evidence suggests that penetrance is close to 100% in those who carry the gene if individuals are examined carefully.

2. Marfan Syndrome

Marfan syndrome is caused by mutations in genes coding for the connective tissue protein fibrillin, but laboratory detection of mutations in clinical practice remains, for the time being, difficult. Clinical diagnostic

criteria have been developed that include disproportionate growth (arachnodactyly and tall stature), joint hyperextensibility, lens dislocation, and dilation of the aortic root. The latter two characteristics are considered major criteria and are diagnostic when accompanied by evidence of connective tissue involvement, usually joint hyperextensibility. The characteristic facies is long and thin, with down-slanting palpebral fissures. The palate is high arched, and dentition is often crowded. The most serious associated medical problems involve the heart. Many patients with Marfan syndrome have mitral valve prolapse. A potentially life-threatening cardiac problem is progressive aortic root dilatation, which may lead to aneurysmal rupture and death.

The diagnosis of Marfan syndrome is still made on a clinical basis, and many cases represent sporadic new mutations. Although the gene for fibrillin has been identified, many unique, family-specific mutations occur, making molecular confirmation difficult.

Medical treatment for patients with Marfan syndrome includes appropriate management of the ophthalmologic, orthopedic, and cardiac issues. Serial echocardiograms are indicated to diagnose and follow the degree of aortic root enlargement, which can be managed medically or surgically, in more severe cases. In individuals with marfanoid habitus and cognitive disabilities, homocystinuria should be excluded through careful metabolic testing. Another connective tissue disorder, Ehlers–Danlos syndrome (EDS), shares some features with Marfan syndrome, including joint hyperextensibility and skin fragility. The skin is the target organ for the most significant symptoms in EDS patients. At least nine forms of EDS occur, most inherited as dominant traits, but the biochemical causes have only been worked out for a few of the forms.

3. Achondroplasia

Achondroplasia is the most common form of skeletal dysplasia, like many forms of skeletal dysplasias is inherited as a dominant condition, and is caused by a mutation in *FGFR3*. The classic phenotype includes relative macrocephaly, midface hypoplasia, short-limbed dwarfism, and trident-shaped hands. The phenotype is apparent at birth and may be diagnosed prenatally on ultrasound. Individuals with achondroplasia are cognitively normal. Bony overgrowth at the level of the foramen magnum may lead to progressive hydrocephalus and may warrant neurosurgical intervention. Because of this, head circumference during infancy must be closely monitored and plotted on a diagnosis-specific head circumference chart. Serial head ultrasounds are helpful every few months. Orthopedic intervention is necessary for spinal problems including severe lumbar lordosis and gibbus deformity. Long

bone lengthening surgery, such as the Ilizarov procedure, are used in some centers to increase height and upper extremity function, but their use is still controversial. Two hemizygous parents with achondroplasia have a 25% risk of having a child homozygous for *FGFR3* mutations, which is a lethal disorder.

4. Osteogenesis Imperfecta

Osteogenesis imperfecta (OI), or brittle bone disease, is a relatively common autosomal dominant disorder, caused by mutations in type I collagen. Most patients with more severe disease represent new mutations for this disorder. There are four types of OI. Types I and IV are relatively mild and generally present with increased incidence of fracturing, but otherwise a fairly normal phenotype. Type II is generally lethal in the newborn period and is the most severe form. Formerly believed to be autosomal recessive, type II is now thought to be caused by a new dominant mutation, with multiple cases within a family attributed to parental germ cell mosaicism. Type III is the severe form causing significant bony deformity secondary to multiple fractures. A major advancement in the treatment of OI patients has been the use of pamidronate, a bisphosphonate compound, which has been reported to lead to a reduced incidence of fracture and improvement in bone density.

5. Craniosynostoses Syndromes

The craniosynostoses disorders are common dominant disorders associated with premature fusion of cranial sutures. This class of disorders is now known to be caused by mutations in *FGFR* genes. Crouzon syndrome is the most common of these disorders and is associated with multiple suture fusions, but with normal limbs. Common problems associated with craniosynostosis include shallow orbits leading to proptosis, midface narrowing that may result in upper airway obstruction, and hydrocephalus that may require shunting. Children with craniosynostosis undergo multiple staged craniofacial/neurosurgical procedures to address these issues. Other craniosynostosis disorders have limb as well as craniofacial anomalies, and include Pfeiffer, Apert, Jackson–Weiss, and Saethre–Chotzen syndromes.

6. Treacher Collins Syndrome

Treacher Collins syndrome is a dominant disorder, although more than half of the patients present as a result of new mutations. This is a craniofacial disorder associated with malar and mandibular hypoplasia, malformed ears with associated hearing loss, and abnormalities of

the eye including lower lid coloboma and absent lashes. Airway anomalies may occur, causing life-threatening problems in the newborn period. Intelligence is generally normal. This disorder has been linked to chromosome 5q32–33.2 in some families.

AUTOSOMAL RECESSIVE DISORDERS

1. Cystic Fibrosis

The gene for cystic fibrosis (CF), *CFTR*, is found on the long arm of chromosome 7. Approximately 1 in 22 persons are carriers. Over 600 different mutations have been identified: the most common in the Caucasian population, known as ΔF 508, is a three-base deletion coding for phenylalanine.

Cloning of the gene for CF and identification of the mutation in the majority of cases have completely changed genetic counseling and prenatal diagnosis for this disorder, although the sweat chloride assay is still important in confirming the diagnosis. The American College of Medical Genetics recommends the 25-mutation assay using PCR-based techniques, which can cover 85–90% of the mutations. If a mutation is found, carriers can be identified and specific prenatal diagnosis can be performed, identifying both carriers and affected fetuses. If a mutation cannot be identified, linkage analysis, DNA haplotyping, and amniotic fluid enzyme studies can be done.

The identification of the mutation in the CF gene has also raised the issue of mass newborn screening, because of the high frequency of this gene in the Caucasian population. Some states, such as Colorado, have offered newborn screening by trypsinogen assay, which can detect 70% of CF patients. Although the argument can be made for such screening (because early detection can ensure good nutritional status starting at birth, which is the key prognostic factor for the classic CF patient), newborn screening is controversial as there is no cure for CF. (For more details of medical management, please see Chapters 18 [Respiratory Tract & Mediastinum] and 20 [Gastrointestinal Tract] in this text).

2. Smith–Lemli–Opitz Syndrome

Smith–Lemli–Opitz (SLO) syndrome, a common autosomal recessive disorder, may have an incidence as high as 1:8000, and the carrier frequency may be as high as 1:31. In 1994, SLO was shown to be caused by a metabolic error in the final step of cholesterol production. This enzyme deficiency results in low cholesterol levels and accumulation of the precursor 7-dehydrocholesterol. Patients with SLO present with a characteristic phenotype, including dysmorphic facial features (Figure 33–12), multiple congenital anomalies (including

Figure 33–12. Child with Smith–Lemli–Opitz syndrome, featuring bitemporal narrowing, upturned nares, ptosis, and small chin.

defects of the CNS, heart, cleft palate, cardiac, kidneys, genitalia and limbs), hypotonia, growth failure, and mental retardation. Treatment with cholesterol can ameliorate the growth failure and lead to improvement in behavior and developmental course, although treatment does not cure this complex disorder.

3. Sensorineural Hearing Loss

Nonsyndromic, recessively inherited deafness is the predominant form of severe inherited childhood deafness. There is marked genetic heterogeneity in causes of sensorineural hearing loss (SNHL), including autosomal dominant, recessive, and X-linked patterns. Of mutations known to cause SNHL, mutations of connexin 26 (*CX26*), a gap junction protein, are present in 49% of cases of prelingual deafness. Gap junctions are regionally specialized structures on plasma membranes of contacting adherent cells. These structures were shown to consist of cell-to-cell channels. Connexins are the

proteins in the gap junctions. There are different kinds of connexins. Some mutations of connexin 26 can follow autosomal dominant inheritance, but the common mutations follow the recessive mode. Molecular testing is available.

Resendes BL et al: At the speed of sound: Gene discovery in the auditory system. *Am J Hum Genet* 2001;69:923 [PMID: 11577373].

4. Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disorder in which anterior horn cells in the spinal cord degenerate. The molecular basis for loss of these cells is incompletely understood, but the mechanism appears to involve apoptosis of neurons in the absence of the product of the *SMN 1* (survival motor neuron) gene located on chromosome 5q. Loss of anterior horn cells leads to progressive atrophy of skeletal muscle. The disorder has an incidence of approximately 1 in 12,000, with the majority of the cases presenting in infancy. Carrier frequencies approach 1 in 50 in populations with European ancestry. Three clinical phenotypes are recognized based on age of onset and rate of progression. SMA I is the most devastating. Mild weakness may be present at birth, but is clearly evident by 3 months and is accompanied by loss of reflexes. Progression of the disorder leads to fasciculations and eventual respiratory failure, usually by age 1 year. Symptoms of SMA II begin later; with weakness and decreased reflexes generally apparent by 2 years of age. Children affected with SMA III begin to become weak as they approach adolescence.

The genetics of SMA are complex and relate to duplication, deletion, and gene conversion events in the region of the *SMN 1* gene. Homozygous deletion of exon 7 is detectable in more than 90% of all forms of SMA and constitutes a genetic test by which the clinical diagnosis can be confirmed. Variability in presentation appears to involve expression of neighboring genes including a more centromeric *SMN 2* pseudogene. The presence and expression of multiple copies of *SMN 2*, and a nearly complete copy of *SMN 1*, introduces complexity into molecular genetic analysis used to detect carriers. Prenatal diagnosis is available through analysis of *SMN 1* or genetic linkage, but carrier testing in individuals not related to affected patients known to have homozygous *SMN 1* deletions is not yet available.

5. Metabolic Disorders

Most inborn errors of metabolism are inherited in an autosomal recessive pattern. See Chapter 32 in this text for detailed explanations of these disorders.

X-LINKED INHERITANCE

1. Duchenne-Type Muscular Dystrophy

Duchenne muscular dystrophy (DMD) results from failure of synthesis of the muscle cytoskeletal protein dystrophin, whose gene is located on the X chromosome, Xp12. Approximately 1 in 4000 male children are affected. Mutations in the same gene that result in partial expression of the dystrophin protein produce a less severe phenotype, Becker muscular dystrophy (BMD). In both disorders, progressive degeneration of skeletal muscle occurs. Cardiac muscle eventually also becomes involved. Boys with DMD exhibit proximal muscle weakness and pseudohypertrophy of calf muscles at age 5–6 years. Patients become nonambulatory at around age 13. Serum creatine kinase levels are markedly elevated. Affected boys frequently die in their early 20s of respiratory failure and cardiac dysfunction. The prognosis for BMD is more variable. Although corticosteroids are useful in maintaining strength, they do not slow progression of the disorder.

The gene for dystrophin is very large and a common target for mutation. Large deletions or duplications can be detected in the gene for dystrophin in 65% of cases. Demonstration of such a mutation provides a useful genetic marker for the disorder, but diagnosis and prognosis require muscle biopsy and immunohistochemistry for the dystrophin protein.

Theoretically, one third of DMD cases presenting with a negative family history are likely to be new mutations. When a mutation in the gene for dystrophin is detected, maternal carrier status is easily determined and work-up of the extended family is straightforward. Nonetheless, risk assessment and counseling must be approached with care since germline mosaicism for mutations in the gene for dystrophin occurs in approximately 15% of families. Thus, it is necessary to look for mutations in all sisters of affected boys. If a mutation has been detected, prenatal diagnosis is routinely offered to mothers regardless of their apparent carrier status based on analysis of blood samples. Since mutations are currently not detected in approximately 35% of cases, alternative approaches that estimate carrier risks based on creatine kinase levels and utilize genetic linkage for prenatal diagnosis remain useful. Counseling and prenatal diagnosis remain difficult in some families.

2. Hemophilia

Hemophilia A is an X-linked, recessive, bleeding disorder caused by a deficiency in the activity of coagulation factor VIII. Affected individuals develop a variable phenotype of hemorrhage into joints and muscles, easy

bruising, and prolonged bleeding from wounds. The disorder is caused by heterogeneous mutations in the factor VIII gene, which maps to Xq28. Carrier detection and prenatal diagnosis can be done by direct detection of selected mutations, especially the inversions, the most common gene change, as well as indirectly by linkage analysis. Replacement of factor VIII is done using a variety of preparations derived from human plasma or recombinant techniques. Although replacement therapy is effective in most cases, 10–15% of treated individuals develop neutralizing antibodies that decrease its effectiveness.

3. Alport Syndrome

Alport syndrome is characterized by variable degrees of hearing loss and nephropathy. It is a clinically heterogeneous disease and at least six different variants have been reported. The most common type is X-linked due to mutations in the gene coding for the alpha chain of type IV collagen. Female carriers with collagen IVA5 mutations may manifest mild clinical findings such as hematuria and later-onset hearing loss. Affected males usually develop end-stage renal disease. Molecular testing for affected males is available, but no single test is available for female carriers.

4. Metabolic Disorders

Some important inborn errors are inherited as X-linked disorders, such as adrenoleukodystrophy. See Chapter 32 in this text for more detailed descriptions.

NONMENDELIAN INHERITANCE DISORDERS OF IMPRINTING

1. Beckwith–Wiedemann Syndrome

The association of macrosomia (enlarged body size), macroglossia (enlarged tongue), and omphalocele constitutes the Beckwith–Wiedemann syndrome (BWS), now known to be related to abnormal expression of genes located at chromosome 11p15. Other associated findings include mild facial dysmorphism (hypertelorism, unusual ear creases), infantile hypoglycemia due to transient hyperinsulinemia, multiple congenital anomalies (cleft palate and genitourinary anomalies common), and increased risk for certain malignancies, especially Wilms tumor (7–10%). A growth factor gene, *IGF2* is normally imprinted such that the maternal allele is ordinarily not expressed during intrauterine development. Chromosomal abnormalities affecting expression of this gene, such as duplication of the paternal

11p15 region, are associated with BWS. Paternal UPD leading to duplication of transcription of *IGF2* on the paternal homolog, with loss of a tumor suppressor gene (*H19*) normally read from the maternal homolog, may lead to the macrosomia and an increased predisposition to cancer seen in this disorder. Supporting the role of imprinting in BWS is that paternal imprinting has been documented in about 10% of BWS patients, and that about 70% of Wilms tumors from BWS patients show loss of imprinting of the genes coding for IGF-2 and H19. Children affected with this condition should undergo ultrasound surveillance for abdominal tumors every 3 months until they reach age 7 years.

2. Prader–Willi Syndrome

Prader–Willi syndrome results from lack of expression of a number of imprinted genes, including *SNRPN*, located on chromosome 15q11. Clinical characteristics include severe hypotonia in infancy that often necessitates placement of a feeding gastrostomy tube. In older children, characteristic facies become obvious, with almond-shaped eyes, and frequent strabismus. Short stature, obesity, hypogonadism, and small hands and feet with tapering fingers are now believed to be associated with growth hormone deficiency. Obsessive hyperphagia (usual onset 3–4 years) and type 2 (adult-onset) diabetes mellitus are common features.

Multiple chromosomal rearrangements and mutations have been reported to disrupt expression of the genes that contribute to this syndrome. Of these, deletion of paternal chromosome 15q11 is the most common, followed by maternal uniparental disomy. Molecular techniques that analyze patterns of methylation of involved DNA sequences provide a practical approach to diagnosis when clinical suspicion exists. But additional studies (eg, FISH) to determine the genetic mechanisms responsible are necessary in confirmed cases for reproductive risk counseling.

3. Angelman Syndrome

Angelman syndrome also involves imprinting and results from a variety of mutations that inactivate a ubiquitin–protein ligase gene, *UBE3A*, located in the same region of chromosome 15 as *SNRPN*, the maternally imprinted gene involved in Prader–Willi syndrome (see preceding section). *UBE3A* is paternally imprinted, and during normal development the maternal allele is expressed only in the brain. The classic phenotype includes severe mental retardation with prognathism, seizures, and marked delay in motor milestones, abnormal puppet-like gait and posturing, poor language development, and paroxysmal laughter and tongue thrusting.

Angelman syndrome is most commonly caused when sequences detectable by FISH on 15q11 are deleted from the maternal homolog. Uniparental paternal disomy 15 is the least common cause. Mutations in *UBE3A* cause the disorder in perhaps one fourth of cases.

With additional studies of mutations in the gene responsible for this syndrome, it is possible that its clinical description will be expanded to include less severely delayed individuals. Recurrence is possible when mothers carry mutations that are paternally imprinted and therefore silent until they are passed on as nonimprinted alleles.

4. UPD 7

Certain genes on chromosome 7 are now known to be imprinted. *UPD 7* has been reported to cause CF in a child who inherited two copies of the $\Delta F 508$ deletion from one parent. That child also had Russell–Silver syndrome, a syndrome associated with intrauterine growth failure and dwarfism. Imprinting abnormalities and UPD may prove to be associated with growth abnormalities.

Elias ER et al: Beckwith–Wiedemann syndrome. In Jameson JL (ed): *Principles of Molecular Medicine*. Humana Press, 1998.

DISORDERS ASSOCIATED WITH ANTICIPATION

1. (Autosomal Dominant) MYOTONIC DYSTROPHY

Internists are most likely to encounter families with myotonic dystrophy, a condition characterized by muscle weakness and tonic muscle spasms (myotonia) along with hypogonadism, frontal balding, cardiac conduction abnormalities, and cataracts. It is unclear how many genes are involved in this disorder. The critical region is on chromosome 19, where an amplified trinucleotide repeat (CTG) occurs in the 3' untranslated region of a protein kinase gene. Normal individuals have from 5 to 30 CTG repeat copies. Repeat copies greater than 50 are meiotically unstable, but individuals carrying this number of repeats may be only mildly affected (eg, cataracts). Most individuals with repeat copies greater than 100 will have symptoms or electrical myotonia as adults. However, as copy numbers approach approximately 400, symptoms become evident in children. Expansion can progress to greater than 1000 copies and in doing so produce fetal and neonatal disease that is often lethal. As the copy numbers enlarge from generation to generation, they become more unstable through meiosis. Dramatic expansion from ap-

proximately 200 to 400 repeat copies, producing mild, often clinically undetected symptoms, to very large copy numbers (800–2000) associated with fetal manifestations (polyhydramnios and arthrogryposis) occur frequently when the expanded repeat copies are passed through female, but not male, meiosis. Therefore, an important component in the work-up of the floppy infant is a careful neurologic assessment of the mother for evidence of weakness or myotonia. Diagnostic molecular testing which measures the number of CTG repeats is now available.

2. (Autosomal Recessive) FRIEDREICH ATAXIA

Symptoms include progressive incoordination (cerebellar dysfunction) with both motor and sensory findings beginning in preadolescence and typically advancing through the teenage years. The gene involved, *FDRA*, is located on chromosome 9. Normal individuals carry 7–22 GAA repeats at this locus. Close to 75% of affected patients are homozygous for repeat expansions, having greater than 200 copies. Point mutations in the gene also occur. Meiotic instability of this repeat sequence is more variable than are others. Contractions occur more frequently than do expansions. Relationships between genotype and phenotype are also more complex. Molecular diagnostic testing requires careful interpretation with respect to prognosis and reproductive risks.

3. (X-Linked) FRAGILE X SYNDROME

Fragile X syndrome, present in approximately 1 in 1000 males, is the most common cause of mental retardation in males. The responsible gene is *FMR-1*, which has unstable CGG repeats at the 5' end. Normal individuals have up to 55 CGG repeats. Individuals with 55–200 CGG repeats have a **premutation** and are generally phenotypically normal. Affected individuals with fragile X syndrome (full mutation) have greater than 200 CGG repeats and also have hypermethylation of both the CGG expansion and an adjacent CpG island. This methylation turns off the *FMR-1* gene. DNA analysis, rather than cytogenetic testing, is the method of choice for confirming the diagnosis of fragile X syndrome.

Most males with fragile X syndrome present with mental retardation, oblong face with large ears, and large testicles, especially after puberty. Other physical signs include symptoms suggestive of a connective tissue disorder (eg, hyperextensible joints, mitral valve prolapse). Many affected individuals are hyperactive and exhibit infantile autism or autistic-like behavior. Some males with the abnormal gene are of normal phenotype.

In contrast, about one half of females with the fragile X full mutation show normal intelligence, but often evidence learning disabilities and behavioral problems. About one half of females with the full mutation have lower IQs in the range of mental retardation and more severe behavioral problems. Females have more mild phenotypic changes than the males. Clinical expression of fragile X differs in male and female offspring depending on which parent is transmitting the gene. The premutation can change into the full mutation only when passed through a female. Identification of the abnormal DNA amplification by direct DNA analysis can confirm the diagnosis of fragile X in an affected individual and can detect asymptomatic gene carriers of both sexes. Therefore, DNA analysis is a reliable test for prenatal and postnatal diagnosis of fragile X syndrome and facilitates genetic counseling.

DISORDERS ASSOCIATED WITH MITOCHONDRIAL INHERITANCE

According to a special mitochondrial issue of the *Seminars in Medical Genetics*, published in the *American Journal of Medical Genetics*, Spring of 2001, more than 100 point mutations and rearrangements of mtDNA have been identified, which cause a large number of human diseases. Symptoms of the mitochondrial disorders are secondary to deficiency in the respiratory chain enzymes of oxidative phosphorylation, which supply energy to all cells. Mitochondrial diseases are progressive disorders with neurologic dysfunction including hypotonia, developmental delay, and seizures. Ophthalmologic issues, hearing loss, GI tract dysfunction with growth failure, renal, endocrine, cardiac, and autonomic dysfunction are some of the many issues which can affect patients with mitochondrial diseases. The following disorders are three of the more common ones.

1. MELAS

MELAS is an acronym for **m**itochondrial **e**ncephalopathy, **l**actic **a**cidosis, and **s**troke-like episodes. Symptoms occur in the pediatric age group and include recurrent episodes resembling stroke (blindness, paralysis), headache, vomiting, weakness of proximal muscles, and elevated blood lactate. (**Note:** Lactate may be falsely elevated secondary to technical difficulties in obtaining a free-flowing blood specimen or delay in laboratory measurement.) The most common mutation causing MELAS is in the tRNA^{Leu} gene (*A3243G*).

2. MERRF

MERRF is an acronym for **m**yoelonus **e**pilepsy with **r**agged **r**ed **f**ibers. Children with MERRF present with a variety of neurologic symptoms, including myoclonus, deafness, weakness of muscles, and seizures. Eighty percent of cases are due to a missense mutation in the mitochondrial tRNA^{lys} gene (*A8344G*).

3. LEIGH SUBACUTE NECROTIZING ENCEPHALOMYELOPATHY

Multiple different abnormalities in respiratory chain function lead to Leigh disease, a very severe disorder associated with progressive loss of developmental milestones associated with extrapyramidal symptoms, and brainstem dysfunction. Episodes of deterioration are frequently associated with an intercurrent febrile illness. Symptoms include hypotonia, unusual choreoathetoid hand movements, feeding dysfunction with failure to thrive, and seizures. Focal necrotic lesions of the brainstem and thalamus are hallmarks on MRI scan. Mitochondrial mutations affecting the respiratory chain, especially complexes I, II and IV, and nuclear DNA mutations affecting complex II have been identified as causing Leigh disease.

MULTIFACTORIAL INHERITANCE

CLEFT LIP & CLEFT PALATE

From a genetic standpoint, cleft lip with or without cleft palate is distinct from isolated cleft palate. The former is more common in males, the latter in females. Although both can occur in a single family, particularly in association with certain syndromes, this pattern is unusual. Racial background is a factor in the incidence of facial clefting. Among Asians, Caucasians, and blacks, the incidence is 1.61, 0.9, and 0.31, respectively, per 1000 live births.

Clinical Findings

A cleft lip may be unilateral or bilateral and complete or incomplete. It may occur with a cleft of the entire palate or just the primary (anterior and gingival ridge)

or secondary (posterior) palate. An isolated cleft palate can involve only the soft palate or both the soft and hard palates. It can be a V-shaped or wide horseshoe cleft. When the cleft palate is associated with micrognathia and glossoptosis (a tongue that falls back and causes respiratory or feeding problems), it is called the Pierre Robin sequence. Among individuals with facial clefts—more commonly those with isolated cleft palate—the incidence of other congenital abnormalities is increased. The incidence of congenital heart disease, for example, is between 1–2% in liveborn infants, but among those with Pierre Robin sequence it can be as high as 15%. Associated abnormalities should be looked for in the period immediately after birth and before surgery.

Differential Diagnosis

A facial cleft may occur in many different circumstances. It may be an isolated abnormality or part of a more generalized syndrome. Prognosis, management, and accurate determination of recurrence risks all depend on accurate diagnosis. In evaluating a child with a facial cleft, the physician must determine if the cleft is nonsyndromic or syndromic.

Nonsyndromic

In the past, nonsyndromic cleft lip or cleft palate was considered a classic example of polygenic or multifactorial inheritance. More recently, however, this mode of inheritance has been questioned, and several studies have suggested one or more major autosomal loci, both recessive and dominant (or co-dominant). Empirically, however, the recurrence risk is still in the range of 2–3% because of nonpenetrance or the presence of other contributing genes.

Syndromic

Cleft lip, with or without cleft palate, and isolated cleft palate may occur in a variety of syndromes that may be environmental, chromosomal, single gene, or of unknown origin (Table 33–3). Prognosis and accurate recurrence risks depend on the correct diagnosis.

Complications & Treatment

Problems associated with facial clefts include early feeding difficulties, which may be severe; recurrent serous otitis media associated with fluctuating hearing and language delays; speech problems, including hypernasality and articulation errors; and dental and orthodontic complications. Long-term management ideally should be through a multidisciplinary cleft palate clinic.

Table 33–3. Syndromic isolated cleft palate (CP) and cleft lip with or without cleft palate (CL/CP).^a

Environmental

Maternal seizures, anticonvulsant usage (CL/CP or CP)
Fetal alcohol syndrome (CP)
Amniotic band syndrome (CL/CP)

Chromosomal

Trisomies 13 and 18 (CL/CP)
Wolf–Hirschhorn or 4p– syndrome (CL/CP)
Shprintzen or 22q11.2 deletion syndrome (CP)

Single-gene disorders

Van der Woude syndrome, AD (CL/CP or CP)
Treacher Collins syndrome, AD (CP)
Stickler syndrome, AD (CP)
Smith–Lemli–Opitz, AR (CP)^b

Unknown cause

Möbius syndrome (CP)
Cornelia de Lange syndrome (CP)

^aAD = autosomal-dominant.

^bAR = autosomal-recessive.

Genetic Counseling

Accurate counseling depends on accurate diagnosis and the differentiation of syndromic from nonsyndromic clefts. A complete family history must be taken, and the patient and both parents must be examined. The choice of laboratory studies is guided by the presence of other abnormalities and clinical suspicions. They may include chromosome analysis, including FISH, eye examination, and radiologic studies. When the risk for a facial cleft is known to be increased, clefts of both the lip and the palate have been sought and detected on ultrasound prenatally. Otherwise, intrauterine diagnosis of clefts is more likely to be established in syndromes in which the identification of other more serious abnormalities prompts the examiner to perform very detailed visualization of all organs.

NEURAL TUBE DEFECTS

Neural tube defects comprise a variety of malformations, including anencephaly, encephalocele, spina bifida or myelomeningocele, sacral agenesis, sacral lipomas, and other spinal dysraphisms. Recent research suggests that the neural tube develops via closure at multiple rather than just two closure sites and that each closure site is probably mediated by different genes and affected by different teratogens. Hydrocephalus associated with the Arnold–Chiari type II malformation commonly occurs with myelomeningocele. Sacral agenesis, also called the caudal regression syndrome, occurs more frequently in infants of diabetic mothers.

Clinical Findings

At birth, neural tube defects can present as an obvious rachischisis (open lesion) or as a more subtle skin-covered lesion associated with a fatty mass, a hemangioma, a tuft of hair, or asymmetrical buttock creases. In the latter case, computed tomography or MRI should be conducted to better define the anatomic defect. The extent of neurologic deficit depends on the level of the lesion and may include clubfeet, dislocated hips, or total flaccid paralysis below the level of the lesion. Hydrocephalus may be apparent at birth or may present with an increase in head circumference, irritability, and poor feeding, with vomiting shortly after the back has been repaired surgically. Neurogenic bladder and bowel are commonly seen. Other anomalies of the CNS may be present, as well as anomalies of the heart or kidneys.

Differential Diagnosis

Neural tube defects (NTD) may occur in isolation or as part of a genetic syndrome. They may result from teratogenic exposure to alcohol or the anticonvulsant valproate. Any infant with dysmorphic features or other major anomalies in addition to the NTD should be evaluated by a geneticist, and a chromosome analysis should be performed.

Complications & Management

A. NEUROSURGICAL

Infants with an open NTD should be placed in prone position, and the lesion kept moist with sterile dressing. Neurosurgical closure should occur within 24–48 hours after birth to reduce risk of infection. The infant should be monitored closely, and a ventriculoperitoneal shunt should be inserted as soon as signs of hydrocephalus become apparent. Shunts are required in about 85% of cases of myelomeningocele. Complications of the shunt include malfunction and infection. Symptoms of the Arnold–Chiari II malformation include feeding dysfunction, abducens nerve palsy, vocal cord paralysis with stridor, and apnea. Shunt malfunction may cause an acute worsening of Arnold–Chiari symptoms that may be life-threatening.

B. ORTHOPEDIC

The child's ability to walk varies according to the level of the lesion. Children with low lumbar and sacral lesions walk with minimal support; those with high lumbar and thoracic lesions are rarely functional walkers; and in those with midlumbar lesions the effects are variable. Orthopedic surgery is necessary to get the child upright and ambulatory and to address foot deformities and scoliosis. Physical therapy services are indicated.

C. UROLOGIC

Neurogenic bladders have variable presentations. Urodynamic studies are recommended early on to define bladder function, and management is guided by the results of these studies. Continence can be achieved in a variety of ways, including use of anticholinergic or sympathomimetic agents, clean intermittent catheterization, and a variety of urologic procedures. Renal function should be monitored regularly, and an ultrasound examination should be periodically repeated. Symptomatic infections should be treated.

Symptoms of neurogenic bowel include incontinence and chronic constipation and are managed with a combination of dietary modifications, laxatives and stool softeners, and rectal stimulation. A recently developed surgical procedure called ACE (antegrade continence enema) uses the appendix to create a conduit from the upper colon to the surface at the umbilicus. An enema is then given through the conduit, cleaning out the colon from above rather than from below. Early results with respect to continence and patient satisfaction have been encouraging.

Special Issues and Prognosis

All children requiring multiple surgical procedures (ie, patients with spina bifida or urinary tract anomalies) have a significant risk for developing hypersensitivity type I (IgE-mediated) allergic reactions to latex. For this reason, nonlatex medical products are now routinely used when caring for patients with NTDs. Most individuals with spina bifida are cognitively normal, but learning disabilities are common. Individuals with encephalocele or other CNS malformations generally have a much poorer intellectual outcome. Individuals with closed spinal cord abnormalities (eg, sacral lipomas) have more mild issues in general, and intelligence is usually normal. Problems in older patients include the development of spinal cord tethering, which usually presents with back pain, progressive scoliosis, and changes in bowel or bladder function. This often requires neurosurgical intervention. Individuals with NTDs have lifelong medical issues, which require the care of multiple medical and surgical specialists, as well as special educational and psychosocial issues requiring support for the patient and family. A good support for families is the national Spina Bifida Association, which has many local chapters. See the following website: sbaa.org

Genetic Counseling

Recurrence risks vary according to the underlying cause, but most isolated NTDs are polygenic, with a recurrence risk of 2–3% for the parents in future pregnancies.

The recurrence risk for siblings of the parents and siblings of the patients is 1–2%. A patient with spina bifida has a 5% chance of having an affected child. Prenatal diagnosis is available, and pregnancies can be monitored in a variety of ways. In fetuses with open NTDs, maternal serum α -fetoprotein levels (AFP) measured at 16–18 weeks' gestation are elevated. AFP and acetylcholine esterase levels in amniotic fluid are also elevated. Ultrasound studies will detect approximately 90% of NTDs. Recent studies have shown that prophylactic folic acid can significantly lower the incidence and recurrence rate of NTDs, but the intake of the folic acid must start at least 3 months prior to conception and continue during the first month of pregnancy. It is now recommended that all women of childbearing age take 0.4 mg of folic acid daily. For the woman at increased risk because of a previous child with an NTD, the current recommendation is to increase folic acid intake to 4 mg daily when pregnancy is planned. Although the data are inconsistent, some evidence indicates that pre-conceptional folic acid supplementation may also lower the incidence of other congenital malformations such as conotruncal heart defects.

COMMON RECOGNIZABLE DISORDERS WITH VARIABLE OR UNKNOWN CAUSE

The text that follows describes several important and common human malformation syndromes. The emphasis is on clinical findings that should suggest their inclusion in differential diagnoses. Likely causes, if known, are also briefly explained. The best illustrations are in *Smith's Recognizable Patterns of Human Malformation*. An excellent Internet site at the University of Kansas Medical Center can be consulted for further information: <http://www.kumc.edu/gec/support>.

Arthrogryposis Multiplex

Arthrogryposis multiplex is due to lack of fetal movement. Causes most often involve constraint, CNS maldevelopment or injury, and neuromuscular disorders. In the neuromuscular disorders, polyhydramnios is often present as a result of lack of fetal swallowing. Pulmonary hypoplasia may also be present, reflecting lack of fetal breathing. The work-up will usually include brain imaging, careful consideration of metabolic disease—especially peroxisomal disorders associated with elevated very-long-chain fatty acids—neurologic consultation, and, in some cases, electrophysiologic studies and muscle biopsy. The family history should be reviewed

carefully for findings such as muscle weakness or cramping, cataracts, and early-onset heart disease, suggesting myotonic dystrophy. Parents should have careful neurologic examinations that include testing for myotonia.

CHARGE Association

CHARGE association affects structures derived from rostral neural crest cells but also includes abnormal development of the eyes and midbrain. It is a sporadic condition whose cause is not understood. The acronym CHARGE serves as a mnemonic for associated abnormalities that include **c**olobomas, **c**ongenital **h**eart disease, **c**hoanal **a**trisia, **g**rowth **r**etardation, **g**enital abnormalities (hypospadias), and **e**ar abnormalities, with deafness.

Abnormal ear development always occurs in association with this condition. Whenever abnormal ears are encountered, careful physical assessment should follow, and ophthalmologic consultation should be considered. Facial asymmetry is a common finding. Studies of surviving patients indicate that neuronal damage due to airway and feeding complications contributes substantially to developmental delays. A number of other syndromes, some with much better prognoses, overlap with this condition. Chromosomal studies are normal but are usually necessary to distinguish this condition from other disorders. The following website of the Charge Syndrome Foundation, Inc, is a helpful source for additional information: <http://www.chargesyndrome.org/>.

Cornelia De Lange Syndrome

Cornelia de Lange syndrome is a sporadically occurring malformation syndrome whose cause remains obscure. It is characterized by severe growth retardation; limb, especially hand, reduction defects (50%); congenital heart disease (25%); and stereotypical facies with hirsutism, medial fusion of eyebrows (synophrys), and thin, downturned lips.

The course and severity are variable, but the prognosis for survival and normal development is poor. Chromosomal analysis is usually normal.

Goldenhar Syndrome

Goldenhar syndrome, also known as vertebroauriculofacial syndrome, is an association of multiple anomalies involving the head and neck. The classic phenotype includes hemifacial microsomia (one side of the face smaller than the other), with abnormalities of the pinna on the same side with associated deafness. Ear anomalies may be quite severe and include anotia. A characteristic benign fatty tumor in the outer eye, called an epibulbar dermoid, is frequently present, as are preauricular ear tags. Vertebral anomalies, particularly of the

cervical vertebrae, are seen, and vertebral anomalies lower down are common. The Arnold–Chiari type I malformation (herniation of the cerebellum into the cervical spinal canal) is a common associated anomaly. Cardiac anomalies and hydrocephalus are seen in more severe cases. Most patients with Goldenhar syndrome have normal intelligence. The cause is unknown.

Kabuki Syndrome

Kabuki syndrome is a disorder of unknown cause characterized by a distinctive facial appearance (hypertelorism with long palpebral fissures, large pinnae), developmental delay, and hearing loss. Most cases are sporadic although a few cases with dominant transmission have been reported. Anomalies of the heart and genitourinary system are occasionally seen.

Noonan Syndrome

Noonan syndrome is an autosomal dominant disorder characterized by short stature, congenital heart disease, abnormalities of cardiac conduction and rhythm, webbed neck, down-slanting palpebral fissures, and low-set ears. Affected children may be large at birth and have mild subcutaneous edema. The phenotype evolves with age and may be difficult to recognize in older relatives. Mild developmental delays are often present. No genes have yet been identified, but a candidate locus has been mapped to chromosome 12q.

Oligohydramnios Sequence (Potter Sequence)

This condition presents in newborns as severe respiratory distress due to pulmonary hypoplasia in association with positional deformities of the extremities, usually bilateral clubfeet, and typical facies consisting of suborbital creases, depressed nasal tip and low-set ears, and retrognathia. The sequence may be due to prolonged lack of amniotic fluid. Most often it is due to leakage, renal agenesis, or severe obstructive uropathy.

Opitz G/BBB

Disrupted development of midline structures is a feature of several overlapping malformation syndromes, a number of them heritable. Hypertelorism (wide set eyes) is a unifying feature for these conditions, but it is the combined association of midbrain anomalies (agenesis of the corpus callosum), cardiac septal defects, and genitourinary tract anomalies, in particular, hypospadias, that has led to the recognition of a commonly disrupted midline developmental field. Current clinical genetic terminology refers to these conditions as Opitz G/BBB syndrome.

In addition to malformation of midline structures, hypotonia and problems with swallowing and gastroesophageal reflux are hallmark symptoms. Mentation is usually subnormal. Many cases are sporadic, but well-documented families with apparent autosomal dominant and X-linked inheritance identify the phenotype as genetically heterogeneous. Linkage studies have recently identified a candidate gene dubbed *M101* on the X chromosome. Mutations in this gene segregate with syndromic phenotypes in affected males. An additional X-chromosomal locus and an autosomal locus very close to the Shprintzen syndrome region, 22q11, are also under investigation. A number of Opitz G/BBB syndrome patients, in fact, have been shown by FISH to have deletions in this region. Additional resources include the Opitz Family Network and the OPITZ G/BBB Family Network and the following website: <http://www.opitznet.org/joinus.html>.

Overgrowth Syndromes

Overgrowth syndromes are becoming increasingly recognized as important childhood conditions. They may present at birth and are characterized by macrocephaly, motor delays (cerebral hypotonia), and, in many cases, asymmetry of extremities. Bone age may be advanced. The most common overgrowth syndrome is Sotos syndrome. Patients with Sotos syndrome have a characteristic facies with a prominent forehead and down-slanting palpebral features. The cause of Sotos syndrome is unknown. There is a small but increased risk of cancer in patients with Sotos syndrome. Other overgrowth syndromes include Beckwith–Wiedemann syndrome (BWS), described in the section on imprinting, and two single gene disorders called Simpson–Golabi–Behmel syndrome and Bannayan–Riley–Ruvalcaba (BRR) syndrome. Simpson–Golabi–Behmel syndrome exhibits a BWS-like phenotype, but with additional anomalies including polydactyly and more severe facial dysmorphism. Unlike BWS patients who have normal intelligence, patients with Simpson–Golabi often have developmental delay. It is inherited as an X-linked disorder. Patients with BRR have macrosomia, macrocephaly, and unusual freckling of the penis. They have mild developmental issues. They may develop hemangiomas/lymphangiomas and have a predisposition to intestinal malignancies. The cause of BRR was recently found to be a mutation of the *P TEN* gene implicated in Cowden's syndrome, the association of intestinal polyposis with malignant potential.

Rubenstein–Taybi Syndrome

Rubenstein–Taybi Syndrome is a genetic disorder of unknown cause, characterized by developmental delay;

growth failure; and a distinctive facial dysmorphism with microcephaly, prominent nose, and small chin. Feeding problems are common. About 25% of patients have been found with a microdeletion of chromosome 16 detectable by FISH, but most patients have a normal karyotype.

Syndromic Short Stature

Short stature is an important component of numerous syndromes, or it may be an isolated finding. In the absence of nutritional deficiencies, endocrine abnormalities, evidence for skeletal dysplasia (disproportionate growth with abnormal skeletal films), or a positive family history, intrinsic short stature can be due to uniparental disomy (see previous discussion) such that only imprinted (silenced) copies of specific sequences are present. The phenotype of Russell–Silver syndrome—short stature with normal head growth (pseudohydrocephalus), normal development, and minor dysmorphic features (especially fifth finger clinodactyly)—has been associated in some cases with maternal uniparental disomy for chromosome 7.

VACTERL Association

VACTERL association is described by an acronym denoting the association of vertebral defects (segmentation anomalies), imperforate anus, cardiac malformation (most often ventricular septal defect), tracheoesophageal fistula, renal anomalies, and limb (most often radial ray) anomalies. The disorder is sporadic, and some of the defects may be life-threatening. The prognosis for normal development is good. The cause is unknown, but a high association with monozygotic twinning suggests a mechanism dating back to events perhaps as early as blastogenesis. Recently, disturbance of the sonic Hedgehog pathway was suggested to be part of the mechanism for VACTERL, based on a mouse model. Careful examination and follow-up are important, because numerous other syndromes with more complicated prognoses also include features present in VACTERL association. Chromosomal studies and genetic consultation are warranted.

PERINATAL GENETICS

TERATOGENS

1. Fetal Alcohol Syndrome

Fetal alcohol syndrome (FAS) results from excessive exposure to alcohol during gestation and affects 30–40% of offspring of mothers whose daily intake of alcohol exceeds 3 oz. Features of the syndrome include short stature; poor head growth (may be postnatal in onset), developmental delay, and midface hypoplasia characterized by a poorly developed long philtrum, narrow palpebral fissures, and short nose with anteverted nares. Facial findings may be subtle, but careful measurements and comparisons with standards (see Figure 33–11) can be useful. Structural abnormalities occur in half of affected children. Cardiac anomalies and NTDs are commonly seen. Genitourinary tract anomalies are frequent. Scientists and clinicians now agree that the term “fetal alcohol effect” may be misleading and should not be applied to apparently incomplete phenotypes. Careful evaluation for other syndromes and chromosomal disorders should be included in the work-up. Behavioral abnormalities in older children may or may not be directly attributable to alcohol, because psychiatric disorders, many with recognized inherited predisposition, affect a large number of women and their partners who abuse alcohol.

2. Maternal Anticonvulsant Effects

Anticonvulsant exposure during pregnancy is now recognized as being associated with adverse outcomes in approximately 10% of children born to women who are taking anticonvulsants. A syndrome characterized by small head circumference, anteverted nares, cleft lip and palate (occasionally), and distal digital hypoplasia was first described in association with maternal use of phenytoin but also occurs with other anticonvulsants. Risks for spina bifida are increased, especially in pregnancies exposed to valproic acid. Carbamazepine (Tegretol), felt to be less teratogenic than other anticonvulsants, has been associated with a characteristic dysmorphic facial appearance and developmental issues.

3. Retinoic Acid Embryopathy

Vitamin A and its analogs are potent morphogens that interact with specific receptors and therefore have considerable teratogenic potential. Developmental toxicity occurs in approximately one third of pregnancies exposed in the first trimester to the synthetic retinoid isotretinoin, commonly prescribed to treat acne. Exposure disrupts developmental fields to which rostral neural crest cells contribute and produces CNS malde-

velopment, especially of the posterior fossa; ear anomalies (often absence of pinnae); congenital heart disease (great vessel anomalies); and tracheoesophageal fistula. These findings constitute a partial phenocopy of Di-George syndrome and demonstrate the continuum of contributing genetic and epigenetic factors in morphogenesis. It is now recognized that vitamin A itself, when taken during pregnancy in the active form of retinoic acid in doses exceeding 25,000 IU/d, can produce partially affected phenotypes. The limit is usually kept at 10,000 IU/d for safety, but evidence of problems is found at dosages above 25,000 IU/d. Maternal ingestion of even large amounts of vitamin A taken as retinol during pregnancy, however, does not increase risks, because conversion of this precursor to active retinoic acid is regulated by the body.

4. Maternal Substance Abuse

Maternal substance abuse is generally associated with increased risks for adverse perinatal outcomes, including miscarriage, preterm delivery, growth retardation, and increased risk for injury to the developing CNS. For most abused substances, the link between exposures and adverse outcomes is less well demonstrated than with alcohol. Multiple factors are probably involved, and it should be recognized that substance abuse often involves more than one drug. Maternal inhalant abuse appears to be associated with findings similar to those of FAS. Reports of abnormal outcomes following cocaine abuse (and the crack baby syndrome) have been contradicted by some studies that found no effects. In these cases the form of the drug used and its route of administration may be important determinants of risk.

PRENATAL DIAGNOSIS

Prenatal screening for birth defects in the form of analyte analyses in maternal blood, fetal and placental tissues, or ultrasound evaluation is now routinely offered to pregnant women. Prenatal diagnosis for specific genetic disorders is indicated in 7–8% of pregnancies. As technology improves, the indications for and the accuracy of prenatal diagnosis are expected to increase. Prenatal diagnosis introduces options for management including interruption of abnormal pregnancies, prenatal surgical and medical interventions, and preparation for specialized perinatal care.

Methods

Prenatal diagnosis techniques analyze maternal blood, image the conceptus, and sample fetal and placental tissues (Table 33–4).

A. MATERNAL BLOOD

The use of maternal serum AFP as a screening test was introduced because higher than normal values were found in association with open NTDs. It was later noted that 25% women who carried a fetus with Down syndrome had a 45% lower AFP value than those in whom the fetus was normal. Additional measurements of human chorionic gonadotropin and unconjugated estradiol (the “triple screen”) can increase rates of detection for trisomy 21 to approximately 60% and predict many cases of trisomy 18 as well. Low estradiol levels can also predict cases of Smith–Lemli–Opitz, a devastating autosomal recessive disorder.

Fetal cells, including lymphocytes, trophoblasts, and nucleated red blood cells, are present in the maternal circulation. Research is being directed toward isolating these cells for prenatal diagnosis using culture, hybridization, and PCR-based techniques.

Table 33–4. Prenatal diagnostic techniques.

Fetal cells for molecular or metabolic studies
Amniotic fluid α -fetoprotein level for neural tube defects
Biochemical studies on fluid
Chorionic villus sampling
Karyotyping
Fetal cells for molecular or metabolic studies
Fetal tissues
Blood by percutaneous umbilical blood sampling
Biopsy of other fetal tissues
Direct fetal visualization via fetoscopy (rarely used today because of the advances in fetal visualization by ultrasound and MRI)

MRI = magnetic resonance imaging.

B. TESTING OF FETAL TISSUE

1. Amniocentesis—This technique has been available for many years. Its accuracy and safety are well established. Fluid surrounding the fetus is sampled, and cells are cultured for cytogenetic, molecular, or metabolic analysis. AFP and other chemical markers can also be measured. This is a safe procedure with a complication rate (primarily for miscarriage) of less than 1% in experienced hands.

2. Chorionic villus sampling (placental)—This means of analysis is now available in most centers and is generally performed at 11–12 weeks' gestation. Tissue obtained by chorionic villus sampling (CVS) provides more DNA for molecular analysis and contains dividing cells (cytotrophoblasts) that can be rapidly karyotyped. However, direct cytogenetic preparations may be of poor quality. In addition, chromosomal abnormalities detected by this technique may be confined to the placenta (**confined placental mosaicism**). Cultured preparations may be more relevant. Certainly, if an unusual cytogenetic picture is found on CVS, further studies should be considered before management decisions are made. Numerous studies have been done comparing the safety of first-trimester CVS with amniocentesis. Of some concern is the possible association of CVS prior to 11 weeks with terminal transverse limb defects, perhaps secondary to vascular disruption.

Fetal blood can be sampled directly in late gestation through ultrasound-guided percutaneous umbilical blood sampling (PUBS).

It is occasionally necessary to biopsy fetal tissues such as liver or muscle for accurate prenatal diagnosis. These procedures are available in only a few perinatal centers.

Amniocentesis or CVS is indicated in the following circumstances:

1. Maternal age over 35 years.
2. Previous child with a chromosomal abnormality.
3. Either parent a translocation carrier. In this case, the risk for a fetus with an unbalanced chromosomal abnormality depends on the type of translocation.
4. A history of any genetic disorder diagnosable by biochemical techniques or by DNA analysis. The list of such conditions changes daily, and a genetic center should be contacted for the most recent information.
5. A request by the parents for fetal sex determination because of a history of an X-linked disorder that is not otherwise diagnosable.
6. Maternal blood testing (eg, triple screen) indicating increased risks for chromosomal abnormalities.

7. As part of the workup of fetal anomalies found by ultrasonography.

3. Fetal ultrasonography—Ultrasonography is indicated whenever an abnormality characterized by a structural defect is suspected. The defect may be suspected because of the family history, potential exposure to teratogens during pregnancy, or questionable abnormalities noted on a routine ultrasound examination done in the obstetrician's office. In any case, the patient should be referred for further evaluation to a medical center staffed by personnel experienced in fetal ultrasonography.

By 16–18 weeks' gestation, transabdominal real-time ultrasonography can visualize all major fetal organs, including the kidneys, heart, brain, spinal cord, bladder, and limbs. Beginning at 12 weeks' gestation, transvaginal ultrasonography can provide even earlier imaging. It is therefore possible to look for almost any genetic syndrome that includes a specific defect. Routine ultrasound screening has demonstrated many unexpected abnormalities. Most of these are major defects, however, and minor anomalies are easily missed, especially if unexpected.

Fetal motion has been a major deterrent to the use of MRI as a tool for prenatal diagnosis. However, new techniques are being developed to overcome this problem, making MRI a potentially valuable noninvasive means of fetal assessment.

Radiologic studies of the fetus are rarely necessary because ultrasonography has improved so greatly. If a skeletal abnormality or bone dysplasia is suspected, however, radiographic films may be helpful.

EVALUATION OF THE DEVELOPMENTALLY DELAYED CHILD

Mental retardation or developmental delays affect 8% of the population. Disorders associated with symptoms of delayed development are heterogeneous but frequently include heritable components. Evaluation should be multidisciplinary; Table 33–5 lists its main features, emphasizing the major clinical and genetic considerations.

Discerning patterns and timing of growth and development are particularly important. For example, prenatal-onset growth retardation is less likely to have a metabolic origin than is postnatal growth delay. Loss of skills raises suspicion about possible metabolic or neurodegenerative disorders. Behavioral abnormalities are commonly associated with developmental delays, but behavioral diagnoses such as attention-deficit/hyperac-

tivity disorder, obsessive–compulsive disorder, autism, or autistic-like behaviors are better viewed as descriptive than as etiologically informative diagnoses.

Physical examination provides helpful clues. Close scrutiny for presence of dysmorphic disorders is a clinical skill that requires practice. Referral to a clinical geneticist is indicated whenever unusual features are encountered. Neurologic, ophthalmologic, and audiologic consultation should be sought when indicated. Brain imaging should be requested in most cases involving otherwise unexplained deviations from normal head growth. Neuroimaging and skeletal studies may also be indicated when dysmorphic features are present. Neurologic consultation can often help sort through indications for imaging.

As molecular explanations for genetic disorders accumulate, opportunities for molecular genetic testing increase. Unlike the majority of the studies listed in Table 33–4, these are not screening tests—they may confirm but often do not entirely rule out specific diagnoses. In general, it will not be cost-effective to proceed with molecular genetic testing without clinical genetic consultation.

Metabolic and genetic testing procedures other than those listed in the table may also be indicated. Appropriate consultations should be sought to coordinate these investigations.

Interpretation & Follow-Up

Clinical experience indicates that specific diagnoses can be made in approximately half of patients evaluated according to the protocol presented here. With specific diagnosis comes prognosis, ideas for management, and insight into recurrence risks. Prenatal diagnosis may also become possible.

Follow-up is important both for patients in whom diagnoses have been made and for those patients initially lacking a diagnosis. Genetic information is accumulating rapidly and can be translated into new diagnoses and better understanding with periodic review of clinical cases.

Mark Boguniewicz, MD

Allergic disorders are among the most common problems seen by pediatricians and primary care physicians, affecting over 25% of the population in developed countries. The economic impact of these illnesses can be measured in billions of dollars.

The prevalence of asthma, allergic rhinitis, and atopic dermatitis has increased in recent years. Among school-age children and adolescents, these illnesses result in significant morbidity and school absenteeism, with adverse consequences for school performance and quality of life, and may cause emotional stress. Understanding the language of allergy and the basic mechanisms involved may help physicians when treating these disorders. In this chapter, atopy refers to a genetically determined predisposition to develop IgE antibodies found in patients with asthma, allergic rhinitis, and atopic dermatitis. The Allergy Report is an easy-to-access compendium of allergic disorders that can be found on the Internet at www.TheAllergyReport.org.

■ THE ALLERGIC CASCADE

Allergic responses begin with sensitization to an allergen in a genetically susceptible host. The CD4 cells of allergic patients respond to allergens by producing interleukins, predominantly IL-3, IL-4, IL-5, and IL-13 (a so-called T helper cell-2, or TH2-type profile). These cytokines are involved in IgE synthesis and in the differentiation and activation of eosinophils (Figure 34-1).

Allergen-specific IgE binds to receptors on mast cells, basophils, and Langerhans cells distributed throughout the skin and respiratory tract and in the circulation. Cross-linking of receptor-bound IgE by allergen activates effector cells to release allergic mediators, including histamine and newly synthesized mediators such as prostaglandins and leukotrienes. Effector cells may also release other enzymes and cytokines. This immediate allergic reaction can cause sneezing, hives, wheezing, vomiting, or anaphylaxis. As part of the allergic cascade, mononuclear cells and eosinophils are recruited to the site of the acute reaction and can cause late phase responses. Activated eosinophils in particular release toxic mediators that cause many of the clinical

symptoms in allergic diseases. It is likely that a number of infiltrating cells such as monocytes, neutrophils, and basophils and resident cells such as epithelial cells and fibroblasts participate in perpetuating this inflammatory process even in the absence of allergens.

■ MAJOR ALLERGIC DISORDERS SEEN IN PEDIATRIC PRACTICE

ASTHMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Episodic symptoms of airflow obstruction including wheezing, cough, and chest tightness.*
- *Airflow obstruction at least partially reversible.*
- *Exclusion of alternative diagnoses.*

General Considerations

Asthma is the most common chronic disease of childhood, affecting over 5 million children in the United States. Despite advances in the understanding of asthma, associated morbidity has increased over the past decade and mortality rates have remained relatively stable. Asthma hospitalization rates are highest in the black population, with death rates consistently highest among African Americans age 15–24 years. The reasons for this are unclear but may be related to a combination of poor access to health care and environmental factors such as smoke and perennial allergen exposure. Alternatively, the “hygiene hypothesis” suggests that reduced exposure in early life to microbial organisms (or endotoxins) may account for the increase in atopic diseases, including asthma.

Up to 80% of children with asthma develop symptoms before their fifth birthday. Atopy is the strongest identifiable predisposing factor. Exposure to tobacco

Figure 34-1. Cellular interactions in allergic responses.

smoke, especially from the mother, is also a risk factor for asthma. About 40% of infants and young children who have wheezing with viral infections in the first few years of life will have continuing asthma through childhood. Sensitization to inhalant allergens increases over time and is found in the majority of children with asthma. The principal allergens associated with asthma are perennial aeroallergens such as dust mites, animal danders, cockroaches, and *Alternaria* (a soil mold). Of note, several recent studies suggest that exposure to high levels of cat allergen may have a protective effect against asthma. Rarely, foods may provoke isolated asthma symptoms. Other triggers include exercise, cold air, cigarette smoke, pollutants, strong chemical odors, and rapid changes in barometric pressure. Aspirin sensitivity is uncommon in children. Psychological factors may precipitate asthma exacerbations and place the patient at high risk from the disease.

Pathologic features of asthma include shedding of airway epithelium, edema, mucus plug formation, mast cell activation, and collagen deposition beneath the basement membrane. The inflammatory cell infiltrate includes eosinophils, lymphocytes, and neutrophils, especially in fatal asthma exacerbations. Airway inflammation contributes to airway hyperresponsiveness, airflow limitation, and disease chronicity. Persistent

airway inflammation can lead to airway wall remodeling and irreversible changes.

Clinical Findings

A. SYMPTOMS AND SIGNS

Wheezing is the most characteristic sign of asthma, although it may be absent in some children, especially in those with cough-variant asthma. Patients may also have cough and shortness of breath. Complaints may include "chest congestion," prolonged cough, exercise intolerance, dyspnea, and recurrent bronchitis or pneumonia. If symptoms are absent or mild, chest auscultation during forced expiration may reveal prolongation of the expiratory phase and wheezing. As the obstruction becomes more severe, wheezes become more high-pitched and breath sounds diminished. With severe obstruction, wheezes may not be heard because of poor air movement. Flaring of nostrils, intercostal and suprasternal retractions, and use of accessory muscles of respiration are signs of severe obstruction. Flushed, moist skin may be noted, and mucous membranes may be dry. Cyanosis of the lips and nail beds may be seen with underlying hypoxia. Tachycardia and pulsus paradoxus also occur. Agitation and lethargy may be signs of impending respiratory failure.

B. LABORATORY FINDINGS

Airway hyperresponsiveness to nonspecific stimuli is a hallmark of asthma. These include inhaled pharmacologic agents such as histamine and methacholine as well as physical stimuli such as exercise and cold air. Airways may exhibit hyperresponsiveness or twitchiness even when pulmonary function tests are normal. Giving increasing amounts of a bronchoconstrictive agent to induce a decrease in lung function (usually a 20% drop in forced expiratory volume in 1 second [FEV₁]) is the most common method of testing airway responsiveness. Hyperresponsiveness in normal children younger than age 5 years is greater than in older children. The level of airway hyperresponsiveness usually correlates with the severity of asthma.

During acute asthma exacerbations, FEV₁ is diminished and the flow-volume curve shows a “scooping out” of the distal portion of the expiratory portion of the loop (Figure 34–2). The residual volume, functional residual capacity, and total lung capacity are usually increased, while the vital capacity is decreased. Reversal or significant improvement of these abnormalities in response to inhaled bronchodilator therapy alone or with anti-inflammatory therapy is observed. Increased airway resistance also results in a decreased peak expiratory flow rate (PEFR). Diurnal variation in PEFR (ie, the difference between morning and evening measurements) of greater than 15–20% has been used as a defining feature of asthma. Significant changes in PEFR may occur before symptoms become evident. In more severe cases, PEFR monitoring enables earlier recognition of suboptimal asthma control. Exercise, cold air, and methacholine or histamine challenges may help to establish a diagnosis of asthma when the history, examination, and pulmonary function tests are not definitive. Alternatively, a diagnostic trial of inhaled bronchodilators and anti-inflammatory medica-

tions may be helpful, especially in infants and young children in whom underdiagnosis and undertreatment are common. Infant pulmonary function can be measured in sedated children with compression techniques. The forced oscillation technique can be used to measure airway resistance in younger children.

Hypoxemia is present early with a normal or low PCO₂ level and respiratory alkalosis. Hypoxemia may be aggravated during treatment with a β₂-agonist due to ventilation–perfusion mismatch. Oxygen saturation less than 91% is indicative of significant obstruction. Respiratory acidosis and increasing CO₂ tension may ensue with further airflow obstruction and signal impending respiratory failure. Hypercapnia is usually not seen until the FEV₁ falls below 20% of predicted value. Metabolic acidosis has also been noted in combination with respiratory acidosis in children with severe asthma and indicates imminent respiratory failure. A PaO₂ less than 60 mm Hg despite oxygen therapy and a PaCO₂ over 60 mm Hg and rising more than 5 mm Hg per hour are relative indications for mechanical ventilation in a child in status asthmaticus.

Pulsus paradoxus may be present with moderate or severe asthma. In moderate asthma in a child, this may be between 10 and 25 mm Hg, and in severe asthma between 20 and 40 mm Hg. Absence of pulsus paradoxus in a child with severe asthma exacerbation may signal respiratory muscle fatigue.

Clumps of eosinophils on sputum smear and blood eosinophilia are frequent findings. Their presence tends to reflect disease activity and does not necessarily mean that allergic factors are involved. Leukocytosis is common in acute severe asthma without evidence of bacterial infection and may be more pronounced after epinephrine administration. Hematocrit can be elevated with dehydration during prolonged exacerbations or in severe chronic disease. Potential noninvasive measures of airway inflammation include serum eosinophil

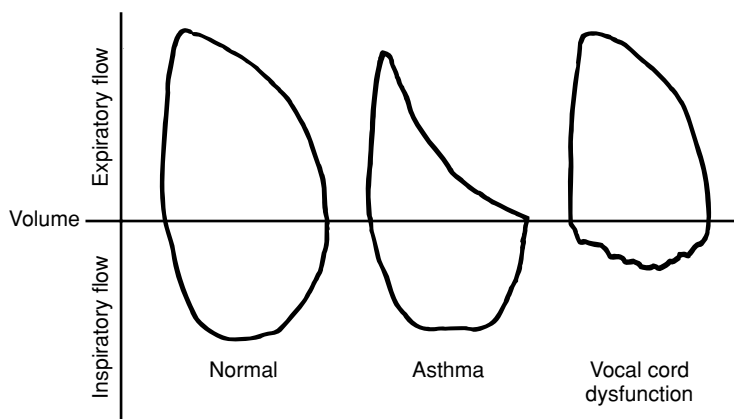

Figure 34–2. Representative flow-volume loops in persons with normal lung function, asthma, and vocal cord dysfunction.

cationic protein levels, exhaled nitric oxide, and induced sputum. Each test has its strengths and weaknesses.

C. IMAGING

On chest radiographs, bilateral hyperinflation with flattening of the diaphragms, peribronchial thickening, prominence of the pulmonary arteries and areas of patchy atelectasis may be present. Atelectasis is often misinterpreted as pneumonia.

Allergy testing is discussed in the General measures section under Treatment, Chronic Asthma.

Differential Diagnosis

Diseases that may be mistaken for asthma are often related to the patient's age (Table 34-1). Congenital abnormalities must be excluded in infants and young children. Asthma can be confused with croup, acute bronchiolitis, pneumonia, and pertussis. Immunodeficiency may be associated with cough and wheezing. Foreign bodies in the airway may cause dyspnea or wheezing of sudden onset, and on auscultation wheezing may be unilateral. Asymmetry of the lungs secondary to air trapping may be seen on a chest radiograph, especially with forced expiration. Cystic fibrosis can be associated with or mistaken for asthma.

Vocal cord dysfunction is an important masquerader of asthma, although the two occasionally coexist. It is characterized by the paradoxical closure of the vocal cords that can result in dyspnea and wheezing. Diagnosis is made by direct visualization of the vocal cords. In normal individuals, the vocal cords abduct during inspiration and may adduct slightly during expiration. Asthmatic patients may have narrowing of the glottis during expiration as a physiologic adaptation to airway obstruction. In contrast, patients with isolated vocal

cord dysfunction typically show adduction of the anterior two thirds of their vocal cords during inspiration, with a small diamond-shaped aperture posteriorly. Because this abnormal vocal cord pattern may be intermittently present, a normal examination does not exclude the diagnosis. Exercise or methacholine challenges can often precipitate symptoms of vocal cord dysfunction. The flow-volume loop may provide additional clues to the diagnosis of vocal cord dysfunction. Truncation of the inspiratory portion can be demonstrated in most patients during an acute episode, and some patients continue to show this pattern even when they are asymptomatic (see Figure 34-2). Children with vocal cord dysfunction, especially adolescents, tend to be overly competitive, primarily in athletics and scholastics. A psychiatric consultation may help define underlying psychological issues and provide appropriate therapy.

Treatment of isolated vocal cord dysfunction includes education regarding the syndrome and appropriate breathing exercises. Hypnosis, biofeedback, and psychotherapy have been effective for some patients. During an acute episode, a helium-oxygen mixture can be administered because the low density of the gas mixture facilitates movement of air through the adducted vocal cords.

Conditions That May Increase Asthma Severity

Chronic hyperplastic sinusitis is frequently found in association with asthma. Upper airway inflammation has been shown to contribute to the pathogenesis of asthma, and asthma may improve after treatment of sinusitis. However, sinus surgery is usually not indicated for initial treatment of chronic mucosal disease associated with allergy.

A significant correlation has been observed between nocturnal asthma and gastroesophageal reflux. Patients may not complain of epigastric burning or have reflux symptoms—cough may be the only sign. For patients with poorly controlled asthma, particularly with a nocturnal component, investigation for gastroesophageal reflux may be warranted even in the absence of suggestive symptoms.

The risk factors for death from asthma include psychological and sociological factors. They are probably related to the consequences of illness denial as well as to nonadherence with prescribed therapy. Recent studies have shown that less than 50% of inhaled asthma medications are taken as prescribed and that compliance does not improve with increasing severity of illness. Moreover, children requiring hospitalization for asthma, or their caregivers, have often failed to institute appropriate home treatment.

Complications

With acute asthma, complications are primarily related to hypoxemia and acidosis and can include generalized seizures. Pneumomediastinum or pneumothorax can be a complication in status asthmaticus. Recent studies point to airway wall remodeling and loss of pulmonary function with persistent airway inflammation. Childhood asthma independent of any corticosteroid therapy has been shown to be associated with delayed maturation and slowing of prepubertal growth velocity. However, attainment of final predicted adult height does not appear to be compromised.

Treatment

A. CHRONIC ASTHMA

1. General measures—Patients should avoid exposure to tobacco smoke and allergens to which they are sensitized, exertion outdoors when levels of air pollution are high, β -blockers, and sulfite-containing foods. Patients with persistent asthma should be given the inactivated influenza vaccine yearly unless they have a contraindication.

For patients with persistent asthma, the clinician should use the patient's history to assess sensitivity to seasonal allergens and *Alternaria* mold; use skin testing or in vitro testing to assess sensitivity to perennial indoor allergens; assess the significance of positive tests in the context of the patient's history; and identify relevant allergen exposures. For dust mite-allergic children, important environmental control measures include encasing the pillow and mattress in an allergen-impermeable cover and washing the sheets and blankets on the patient's bed weekly in hot water. Other measures include keeping indoor humidity below 50%, minimizing the number of stuffed toys, and washing such toys weekly in hot water. Children allergic to furred animals or feathers should avoid indoor exposure to pets, especially for prolonged periods of time. If removal of the pet is not possible, the animal should be kept out of the bedroom with the door closed. Carpeting and upholstered furniture should be removed. While a high-efficiency particle-arresting (HEPA) filter unit in the bedroom may reduce allergen levels, clinical symptoms may persist if the pet remains indoors. For cockroach-allergic children, control measures need to be instituted when infestation is present in the home. Poison baits, boric acid, and traps are preferred to chemical agents, which can be irritating if inhaled by asthmatic individuals. Indoor molds are especially prominent in humid environments or in homes with dampness. Measures to control dampness or fungal growth in the home may be of benefit. Patients can reduce exposure to outdoor allergens by staying in an air-conditioned environment.

Allergen immunotherapy may be useful for implicated aeroallergens that cannot be avoided. However, it should be administered only in facilities staffed and equipped to treat life-threatening reactions.

The patient and family must understand the role of asthma triggers, the importance of disease activity even without obvious symptoms, how to use objective measures to gauge disease activity, and the importance of airway inflammation—and they must learn to recognize the warning signs of worsening asthma, allowing for early intervention. A stepwise care plan should be developed for all patients with asthma. This educational process extends to school personnel and all those who care for children with asthma.

Because the degree of airflow limitation is poorly perceived by many patients, peak flow meters can aid in the assessment of airflow obstruction and day-to-day disease activity. Peak flow rates may provide early warning of worsening asthma. They are also helpful in monitoring the effects of medication changes. Spacer devices optimize delivery of medication from metered-dose inhalers to the lungs and, with inhaled steroids, minimize side effects. Large-volume spacers are preferred.

Patients should be treated for rhinitis, sinusitis, or gastroesophageal reflux, if present. Treatment of upper respiratory tract symptoms is an integral part of asthma management. Intranasal corticosteroids are recommended to treat chronic rhinitis in patients with persistent asthma because they reduce lower-airway hyperresponsiveness and asthma symptoms. Intranasal cromolyn reduces asthma symptoms during the ragweed season but less so than intranasal corticosteroids. Treatment of sinusitis includes medical measures to promote drainage and the use of antibiotics for acute bacterial infections. Medical management of gastroesophageal reflux includes avoiding eating or drinking 2 hours before bedtime, elevating the head of the bed with 6- to 8-inch blocks, and using appropriate pharmacologic therapy.

2. Pharmacologic therapy—A revised stepwise approach to pharmacologic therapy is recommended in the National Asthma Education and Prevention Program's *Expert Panel Report: Update on Selected Topics 2002* (www.nhlbi.nih.gov) (Tables 34-2 and 34-3). The choice of therapy is based on assessment of clinical features prior to treatment. The following key issues regarding pediatric asthma are discussed or updated compared with the 1997 guidelines:

1. Use of inhaled corticosteroids as the preferred treatment for mild or moderate persistent asthma.
2. Initiation of long-term controller therapy in infants or children who have risk factors for asthma (parental history of asthma or physician-diagnosed atopic dermatitis or two of the following:

Table 34–2. Stepwise approach for treating infants and young children (5 years of age and younger) with acute or chronic asthma.

Classify Severity: Clinical Features Before Treatment or Adequate Control		Medications Required to Maintain Long-Term Control
	Symptoms/Day Symptoms/Night	Daily Medications
Step 4: Severe persistent	Continual Frequent	Preferred treatment: High-dose inhaled corticosteroids AND Long-acting inhaled β_2 -agonists AND, if needed, Corticosteroid tablets or syrup long term (2 mg/kg/d generally do not exceed 60 mg/d). (Make repeat attempts to reduce systemic corticosteroids and maintain control with high-dose inhaled corticosteroids.)
Step 3: Moderate persistent	Daily > 1 night/wk	Preferred treatments: Low-dose inhaled corticosteroids and long-acting inhaled β_2 -agonists OR Medium-dose inhaled corticosteroids. Alternative treatment: Low-dose inhaled corticosteroids and either leukotriene receptor antagonist or theophylline. If needed (particularly in patients with recurring severe exacerbations): Preferred treatment: Medium-dose inhaled corticosteroids and long-acting β_2 -agonists. Alternative treatment: Medium-dose inhaled corticosteroids and either leukotriene receptor antagonist or theophylline.
Step 2: Mild persistent	> 2/wk but < 1/d > 2 nights/mo	Preferred treatment: Low-dose inhaled corticosteroid (with nebulizer or MDI with holding chamber with or without face mask or DPI). Alternative treatment (listed alphabetically): Cromolyn (nebulizer is preferred or MDI with holding chamber) OR leukotriene receptor antagonist.
Step 1: Mild intermittent	\leq 2 d/wk \leq 2 nights/mo	No daily medication needed.
All patients	Bronchodilator as needed for symptoms \leq 2 times a week. Intensity of treatment will depend upon severity of exacerbation. Preferred treatment: Inhaled short-acting β_2 -agonist by nebulizer or face mask and space-holding chamber Alternative treatment: Oral β_2 -agonist With viral respiratory infection Bronchodilator q4–6h up to 24 h (longer with physician consult); in general no more than once every 6 wk Consider systemic corticosteroid if exacerbation is severe or patient has history of previous severe exacerbations Use of short-acting β_2 -agonist daily indicates the need to initiate or increase long-term control therapy	
Step down	Review treatment every 1–6 mos; a gradual stepwise reduction in treatment may be possible.	
Step up	If control is not maintained, consider step up. First, review patient medication technique, adherence, and environmental control.	

(continued)

Table 34–2. Stepwise approach for treating infants and young children (5 years of age and younger) with acute or chronic asthma. (continued)

Minimal or no chronic symptoms day or night
 Minimal or no exacerbations
 No limitations on activities; no school/parent's work missed
 Minimal use of inhaled short-acting β_2 -agonist (< 1/d, < 1 canister/mo)
 Minimal or no adverse effects from medications

Notes

The stepwise approach is intended to assist, not replace, the clinical decisionmaking required to meet individual patient needs.

Classify severity: assign patient to most severe step in which any feature occurs.

There are very few studies on asthma therapy for infants.

Gain control as quickly as possible (a course of short systemic corticosteroids may be required); then step down to the least medication necessary to maintain control.

Provide parent education on asthma management and controlling environmental factors that make asthma worse (e.g., allergies and irritants).

Consultation with an asthma specialist is recommended for patients with moderate or severe persistent asthma. Consider consultation for patients with mild persistent asthma.

Reprinted, with permission, from the National Asthma Education and Prevention Program: *Expert Panel Report: Update on Selected Topics 2002*.

physician-diagnosed allergic rhinitis, wheezing apart from colds, peripheral eosinophilia) with more than three episodes of wheezing over the past year that lasted longer than one day and affected sleep.

3. Benefits of inhaled corticosteroids at recommended doses (Table 34–4) versus potential risks.
4. Use of combination therapy including addition of long-acting inhaled β_2 -agonists to low-to-medium doses of inhaled corticosteroids as the preferred treatment for children older than 5 years with moderate persistent asthma and either addition of long-acting inhaled β_2 -agonists to a low dose of inhaled corticosteroids or medium-dose inhaled corticosteroids as monotherapy in children 5 years of age or younger. The preferred strategy is to initiate therapy at a higher level at the onset to gain prompt control and then step down, rather than gradually stepping up treatment if control is not achieved. A rescue course of systemic corticosteroids may be necessary at any step. A short course of systemic corticosteroids may be required for patients with intermittent asthma who experience infrequent but severe exacerbations—typically triggered by respiratory infections—with normal lung function between episodes.

Asthma medications are classified as long-term control medications and quick-relief medications. The for-

mer include anti-inflammatory agents, long-acting bronchodilators, and leukotriene modifiers. Inhaled corticosteroids delivered by aerosol, dry powder inhaler, or nebulizer are the most potent inhaled anti-inflammatory agents currently available. Recent data suggest that different inhaled corticosteroids are not equivalent on a per puff or microgram basis (see Table 34–4). Early intervention with inhaled corticosteroids can improve asthma control and may prevent airway remodeling. Inhaled corticosteroids may be associated with slowing of growth velocity in children, although a study of asthmatic children treated with budesonide (mean dose 412 $\mu\text{g}/\text{d}$) for a mean of 9.2 years showed no adverse effect on final adult height. Possible risks from inhaled corticosteroids need to be weighed against the risks from undertreated asthma. Only inhaled corticosteroids have been shown to be effective in long-term clinical studies with infants. Nebulized budesonide is approved for children as young as 12 months. The suspension (available in quantities of 0.25 mg/2 mL and 0.5 mg/2 mL) is usually administered at 0.5 mg/d, either once or twice a day in divided doses. Notably, this drug should not be given by ultrasonic nebulizer. Limited data suggest that inhaled corticosteroids may be effective even in very young children when delivered by metered-dose inhaler with a spacer with mask.

Fewer data are available with nedocromil, although comparative data from the Childhood Asthma Management Program study showed that an inhaled cortico-

Table 34–3. Stepwise approach for managing asthma in adults and children older than 5 years of age: Treatment.

Classify Severity: Clinical Features Before Treatment or Adequate Control		Medications Required to Maintain Long-Term Control	
	Symptoms/Day Symptoms/Night	PEF or FEV ₁ PEF Variability	Daily Medications
Step 4: Severe persistent	Continual Frequent	≤ 60% > 30%	Preferred treatment: High-dose inhaled corticosteroids AND Long-acting inhaled β ₂ -agonists AND, if needed, Corticosteroid tablets or syrup long term (2 mg/kg/d, generally do not exceed 60 mg/d). (Make repeat attempts to reduce systemic corticosteroids and maintain control with high-dose inhaled corticosteroids.)
Step 3: Moderate persistent	Daily > 1 night/wk	> 60%–< 80% > 30%	Preferred treatment: Low-to-medium dose inhaled corticosteroids and long-acting inhaled β ₂ -agonists Alternative treatment (listed alphabetically): Increase inhaled corticosteroids within medium-dose range OR Low-to-medium dose inhaled corticosteroids and either leukotriene modifier or theophylline. If needed (particularly in patients with recurring severe exacerbations): Preferred treatment: Increase inhaled corticosteroids within medium-dose range, and add long-acting inhaled β ₂ -agonists. Alternative treatment (listed alphabetically): Increase inhaled corticosteroids in medium-dose range, and add either leukotriene modifier or theophylline.
Step 2: Mild persistent	> 2/wk but < 1/d > 2 nights/mo	≥ 80% 20–30%	Preferred treatment: Low-dose inhaled corticosteroids Alternative treatment (listed alphabetically): cromolyn, leukotriene modifier, nedocromil, OR sustained release theophylline to serum concentration of 5–15 μg/mL.
Step 1: Mild intermittent	≤ 2 d/wk ≤ 2 nights/mo	≥ 80% < 20%	No daily medication needed. Severe exacerbations may occur, separated by long periods of normal lung function and no symptoms. A course of systemic corticosteroids is recommended.
All patients	Short-acting bronchodilator: 2–4 puffs short-acting inhaled β ₂ -agonists as needed for symptoms. Intensity of treatment will depend on severity of exacerbation: up to 3 treatments at 20-min intervals or a single nebulizer treatment as needed. Course of systemic corticosteroids may be needed. Use of short-acting inhaled β ₂ -agonists on a daily basis, or increasing use, indicates the need to initiate or increase long-term control therapy.		
Step down	Review treatment every 1–6 mos; a gradual stepwise reduction in treatment may be possible.		
Step up	If control is not maintained, consider step up. First, review patient medication technique, adherence, and environmental control.		

(continued)

Table 34–3. Stepwise approach for managing asthma in adults and children older than 5 years of age: Treatment. (continued)

Minimal or no chronic symptoms day or night
 Minimal or no exacerbations
 No limitations on activities; no school/parent’s work missed
 Minimal use of inhaled short-acting β_2 -agonist (< 1/d < 1 canister/mo)
 Minimal or no adverse effects from medications

Notes

The stepwise approach is intended to assist, not replace, the clinical decision making required to meet individual patient needs. Classify severity: assign patient to most severe step in which any feature occurs (PEF is % of personal best; FEV₁ is % predicted). Gain control as quickly as possible (consider a short course of systemic corticosteroids); then step down to the least medication necessary to maintain control. Provide education on self-management and controlling environmental factors that make asthma worse (eg, allergens and irritants). Refer to an asthma specialist if there are difficulties controlling asthma or if step 4 care is required. Referral may be considered if step 3 care is required. Reprinted with permission. (See Table 34–2).

steroid was superior to nedocromil with respect to a number of efficacy parameters, including rate of hospitalization, symptom-free days, need for albuterol rescue, and longer time to treatment with prednisone.

Sustained-release theophylline, an alternative long-term control medication for older children, may have particular risks of adverse side effects in infants, who frequently have febrile illnesses that increase theophylline concentrations.

Salmeterol, a long-acting β_2 -agonist, is available as an inhalation powder (1 inhalation twice daily for patients age 4 years and older). Salmeterol in a metered-dose inhaler has recently been discontinued. Salmeterol can be used as adjunctive therapy with anti-inflammatory med-

ications for long-term symptom control. Salmeterol should not be used for treatment of acute symptoms, and anti-inflammatory medication should not be discontinued when salmeterol is initiated, even if the patient feels better. Salmeterol, 50 μ g, is available combined with fluticasone (100, 250, or 500 μ g) in a dry powder inhaler. For children 12 years and older, one inhalation is taken twice daily. (Note: The 100/50 fluticasone/salmeterol combination is approved in children age 4 and older.) It can also be used 30 minutes before exercise (but not in addition to regularly used long-acting β_2 -agonists). Formoterol is another long-acting β_2 -agonist with a more rapid onset of action in a dry powder inhaler. It is approved for use in children 5 years and older, one inhala-

Table 34–4. Estimated comparative daily dosages for inhaled corticosteroids.

Drug	Low Daily Dose Child	Medium Daily Dose Child	High Daily Dose Child
Beclomethasone CFC 42 or 84 μ g/puff	84–336 μ g	336–672 μ g	> 672 μ g
Beclomethasone HFA 40 or 80 μ g/puff	80–160 μ g	160–320 μ g	> 320 μ g
Budesonide DPI 200 μ g/inhalation	200–400 μ g	400–800 μ g	> 800 μ g
Budesonide suspension for nebulization (child dose)	0.5 mg	1.0 mg	2.0 mg
Flunisolide 250 μ g/puff	500–750 μ g	1000–1250 μ g	> 1,250 μ g
Fluticasone MDI: 44, 110, or 220 μ g/puff DPI: 50, 100, or 250 μ g/inhalation	88–176 μ g	176–440 μ g	> 440 μ g
Triamcinolone acetonide 100 μ g/puff	400–800 μ g	800–1200 μ g	> 1200 μ g

tion (12 µg) twice daily. For long-term control, it should be used in combination with an anti-inflammatory agent. It can be used for exercise-induced bronchospasm in patients 12 years and older, (1 inhalation at least 15 minutes before exercise (but not in addition to regularly used long-acting β_2 -agonists).

Montelukast and zafirlukast are leukotriene receptor antagonists available in oral formulations. Montelukast is given once daily and has been approved for children age 1 year and older. To date, no drug interactions have been noted. The dosage is 4 mg for children 1–5 years (oral granules are available for children 12–23 months), 5 mg for children age 6–14 years, and 10 mg for those age 15 years and older. The drug is given without regard to mealtimes, preferably in the evening. Zafirlukast is approved for patients age 5 years and older. The dose is 10 mg twice daily for 5–11 years and 20 mg twice daily for 12 years and older. It should be taken 1 hour before or 2 hours after meals. Rare cases of Churg–Strauss syndrome in adult patients with severe asthma whose steroids were being tapered have been reported with concomitant treatment with leukotriene receptor antagonists (but also with inhaled corticosteroids), and no causal link has been established.

Quick-relief medications include short-acting inhaled β_2 -agonists such as albuterol, pirbuterol, or terbutaline, 1–2 puffs by inhaler. Albuterol HFA contains a nonchlorofluorocarbon propellant. Albuterol can be given by nebulizer, 0.05 mg/kg (with a minimal dose of 1.25 mg and a maximum of 2.5 mg) in 2–3 mL saline. It is better to use β_2 -agonists as needed rather than on a regular basis. Increasing use, including more than one canister per month, may signify inadequate asthma control and the need to intensify anti-inflammatory therapy. Levalbuterol, the (*R*)-enantiomer of racemic albuterol, is available in solution for nebulization for patients age 6–11 years 0.31 mg tid and for patients 12 years and older 0.63–1.25 mg tid. Anticholinergic agents such as ipratropium, 1–3 puffs or 0.25–0.5 mg by nebulizer every 6 hours, may provide additive benefit when used together with inhaled β_2 -agonists. Systemic corticosteroids such as prednisone, prednisolone, and methylprednisolone can be given in a dosage of 1–2 mg/kg, usually up to 60 mg/d in single or divided doses for 3–10 days. There is no evidence that tapering the dose following a “burst” prevents relapse.

Anti-IgE (omalizumab) is a recombinant DNA-derived humanized IgG₁ monoclonal antibody that selectively binds to human IgE. It inhibits the binding of IgE to the high-affinity IgE receptor (Fc ϵ -RI) on the surface of mast cells and basophils. Reduction in surface-bound IgE on Fc ϵ -RI-bearing cells limits the degree of release of mediators of the allergic response. Treatment with omalizumab also reduces the number of

Fc ϵ -RI receptors on basophils in atopic patients. Omalizumab is indicated for patients 12 years of age and older with moderate to severe persistent asthma who have a positive skin test or in vitro reactivity to a perennial aeroallergen with serum IgE \leq 700 IU/mL and whose symptoms are inadequately controlled with inhaled corticosteroids. Omalizumab has been shown to decrease the incidence of asthma exacerbations in these patients. Dosing is based on the patient's weight and serum IgE level and is given subcutaneously every 2–4 weeks. Continual monitoring is necessary to ensure that control of asthma is achieved and sustained. Once control is established, gradual reduction in therapy is appropriate and may help determine the minimum amount of medication necessary to maintain control. Regular follow-up visits with the clinician are important to assess the degree of control and consider appropriate adjustments in therapy. At each step, patients should be instructed to avoid or control exposure to allergens, irritants, or other factors that contribute to asthma severity. Referral to an asthma specialist for consultation or comanagement is recommended if there are difficulties in achieving or maintaining control or if the patient has severe persistent asthma. Referral is also recommended if allergen immunotherapy is being considered.

Referral may be considered for patients with moderate persistent asthma. For children younger than age 3 years, referral is recommended if the patient requires step 3 or 4 care and should be considered if the patient requires step 2 care (see Table 34–3).

3. Exercise induced bronchospasm—Exercise-induced bronchospasm should be anticipated in all asthma patients. It typically occurs during or minutes after vigorous activity, reaches its peak 5–10 minutes after stopping the activity, and usually resolves over the next 20–30 minutes. Participation in physical activity should be encouraged in children with asthma, although the choice of activity may need to be modified based on the severity of illness, triggers such as cold air, and, rarely, confounding factors such as osteoporosis. Treatment immediately prior to vigorous activity or exercise is usually effective. Short-acting inhaled β_2 -agonists, cromolyn or nedocromil can be used before exercise. The combination of a short-acting inhaled β_2 -agonist with either cromolyn or nedocromil is more effective than either drug alone. Salmeterol and formoterol may block exercise-induced bronchospasm for up to 12 hours (as discussed earlier). Montelukast may be effective up to 24 hours. Occasionally an extended warm-up period may induce a refractory state, allowing patients to exercise without a need for repeat medications. If symptoms occur during usual play activities, a

step-up in long-term therapy is warranted. Poor endurance or exercise-induced bronchospasm can be an indication of poorly controlled persistent asthma.

B. ACUTE ASTHMA

1. General measures—The most effective strategy in managing asthma exacerbations involves early recognition of warning signs and early treatment. For patients with moderate or severe persistent asthma or a history of severe exacerbations, this should include a written action plan. The latter usually defines the patient's peak flow zones and what steps to take if peak flows are between 50% and 80% or below 50% of personal best. The child, parents, and other caregivers must be able to assess asthma severity accurately. Prompt communication with the clinician is indicated with severe symptoms or a drop in peak flow or with decreased response to short-acting inhaled β_2 -agonists. At such times, intensification of therapy may include a short course of oral corticosteroids. The child should be removed from exposure to any irritants or allergens that could be contributing to the exacerbation.

2. Management at home—Early treatment of asthma exacerbations may prevent progression to severe disease. Initial treatment should be with a short-acting inhaled β_2 -agonist such as albuterol; 2–4 puffs from a metered-dose inhaler can be given every 20 minutes up to three times, or a single treatment can be given by nebulizer (0.05 mg/kg; minimum 1.25 mg, maximum 2.5 mg of 0.5% solution of albuterol in 2–3 mL saline). If the response is good as assessed by sustained symptom relief or improvement in PEF_R to over 80% of the patient's best, the short-acting β_2 -agonist can be continued every 3–4 hours for 24–48 hours. For patients taking inhaled corticosteroids, the dose may be doubled for 7–10 days. If the patient does not completely improve from the initial therapy, with PEF_R between 50% and 80%, the β_2 -agonist should be continued, an oral corticosteroid should be added, and the patient should contact the physician. If the child experiences marked distress or if PEF_R persists at under 50%, the patient should repeat the β_2 -agonist immediately and go to the emergency department or call 911 or another emergency number for assistance.

3. Management in the office or emergency department—Functional assessment of the patient includes obtaining objective measures of airflow limitation with PEF_R or FEV₁ and monitoring the patient's response to treatment. Other tests may include oxygen saturation and blood gases. If the initial FEV₁ or PEF_R is over 50%, initial treatment can be with a β_2 -agonist by inhaler (albuterol, 4–8 puffs) or nebulizer (0.15 mg/kg

of albuterol 0.5% solution, minimum dose 2.5 mg), up to three doses in the first hour. Oxygen should be given to maintain oxygen saturation at greater than 90%. Oral corticosteroids (1 mg/kg q6h for 48 hours, then 1–2 mg/kg/d in divided doses, maximum 60 mg/d) should be instituted if the patient responds poorly to therapy or if the patient has been on oral corticosteroids recently. Sensitivity to adrenergic drugs may improve after initiation of corticosteroids. If the initial FEV₁ or PEF_R is under 50%, initial treatment should be with a high-dose β_2 -agonist by nebulizer every 20 minutes or continuously for the first hour (0.5 mg/kg/h). Ipratropium can be added to albuterol, 0.25 mg every 20 minutes for three doses, then every 2–4 hours. Oxygen should be given to maintain oxygen saturation at greater than 90%, and systemic corticosteroids should be instituted. For patients with severe asthma unresponsive to initial aerosolized therapy, or for those who cannot cooperate with or who resist inhalation therapy, epinephrine 1:1000 or terbutaline 1 mg/mL (both 0.01 mg/kg up to 0.3–0.5 mg) may be administered subcutaneously every 20 minutes for three doses. The role of theophylline or aminophylline remains questionable when added to optimal β_2 -agonist therapy and may be associated with adverse events. For impending or ongoing respiratory arrest, patients should be intubated and ventilated with 100% oxygen and admitted to an intensive care unit (see Asthma (life-threatening) in Chapter 13). Further treatment is based on clinical response and objective laboratory findings. Hospitalization should be considered strongly for any patient with a history of respiratory failure.

4. Hospital management—For patients who do not respond to outpatient therapy, admission to the hospital becomes necessary for more aggressive care and support. Fluids should be given at maintenance requirements unless the patient has poor oral intake secondary to respiratory distress or vomiting, because overhydration may contribute to pulmonary edema associated with high intrapleural pressures generated in severe asthma. Potassium requirements should be kept in mind because both corticosteroids and β_2 -agonists can cause potassium loss. Moisturized oxygen should be titrated by oximetry to maintain SaO₂ above 90%. Inhaled β_2 -agonist should be continued by nebulization in single doses as needed or by continuous therapy, along with ipratropium and systemic corticosteroids (as discussed earlier). In addition, the role of methylxanthines in hospitalized children remains controversial. Antibiotics may be necessary to treat coexisting bacterial infection. Sedatives and anxiolytic agents are contraindicated in severely ill patients owing to their de-

pressant effects on respiration. Chest physiotherapy is usually not recommended for acute exacerbations.

5. Patient discharge—Criteria for discharging patients home from the office or emergency department should include a sustained response of at least 1 hour to bronchodilator therapy with FEV₁ or PEFr greater than 70% and oxygen saturation greater than 90% in room air. Prior to discharge, the patient's or caregiver's ability to continue therapy and assess symptoms appropriately needs to be considered. Patients should be given an action plan for management of recurrent symptoms or exacerbations, and instructions about medications should be reviewed. The inhaled β_2 -agonist and oral corticosteroids should be continued, the latter for 3–10 days. Finally, the patient or caregiver should be instructed about the follow-up visit, typically within 1 week. Hospitalized patients should receive more intensive education prior to discharge. Referral to an asthma specialist should be considered for all children with severe exacerbations or multiple emergency department visits or hospitalizations.

Prognosis

Since the 1970s, morbidity and mortality rates for asthma have increased. Mortality statistics indicate that a high percentage of deaths have resulted from underrecognition of asthma severity and undertreatment, particularly in labile asthmatic patients and in asthmatic patients whose perception of pulmonary obstruction is poor. Long-term outcome studies suggest that children with mild symptoms generally outgrow their asthma, while patients with more severe symptoms, marked airway hyperresponsiveness, and a greater degree of atopy tend to have persistent disease. In a recently published unselected birth cohort from New Zealand, more than one in four children had wheezing that persisted from childhood to adulthood or that relapsed after remission. It is possible that early intervention with anti-inflammatory therapy and environmental control measures may alter the natural history of childhood asthma. In this respect, the pediatrician or primary care provider together with the asthma specialist has a critical opportunity to affect the course of this increasingly common disease.

ALLERGIC RHINOCONJUNCTIVITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

After exposure to allergen:

- Sneezing.
- Itching of nose and eyes.
- Clear rhinorrhea or nasal congestion.

General Considerations

Allergic rhinoconjunctivitis is the most common allergic disease and significantly affects quality of life as well as school performance and attendance. It frequently coexists with asthma and is a risk factor for subsequent development of asthma. Prevalence of this disease increases during childhood, peaking at 15% in the postadolescent years. Although allergic rhinoconjunctivitis is more common in boys during early childhood, there is little difference in incidence between the sexes after adolescence. Race and socioeconomic status are not considered to be important factors.

The pathologic changes in allergic rhinoconjunctivitis are chiefly hyperemia, edema, and increased serous

and mucoid secretions caused by mediator release, all of which lead to variable degrees of nasal obstruction, pruritus, and rhinorrhea. This process may involve the eyes and other structures, including the sinuses and possibly the middle ear. Inhalant allergens are primarily responsible for symptoms, but food allergens can cause symptoms as well. Children with allergic rhinitis seem to be more susceptible to—or at least may experience more symptoms from—upper respiratory infections, which, in turn, may aggravate the allergic rhinitis.

Allergic rhinoconjunctivitis may be perennial, seasonal (hay fever), or episodic. Perennial allergic rhinitis occurs to some degree all year long but may be more severe in winter. Greater exposure to indoor allergens results from well-insulated homes, an increase in the amount of time spent indoors, and heating systems that disperse the allergens. Seasonal allergic rhinitis occurs as a result of exposure to specific aeroallergens, including pollens and molds. The major pollen groups in the temperate zones include trees (late winter to early spring), grasses (late spring to early summer), and weeds (late summer to early fall), but seasons can vary significantly in different parts of the country. Mold spores also cause seasonal allergic rhinitis, principally in the summer and fall. Seasonal allergy symptoms may be aggravated by coincident exposure to perennial allergens.

Clinical Findings

A. SYMPTOMS AND SIGNS

Patients may complain of itching of the nose, eyes, palate, or pharynx. Nasal itching can cause paroxysmal sneezing and epistaxis. Repeated rubbing of the nose (so-called allergic salute) may lead to a horizontal crease across the lower third of the nose. Nasal obstruction is associated with mouth breathing, nasal speech, allergic salute, and snoring. Nasal turbinates may appear pale blue and swollen, with dimpling, or injected, with minimal edema. Typically, clear and thin nasal secretions are increased, with anterior rhinorrhea, sniffing, post-nasal drip, and congested cough. Nasal secretions often cause poor appetite, fatigue, and pharyngeal irritation. Conjunctival injection, tearing, periorbital edema, and infraorbital cyanosis (so-called allergic shiners) are frequently observed. Increased pharyngeal lymphoid tissue (“cobblestoning”) from chronic drainage and enlarged tonsillar and adenoidal tissue may be present.

B. LABORATORY FINDINGS

Eosinophilia often can be demonstrated on smears of nasal secretions or blood. This is a frequent but nonspecific finding and may occur in nonallergic conditions. Although serum IgE may be elevated, measurement of total IgE is a poor screening tool owing to the wide

overlap between atopic and nonatopic subjects. Skin testing to identify allergen-specific IgE is the most sensitive and specific test for inhalant allergies; alternatively, radioallergosorbent assay test (RAST), ImmunoCAP, or other in vitro tests can be done for suspected allergens.

Differential Diagnosis

Disorders that need to be differentiated from allergic rhinitis include infectious rhinitis and sinusitis. Foreign bodies and structural abnormalities such as choanal atresia, marked septal deviation, nasal polyps, and adenoidal hypertrophy may cause chronic symptoms. Overuse of topical nasal decongestants may result in rhinitis medicamentosa (rebound congestion). Use of medications such as propranolol, clonidine, and some psychoactive drugs may cause nasal congestion. Illicit drugs like cocaine can cause rhinorrhea. Spicy or hot foods may cause gustatory rhinitis. Nonallergic rhinitis with eosinophilia syndrome is usually not seen in young children. Vasomotor rhinitis is associated with persistent symptoms but without allergen exposure. Less common causes of symptoms that may be confused with allergic rhinitis include pregnancy, congenital syphilis, hypothyroidism, tumors, and cerebrospinal fluid rhinorrhea.

Complications

Sinusitis may accompany allergic rhinitis. Allergic mucosal swelling of the sinus ostia can obstruct sinus drainage, interfering with normal sinus function and predisposing to chronic mucosal disease. Nasal polyps due to allergy are unusual in children, and cystic fibrosis should be considered if they are present.

Treatment

A. GENERAL MEASURES

The value of identification and avoidance of causative allergens cannot be overstated. Reducing indoor allergens through environmental control measures as discussed in the section on asthma can be very effective. Nasal saline irrigation may be useful.

B. PHARMACOLOGIC THERAPY

1. Antihistamines—Antihistamines help control itching, sneezing, and rhinorrhea. Sedating antihistamines include diphenhydramine, chlorpheniramine, hydroxyzine, and clemastine. Sedating antihistamines may cause daytime somnolence and negatively affect school performance and other activities, especially driving. Second-generation antihistamines include loratadine, desloratadine, cetirizine, and fexofenadine. Cetirizine is

approved for use in children age 6–23 months (2.5 mg daily), 2–5 years (2.5–5 mg/d or 2.5 mg bid), and 6 years or older (5–10 mg/d). Loratadine is approved for use in children aged 2–5 years (5 mg/d) and 6 years or older (10 mg/d), and is available without prescription in tablet, rapidly disintegrating tablet, and liquid formulations. Desloratadine 5 mg/d is approved for patients 12 years and older. Fexofenadine is approved for children age 6–11 years (30 mg bid) and 12 years or older (60 mg bid or 180 mg once daily). Loratadine, fexofenadine, and cetirizine are available in combination with pseudoephedrine for patients age 12 years or older. Azelastine is available in a nasal spray and levocabastine as an ophthalmic preparation.

2. Decongestants— α -Adrenergic agents help to relieve nasal congestion. Topical decongestants such as phenylephrine and oxymetazoline should not be used for more than 4 days for severe episodes because prolonged use may be associated with rhinitis medicamentosa. Oral decongestants, including pseudoephedrine and phenylpropanolamine, are often combined with antihistamines or expectorants and cough suppressants in over-the-counter cold medications. They may cause insomnia, agitation, tachycardia, and, rarely, cardiac arrhythmias. Of note, the US Food and Drug Administration has recommended the removal of phenylpropanolamine from all drug products due to a public health advisory concerning the risk of hemorrhagic stroke associated with its use.

3. Corticosteroids—Intranasal corticosteroid sprays are effective in controlling allergic rhinitis if used chronically. They are minimally absorbed in usual doses and are available in pressurized nasal inhalers and aqueous sprays. Mometasone nasal spray has been approved for use in children as young as age 2 years (1 spray in each nostril once daily) and in children 12 years or older (2 sprays/nostril once daily). Fluticasone nasal spray is approved for children 4 years or older, and budesonide and triamcinolone nasal sprays are approved for 6 years or older, 1–2 sprays/nostril once daily. Flunisolide is approved for ages 6–14 years 1 spray/nostril tid or 2 sprays/nostril bid. Side effects include nasal irritation, soreness, and bleeding, although epistaxis occurs commonly in patients with allergic rhinitis if corticosteroids are used chronically. Rarely they can cause septal perforation. Excessive doses may produce systemic effects, especially if used together with orally inhaled steroids for asthma. Onset of action is within hours, although clinical benefit is usually not observed for a week or more. They may be effective alone or together with antihistamines.

4. Other pharmacologic agents—Montelukast is approved for seasonal allergic rhinitis in children 2 years and older in doses as discussed under the preceding sec-

tion, Asthma Pharmacologic Therapy. Intranasal ipratropium can be used as adjunctive therapy for rhinorrhea. Intranasal cromolyn may be used alone or in conjunction with oral antihistamines and decongestants. It is most effective when used prophylactically, 1–2 sprays per nostril, qid. This dose may be tapered if symptom control is achieved. Rarely patients complain of nasal irritation or burning. Most patients find complying with four-times-daily dosing difficult. Cromolyn is also available in an ophthalmic solution (see also Chapter 15, Eye). Other ophthalmic mast cell stabilizers include lodoxamide 0.1% solution, 1–2 drops qid, and nedocromil, 1–2 drops bid. Olopatadine and ketotifen ophthalmic solutions have antihistamine and mast cell-stabilizing actions and can be given to children older than age 3 years as 1 drop bid (8 hours apart) and q8–12h, respectively.

C. SURGICAL THERAPY

Surgical procedures, including turbinectomy, polypectomy, and functional endoscopic sinus surgery, are rarely indicated in allergic rhinitis or chronic hyperplastic sinusitis.

D. IMMUNOTHERAPY

Allergen immunotherapy should be considered when symptoms are severe and due to unavoidable exposure to inhalant allergens, especially if symptomatic measures have failed. Immunotherapy is the only form of therapy that may alter the course of the disease. It should not be prescribed by sending the patient's serum to a laboratory where extracts based on *in vitro* tests are prepared for the patient (ie, the remote practice of allergy). Immunotherapy should be done in a facility where a physician prepared to treat anaphylaxis is present. Patients with concomitant asthma should not receive an injection if their asthma is not under good control (ie, peak flows preinjection are below 80% of personal best), and the patient should wait for 25–30 minutes after an injection before leaving the facility.

Outcomes with single allergen immunotherapy show success rates of approximately 80%. The optimal duration of therapy is unknown, but data suggest that immunotherapy for 3–5 years may have lasting benefit.

Prognosis

Perennial allergic rhinoconjunctivitis tends to be protracted unless specific allergens can be identified and eliminated from the environment. In seasonal allergic rhinoconjunctivitis, symptoms are usually most severe from adolescence through mid adult life. After moving to a region devoid of problem allergens, patients may

be symptom-free for several years, but they can develop new sensitivities to local aeroallergens.

ATOPIC DERMATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pruritus.
- Facial and extensor involvement in infants and young children.
- Flexural lichenification in older children and adolescents.
- Chronic or relapsing dermatitis.
- Personal or family history of atopic disease.

General Considerations

Atopic dermatitis is a chronically relapsing inflammatory skin disease typically associated with respiratory allergy. Over half of patients with atopic dermatitis will develop asthma and allergic rhinitis—often as they outgrow their atopic dermatitis. Atopic dermatitis may result in significant morbidity, leading to school absenteeism, occupational disability, and emotional stress. Atopic dermatitis presents in early childhood, with onset prior to age 5 years in approximately 90% of patients.

Clinical Findings

A. SYMPTOMS AND SIGNS

Atopic dermatitis has no pathognomonic skin lesions or laboratory parameters. Diagnosis is based on the clinical features, including severe pruritus, a chronically relapsing course, and typical morphology and distribution of the skin lesions. Acute atopic dermatitis is characterized by intensely pruritic, erythematous papules associated with excoriations, vesiculations, and serous exudate; subacute atopic dermatitis by erythematous, excoriated, scaling papules; chronic atopic dermatitis by thickened skin with accentuated markings (lichenification) and fibrotic papules. Patients with chronic atopic dermatitis may have all three types of lesions present concurrently. Patients usually have dry,

“lackluster” skin. During infancy, atopic dermatitis involves primarily the face, scalp, and extensor surfaces of the extremities. The diaper area is usually spared. When involved, it may be secondarily infected with *Candida*. In older patients with long-standing disease, the flexural folds of the extremities are the predominant location of lesions.

B. LABORATORY FINDINGS

Identification of allergens involves taking a careful history and performing selective immediate hypersensitivity skin tests or in vitro tests when appropriate. Negative skin tests with proper controls have a high predictive value for ruling out a suspected allergen. Positive skin tests have a lower correlation with clinical symptoms in suspected food allergen-induced atopic dermatitis and should be confirmed with double-blind, placebo-controlled food challenges unless there is a coincidental history of anaphylaxis to the suspected food. Alternatively, specific IgE levels to milk, egg, peanut, and fish proteins have been established with the Pharmacia ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction.

Elevated serum IgE levels can be demonstrated in 80–85% of patients with atopic dermatitis, and a similar number have positive immediate skin tests or in vitro tests with food and inhalant allergens. A number of well-controlled studies suggest that specific allergens can influence the course of this disease. However, triggers for clinical disease cannot be predicted simply by performing allergy testing. Double-blind, placebo-controlled food challenges show that food allergens can cause exacerbations in a subset of patients with atopic dermatitis. Although lesions induced by single positive challenges are usually transient, repeated challenges, more typical of real-life exposure, can result in eczematous lesions. Furthermore, elimination of food allergens results in amelioration of skin disease and a decrease in spontaneous basophil histamine release. Exacerbation of atopic dermatitis can occur with exposure to aeroallergens such as house dust mites, and environmental control measures have been shown to result in clinical improvement. Patients can make specific IgE directed at *Staphylococcus aureus* toxins secreted on the skin, and this correlates with clinical severity better than total serum IgE levels. Eosinophilia may occur. Routine skin biopsy does not differentiate atopic dermatitis from other eczematous processes and is not usually indicated.

Differential Diagnosis

Scabies can present as a pruritic skin disease. However, distribution in the genital and axillary areas and the presence of linear lesions as well as skin scrapings may help to distinguish it from atopic dermatitis. Seborrheic

dermatitis may be distinguished by a lack of significant pruritus; its predilection for the scalp (so-called cradle cap); and its coarse, yellowish scales. Allergic contact dermatitis may be suggested by the distribution of lesions with a greater demarcation of dermatitis than in atopic dermatitis. Occasionally, allergic contact dermatitis superimposed on atopic dermatitis may appear as an acute flare of the underlying disease. Nummular eczema is characterized by coin-shaped plaques. Although unusual in children, mycosis fungoides or cutaneous T-cell lymphoma has been described and is diagnosed by skin biopsy. Eczematous rash has been reported in patients with human immunodeficiency virus (HIV) infection. Other disorders that may resemble atopic dermatitis include Wiskott–Aldrich syndrome, severe combined immunodeficiency disease, hyper-IgE syndrome, zinc deficiency, phenylketonuria, and Letterer–Siwe disease.

Complications

Ocular complications associated with atopic dermatitis can lead to significant morbidity. Atopic keratoconjunctivitis is always bilateral, and symptoms include itching, burning, tearing, and copious mucoid discharge. It is frequently associated with eyelid dermatitis and chronic blepharitis, and may result in visual impairment from corneal scarring. Vernal conjunctivitis is a severe bilateral recurrent chronic inflammatory process of the upper eyelid conjunctiva, occurring primarily in younger patients (see Chapter 15, Eye). It has a marked seasonal incidence, often in the spring. The associated intense pruritus is exacerbated by exposure to irritants, light, or perspiration. Examination of the eye reveals a papillary hypertrophy or cobblestoning of the upper inner eyelid surface. Keratoconus in atopic dermatitis is believed to result from persistent rubbing of the eyes in patients with atopic dermatitis and allergic rhinitis. Anterior subcapsular cataracts may develop during adolescence or early adult life.

Patients with atopic dermatitis have increased susceptibility to infection or colonization with a variety of organisms. These include viral infections with herpes simplex, molluscum contagiosum, and human papillomavirus. Of note, even a past history of atopic dermatitis is considered a contraindication for receiving the current smallpox (vaccinia) vaccine. Superimposed dermatophytosis may cause atopic dermatitis to flare.

S aureus can be cultured from the skin of more than 90% of patients with atopic dermatitis, compared with only 5% of normal subjects. Atopic dermatitis patients often have toxin-secreting *S aureus* cultured from their skin. These patients make specific IgE antibodies directed against the toxins found on their skin. *S aureus* toxins can act as superantigens, contributing to persis-

tent inflammation or exacerbations of atopic dermatitis. In addition, patients with atopic dermatitis may be predisposed to colonization and infections by *S aureus* and other microbial organism due to decreased synthesis of antimicrobial peptides in the skin, which may be mediated by increased levels of TH2-type cytokines. Patients without obvious superinfection may show a better response to combined antistaphylococcal and topical corticosteroid therapy than to corticosteroids alone. Although recurrent staphylococcal pustulosis can be a significant problem in atopic dermatitis, invasive *S aureus* infections occur rarely and should raise the possibility of an immunodeficiency such as hyper-IgE syndrome.

Patients with atopic dermatitis often have a nonspecific hand dermatitis. This is frequently irritating in nature and aggravated by repeated wetting, especially in the occupational setting.

Nutritional disturbances may result from unwarranted and unnecessarily vigorous dietary restrictions imposed by physicians and parents.

Poor academic performance and behavioral disturbances may be a result of uncontrolled intense or frequent itching, sleep loss, and poor self-image. Severe disease may lead to problems with social interactions and self-esteem.

Treatment

A. GENERAL MEASURES

Patients with atopic dermatitis have a lowered threshold of irritant responsiveness. Avoidance of irritants such as detergents, chemicals, and abrasive materials as well as extremes of temperature and humidity is important in managing this disease. New clothing should be washed to reduce the content of formaldehyde and other chemicals. Because residual laundry detergent in clothing may be irritating, using a liquid rather than a powder detergent and adding an extra rinse cycle is beneficial. Occlusive clothing should be avoided in favor of cotton or cotton blends. Temperature in the home and work environments should be controlled to minimize sweating. Swimming is usually well tolerated; however, because swimming pools are treated with chlorine or bromine, patients should shower and use a mild cleanser to remove these irritating chemicals, then apply a moisturizer or occlusive agent. Sunlight may be beneficial to some patients with atopic dermatitis, but nonsensitizing sunscreens should be used to avoid sunburn. Prolonged sun exposure can cause evaporative losses, overheating, and sweating, all of which can be irritating.

In children who have undergone controlled food challenges, eggs, milk, peanuts, soy, wheat, and fish ac-

count for approximately 90% of the food allergens that exacerbate atopic dermatitis. Avoidance of foods implicated in controlled challenges can lead to clinical improvement. Extensive elimination diets, which can be nutritionally unsound and burdensome, are almost never warranted because even patients with multiple positive skin tests rarely react to more than three foods on blinded challenges.

In patients who demonstrate specific IgE to dust mite allergen, environmental control measures aimed at reducing the dust mite load improve atopic dermatitis. These include use of dust mite-proof covers on pillows and mattresses, washing linens weekly in hot water, decreasing indoor humidity levels, and in some cases removing bedroom carpeting.

Counseling may be of benefit when dealing with the frustrations associated with atopic dermatitis. Relaxation, behavioral modification, or biofeedback training may help patients with habitual scratching. Patients with severe or disfiguring disease may require psychotherapy.

Clinicians should provide the patient and family with both general information and specific written skin care recommendations. The patient or parent should demonstrate an appropriate level of understanding to help ensure a good outcome. Educational pamphlets and a video about atopic dermatitis can be obtained from the Eczema Association for Science and Education, a national non-profit, patient-oriented organization, at 1-800-818-7546 or at <http://www.nationaleczema.org/>.

B. HYDRATION

Patients with atopic dermatitis have evaporative losses due to a defective skin barrier, so soaking the affected area or bathing for 15–20 minutes in warm water, then applying an occlusive agent to retain the absorbed water, is an essential component of therapy. Oatmeal or baking soda added to the bath may feel soothing to certain patients but does not improve water absorption. Atopic dermatitis of the face or neck can be treated by applying a wet facecloth or towel to the involved area for 15–20 minutes. The washcloth may be more readily accepted by a child if it is turned into a mask and also allows the older patient to remain functional. Lesions limited to the hands or feet can be treated by soaking in a basin. Daily baths may be needed and increased to several times daily during flares of atopic dermatitis, while showers may be adequate for patients with mild disease. It is important to use an occlusive preparation within a few minutes after soaking the skin to prevent evaporation, which is both drying and irritating.

C. MOISTURIZERS AND OCCLUSIVES

An effective emollient combined with hydration therapy will help skin healing and can reduce the need for

topical corticosteroids. Moisturizers are available as lotions, creams, and ointments. Because lotions contain more water than creams, they are more drying because of their evaporative effect. Preservatives and fragrances in lotions and creams may cause skin irritation. Moisturizers often need to be applied several times daily on a long-term basis and should be obtained in the largest size available. Crisco shortening can be substituted as an inexpensive alternative. Petroleum jelly (Vaseline) is an effective occlusive agent when used to seal in water after bathing.

D. CORTICOSTEROIDS

Corticosteroids reduce the inflammation and pruritus in atopic dermatitis. Topical corticosteroids can decrease *S aureus* colonization. Systemic corticosteroids, including oral prednisone, should be avoided in the management of this chronic relapsing disease. The dramatic improvement observed with systemic corticosteroids may be associated with an equally dramatic flaring of atopic dermatitis following their discontinuation. If a short course of oral corticosteroids is given, it is usually best to prescribe a tapering dose.

Topical corticosteroids are available in a wide variety of formulations, ranging from extremely high-potency to low-potency preparations (see Table 14–3). Choice of a particular product depends on the severity and distribution of skin lesions. Patients need to be counseled regarding the potency of their corticosteroid preparation and its potential side effects. In general, the least potent agent that is effective should be used. However, choosing a preparation that is too weak may result in persistence or worsening of the atopic dermatitis. Side effects include thinning of the skin, telangiectasias, bruising, hypopigmentation, acne, and striae, although these occur infrequently when low- to medium-potency topical corticosteroids are used appropriately. In contrast, use of potent topical corticosteroids for prolonged periods—especially under occlusion—may result in significant atrophic changes as well as systemic side effects. The face (especially the eyelids) and intertriginous areas are especially sensitive to corticosteroid side effects, and only low-potency preparations should be used routinely on these areas. Because topical corticosteroids are commercially available in a variety of bases, including ointments, creams, lotions, solutions, gels, and sprays, there is no need to compound them. Ointments are most occlusive and in general provide better delivery of the medication while preventing evaporative losses. However, in a humid environment, creams may be better tolerated than ointments because the increased occlusion may cause itching or even folliculitis. Creams and lotions, while easier to spread, can contribute to skin dryness and irritation. Solutions can be used on the scalp and hirsute areas, although they can be irritating,

especially to open lesions. With clinical improvement, a less potent corticosteroid should be prescribed and the frequency of use decreased. Topical corticosteroids can be discontinued when inflammation resolves, but hydration and moisturizers need to be continued.

Of note, fluticasone 0.05% cream has been shown to be safe in infants as young as 3 months of age with extensive atopic dermatitis. In addition, several studies with fluticasone 0.05% cream have shown that once atopic dermatitis is stabilized, long-term control can be maintained with twice weekly therapy. Of note, during the maintenance phase, fluticasone 0.05% cream was also applied to areas that had healed, which resulted in delayed relapses.

E. TOPICAL CALCINEURIN INHIBITORS

Tacrolimus and pimecrolimus are immunomodulatory agents that inhibit the transcription of proinflammatory cytokines as well as other allergic mediators and target key cells in allergic inflammation. They are available in topical formulations, and long-term studies up to 12 months have confirmed both efficacy and safety. Local burning at the site of application, which occurs more frequently with tacrolimus ointment, has been the most common side effect, although this is usually a transient problem. Tacrolimus ointment—0.03% for children 2–15 years of age and 0.1% for older patients—is approved for twice daily short-term and intermittent long-term use in moderate-to-severe atopic dermatitis. Pimecrolimus 1% cream is approved for patients 2 years of age or older who have mild-to-moderate atopic dermatitis. As a precaution, patients should wear sunscreen with both drugs. More recently, several studies in children as young as 3 months of age with all disease severities have been performed for up to 12 months with pimecrolimus 1% cream used at the earliest sign of disease activity (eg, erythema, pruritus). With this early intervention approach, the need for topical steroid rescue was significantly decreased.

F. TAR PREPARATIONS

Tar preparations are used primarily in shampoos and rarely as bath additives. Side effects associated with tar products include skin dryness or irritation, especially if applied to inflamed skin, and, less commonly, photosensitivity reactions and folliculitis.

G. WET DRESSINGS

Wet dressings are used together with hydration and topical corticosteroids primarily for the treatment of severe atopic dermatitis. They can also serve as an effective barrier against the persistent scratching that often undermines therapy. Total body dressings can be applied by using wet pajamas or long underwear with dry pajamas or a sweat suit on top. Hands and feet can be

covered by wet tube socks with dry tube socks on top. Alternatively, wet gauze with a layer of dry gauze over it can be used and secured in place with an elastic bandage. Dressings can be removed when they dry out, usually after several hours, and are often best tolerated at bedtime. Incorrect use of wet dressings can result in chilling, maceration of the skin, or secondary infection.

H. ANTI-INFECTIVE THERAPY

Systemic antibiotic therapy may be important when treating atopic dermatitis secondarily infected with *S aureus*. For limited areas of involvement, a topical antibiotic such as mupirocin may be effective. First- or second-generation cephalosporins or a semisynthetic penicillin are usually the first choice for oral therapy, as erythromycin-resistant organisms are fairly common. Maintenance antibiotic therapy is rarely indicated and may result in colonization by methicillin-resistant bacteria.

Disseminated eczema herpeticum usually requires treatment with systemic acyclovir. Patients with recurrent cutaneous herpetic lesions can be given prophylactic oral acyclovir. Superficial dermatophytosis and *Pityrosporum ovale* infection can be treated with topical or (rarely) systemic antifungal agents.

I. ANTIPRURITIC AGENTS

Pruritus is usually the least well tolerated symptom of atopic dermatitis. Oral antihistamines and anxiolytics may be effective owing to their tranquilizing and sedating effects and can be taken mostly in the evening to avoid daytime somnolence. Nonsedating antihistamines may be less effective in treating pruritus, although beneficial effects have been reported in blinded studies. Use of topical antihistamines and local anesthetics should be avoided because of potential sensitization.

J. RECALCITRANT DISEASE

Patients who are erythrodermic or who appear toxic may need to be hospitalized. Hospitalization may also be appropriate for cases of severe disease that fail outpatient management. Marked clinical improvement often occurs when the patient is removed from environmental allergens or stressors. In the hospital, compliance with therapy can be monitored, the patient and family can receive intense education, and controlled provocative challenges can be conducted to help identify triggering factors.

Ultraviolet light therapy can be useful for chronic recalcitrant atopic dermatitis in a subset of patients under the supervision of a specialist. Photochemotherapy with oral methoxypsoralen therapy followed by UVA has been used in a limited number of children with severe atopic dermatitis unresponsive to other

therapy, and significant improvement has been noted. However, the increased long-term risk of cutaneous malignancies from this therapy prevents its widespread use.

Limited published data are available on use of the systemic immunosuppressive agent cyclosporine. In an open study, children given oral cyclosporine, 5 mg/kg daily for 6 weeks, improved significantly and tolerated the treatment well. Unfortunately, discontinuation of treatment resulted in relapse, although the relapse rate was variable. Patients treated with this agent should have their dose titrated to the lowest effective dose after the disease is brought under control with appropriate monitoring, under the care of a specialist familiar with the drug.

K. EXPERIMENTAL AND UNPROVED THERAPIES

A number of uncontrolled trials have suggested that desensitization to specific allergens may improve atopic dermatitis; however, controlled trials with standardized extracts of relevant allergens in atopic dermatitis are needed before this form of therapy can be recommended.

Traditional Chinese herbal therapy in the form of decoctions has also been proposed for atopic dermatitis. The herbs used may have antimicrobial, sedative, anti-inflammatory, and corticosteroid-like activities. Despite studies showing clinical efficacy, toxicity and idiosyncratic reactions remain a concern, and traditional Chinese herbal therapy should be considered investigational at best. Finally, although disturbances in the metabolism of essential fatty acids have been reported in patients with atopic dermatitis, well-controlled trials with fish oil and evening primrose have shown no clinical benefit.

Prognosis

Although it has been held that most children outgrow atopic dermatitis by adolescence, recent studies present less optimistic outcomes. In one study, atopic dermatitis had disappeared in only 18% of children followed from infancy until age 13 years, although the symptoms had become less severe in 65%. In a prospective study from Finland, 77–91% of adolescent patients receiving treatment for moderate or severe atopic dermatitis had persistent or frequently relapsing dermatitis as adults, although only 6% had severe disease. More than half of adolescents receiving treatment for mild dermatitis experienced a relapse of disease as adults. Adults whose childhood atopic dermatitis has been in remission for a number of years may present with hand dermatitis, especially if daily activities require repeated hand wetting.

URTICARIA & ANGIOEDEMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Urticaria: Erythematous, blanchable, circumscribed, pruritic, edematous papules ranging from 1–2 mm to several centimeters in diameter and involving the superficial dermis. Individual lesions can coalesce.*
- *Angioedema: Edema extending into the deep dermis or subcutaneous tissues.*
- *Both resolve without sequelae—urticaria usually within hours (individual lesions rarely lasting up to 24 hours), angioedema within 72 hours.*

General Considerations

Urticaria and angioedema are common dermatologic conditions, occurring at some time in up to 25% of the population. About half of patients will have concomitant urticaria and angioedema, whereas 40% will have only urticaria and 10% only angioedema. Urticarial lesions are arbitrarily designated as acute, lasting less than 6 weeks, or chronic, lasting more than 6 weeks. Acute versus chronic urticaria can also be distinguished by differences in histologic features. A history of atopy is common with acute urticaria or angioedema. In contrast, atopy does not appear to be a factor in chronic urticaria.

Mast cell degranulation, dilated venules, and dermal edema are present in most forms of urticaria or angioedema. The dermal inflammatory cells may be sparse or dense depending on the chronicity of the lesions. Mast cells are thought to play a critical role in the pathogenesis of urticaria or angioedema through release of a variety of vasoactive mediators. Mast cell activation and degranulation

tion can be triggered by different stimuli, including cross-linking of Fc receptor-bound IgE by allergens or anti-FcεRI antibodies. Non-IgE-mediated mechanisms have also been identified, including complement anaphylatoxins (C3a, C5a), radiocontrast dyes, or physical stimuli. Chronic urticarial lesions have greater numbers of perivascular mononuclear cells, consisting primarily of T cells. There is also a marked increase in cutaneous mast cells. The cause of acute disease can be identified in about half of patients and include allergens such as foods, aeroallergens, latex, drugs, and insect venoms. Infectious agents, including streptococci, mycoplasmas, hepatitis B virus, and Epstein-Barr virus (EBV), can cause acute urticaria. Urticaria or angioedema can occur after the administration of blood products or immunoglobulin. This results from immune complex formation with complement activation, vascular alterations, and triggering of mast cells by anaphylatoxins. Opiate analgesics, polymyxin B, tubocurarine, and radiocontrast media can induce acute urticaria by direct mast cell activation. These disorders can also occur following ingestion of aspirin or nonsteroidal anti-inflammatory agents (see Adverse Reactions to Drugs & Biologicals section).

Physical urticarias represent a heterogeneous group of disorders in which urticaria or angioedema is triggered by physical stimuli, including pressure, cold, heat, water, or vibrations. Dermographism is the most common form of physical urticaria, affecting up to about 4% of the population and occurring at skin sites subjected to mechanical stimuli. Many physical urticarias are considered to be acute because the lesions are usually rapid in onset, with resolution within hours. However, symptoms can recur for months to years.

The cause of chronic urticaria is usually not due to allergies and typically cannot be determined. It can be associated with an underlying systemic disease such as thyroid disease. Some studies have demonstrated IgG autoantibodies directed at the high-affinity receptor for IgE or at IgE, suggesting that chronic urticaria may be an autoimmune disease.

Clinical Findings

A. SYMPTOMS AND SIGNS

Cold-induced urticaria or angioedema can occur within minutes of exposure to a decreased ambient temperature or as the skin is warmed following direct cold contact. Systemic features include headache, wheezing, and syncope. If the entire body is cooled, as may occur during swimming, hypotension and collapse can occur. Two forms of dominantly inherited cold urticaria have been described. The immediate form is known as familial cold urticaria, in which erythematous macules appear rather than wheals, along with fever, arthralgias,

and leukocytosis. The delayed form consists of erythematous, deep swellings that develop 9–18 hours after local cold challenge without immediate lesions.

In solar urticaria, which occurs within minutes after exposure to light of appropriate wavelength, pruritus is followed by morbilliform erythema and urticaria.

Cholinergic urticaria occurs after increases in core body and skin temperatures and typically develops after a warm bath or shower, exercise, or episodes of fever. Occasional episodes are triggered by stress or the ingestion of certain foods. The eruption appears as small punctate wheals surrounded by extensive areas of erythema. Rarely the urticarial lesions become confluent and angioedema develops. Associated features can include one or more of the following: headache, syncope, bronchospasm, abdominal pain, vomiting, and diarrhea. In severe cases, systemic anaphylaxis may develop. In pressure urticaria or angioedema, red, deep, painful swelling occurs immediately or 4–6 hours after the skin has been exposed to pressure. The immediate form is often associated with dermographism. The delayed form, which may be associated with fever, chills, and arthralgias, may be accompanied by elevated erythrocyte sedimentation rate and leukocytosis. Lesions are frequently diffuse, tender, and painful rather than pruritic. They typically resolve within 48 hours.

B. LABORATORY FINDINGS

Laboratory tests are selected on the basis of the history and physical findings. Testing for specific IgE antibody to food or inhalant allergens may be helpful in implicating a potential cause. Specific tests for physical urticarias, such as an ice cube test or a pressure test, may be indicated. Intradermal injection of methacholine reproduces clinical symptoms locally in about one third of patients with cholinergic urticaria. A throat culture for streptococcal infection may be warranted with acute urticaria. In chronic urticaria, selected screening studies to look for an underlying disease may be indicated, including a complete blood count (CBC), erythrocyte sedimentation rate, biochemistry panel, and urinalysis. Antithyroid antibodies may be considered. Intradermal testing with the patient's serum has been suggested as a method of detecting histamine-releasing activity, including autoantibodies. Other tests should be done based on suspicion of a specific underlying disease. If the history or appearance of the urticarial lesions suggests vasculitis, a skin biopsy for immunofluorescence is indicated. Patient diaries occasionally may be helpful to determine the cause of recurrent hives. A trial of food or drug elimination may be considered.

Differential Diagnosis

Urticarial lesions are usually easily recognized—the major dilemma is the etiologic diagnosis. Lesions of ur-

ticarial vasculitis typically last for more than 24 hours. “Papular urticaria” is a term used to characterize multiple papules from insect bites, found especially on the extremities, and is not true urticaria. Angioedema can be distinguished from other forms of edema because it is transient, asymmetrical, and nonpitting and does not occur predominantly in dependent areas. Hereditary angioedema is a rare autosomal dominant disorder caused by a quantitative or functional deficiency of C1-esterase inhibitor and characterized by episodic, frequently severe, nonpruritic angioedema of the skin, gastrointestinal tract, or upper respiratory tract. Life-threatening laryngeal angioedema may occur.

Complications

In severe cases of cholinergic urticaria, systemic anaphylaxis may develop. In cold-induced disease, sudden cooling of the entire body as can occur with swimming can result in hypotension and collapse.

Treatment

A. GENERAL MEASURES

The most effective treatment is identification and avoidance of the triggering agent. Underlying infection should be treated appropriately. Patients with physical urticarias should avoid the relevant physical stimulus. Epinephrine can be used for treatment of acute episodes, especially when laryngeal edema complicates an attack (see Anaphylaxis section). Intubation may be indicated for life-threatening laryngeal edema.

B. ANTIHISTAMINES

For the majority of patients, H₁ antihistamines given orally or systemically are the mainstay of therapy. Antihistamines are more effective when given on an ongoing basis rather than after lesions appear. For breakthrough symptoms, the dose may need to be increased. In the case of cold urticaria, the best treatment appears to be cyproheptadine. Cholinergic urticaria can be treated with hydroxyzine and dermographism with hydroxyzine or diphenhydramine. The addition of H₂ antihistamines may benefit some patients who fail to respond to H₁ receptor antagonists alone. Second-generation antihistamines (discussed previously under Allergic Rhinitis) are long acting, show good tissue levels, are non- or minimally sedating at usual dosing levels, and lack anticholinergic effects.

C. CORTICOSTEROIDS

Although corticosteroids are usually not indicated in the treatment of acute or chronic urticaria, severe recalcitrant cases may require alternate-day therapy in an attempt to diminish disease activity and facilitate control

with antihistamines. Systemic corticosteroids may also be needed in the treatment of urticaria or angioedema secondary to necrotizing vasculitis, an uncommon occurrence in patients with serum sickness or collagen-vascular disease.

D. OTHER PHARMACOLOGIC AGENTS

Limited studies suggest that some patients may benefit from treatment with a leukotriene receptor antagonist. The tricyclic antidepressant doxepin blocks both H₁ and H₂ histamine receptors and may be particularly useful in chronic urticaria, although its use may be limited by the sedating side effect. A limited number of patients—including euthyroid patients—with chronic urticaria and antithyroid antibodies have improved when given thyroid hormone. Treatment of chronic urticaria with hydroxychloroquine, nifedipine, colchicine, dapsone, sulfasalazine, cyclosporine, or intravenous immune globulin should be considered investigational.

Prognosis

Spontaneous remission of urticaria and angioedema is frequent, but some patients have a prolonged course. Reassurance is important, because this disorder can cause significant frustration. Periodic follow-up is indicated, particularly for patients with laryngeal edema, to monitor for possible underlying cause.

ANAPHYLAXIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Rapid onset of allergic symptoms after exposure to allergen in a previously sensitized person.*
- *Generalized pruritus, anxiety, urticaria, angioedema, throat fullness, dyspnea, hypotension, and collapse.*

General Considerations

Anaphylaxis is an acute life-threatening clinical syndrome that occurs when large quantities of inflammatory mediators are rapidly released from mast cells and basophils after exposure to an allergen in a previously

sensitized patient. Anaphylactoid reactions mimic anaphylaxis but are not mediated by IgE. They may be mediated by anaphylatoxins such as C3a or C5a or through nonimmune mast cell degranulating agents. Some of the common causes of anaphylaxis or anaphylactoid reactions are listed in Table 34–5. Idiopathic anaphylaxis by definition has no recognized external cause.

Clinical Findings

A. SYMPTOMS AND SIGNS

The symptoms and signs of anaphylaxis or anaphylactoid reactions depend on the organs affected. Onset typically occurs within minutes after exposure to the offending agent and can be short-lived, protracted, or biphasic, with recurrence after several hours despite treatment. Patients may report generalized pruritus or a feeling of impending doom. Cutaneous signs include erythema, urticaria, and angioedema. Tearing, rhinorrhea, sneezing, and nasal congestion may occur. Respiratory symptoms include a sensation of having a lump in the throat or shortness of breath; signs include uvular edema, hoarseness, dysphonia, stridor, tachypnea, and wheezing. Cardiovascular findings include tachycardia, arrhythmias, hypotension, and collapse. The patient may complain of nausea and cramping pain with associated vomiting, and diarrhea. There may be anxiety or generalized seizures. Shock, upper airway edema, and bronchial obstruction are the principal life-threatening features.

Table 34–5. Common causes of systemic allergic and pseudoallergic reactions.

Causes of anaphylaxis

- Drugs
 - Antibiotics
 - Anesthetic agents
- Foods
 - Peanuts, tree nuts, shellfish, and others
- Biologicals
 - Latex
 - Insulin
 - Allergen extracts
 - Antisera
 - Blood products
 - Enzymes
- Insect venoms

Causes of anaphylactoid reactions

- Radiopaque contrast media
- Aspirin and other nonsteroidal anti-inflammatory drugs
- Anesthetic agents

B. LABORATORY FINDINGS

Tryptase released by mast cells can be measured in the serum and may remain elevated for up to 24 hours after an acute reaction. This may be helpful when the diagnosis of anaphylaxis is in question. The CBC may show an elevated hematocrit due to hemoconcentration. Elevation of serum creatine kinase, aspartate aminotransferase, and lactic dehydrogenase may be seen with myocardial involvement. Electrocardiographic abnormalities may include ST wave depression, bundle branch block, and various arrhythmias. Arterial blood gases may show hypoxemia, hypercapnia, and acidosis. The chest radiograph may show hyperinflation.

Differential Diagnosis

Although shock may be the only sign of anaphylaxis, other diagnoses should be considered, especially in the setting of sudden collapse without typical allergic findings. Other causes of shock along with cardiac arrhythmias must be ruled out (see Chapters 11 and 13). Respiratory failure associated with asthma may be confused with anaphylaxis. Mastocytosis, hereditary angioedema, scombroid poisoning, vasovagal reactions, vocal cord dysfunction, and anxiety attacks may cause symptoms mistaken for anaphylaxis.

Complications

Depending on the organs involved and the severity of the reaction, complications may vary from none to aspiration pneumonitis, acute tubular necrosis, bleeding diathesis, or sloughing of the intestinal mucosa. With irreversible shock, heart and brain damage can be terminal.

Treatment

A. GENERAL MEASURES

Anaphylaxis is a medical emergency that requires rapid assessment and treatment. Exposure to the triggering agent should be discontinued. Airway patency should be maintained and blood pressure and pulse monitored. The patient should be placed in a supine position with the legs elevated. Oxygen should be delivered by mask or nasal cannula with pulse oximetry monitoring. If the reaction is secondary to a sting or injection into an extremity, a tourniquet may be applied proximal to the site, briefly releasing it every 10–15 minutes.

B. EPINEPHRINE

Epinephrine 1:1000, 0.01 mL/kg to a maximum of 0.3 mL, should be injected intramuscularly, without delay. This dose may be repeated at intervals of 15–20 minutes two or three times as necessary. If the

precipitating allergen has been injected intradermally or subcutaneously, absorption may be delayed by giving 0.1 mL of epinephrine subcutaneously at the injection site unless the site is a digit.

C. ANTIHISTAMINES

Diphenhydramine, an H₁-blocker, 1–2 mg/kg up to 50 mg, can be given intramuscularly or intravenously. Intravenous antihistamines should be infused over a period of 5–10 minutes to avoid inducing hypotension. Addition of ranitidine, an H₂-blocker, 1 mg/kg up to 50 mg intravenously, may be more effective than an H₁-blocker alone, especially for hypotension.

D. FLUIDS

Treatment of persistent hypotension requires restoration of intravascular volume by fluid replacement, initially with a crystalloid solution, 20–30 mL/kg in the first hour.

E. BRONCHODILATORS

Nebulized β₂-agonists such as albuterol 0.5% solution, 2.5 mg (0.5 mL) diluted in 2–3 mL saline, may be useful for reversing bronchospasm. Intravenous methylxanthines are generally not recommended because they provide little benefit over inhaled β₂-agonists and may contribute to toxicity.

F. CORTICOSTEROIDS

Although corticosteroids do not provide immediate benefit, when given early they may prevent protracted or biphasic anaphylaxis. Intravenous methylprednisolone, 1–2 mg/kg, or hydrocortisone, 5 mg/kg, can be given q4–6h.

G. VASOPRESSORS

Refractory hypotension should be treated with intravenous vasopressors such as dopamine or epinephrine (see Chapter 13).

H. OBSERVATION

The patient should be monitored after the initial symptoms have subsided, because biphasic or protracted anaphylaxis can occur despite ongoing therapy.

Prevention

Strict avoidance of the causative agent is extremely important. An effort to determine its cause should be made, beginning with a thorough history. Typically there is a strong temporal relationship between exposure and onset of symptoms. Testing for specific IgE to allergen with either *in vitro* or skin testing may be indicated. With exercise-induced anaphylaxis, patients should be instructed to exercise with another person and to stop exercising at the first sign of symptoms. If

prior ingestion of food has been implicated, eating within 4 hours—perhaps up to 12 hours—before exercise should be avoided. Patients with a history of anaphylaxis should carry epinephrine for self-administration (eg, EpiPen, EpiPen Jr), and they and all caregivers should be instructed on its use. They should also carry an oral antihistamine such as diphenhydramine and wear a medical alert bracelet. Patients with idiopathic anaphylaxis may require prolonged treatment with oral corticosteroids. Specific measures for dealing with food, drug, latex, and insect venom allergies as well as radiocontrast media reactions are discussed in a later section.

Prognosis

Anaphylaxis can be fatal. In one study of children and adolescents who died from food-induced anaphylaxis (eg, from peanuts, tree nuts, or egg), treatment with epinephrine was delayed for more than 1 hour after onset. The prognosis is good when signs and symptoms are recognized promptly and treated aggressively and the offending agent is avoided subsequently. Exercise-induced and idiopathic anaphylaxis may be recurrent. Because accidental exposure to the causative agent may occur, patients, parents, and caregivers must be prepared to recognize and treat anaphylaxis.

Sampson HA: Anaphylaxis and emergency treatment. *Pediatrics* 2003;111:1601 [PMID: 12667272].

ADVERSE REACTIONS TO DRUGS & BIOLOGICALS

The majority of adverse drug reactions are not immunologically mediated and may be due to idiosyncratic reactions, overdose, pharmacologic side effects, nonspecific release of pharmacologic effector molecules, or drug interactions.

Patients often describe themselves as being allergic to medications or biologicals, and clinicians may document a drug allergy in the patient's medical record based solely on this history. Adverse drug reactions are any undesirable and unintended response elicited by a drug. Allergic or hypersensitivity drug reactions are adverse reactions involving immune mechanisms. Although hypersensitivity reactions account for only 5–10% of all adverse drug reactions, they are the most serious, with 1:10,000 resulting in death.

1. Antibiotics

Antibiotics constitute the most frequent cause of allergic drug reactions. Amoxicillin, trimethoprim-sulfamethoxazole, and ampicillin are the most common causes of cutaneous drug reactions.

Most antibiotics and their metabolites are low-molecular-weight compounds that do not stimulate immunity until they have become covalently bound to a carrier protein. The penicillins and other β -lactam antibiotics, including cephalosporins, carbacephems, carbapenems, and monobactams, share a common β -lactam ring structure and a marked propensity to couple to carrier proteins. Penicilloyl is the predominant metabolite of penicillin and is called the major determinant. The other penicillin metabolites are present in low concentrations and are referred to as minor determinants. Sulfonamide reactions are mediated presumably by a reactive metabolite (hydroxylamine) produced by cytochrome P-450 oxidative metabolism. Slow acetylators appear to be at increased risk. Other risk factors for drug reactions include previous exposure, previous reaction, age (20–49 years), route (parenteral), and dose of administration (high, intermittent). Atopy does not predispose to development of a reaction, but atopic individuals have more severe reactions.

Immunopathologic reactions to antibiotics include type I (IgE-mediated) reactions resulting from a drug or metabolite interaction with preformed specific IgE bound to the surfaces of tissue mast cells or circulating basophils. Release of mediators such as histamine and leukotrienes contributes to the clinical development of angioedema, urticaria, bronchospasm, or anaphylaxis. Type II (cytotoxic) reactions involve IgG or IgM antibodies that recognize drug bound to cell membranes. In the presence of serum complement, the antibody-coated cell is either cleared or destroyed, causing drug-induced hemolytic anemia or thrombocytopenia. Type III (immune complex) reactions are caused by soluble complexes of drug or metabolite with IgG or IgM antibody. If the immune complex is deposited on blood vessel walls and activates the complement cascade, serum sickness may result. Type IV (T-cell-mediated) reactions require activated T lymphocytes that recognize a drug or its metabolite as seen in allergic contact dermatitis. Sensitization usually occurs via the topical route of administration. Immunopathologic reactions not fitting into the type I–IV classification include Stevens–Johnson syndrome, exfoliative dermatitis, and the maculopapular rash associated with penicillin or ampicillin. The prevalence of morbilliform rashes in patients given ampicillin is between 5.2% and 9.5% of treatment courses. However, patients given ampicillin during EBV and cytomegalovirus infections or with acute lymphoblastic anemia have a 69–100% incidence of non-IgE-mediated rash. Serum-sickness-like reactions resemble type III reactions, although immune complexes are not documented; β -lactams, especially cefaclor, and sulfonamides, have been implicated most often. They may result from an inherited propensity for hepatic biotransformation of drug into toxic or im-

munogenic metabolites. The incidence of “allergic” cutaneous reactions to trimethoprim–sulfamethoxazole in patients with acquired immunodeficiency syndrome (AIDS) has been reported to be as high as 70%. The mechanism is thought to relate to the severe immune dysregulation, although it may be due to glutathione deficiency resulting in toxic metabolites.

Clinical Findings

A. SYMPTOMS AND SIGNS

Allergic reactions can result in pruritus, urticaria, angioedema, or anaphylaxis. Serum sickness is characterized by fever, rash, lymphadenopathy, myalgias, and arthralgias. Cytotoxic drug reactions can result in symptoms and signs associated with the underlying anemia or thrombocytopenia. Delayed-type hypersensitivity may cause contact dermatitis.

B. LABORATORY FINDINGS

Skin testing is the most rapid, useful, and sensitive method of demonstrating the presence of IgE antibody to a specific allergen. Skin testing to nonpenicillin antibiotics may be difficult, however, because many immunologic reactions are due to metabolites rather than to the parent drug and because the relevant metabolites for most drugs other than penicillin have not been identified. Because metabolites are usually low-molecular-weight haptens, they must combine with carrier proteins to be useful for diagnosis. In the case of contact sensitivity reactions to topical antibiotics, a 48-hour patch test can be useful.

Solid-phase in vitro immunoassays for IgE to penicillins are available for identification of IgE to penicilloyl but are considerably less sensitive and give less information than skin testing. Assays for specific IgG and IgM have been shown to correlate with a drug reaction in immune cytopenias, but in most other instances such assays are not clinically useful. Skin testing for immediate hypersensitivity is helpful only in predicting reactions caused by IgE antibodies. Most nonpruritic maculopapular rashes will not be predicted by skin testing.

Approximately 80% of patients with a history of penicillin allergy will have negative skin tests. Penicillin therapy in patients with a history of an immediate hypersensitivity reaction to penicillin, but with negative skin tests to both penicilloyl and the minor determinant mixture, is accompanied by a 1–3% chance of urticaria or other mild allergic reactions at some time during therapy, with anaphylaxis occurring in less than 0.1% of patients. In contrast, the predictive value of a positive skin test is approximately 60%. Testing with penicilloyl linked to polylysine (PPL) alone carries about a 76% sensitivity; use of both PPL and penicillin G (used as a minor determinant) increases sensitivity to about 95%. Not the using minor de-

terminant mixture in skin testing can result in failure to predict potential anaphylactic reactions. Unfortunately the minor determinant mixture is still not commercially available, although most academic allergy centers make their own. Approximately 4% of subjects tested with no history of penicillin allergy have positive skin tests, and most fatalities occur in patients with no prior history of reaction. Rarely patients may have skin test reactivity only to a specific semisynthetic penicillin. Resensitization in skin-test-negative children occurs infrequently (< 1%) after a course of oral antibiotic.

The degree of cross-reactivity of determinants formed from cephalosporins with IgE to other β -lactam drugs remains unresolved, especially because haptens that may be unique to cephalosporin metabolism remain unknown. The degree of clinical cross-reactivity is much lower than the in vitro cross-reactivity. A clinical adverse reaction rate of 3–7% for cephalosporins may be expected in patients with positive histories of penicillin allergy. Antibodies to the second- and third-generation cephalosporins appear to be directed at the unique side chains rather than at the common ring structure. The present literature suggests that a positive skin test to a cephalosporin used at a concentration of 1 mg/mL would place the patient at increased risk for an allergic reaction to that antibiotic. However, a negative skin test would not exclude sensitivity to a potentially relevant metabolite. One review concluded that there is no increased incidence of allergy to second- and third-generation cephalosporins in patients with penicillin allergy and that penicillin skin testing does not identify patients who develop cephalosporin allergy. However, another study suggested that although only 2% of penicillin-allergic patients would react to a cephalosporin, they would be at risk for anaphylaxis.

Carbacephems (loracarbef) are similar to cephalosporins, although the degree of cross-reactivity is undetermined. Carbapenems (imipenem) represent another class of β -lactam antibiotics with a bicyclic nucleus and a high degree of cross-reactivity with penicillin. In contrast, monobactams (aztreonam) contain a monocyclic rather than bicyclic ring structure and limited data suggests that aztreonam can be safely administered to most penicillin-allergic subjects.

Skin testing for non- β -lactam antibiotics is less reliable, because the relevant degradation products are for the most part unknown or multivalent reagents are unavailable.

Treatment

A. GENERAL MEASURES

Withdrawal of the implicated drug is usually a central component of management. Acute IgE-mediated reac-

tions such as anaphylaxis, urticaria, and angioedema are treated according to established therapeutic guidelines that include the use of epinephrine, H_1 and H_2 receptor blocking agents, volume replacement, and systemic corticosteroids (see previous sections). Antibiotic-induced immune cytopenias can be managed by withdrawal of the offending agent or reduction in dose. Drug-induced serum sickness can be suppressed by drug withdrawal, antihistamines, and corticosteroids. Contact allergy can be managed by avoidance and treatment with antihistamines and topical corticosteroids. Reactions such as toxic epidermal necrolysis and Stevens–Johnson syndrome require immediate drug withdrawal and supportive care.

B. ALTERNATIVE THERAPY

If possible, subsequent therapy should be with an alternative drug that has therapeutic actions similar to the drug in question but with no immunologic cross-reactivity.

C. DESENSITIZATION

Administering gradually increasing doses of an antibiotic either orally or parentally over a period of hours to days may be considered if alternative therapy is not acceptable. This should be done only by a physician familiar with desensitization, typically in an intensive care setting. Desensitization does not reduce or prevent non-IgE-mediated reactions. Patients with Stevens–Johnson syndrome should not be desensitized because of the high mortality rate.

Prognosis

The prognosis is good when drug allergens are identified early and avoided. Stevens–Johnson syndrome and toxic epidermal necrolysis may be associated with a high mortality rate.

2. Latex Allergy

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Immediate hypersensitivity reaction after exposure to latex, including airborne particles.
- Allergic contact dermatitis 24–48 hours after exposure to rubber accelerators or antioxidants.

General Considerations

Allergic reactions to latex and rubber products have become increasingly common since the institution of universal precautions for exposure to bodily fluids. Children with spina bifida appear to have a unique sensitivity to latex, perhaps because of early and frequent latex exposure as well as altered neuroimmune interactions. Atopy—especially symptomatic latex allergy—appears to be significantly increased in patients with spina bifida experiencing anaphylaxis during general anesthesia. Other conditions requiring chronic or recurrent exposure to latex such as urogenital anomalies and ventriculoperitoneal shunt have also been associated with latex hypersensitivity. The combination of atopy and frequent exposure seems to synergistically increase the risk of latex hypersensitivity.

Latex is the milky fluid obtained by tapping the cultivated rubber tree, *Hevea brasiliensis*. During manufacture of latex products, various antioxidants and accelerators such as thiurams, carbamates, and mercaptobenzothiazoles are added. Latex products are typically produced by dipping a porcelain mold into a tank of latex and then vulcanizing it to enhance mechanical stability. The product is washed or “leached” of excess proteins, then dry-lubricated with a powder such as corn starch.

Latex is a complex biologic mixture composed of rubber particles in a phospholipoprotein envelope and a serum containing sugars, lipids, nucleic acids, minerals, and various proteins. The protein component is thought to contain the allergenic properties. Extra leaching steps may reduce the protein content and hence the allergenicity of the final product. IgE from latex-sensitized individuals reacts with different protein components, supporting the notion that more than one clinically important latex antigen exists. New allergenic epitopes are generated during the manufacturing process. Thus polypeptides from latex glove extracts vary both quantitatively and qualitatively with different brands and lots of gloves. Identification of the causative antigens is important because it may be possible to alter the manufacturing process to reduce the final allergen content.

Latex is ubiquitous in medical settings, and many sources may be inconspicuous. Synthetic alternatives to some latex products—including gloves, dressings, and tape—are available. Avoidance of contact with latex-containing items, however, may be insufficient to prevent allergic reactions, because lubricating powders may serve as vehicles for aerosolized latex antigens. The use of powder-free latex gloves is an important control measure for airborne latex allergen.

Nonmedical sources of latex are also common and include balloons, toys, rubber bands, erasers, condoms,

and shoe soles. Pacifiers and bottle nipples have also been implicated as sources of latex allergen, although these products are molded rather than dipped, and allergic reactions to molded products are less common. Latex-allergic patients and their caregivers must be continuously vigilant for hidden sources of exposure.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical manifestations of IgE-mediated reactions to latex can involve the full spectrum of symptoms associated with mast cell degranulation. Localized pruritus and urticaria occur after cutaneous contact; conjunctivitis and rhinitis can result from aerosol exposure or direct facial contact. Systemic reactions, including bronchospasm, laryngospasm, and hypotension, may occur with more substantial exposure or in extremely sensitive individuals. Finally, vascular collapse and shock leading to fatal cardiovascular events may occur. Intraoperative anaphylaxis represents a common and serious manifestation of latex allergy.

Allergic contact dermatitis to rubber products typically appears 24–48 hours after contact. The primary allergens include accelerators and antioxidants used in the manufacturing process. The diagnosis is established by patch testing. Shoe soles are an important source of exposure. The skin lesions appear primarily as a patchy eczema on exposed surfaces, although reactions can become generalized.

B. LABORATORY FINDINGS

Epicutaneous prick testing is a rapid, inexpensive, and sensitive test that detects the presence of latex-specific IgE on skin mast cells. Obstacles to its use include lack of a standardized antigen. Reports of life-threatening anaphylactic events have been associated with skin testing to latex, and intradermal testing may be especially dangerous. A commercially available extract is pending FDA approval.

Immunoassay testing involves the *in vitro* measurement of specific IgE, which binds latex antigens. Antigen sources used for testing have included native plant extracts, raw latex, and finished products. When compared with a history of latex-induced symptoms or positive skin tests, the sensitivity of immunoassays testing for latex antigens ranges from 50% to 100% with specificity between 63% and 100%. These broad ranges may reflect the patient population studied and the source of latex antigen as well as the assay employed. A positive immunoassay test to latex in the presence of a highly suggestive latex allergy history is useful and may circumvent the potential concerns associated with prick skin testing in certain patients.

Cross-reactivity has been demonstrated between latex and a number of other antigens such as foods. Banana, avocado, and chestnut have been found to be antigenically similar to latex both immunologically and clinically.

Complications

Complications may be similar to those caused by other allergens. Prolonged exposure to aerosolized latex may lead to persistent asthma. Chronic allergic contact dermatitis, especially on the hands, can lead to functional disability.

Treatment

Avoidance remains the cornerstone of treatment for latex allergy. Prevention and supportive therapy are the most common methods for managing this problem. Patients identified as being allergic to latex may need to have a personal supply of vinyl or latex-free gloves for use when visiting a physician or dentist. “Hypoallergenic gloves” are poorly classified with respect to their ability to induce IgE-mediated reactions; the FDA currently uses this term to designate products that have a reduced capacity to induce contact dermatitis. Gloves made from synthetic materials include Neolon (Becton-Dickinson), Tactyl 1 (Smart Practice), and Elastyren (Hermal). Autoinjectable epinephrine and medical identification bracelets may be prescribed for latex-allergic patients along with avoidance counseling.

Prophylactic premedication of latex-allergic individuals has been used in some surgical patients at high risk for latex allergy. The rationale for this therapy is derived from the pretreatment protocols developed for iodinated radiocontrast media and anesthetic reactions. Although there has been some success using this regimen, anaphylaxis has occurred despite pretreatment. This approach should not substitute for careful avoidance measures.

Prognosis

Owing to the ubiquitous nature of natural rubber, the prognosis is guarded for patients with severe latex allergy. Chronic exposure to airborne latex particles may lead to chronic asthma. Chronic dermatitis can lead to functional disability.

3. Vaccines

Mumps–measles–rubella (MMR) vaccine has been shown to be safe in egg-allergic patients (although rare reactions to gelatin or neomycin can occur). The ovalbumin content in influenza vaccine is variable, and skin testing with the specific vaccine lot is warranted in pa-

tients with egg allergy (**Note:** Some patients who tolerate cooked egg, that is, denatured protein, may still react to the vaccine). In addition, the newly introduced live intranasal influenza vaccine is contraindicated in egg-allergic children.

4. Radiocontrast Media

Non-IgE-mediated anaphylactoid reactions may occur with radiocontrast media with up to a 30% reaction rate on reexposure. Management involves using a low-molarity agent and premedication with prednisone, diphenhydramine, and possibly an H₂-blocker.

5. Insulin

Approximately 50% of patients receiving insulin have positive skin tests, but IgE-mediated reactions occur rarely. Insulin resistance is mediated by IgG. If less than 24 hours has elapsed after an allergic reaction to insulin, do not discontinue insulin but rather reduce the dose by one third, then increase by 2–5 units per injection. Skin testing and desensitization are necessary if the interval between the allergic reaction and subsequent dose is greater than 24 hours.

6. Local Anesthetics

Less than 1% of reactions to local anesthetics are IgE-mediated. Management involves selecting a local anesthetic from another class. Esters of benzoic acid include benzocaine and procaine; amides include lidocaine and mepivacaine. Alternatively, the patient can be skin tested with the suspected agent, followed by a provocative challenge. To rule out paraben sensitivity, skin testing can be done with 1% lidocaine from a multidose vial.

7. Aspirin & Other Nonsteroidal Anti-Inflammatory Drugs

Adverse reactions to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) include urticaria and angioedema; rhinosinusitis, nasal polyps, and asthma; anaphylactoid reactions; and NSAID-related hypersensitivity pneumonitis. After a systemic reaction, a refractory period of 2–7 days occurs. Most aspirin-sensitive patients tolerate sodium salicylate. All NSAIDs inhibiting cyclooxygenase cross-react with aspirin. Cross-reactivity between aspirin and tartrazine (yellow dye No. 5) has not been substantiated in controlled trials. No skin test or in vitro test is available to diagnose aspirin sensitivity. Oral challenge can induce severe bronchospasm. Desensitization and cross-desensitization to NSAIDs can be achieved in most patients and maintained long-

term. Leukotriene receptor antagonists or 5-lipoxygenase inhibitors attenuate the reaction to aspirin challenge and may be beneficial adjunct treatment in aspirin-sensitive asthmatic patients. Preliminary studies suggest that COX-2 inhibitors may be tolerated by patients with ASA-induced asthma.

FOOD ALLERGY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Temporal relationship between ingestion of a suspected food and onset of allergic symptoms.*
- *Positive prick skin test or in vitro test to a suspected food allergen confirmed by a double-blind, placebo-controlled food challenge (except in cases of anaphylaxis).*

General Considerations

Adverse reactions to foods are common in young children, especially in the first 3 years of life. The highest prevalence of food allergy is found in children with moderate-to-severe atopic dermatitis, with up to 33% affected. Up to 16% of children with asthma have been found to have food-induced wheezing in some studies. The most common food allergens in young children are eggs, milk, peanuts, soy, and wheat. In older children and adolescents, fish, shellfish, and nuts are most often involved in allergic reactions, and these may be lifelong.

Some reactions often diagnosed by patients or physicians as food allergy involve pharmacologic or metabolic mechanisms and reactions to food toxins. Foods containing significant amounts of vasoactive amines such as chocolate, cheese, and some wines and beers may precipitate migraine headaches in some patients. Claims that dyes, sugar, and food additives may contribute to hyperactivity in children with attention-

deficit/hyperactivity disorder are controversial. In the occasional case in which a child appears to benefit from a restricted diet, there is no evidence for an IgE-mediated reaction.

Clinical Findings

A. SYMPTOMS AND SIGNS

Most reactions to foods occur minutes to 2 hours after ingestion. A history of a temporal relationship between the ingestion of a suspected food and onset of a reaction—as well as the nature and duration of symptoms observed—is important in establishing the diagnosis of food allergy. With chronic atopic dermatitis or persistent urticaria, the association with food may be less obvious (see Atopic Dermatitis and Urticaria sections). At times, acute symptoms may occur, but the cause may not be obvious because of hidden food allergens. A symptom diary kept for 7–14 days may be helpful in establishing an association between ingestion of foods and symptoms and also provides a baseline observation for the pattern of symptom expression. It is important to record both the form in which the food was ingested and the foods ingested concurrently.

Hives, flushing, facial angioedema, and mouth or throat itching are common. In severe cases, angioedema of the tongue, uvula, pharynx, or upper airway can occur. Contact urticaria can occur without systemic symptoms in some children. Gastrointestinal symptoms include abdominal discomfort or pain, nausea, vomiting, and diarrhea. Children with food allergy may occasionally have isolated rhinoconjunctivitis or wheezing. Rarely anaphylaxis to food may involve only cardiovascular collapse (see Anaphylaxis section). Anaphylactoid reactions can occur after ingestion of foods such as certain fish containing high amounts of histamine.

B. LABORATORY FINDINGS

Typically, fewer than 50% of histories of food allergy will be confirmed by blinded challenge (although this percentage is much higher in food-induced anaphylaxis). Prick skin testing is useful to rule out a suspected food allergen, because the predictive value is high for a properly performed negative test with an extract of good quality. In contrast, the predictive value for a positive test is approximately 50%. RAST and other in vitro tests have lower specificity and positive predictive values. In contrast, specific IgE levels to milk, egg, peanut, and fish proteins have been established with the Pharmacia ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction. Measurement of IgG to foods is not clinically useful. Eosinophilia of stool mucus may be present in cases of gastrointestinal allergy; elevated circulating eosinophils may be present as well.

Double-blind, placebo-controlled food challenge is considered the standard method for diagnosing food allergy except in severe reactions. Even when multiple food allergies are suspected, most patients will be positive to three or fewer foods on blinded challenge. Therefore, extensive elimination diets are almost never indicated. Elimination without controlled challenge is a less desirable but at times more practical approach for suspected food allergy.

Differential Diagnosis

Repeated vomiting in infancy may be due to pyloric stenosis or gastroesophageal reflux. With chronic gastrointestinal symptoms, enzyme deficiency (eg, lactase), cystic fibrosis, celiac disease, chronic intestinal infections, gastrointestinal malformations, and irritable bowel syndrome should be considered.

Treatment

Treatment consists of eliminating and avoiding foods that have been documented to cause allergic reactions. This involves educating the patient, parent, and caregivers regarding hidden food allergens, the necessity for reading labels, and the signs and symptoms of food allergy and its appropriate management. Examples of ingredients that may indicate an implicated food protein include “emulsifier” (egg), “lecithin” (egg or soy), “natural flavoring” (milk), and “thickener” (soy). Consultation with a dietitian familiar with food allergy may be helpful, especially when common foods such as milk, egg, peanut, soy, or wheat are involved. Patients with a history of food-induced anaphylaxis or respiratory distress should carry epinephrine (see Anaphylaxis section). A study of peanut-allergic patients demonstrated that treatment with monoclonal anti-IgE significantly increased the threshold of sensitivity to peanut on oral food challenge, although this treatment is currently approved only for patients with asthma (see Asthma section).

Prognosis

The prognosis is good if the offending food can be identified and avoided. Unfortunately, accidental exposure to food allergens in severely allergic patients can result in death. Most children outgrow their food allergies to egg, milk, or soy but not to peanut or tree nuts. The natural history of food allergy to milk, egg, peanut and fish proteins can be followed by measuring specific IgE levels by ImmunoCAP assay as discussed earlier. Approximately 2% will have food allergy as adults. Resources for food-allergic patients include the Food Al-

lergy and Anaphylaxis Network and the National Peanut and Tree Nut Registry (800-929-4040).

INSECT ALLERGY

Allergic reactions to insects include symptoms of respiratory allergy as a result of inhalation of particulate matter of insect origin, local cutaneous reactions to insect bites, and anaphylactic reactions to stings. The latter are almost exclusively caused by Hymenoptera and result in approximately 40 deaths each year in the United States. The order Hymenoptera includes honey bees, yellow jackets, yellow hornets, white-faced hornets, wasps, and fire ants. Africanized honey bees, also known as killer bees, are a concern because of their aggressive behavior and excessive swarming and not because their venom is more toxic. Rarely, patients sensitized to reduviid bugs (also known as kissing bugs) may have episodes of nocturnal anaphylaxis. Lepidopterism refers to adverse effects secondary to contact with larval or adult butterflies and moths. Salivary gland antigens are responsible for immediate and delayed skin reactions in mosquito-sensitive patients.

Clinical Findings

A. SYMPTOMS AND SIGNS

Insect bites or stings can cause local or systemic reactions ranging from mild to fatal responses in susceptible persons. The frequency increases in the summer months and with outdoor exposure. Local cutaneous reactions include urticaria as well as papulovesicular eruptions and lesions that resemble delayed hypersensitivity reactions. Papular urticaria is almost always the result of insect bites, especially of mosquitoes, fleas, and bedbugs. Toxic systemic reactions consisting of gastrointestinal symptoms, headache, vertigo, syncope, convulsions, or fever can occur following multiple stings. These reactions result from histamine-like substances in the venom. In children with hypersensitivity to fire ant venom, sterile pustules occur at sting sites on a nonimmunologic basis due to the inherent toxicity of piperidine alkaloids in the venom. Mild systemic reactions include itching, flushing, and urticaria. Severe systemic reactions may include dyspnea, wheezing, chest tightness, hoarseness, fullness in the throat, hypotension, loss of consciousness, incontinence, nausea, vom-

iting, and abdominal pain. Delayed systemic reactions occur from 2 hours to 3 weeks following the sting and include serum sickness, peripheral neuritis, allergic vasculitis, and coagulation defects.

B. Laboratory Findings

Skin testing is indicated for children with systemic reactions. Venoms of honeybee, yellow jacket, yellow hornet, white-faced hornet, and wasp are available for skin testing and treatment. Fire ant venom is not yet commercially available, but an extract made from fire ant bodies appears adequate to establish the presence of IgE antibodies to fire ant venom. Of note, venom skin test results can be negative in patients with systemic allergic reactions, especially in the first few weeks after a sting, and the tests may need to be repeated. The presence of a positive skin test denotes prior sensitization but does not predict whether a reaction will occur with the patient's next sting, nor does it differentiate between local and systemic reactions. It is common for children who have had an allergic reaction to have positive skin tests to more than one venom. This might reflect sensitization from prior stings that did not result in an allergic reaction or cross-reactivity between closely related venoms. *In vitro* testing (compared with skin testing) has not substantially improved the ability to predict anaphylaxis. With venom RAST, there is a 15–20% incidence of both false-positive and false-negative results. Tests for mosquito saliva antigens or other insect allergy are not commercially available.

Complications

Secondary infection can complicate allergic reactions to insect bites or stings. Serum sickness, nephrotic syndrome, vasculitis, neuritis, and encephalopathy may be seen as late sequelae of reactions to stinging insects.

Treatment

For cutaneous reactions caused by biting insects, symptomatic therapy includes cold compresses, antipruritics

(including antihistamines), and occasionally potent topical corticosteroids. Treatment of stings includes careful removal of the stinger, if present, by flicking it away from the wound and not by grasping in order to prevent further envenomation. Topical application of monosodium glutamate, baking soda, or vinegar compresses is of questionable efficacy. Local reactions can be treated with ice, elevation of the affected extremity, oral antihistamines, and NSAIDs as well as potent topical corticosteroids. Large local reactions in which swelling extends beyond two joints or an extremity, may require a short course of oral corticosteroids. Anaphylactic reactions following Hymenoptera stings should be managed essentially the same as anaphylaxis (see Anaphylaxis section). Children who have had severe or anaphylactic reactions to Hymenoptera stings—or their parents and caregivers—should be instructed in the use of epinephrine. Patients at risk for anaphylaxis from an insect sting should also wear a medical alert bracelet indicating their allergy. Children at risk from insect stings should avoid wearing bright-colored clothing and perfumes when outdoors and should wear long pants and shoes when walking in the grass. Patients who experience severe systemic reactions and have a positive skin test should receive venom immunotherapy. Immunotherapy is not indicated for children with only urticarial or local reactions.

Prognosis

Children generally have milder reactions than adults after insect stings, and fatal reactions are extremely rare. Patients age 3–16 years with reactions limited to the skin, such as urticaria and angioedema, appear to be at low risk for more severe reactions with subsequent stings.

John W. Ogle, MD

PRINCIPLES OF ANTIMICROBIAL THERAPY

Antimicrobial therapy of bacterial infections is arguably the most important scientific development of twentieth-century medicine. It contributes significantly to the quality of life of many people and reduces the morbidity and mortality due to infectious disease. The remarkable success of antimicrobial therapy has been achieved with comparatively little toxicity and expense. The relative ease of administration and the widespread availability of these drugs have led many to adopt a philosophy of broad-spectrum empiric antimicrobial therapy for many common infections.

Unfortunately this era of cheap, safe, and reliable therapy may be coming to a close owing to the increasing frequency of antimicrobial resistance in previously susceptible microorganisms. The problem of antimicrobial resistance is certainly not new—resistance was recognized for sulfonamides and penicillins shortly after their introduction. What is new is the worldwide dissemination of resistant clones of microorganisms, such as *Streptococcus pneumoniae* and *Staphylococcus aureus*, which are inherently virulent and commonly cause serious infections, not only among hospitalized patients but also among outpatients.

Until recently the recognition of new resistant clones was balanced by the promise of newer and more potent antimicrobial agents. Today, because fewer new agents are under development, clinicians are beginning to encounter limitations in their ability to treat some serious bacterial infections. Many factors contribute to the selection of resistant clones. Our success in treating chronic diseases and immune-compromising conditions, which has resulted in additional years of life for patients, has increased opportunities for selection of resistant strains in inpatient units and chronic care facilities. Overuse of antimicrobial agents by well-intentioned clinicians also contributes to the selection of resistant strains. Examples include medications for mildly ill patients with self-limited conditions such as viral infections, and administration of broad-spectrum antimicrobials for patients whose condition can be treated with narrow-spectrum agents. Similarly, failure to document infection with cultures obtained prior to starting therapy limits our willingness to stop or narrow the spectrum of

antimicrobials. Little research has been conducted to determine the necessary duration of therapy, with the result that we probably often treat longer than is necessary. Prophylactic strategies, as used for prevention of recurrent otitis media or urinary tract infection, create a selection pressure for antibiotic resistance.

The decision-making process for choosing an appropriate antimicrobial agent is summarized in Table 35–1. Accurate clinical diagnosis is based on the history, physical examination, and initial laboratory tests. The clinical diagnosis then leads to a consideration of the organisms most commonly associated with the clinical condition, the usual pattern of antimicrobial susceptibility of these organisms, and past experience with successful treatment regimens.

Cultures should be obtained in potentially serious infections. Empiric antimicrobial therapy may be initiated, then modified according to the patient's response and the culture results. Often several equally safe and efficacious antimicrobials are available. In this circumstance, the relative cost and ease of administration of the different choices should be considered.

Other important considerations include the patient's age, immune status, and exposure history. Neonates and young infants may present with nonspecific signs of infection, making the differentiation of serious disease from mild illness difficult. In older children, clinical diagnosis is more precise, which may permit no therapy or use of a narrower-spectrum antibiotic. Immune deficiency may increase the number and types of potential infecting organisms that need to be considered, including organisms that are usually avirulent but that may cause infections that are serious and difficult to treat. An abnormal immune response may also diminish the severity of the clinical signs and symptoms of infection and thus lead to underestimation of the severity of illness. The exposure history may suggest the greater likelihood of certain types of infecting organisms. This history includes exposures from family members, classmates, and day care environments and exposure to unusual organisms by virtue of travel, diet, or contact with animals.

Final important considerations are the pace and seriousness of the illness. A rapidly progressive and severe illness should be treated initially with broad-spectrum antimicrobials until a specific etiologic diagnosis is

Table 35–1. Steps in decision making for use of antimicrobial agents.

Step	Action	Example
1	Determine diagnosis.	Septic arthritis
2	Consider age and preexisting condition.	Previously healthy 2-year-old child
3	Consider common organisms.	<i>Staphylococcus aureus</i> , <i>Kingella kingae</i>
4	Consider organism susceptibility.	Penicillin- or ampicillin-resistant, frequency MRSA ^a in community
5	Obtain proper cultures. ^b	Blood, joint fluid
6	Initiate empiric therapy based on above considerations and past experience (eg, personal, literature).	Nafcillin and cefotaxime, substitute vancomycin for nafcillin if obviously ill or MRSA prevalent.
7	Modify therapy based on culture results and patient response.	<i>S aureus</i> isolated. Discontinue cefotaxime. Substitute nafcillin for vancomycin if susceptible.
8	Follow clinical response.	Interval physical examination
9	Stop therapy.	Clinically improved or well, minimum 3–4 weeks

^aMethicillin-resistant *S. aureus*.

^bIndicated for serious or unusual infections or those with unpredictable clinical response to empiric therapy.

made. A mildly ill outpatient should receive treatment preferentially with narrow-spectrum antimicrobials.

Antimicrobial susceptibility, antimicrobial families, and dosing recommendations are listed in Tables 35–2 to 35–6.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Cultures and other diagnostic material must be obtained prior to initiating antimicrobial therapy—especially when the patient has a serious infection, initial attempts at therapy have failed, or multiagent therapy is anticipated. Whenever cultures identify the causative organism, therapy can be narrowed or optimized according to susceptibility results. Antimicrobial susceptibility testing should be done in a laboratory using carefully defined procedures (National Committee for Clinical Laboratory Standards). The use of nonstandard media, inoculum size, or growth conditions may give markedly different and undependable results.

There are several ways to test antimicrobial susceptibility. Identification of an antibiotic-destroying enzyme (eg, β -lactamase) implies resistance to β -lactam-containing antimicrobial agents. Tube or microtiter broth dilution techniques can be used to determine the minimum inhibitory concentration (MIC) of antibiotic, which is the amount of antibiotic (in $\mu\text{g}/\text{mL}$) necessary to inhibit the organism under specific laboratory conditions. Disk susceptibility testing (also performed under carefully controlled conditions) yields similar results.

The E-test is a standardized test for some organisms that correlates well with MICs. Clinical laboratories usually define antimicrobial susceptibility (susceptible, intermediate, resistant) in relation to levels of the test antibiotic achievable in the blood (or serum).

Organisms are usually considered susceptible to an antibiotic if the MIC of the antibiotic for the organism is lower than levels of that agent achievable in the blood using appropriate parenteral dosages. This assumption of susceptibility should be reconsidered whenever the patient has a focus of infection (eg, meningitis, osteomyelitis, abscess) in which poor antibiotic penetration might occur, because the levels of antibiotic in such areas might be lower than the MIC. Conversely, although certain organisms may be reported resistant to an antibiotic because sufficiently high blood concentrations cannot be achieved, urine concentrations may be much higher. If so, a urinary tract infection might respond to an antibiotic that would not be adequate for treatment of septicemia.

Thus antimicrobial susceptibility testing, although a very important part of therapeutic decision making, reflects assumptions that the clinician must understand, especially for management of serious infections. Ultimately the true test of the efficacy of therapy is patient response. Patients who do not respond to seemingly appropriate therapy may require reassessment, including reconsidering the diagnosis, reculturing, and repeat susceptibility testing, to determine whether resistant strains have evolved or superinfection with a resistant organism is present. Antimicrobial therapy cannot be expected to cure some infections unless additional supportive treatment (usually surgical) is undertaken.

Table 35–2. Susceptibility of some common pathogenic microorganisms to various antimicrobial drugs.

Organism	Potentially Useful Antibiotics ^a
BACTERIA	
Anaerobic bacteria ^b	Cefoxitin, ^c cefotetan, ^c clindamycin, ertapenem, ^c imipenem, ^c meropenem, metronidazole, penicillins with or without β -lactamase inhibitor, trovofloxacin ^c
<i>Bacillus anthracis</i>	Amoxicillin, ciprofloxacin, clindamycin, doxycycline, rifampin
<i>Bartonella henselae</i>	Azithromycin, ciprofloxacin, clarithromycin, doxycycline, erythromycin
<i>Bordetella pertussis</i>	Amoxicillin, azithromycin, clarithromycin, erythromycin, trimethoprim–sulfamethoxazole
<i>Borrelia burgdorferi</i>	Amoxicillin, cefuroxime, cephalosporins (III), ^h clarithromycin, doxycycline
<i>Campylobacter</i> spp	Azithromycin, carbapenems, erythromycin, fluoroquinolones, ^{c,f} tetracyclines
<i>Clostridium</i> spp	Clindamycin, metronidazole, penicillins, tetracyclines
<i>Clostridium difficile</i>	Bacitracin (PO), metronidazole, vancomycin (PO)
<i>Corynebacterium diphtheriae</i>	Clindamycin, erythromycin, penicillins
Enterobacteriaceae ^d	Aminoglycosides, ^e ampicillin, aztreonam, cefepime, cephalosporins, ertopenem, imipenem, meropenem, fluoroquinolones, ^{c,f} trimethoprim–sulfamethoxazole
<i>Enterococcus</i>	Ampicillin (with aminoglycoside), carbapenems (not <i>E faecium</i>), vancomycin, linezolid, ^c quinupristin/dalfopristin ^c (<i>E faecium</i> only)
<i>Haemophilus influenzae</i>	Amoxicillin/clavulanate, ampicillin (if β -lactamase negative), ^g cephalosporins (II and III), ^h chloramphenicol, fluoroquinolones, ^{c,f} rifampin, trimethoprim–sulfamethoxazole
<i>Listeria monocytogenes</i>	Ampicillin with aminoglycoside, trimethoprim–sulfamethoxazole, vancomycin
<i>Moraxella catarrhalis</i>	Amoxicillin/clavulanate, ampicillins (if β -lactamase-negative), ^g cephalosporins (II, III), ^h erythromycin, fluoroquinolones, trimethoprim-sulfamethoxazole
<i>Neisseria gonorrhoeae</i>	Ampicillin (if β -lactamase-negative), ^g cephalosporins (II and III), ^h penicillins, selected fluoroquinolones, ^{c,f} spectinomycin
<i>Neisseria meningitidis</i>	Ampicillin, cephalosporins (II and III), ^h chloramphenicol, fluoroquinolones ^{c,f} penicillins, rifampin
<i>Nocardia asteroides</i>	Tetracycline, trimethoprim–sulfamethoxazole (+ amikacin for severe infections); meropenem or cephalosporins (II) ^h for brain abscess
<i>Pasteurella multocida</i>	Amoxicillin/clavulanate, ampicillins, penicillins, tetracyclines
<i>Pseudomonas aeruginosa</i>	Aminoglycosides, ^e anti- <i>Pseudomonas</i> penicillins, ^c aztreonam, cefepime, ceftazidime, imipenem, meropenem, ciprofloxacin ^c
<i>Salmonella</i> spp	Ampicillin, azithromycin, cephalosporins (III), ^h fluoroquinolones, ^{c,f} trimethoprim–sulfamethoxazole
<i>Shigella</i> spp	Ampicillin, azithromycin cephalosporins (III), ^h fluoroquinolones, ^{c,f} tetracyclines, trimethoprim–sulfamethoxazole
<i>Staphylococcus aureus</i>	Antistaphylococcal penicillins, ^j cefepime, cephalosporins (I and II), ciprofloxacin, clindamycin, erythromycin, rifampin, trimethoprim–sulfamethoxazole, vancomycin
<i>S aureus</i> (methicillin-resistant)	Trimethoprim–sulfomethoxazole, vancomycin, linezolid, ^c quinupristin/dalfopristin ^c
Staphylococci (coagulase-negative)	Cephalosporins (I and II), ^k clindamycin, rifampin, vancomycin
Streptococci (most species)	Ampicillin, cephalosporins, clindamycin, enhanced fluoroquinolones, ^{c,n} erythromycin, meropenem, penicillins, vancomycin
<i>Streptococcus pneumoniae</i> ^l	Ampicillin, cephalosporins, enhanced fluoroquinolones, ^{c,n} erythromycin, meropenem, penicillin, vancomycin ¹²

(continued)

Table 35–2. Susceptibility of some common pathogenic microorganisms to various antimicrobial drugs (continued).

Organism	Potentially Useful Antibiotics ^a
INTERMEDIATE ORGANISMS	
<i>Chlamydia</i> spp	Clarithromycin, erythromycin, levofloxacin, ^c ofloxacin ^{cf} tetracyclines
<i>Mycoplasma</i> spp	Azithromycin, clarithromycin, erythromycin, fluoroquinolones, ^{cf} tetracyclines
<i>Rickettsia</i> spp	Fluoroquinolones, ^{cf} tetracyclines
FUNGI	
<i>Candida</i> spp	Amphotericin B, caspofungin; fluconazole, flucytosine, itraconazole, ketoconazole, voriconazole
Fungi, systemic ^b	Amphotericin B, caspofungin; fluconazole, itraconazole, ^c ketoconazole, miconazole, voriconazole
Dermatophytes	Butenafine, ciclopirox olamine, clotrimazole, econazole, fluconazole, griseofulvin, naftifine, itraconazole, ^c ketoconazole, miconazole, oxiconazole, sulconazole, terbinafine, torconazole
<i>Pneumocystis jiroveci</i>	Atovaquone, clindamycin+primaquin, dapsone, pentamidine, trimethoprim-sulfamethoxazole
VIROSES	
Herpes simplex	Acyclovir, famciclovir ^c , foscarnet, trifluridine, valacyclovir ^c
Human immunodeficiency virus	Four classes: (1) nucleoside reverse transcriptase inhibitor (7 drugs); (2) non-nucleoside reverse transcriptase inhibitors (3 drugs); (3) protease inhibitors (7 drugs); (4) fusion inhibitors (1 drug). Generally in combinations of ≥ 3 drugs used (see Chapter 37).
Influenza virus	Amantadine, ^o oseltamivir, rimantidine, ^o zanamivir
Respiratory syncytial virus	Ribavirin ^m
Varicella-zoster virus	Acyclovir, famciclovir, ^c valacyclovir ^c
Cytomegalovirus	Cidofovir, foscarnet, ganciclovir, valgancyclovir

^aIn alphabetical order. Selection depends on patient's age, diagnosis, site of infection, severity of illness, antimicrobial susceptibility of suspected organism, and drug risk.

^bSpecies-dependent.

^cNot FDA-approved for use in children.

^dIncludes *E coli*, *Klebsiella* spp, *Enterobacter* spp, and others; antimicrobial susceptibilities should always be measured.

^eAmikacin, gentamicin, kanamycin, tobramycin.

^fIncludes ciprofloxacin, enoxacin, grepifloxacin, levofloxacin, lomefloxacin, norfloxacin, ofloxacin, sparfloxacin.

^gAlso applies to amoxicillin and related compounds.

^hRefer to second- (II) or third- (III) generation cephalosporins.

ⁱCarbenicillin, mezlocillin, piperacillin, ticarcillin.

^jCloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin.

^kOnly if the coagulase-negative *Staphylococcus* is also methicillin- or oxacillin-sensitive.

^lBecause of increasing frequency of *S pneumoniae* strains resistant to penicillin and cephalosporins, therapy for presumed severe infections (eg, meningitis) should include vancomycin until susceptibility studies are available.

^mFDA-approved for therapy of RSV by aerosol, but clinical studies show variable efficacy.

ⁿIncludes grepifloxacin, levofloxacin, lomefloxacin, sparfloxacin.

^oInfluenza A only.

ALTERATION OF DOSE & MEASUREMENT OF BLOOD LEVELS

Certain antimicrobial agents have not been approved (and often not tested) for use in newborns. For those that have been approved, it is important to recognize

that both dose and frequency of administration may need to be altered (see Tables 35–4 and 35–5), especially in young (7 days or younger) or low-birth-weight neonates (≤ 2000 g).

Antimicrobial agents are excreted or metabolized through various physiologic mechanisms (eg, renal, he-

Table 35–3. Groups of common antibacterial agents.

Group	Examples	Some Common Susceptible Organisms ^a	Common Resistant Organisms	Common or Unique Adverse Reactions
PENICILLIN GROUP				
Penicillins	Penicillin G, V	<i>Streptococcus</i> , <i>Neisseria</i>	<i>Staphylococcus</i> , <i>Haemophilus</i> , Enterobacteriaceae	Rash, anaphylaxis, drug fever, bone marrow suppression
Ampicillins	Ampicillin, amoxicillin	(Same as penicillins), plus <i>Haemophilus</i> (β -lactamase negative), <i>Escherichia coli</i> , <i>Enterococcus</i>	<i>Staphylococcus</i> , many Enterobacteriaceae	Diarrhea
Antistaphylococcal penicillins	Cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin	<i>Streptococcus</i> , <i>Staphylococcus aureus</i>	Gram-negative, <i>Staphylococcus</i> (coagulase-negative), <i>Enterococcus</i>	Renal (interstitial nephritis)
Anti- <i>Pseudomonas</i> penicillins	Azlocillin, piperacillin, ticarcillin	(Same as ampicillins), plus <i>Pseudomonas</i>	(Same as ampicillins)	Decreased platelet adhesiveness, hypokalemia, hypernatremia
Penicillin and β -lactamase inhibitor combination	Amoxicillin–clavulanate, ampicillin–sulbactam, ticarcillin–clavulanate	Broad-spectrum	Some enterobacteriaceae, <i>Pseudomonas</i>	Diarrhea
Carbapenems	Imipenem–cilastatin, meropenem, ertapenem	Broad-spectrum, gram-negative rods, anaerobes, <i>Pseudomonas</i>	MRSA, ^b many enterococci	CNS, seizures
CEPHALOSPORIN GROUP				
First generation (I)	Cefazolin, cephalexin, cephalothin, cephapirin, cephadrine	Gram-positive	Gram-negative, <i>Enterococcus</i> , some <i>Staphylococcus</i> (coagulase-negative)	Rash; anaphylaxis, drug fever
Second generation (II)	Cefaclor, cefamandole, cefprozil, cefonicid, cefuroxime, loracarbef	Gram-positive, some <i>Haemophilus</i> , some Enterobacteriaceae	<i>Enterococcus</i> , <i>Pseudomonas</i> , some <i>Staphylococcus</i> (coagulase-negative)	Serum sickness (cefaclor)
	Cefoxitin, cefotetan	Same as second-generation plus anaerobes		
Third generation (III)	Cefotaxime, ceftizoxime, ceftriaxone, cefpodoxime, ceftibuten, cefdinir	<i>Streptococcus</i> , <i>Haemophilus</i> , Enterobacteriaceae, <i>Neisseria</i>	<i>Pseudomonas</i> , <i>Staphylococcus</i>	Biliary sludging (ceftriaxone) rash
	Ceftazidime, cefepime	(Same as other third-generation cephalosporins), plus <i>Pseudomonas</i>	<i>Staphylococcus</i>	
OTHER DRUGS				
Clindamycin	Clindamycin	Gram-positive, anaerobes	Gram-negative, <i>Enterococcus</i> , MRSA	Nausea, vomiting, hepatotoxicity
Vancomycin	Vancomycin	Gram-positive	Gram-negative	“Red man” syndrome, shock, ototoxicity, renal

(continued)

Table 35–3. Groups of common antibacterial agents. (continued)

Group	Examples	Some Common Susceptible Organisms ^a	Common Resistant Organisms	Common or Unique Adverse Reactions
OTHER DRUGS (con't) Macrolides and azilides	Erythromycin, clarithromycin, azithromycin	Gram-positive <i>Bordetella</i> , <i>Haemophilus</i> , <i>Mycoplasma</i> , <i>Chlamydia</i> , <i>Legionella</i>	Gram-negative	Nausea and vomiting
Monobactams	Aztreonam	Gram-negative aerobes, <i>Pseudomonas</i>	Gram-positive cocci	Rash, diarrhea
Oxazolidinones	Linezolid	Gram-positive aerobes	Gram-negative aerobes	Diarrhea Thrombocytopenia
Streptogamins	Quinupristin/dalfopristin	Gram-positive aerobes	Gram-negative aerobes	Arthralgia myalgia
Fluoroquinolones ^c	Ciprofloxacin, ofloxacin	Gram-negative, <i>Chlamydia Pseudomonas</i> (ciprofloxacin)	<i>Enterococcus</i> , <i>Streptococcus</i> , <i>S pneumoniae</i> , anaerobes, <i>Staphylococcus</i>	GI, rash, CNS
	Norfloxacin (urinary tract infections only)	Gram-negative	<i>Enterococcus</i> , <i>Streptococcus</i> , <i>S pneumoniae</i> , anaerobes <i>Staphylococcus</i>	GI, rash, CNS
	Grepifloxacin, lomefloxacin, sparfloxacin	Gram-negative, streptococcus, some enterococci	Some <i>Enterococcus</i>	GI, rash, CNS
	Gatifloxacin, levofloxacin, moxifloxacin, trovofloxacin	Gram-negative, streptococci, <i>S pneumoniae</i> , staphylococci, anaerobes ^e	Some <i>Enterococcus</i>	GI, rash, CNS, severe hepatitis ^e
Tetracyclines	Chlortetracycline, tetracycline, doxycycline, minocycline	Anaerobes, <i>Mycoplasma</i> , <i>Chlamydia</i> , <i>Rickettsia</i> , <i>Ehrlichia</i>	Many Enterobacteriaceae, <i>Staphylococcus</i>	Teeth staining, ^d rash, flora overgrowth, hepatotoxicity, pseudotumor cerebri
Sulfonamides	Many	Gram-negative (urine)	Gram-positive	Rash, renal, bone marrow suppression, Stevens–Johnson syndrome
Trimethoprim–sulfamethoxazole	Trimethoprim-sulfamethoxazole	<i>S aureus</i> , gram-negative, <i>S pneumoniae</i> <i>H influenzae</i>	<i>Streptococcus</i> , <i>Pseudomonas</i> , anaerobes	Rash, renal, bone marrow suppression, Stevens–Johnson syndrome
Rifampin	Rifampin	<i>Neisseria</i> , <i>Haemophilus</i> , <i>Staphylococcus</i> , <i>Streptococcus</i>	Resistance develops rapidly if used as sole agent	Rash, GI, hepatotoxicity, CNS, bone marrow suppression, alters metabolism of other drugs
Aminoglycosides	Amikacin, gentamicin, kanamycin, streptomycin, tobramycin	Gram-negative, including <i>P aeruginosa</i>	Gram-positive, anaerobes, some pseudomonads	Nephrotoxicity, ototoxicity, potentiates neuromuscular blocking agents

^aNot all strains susceptible; always obtain antimicrobial susceptibility tests on significant isolates.

^bMRSA = methicillin-resistant *S aureus*.

^cNot approved for children.

^dDose-dependent in children < age 9 years.

^eTrovofloxacin only.

Table 35–4. Guidelines for use of common parenteral antibacterial agents^a in children age 1 month or older.

	Route	Dose ^b (mg/kg/d)	Maximum Daily Dose	Interval (hours)	Adjustment ^c	Blood Levels ^d (µg/mL)	
						Peak	Trough
Amikacin	IM, IV	15–22.5	1.5 g	8	R	15–25	5–10

Penicillin G	IM, IV	100,000–250,000 units/kg	20 million units	4–6	H, R		
Pencillin G (benzathine)	IM	50,000 units/kg	2.4 million units	Single dose	None		
Penicillin G (procaine)	IM	25,000–50,000 units/kg	4.8 million units	12–24	R		
Tetracycline ^e	IV ^e	20–30	2 g	12	R		
Ticarcillin	IV	200–300	24 g	4–6	R		
Tobramycin	IM, IV	3–6	300 mg	8	R	5–10	< 2
Vancomycin	IV	40–60	2 g	6	R	20–40 ^f	< 10 ^f

^aNot including some newly released drugs, ones not recommended for use in children, or ones not widely used.

^bAlways consult package insert for complete prescribing information. Dosage may differ for alternative routes, newborns (see Table 34–6), or patients with liver or renal failure (see Adjustment column) and may not be recommended for use in pregnant women or newborns. Maximum dosage may be indicated only in severe infections or by parenteral routes.

^cMode of excretion (R = renal, H = hepatic) of antimicrobial agent should be assessed at the onset of therapy and dosage modified or levels determined as indicated in package insert.

^dSuggested levels to reduce toxicity.

^eUse with caution in children < age 9 years because of tooth staining with repeated doses.

^fTarget peak and trough vancomycin levels are not well correlated with either toxicity or outcome. Measure selectively in meningitis, impaired or changing renal function, or altered volume of distribution.

^gSafety and efficacy are not established in children < age 2 months.

Table 35–5. Guidelines for use of common oral antibacterial agents in children age 1 month or older.

Agent ^a	Dose ^b (mg/kg/d)	Interval (hours)	Other Considerations
Amoxicillin	40	8–12	GI side effects
Amoxicillin ^c (high dose)	80–90	12	GI side effects
Amoxicillin-clavulanate	45	12	GI side effects

Vancomycin ^c	IV		20 [q12h]	30 [q8h]	20–40	

^aNeonates weighting < 1200 g may require even smaller doses. Antibiotic levels should be closely monitored.

^bPenicillin dosages are in units/kg/d. Other preparations (eg, benzathine penicillin) may be given IM. See specific diseases for dosage.

^cTarget peak and trough vancomycin levels are not well correlated with either toxicity or outcome.

patric). It is important to consider these routes of excretion and alter the antimicrobial dosage appropriately in any patient with some degree of organ dysfunction (see Drug Therapy, Chapter 41). As indicated in Table 35–4, an assessment of renal or hepatic function may be routinely necessary for patients receiving certain drugs (eg, renal function for aminoglycosides, hepatic function for erythromycin or clindamycin); otherwise, harmful drug levels may accumulate. If significant organ dysfunction is present, drug clearance may be delayed and dosage modification may be necessary (see detailed descriptions in individual drug information packets), and measurement of drug levels may be indicated.

Serum levels of drugs posing a high risk of toxicity (eg, aminoglycosides) are ordinarily measured, and

measurement of other drugs (eg, vancomycin) may be useful in selected circumstances (see following discussion). For certain other serious bacterial infections (eg, bacterial endocarditis), measurement of the serum concentration of an antimicrobial may be important to deliver optimal therapy.

Certain drug interactions may require modification of drug dosage or other therapeutic alterations. (See Chapter 41, Drug Therapy.) For example, rifampin stimulates the metabolism of warfarin, birth control pills, and anticonvulsants by stimulating the P-450 metabolic pathway. Dosage adjustments or alternative medications may be necessary to avoid significant adverse events. Another common example is erythromycin, which may inhibit the metabolism of theophylline, resulting in toxic theophylline levels. Although

many drug interactions are known and well documented, it may be difficult to predict interactions that result from a combination of four, five, or more different medications. A high level of suspicion regarding adverse clinical events should be maintained.

THE USE OF NEW ANTIMICROBIAL AGENTS

New antibiotics are introduced frequently, often with claims about unique features that distinguish these usually more expensive products from existing compounds. Often, these drugs share many properties with existing drugs. The role that any new antimicrobial will play can only be determined over time, during which new or previously unrecognized side effects might be described and the clinical efficacy established. Clinical trials may not be confirmed in the larger number of patients subsequently treated in practice. Because this may take many years, a conservative approach to using new antibiotics seems fitting, especially because their costs are often higher, and appropriate antimicrobial choices for most common infections already exist. It is appropriate to ask if a new antimicrobial has been proved to be as effective as (or more effective than) the current drug of choice, and whether its side effects are comparable or less common and its cost reasonable. The withdrawal of moxalactam and caution regarding use of trovafloxacin due to unexpected serious side effects, which were not anticipated despite extensive premarket testing, highlight the caution necessary before using new antimicrobials. The heavy marketing of new cephalosporins and fluoroquinolones, which are very similar to existing drugs, is typical of the difficulty faced by the primary physician in evaluating antimicrobials.

The development of new antibiotics is important as a response to the emergence of resistant organisms and for treatment of infections that are clinically difficult to treat (eg, viruses, fungi, and some resistant bacteria). Fortunately these infections are either rare or (usually) self-limited in immunocompetent hosts.

PROPHYLACTIC ANTIMICROBIAL AGENTS

Antimicrobials can be used to decrease the incidence of postoperative infections (Table 35-7). A dose of an antimicrobial given 30 minutes to 2 hours prior to surgery can reduce postoperative wound infection. The goal is to achieve high levels in the serum at the time of incision and by this means—along with good surgical technique—to minimize bacterial contamination of the wound. During a lengthy procedure, a second dose may be given. No evidence exists that multiple subsequent doses of antimicrobials confer additional benefit. The

antimicrobial(s) used for prophylaxis are directed toward the flora that most commonly cause postoperative infection at a given anatomic site. Gram-positive cocci such as *S aureus* are usually targeted, and a first-generation cephalosporin (eg, cefazolin) is a cost-effective choice. Third-generation cephalosporins and other broad-spectrum agents are more expensive and offer less benefit because they are less active than cefazolin against *S aureus*. Cefoxitin or cefotetan is useful for procedures such as colorectal surgery, although cefazolin is appropriate for most gynecologic patients. In colorectal surgery, oral antimicrobials such as neomycin and erythromycin may be as effective as parenteral therapy.

In hospitals where the predominant *S aureus* strains are methicillin-resistant or in cases where the patient is allergic to penicillin and cephalosporins, vancomycin can be considered. However, prophylactic vancomycin has caused hypotension at the time of induction of general anesthesia. Frequent use of vancomycin as a prophylactic antimicrobial will contribute to the development of vancomycin-resistant strains such as *Enterococcus faecalis*. For these reasons, vancomycin should generally not be used for prophylaxis, although it might prove useful for individual patients at extremely high risk.

Prophylactic antimicrobials are given in several other circumstances. Endocarditis prophylaxis is indicated during dental and colorectal or genitourinary procedures in patients with high-risk heart lesions, such as prosthetic cardiac valves, surgically corrected systemic pulmonary shunts, and mitral valve prolapse with regurgitation. Patients with indwelling vascular catheters, such as Broviac catheters, should receive prophylaxis during similar procedures, which are likely to induce a transient bacteremia. Prophylaxis against infection with group A streptococci reduces the recurrence rate for acute rheumatic fever. Postexposure prophylaxis is given after exposure to pertussis, *Haemophilus influenzae* type b (HIB) infection (depending on age), meningococcus, gonococcus, tuberculosis (household exposure), plague, aerosolized tularemia, and other high-risk infections. Family or close contacts of patients with severe invasive streptococcal disease may benefit from prophylaxis. Silver nitrate, erythromycin, povidone-iodine, and tetracycline can be used in ophthalmic preparations for prevention of gonococcal ophthalmia neonatorum. Children with asplenia or sickle cell disease receive prophylactic penicillin to protect against overwhelming *Streptococcus pneumoniae* sepsis, usually started immediately with the onset of fever.

Prophylactic antimicrobials are sometimes used during the viral respiratory season in children at high risk for recurrent otitis media and for some children with recurrent urinary tract infection. However, because of the increasing frequency of resistant *S pneumoniae*, de-

Table 35–7. Antimicrobial prophylaxis and preferred prophylactic agents: Selected conditions and pathogens.^a

Pathogen (Indication)	Prophylactic Agent
<i>Bacillus anthracis</i> ^b	Ciprofloxacin, doxycycline, amoxicillin (if proved susceptible)
Bacterial endocarditis ^c	Ampicillin, ampicillin and gentamicin, amoxicillin, or other approved regimens
<i>Bordetella pertussis</i> (exposure to respiratory secretions)	Azithromycin, clarithromycin, erythromycin
<i>Chlamydia trachomatis</i> (genital contact or neonate)	Erythromycin
<i>Haemophilus influenzae</i> type b ^d (household exposure)	Rifampin
<i>Mycobacterium tuberculosis</i> (household exposure)	Isoniazid
<i>Neisseria meningitidis</i> (household exposure)	Rifampin, sulfadiazine, ^e ciprofloxacin
<i>N gonorrhoeae</i> (ophthalmia neonatorum)	Erythromycin, silver nitrate ophthalmic
<i>N gonorrhoeae</i> (sexual contact)	Ceftriaxone, cefixime, cefpodoxime, fluoroquinolone
<i>Treponema pallidum</i> (sexual contact)	Penicillin
<i>Streptococcus pneumoniae</i> (sickle cell disease, asplenia)	Penicillin
Postoperative wound infection ^f	Cefazolin, other regimens ^f
Group A streptococci (rheumatic fever) ^g	Benzathine penicillin G, penicillin, sulfadiazine
Group B streptococcal sepsis	Ampicillin to mother prior to delivery
Pneumonic <i>Yersinia pestis</i> ^h (exposure)	Tetracycline, ⁱ
<i>Francisella tularensis</i> ^h (aerosolized exposure)	Tetracycline, ⁱ
<i>Vibrio cholera</i>	Tetracycline, ⁱ trimethoprim–sulfamethoxazole
Recurrent otitis media	Amoxicillin, sulfadiazine
Recurrent urinary tract infection	Nitrofurantoin, trimethoprim–sulfamethoxazole
<i>Pneumocystis jiroveci</i> (formerly <i>Pneumocystis carinii</i>)—(HIV, some immunocompromised patients)	Trimethoprim–sulfamethoxazole, pentamidine

^aDecisions for prophylaxis must take a number of factors into account, including the evidence for efficacy of therapy, the degree of the exposure to an infecting agent, the risk and consequences of infection, the susceptibility of the infecting agent to antimicrobials, and the patient's ability to tolerate and comply with the antimicrobial agent. See individual chapters of the text for discussion.

^bDecisions for prophylaxis should be made in accordance with the responsible public health department recommendations.

^cSee discussion in Chapter 19.

^dProphylaxis provided to family if contacts include children < age 4 years. Some experts provide prophylaxis in day care settings after one case and some after two cases of HiB.

^eOnly for known sulfadiazine-susceptible strains.

^fAlternative regimens may be used, depending on the site of surgery and the degree of contamination.

^gOral prophylaxis may be indicated in some patients. Alternative regimens indicated for penicillin-allergic patients. See discussion in chapter.

^hProphylaxis not well established. Carefully assess risk on a case-by-case basis.

ⁱUsually not indicated for children < age 9 years because of tooth staining with repeated doses.

isions for antimicrobial prophylaxis are generally discouraged and should be considered carefully for each child.

INITIAL EMPIRIC ANTIMICROBIAL CHOICES FOR SELECTED CONDITIONS

General recommendations for specific conditions are as follows. A specific selection depends on the patient's age, diagnosis, site of infection, severity of illness, antimicrobial susceptibility of bacterial isolates, and history of drug allergy. Always consult the package insert for detailed prescribing information. Tables 35–2 to 35–6 include further information.

Neonatal Sepsis & Meningitis

The newborn with sepsis may have signs of focal infection such as pneumonia or respiratory distress syndrome or may have subtle nonfocal signs. Group B streptococci, *Escherichia coli*, other gram-negative rods, and *Listeria monocytogenes* are commonly encountered. Ampicillin and gentamicin (or another aminoglycoside) are preferred. If meningitis is present, many clinicians substitute a third-generation cephalosporin for the aminoglycoside. *S pneumoniae* is an uncommon cause of meningitis in neonates. However, if the Gram stain shows gram-positive cocci suggesting *S pneumoniae*, substitution of vancomycin for ampicillin should be considered. In the newborn with cellulitis, *Staphylococcus aureus* and group A streptococci are additional considerations. Nafcillin, oxacillin, or a first-generation cephalosporin is usually added. Omphalitis is often polymicrobial, and *Enterococcus* species, gram-negative aerobes, and anaerobes may be causative. Clindamycin, ampicillin, and an aminoglycoside or cefotaxime cover the most likely organisms; early surgical intervention is indicated.

Sepsis in an Infant

S pneumoniae and *Neisseria meningitidis* are most commonly encountered in infants. *H influenzae* type b infection may occur in unimmunized children. A third-generation cephalosporin is appropriate. Intermediate-level penicillin and cephalosporin resistance in *S pneumoniae* usually do not cause therapy to fail unless meningitis or another difficult-to-treat infection such as endocarditis or osteomyelitis is present.

Occult bacteremia may be encountered in young infants with high fever, and some experts recommend presumptive therapy to clear the bacteremia and to prevent complications. Prior to immunization with vaccines effective against HIB, persistent bacteremia and complications including meningitis were seen in approximately 50% of children infected with occult HIB

bacteremia. With widespread use of HIB vaccine, HIB is a very uncommon cause of occult bacteremia in young children with fever. *S pneumoniae* bacteremia is demonstrated in 3–5% of infants age 3–36 months who have a fever of 39°C or greater, no identified source for fever on examination, and a white blood cell count (WBC) = 15,000/mm³. The risk of bacteremia increases to 6–10% in younger children with progressively high fever and high WBCs. The risk of developing meningitis due to persistent *S pneumoniae* is estimated at 3% of those who are known to be bacteremic. The risk of *S pneumoniae* bacteremia and its complications is currently decreasing due to widespread administration of a conjugate-7-valent pneumococcal vaccine. In clinical trials, this vaccine reduced the incidence of invasive pneumococcal diseases by approximately 90%. This decrease in the incidence of HIB and *S pneumoniae* occult bacteremia in young febrile children has led some experts to reconsider the recommendations for empiric presumptive therapy. Observation without antimicrobials, but with appropriate plans for follow-up examinations, is appropriate for most febrile young children who are fully immunized.

Nosocomial Sepsis

Many bacterial pathogens can cause infection in hospitalized patients. Recent local experience is usually the best guide to etiologic diagnosis. For example, some neonatal units experience frequent infections due to *Enterobacter cloacae*, whereas in other units *Klebsiella pneumoniae* is the most common nosocomial isolate. Initial therapy should include antibiotics effective for methicillin-resistant *S aureus* (MRSA) and resistant *Pseudomonas aeruginosa* if these are frequent isolates. *Enterococcus faecalis* is a common cause of nosocomial bacteremia in patients with central catheters, particularly in units where cephalosporins are heavily used. Coagulase-negative staphylococci are commonly isolated from patients with indwelling central catheters. In seriously ill patients, when the local experience suggests that *Enterococcus* species or coagulase-negative staphylococci are common, the initial regimen should include vancomycin. Because *Enterococcus* species and coagulase-negative staphylococci commonly cause fever without significant morbidity or mortality, initial regimens without vancomycin are appropriate, with adjustment of treatment after susceptibility is known. If *P aeruginosa* or other resistant gram-negative rods are common, ceftazidime or cefepime should be included in initial therapy.

Meningitis

Bacterial meningitis in neonates is usually caused by infection with group B streptococci, *E coli*, or *L monocy-*

togenes. A combination of ampicillin and gentamicin or another aminoglycoside—or ampicillin and a third-generation cephalosporin—is started initially. In an infant or older child, *S pneumoniae* or *N meningitidis* is the most common isolate. Hib is uncommon now because of widespread immunization. Increasingly, *S pneumoniae* with multiple resistances to penicillin, cephalosporins, and other drugs is isolated. In some communities, 30–40% of *S pneumoniae* isolates have intermediate susceptibility to penicillin (MIC between 0.1 and 2 µg/mL) and 5–10% of isolates may be highly resistant to penicillin (MIC > 2 µg/mL). Resistance to a third-generation cephalosporin (MIC > 2 µg/mL) may occur in 3–5% of isolates.

In bacterial meningitis, peak cerebrospinal fluid (CSF) antimicrobial concentrations 10 or more times greater than the MIC of the organism are desirable, but this may be difficult to achieve if organisms are resistant. The therapeutic problem is complicated if dexamethasone, which reduces the entry of some antimicrobials into the CSF, is also given.

Initial therapy of bacterial meningitis in an older child thus should include vancomycin and a third-generation cephalosporin. Alternatively, clinical experience with meropenem has also been successful. A lumbar puncture should be considered 24–48 hours after the start of therapy to assess the sterility of the CSF. Rifampin should be added if the Gram stain or cultures of CSF are positive on repeated lumbar puncture, if the child has failed to improve, or if an organism with a very high MIC to ceftriaxone is isolated. The optimal therapy of highly resistant *S pneumoniae* meningitis is not well established by clinical data.

Meningitis in a child with a ventriculoperitoneal shunt is most commonly caused by coagulase-negative staphylococci, many of which are methicillin-resistant, and *Corynebacterium* species, which are resistant to many antimicrobials. In many of these patients who are not seriously ill, therapy should be postponed while awaiting the appropriate shunt fluid for Gram stain and culture. Seriously ill patients should initially be given vancomycin and a third-generation cephalosporin, because *S aureus* and gram-negative rods are also possible and can cause serious infection.

Urinary Tract Infection

E coli is the most common isolate from the urinary tract. Outpatients with symptoms of lower urinary tract disease or with mild illness can be given ampicillin, cephalexin, or a sulfonamide. Local experience and resistance rates should guide initial therapy. In selected patients with pyelonephritis, outpatient therapy is effective using parenteral aminoglycosides or ceftriaxone once per day. Oral cefixime has been used in place of

ceftriaxone for outpatient therapy; unfortunately, cefixime is no longer available and there are little data on initial therapy with other third-generation cephalosporins. For hospitalized patients with genitourinary tract infection and suspected bacteremia, ampicillin and gentamicin or a third-generation cephalosporin is appropriate. Gram stain may be used to guide the initial choice. For patients with known or suspected resistant organisms, such as *P aeruginosa*, or for patients with urosepsis, an aminoglycoside and ceftazidime, cefepime, or ticarcillin may be started. Unit-specific data on typical bacterial species and their patterns of susceptibility should guide the antimicrobial choice for nosocomial urinary tract infections.

Bacterial Pneumonia

Bacterial pneumonia in newborns generally should be treated the same as is sepsis. Infants and older children are frequently infected with *S pneumoniae*. Ampicillin and amoxicillin are effective in most patients eligible for outpatient therapy. Children who require hospitalization may benefit from a second- or third-generation cephalosporin. The broader initial coverage is indicated because of the greater severity of disease. A rapidly progressive pneumonia, with pneumatoceles or large pleural effusions, may be due to *S aureus* or group A streptococci, Hib, or another gram-negative rod. Oxacillin, nafcillin, or another effective antistaphylococcal agent should be used in addition to a third-generation cephalosporin.

Children age 6 years and older frequently have infection with *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or *S pneumoniae*. Erythromycin, clarithromycin, or azithromycin is usually indicated for initial empiric therapy.

SPECIFIC ANTIMICROBIAL AGENTS

PENICILLINS

1. Aminopenicillins

Penicillin remains the drug of choice for streptococcal infections, acute rheumatic fever prophylaxis, syphilis, oral anaerobic infections, dental infections, *N meningitidis* infection, leptospirosis, rat-bite fever, actinomycosis, and infections due to *Clostridium* and *Bacillus* species. For oral therapy of minor infections, amoxicillin or ampicillin is usually equivalent. For systemic therapy, aqueous penicillin G is preferable. Amoxicillin is preferred for oral therapy of Lyme disease in children.

For dog or cat bites, where *Pasteurella multocida* is commonly encountered, amoxicillin–clavulanate provides good coverage of *Pasteurella* as well as *Staphylococcus*. An alternative is separate prescriptions for penicillin and an antistaphylococcal drug such as cephalixin, or clindamycin and trimethoprim–sulfamethoxazole (TMP–SMX) in penicillin-allergic patients. As for human bites, amoxicillin–clavulanate provides adequate therapy for *Eikenella corrodens* and other mixed oral aerobes and anaerobes. The β -lactamase inhibitor sulbactam combined with ampicillin is given parenterally for human and animal bites, and some other infections due to organisms from the oral flora where mixed aerobic and anaerobic bacteria may be resistant to ampicillin due to β -lactamase production.

2. Penicillinase-Resistant Penicillins

S aureus is usually resistant to penicillin and amoxicillin owing to penicillinase production. Nafcillin, oxacillin, methicillin, and first- and second-generation cephalosporins are stable to penicillinase and are usually equivalent for intravenous therapy. Methicillin is associated with more frequent interstitial nephritis. Oxacillin and methicillin are renally excreted, whereas nafcillin is excreted through the biliary tract. These properties are occasionally considered in children with renal or liver failure. Cost should usually be the deciding factor for choosing an agent. Often both *S aureus* and *Streptococcus pyogenes* are suspected initially (eg, in cellulitis or postoperative wound infections). The penicillinase-resistant penicillins (PRPs) and first- and second-generation cephalosporins are efficacious for most streptococcal infections, although penicillin remains the drug of choice.

MRSA is an increasing community-acquired infection in children and may cause nosocomial infection. MRSA infections are also resistant to other PRPs and to first- and second-generation cephalosporins. Vancomycin is effective against MRSA and coagulase-negative staphylococci. *S aureus* infections range in severity from minor infections treated on an outpatient basis to life-threatening infections. However, progressively severe infections due to MRSA are a serious concern in some communities. It is important to culture and determine antimicrobial susceptibility of suspected *S aureus* infections in communities where MRSA is common. In communities with frequent MRSA infections in children, initial therapy of seriously ill children should include vancomycin. MRSA may also be resistant to macrolides and clindamycin by alteration in the bacterial 23S ribosomal RNA. Alternatively, strains with efflux mechanisms are frequently susceptible to clindamycin, but resistant to erythromycin. Inducible resistance to clindamycin may be detected in erythro-

mycin-resistant MRSA that demonstrate a D-zone in disk susceptibility testing to clindamycin. Community-acquired MRSA are more likely to be susceptible to TMP–SMX, clindamycin and gentamicin than hospital-acquired infections.

For outpatient therapy, cloxacillin, dicloxacillin, and first- or second-generation cephalosporins are usually equally effective for infections due to susceptible *S aureus*. Cost may determine the choice between drugs.

3. Anti-Pseudomonas Penicillins

Ticarcillin, mezlocillin, and piperacillin are active intravenously against streptococci, ampicillin-susceptible enterococci, *H influenzae*, gram-negative rods (including more resistant gram-negative rods such as *Enterobacter*, *Proteus*, and *Pseudomonas aeruginosa*), and gram-negative anaerobes such as *Bacteroides fragilis*. *P aeruginosa* is inherently resistant to most antimicrobials, and high levels of these drugs are usually required. The combination of ticarcillin and an aminoglycoside is synergistic against *P aeruginosa* and many other enteric gram-negative rods. Ticarcillin in a fixed combination with clavulanic acid has activity against β -lactamase-producing strains of *Klebsiella*, *S aureus*, and *Bacteroides*. Piperacillin is more active in vitro against many gram-negative enteric infections and may be advantageous in some circumstances, but it is not approved in children. Piperacillin–tazobactam is another combination antimicrobial and β -lactamase inhibitor that has enhanced activity against many β -lactamase producers.

Antipseudomonal penicillins cause the same toxicities as penicillin and therefore are usually very safe. Carbenicillin, ticarcillin, and piperacillin contain large amounts of sodium, which may cause problems for some patients with cardiac or renal disease.

GLYCOPEPTIDE AGENTS

Vancomycin and teicoplanin are glycopeptide antimicrobial agents active against the cell wall of gram-positive organisms. Only vancomycin is licensed in the United States. Vancomycin is useful for parenteral therapy of resistant gram-positive cocci such as penicillin- and cephalosporin-resistant *S pneumoniae*, MRSA, methicillin-resistant coagulase-negative staphylococci, and ampicillin-resistant enterococci. Vancomycin is also used orally for therapy of colitis due to *Clostridium difficile*, although it should not be used as the drug of first choice.

The empiric use of vancomycin has increased tremendously over the last several years. As a result, vancomycin-resistant enterococci (VRE) and coagulase-negative staphylococci have become problems, particularly in inpatient units, intensive care units, and oncol-

ogy wards. *S aureus* with increased MICs to vancomycin has been reported in the United States and Japan. This resistance is of concern because of the inherent virulence of many *S aureus* strains. Vancomycin use should be monitored carefully in hospitals and in their intensive care units. It should not be used empirically when an infection is mild or when other antimicrobial agents are likely to be effective. Vancomycin should be stopped promptly if infection is found to be due to organisms susceptible to other antimicrobials. Infection control guidelines for prevention of spread of VRE are published by the Centers for Disease Control and Prevention. Laboratory-based monitoring for VRE and vancomycin-resistant *S aureus* is warranted.

Rapid infusion of vancomycin is associated with the “red man syndrome,” characterized by diffuse red flushing, at times pruritus, and occasionally tachycardia and hypotension. As a result, vancomycin is infused slowly over 1 hour or longer in some cases. Diphenhydramine or hydrocortisone (or both) may also be used as premedication.

Measurement of peak-and-trough serum vancomycin concentrations is not necessary in most clinical situations, because the levels achieved with standard dosing are usually predictable and nontoxic. Measurement of serum concentrations is helpful in patients with abnormal or unpredictable renal function; in those with altered volume of distribution, as occurs in nephrotic syndrome or shock; and in those receiving higher-dose therapy, for example, for meningitis or other difficult-to-treat infections. For patients receiving antimicrobials for weeks to months, weekly monitoring of clinical signs and symptoms and of urinalysis, creatinine, and CBC will allow detection of toxicity.

OXAZOLIDINONES

Linezolid is the first drug in this new class of antimicrobials which have a distinct new mechanism of action; they bind to the 50s-ribosomal RNA subunit and prevent initiation of protein synthesis. Because of this unique mechanism, there is no cross-resistance with other classes of antimicrobials. The *in vitro* development of resistance has also been uncommon.

Linezolid is active against aerobic gram-positive organisms, including streptococci, staphylococci, enterococci, and pneumococci. Because linezolid is active against gram-positive organisms resistant to other antimicrobials (eg, MRSA, methicillin-resistant, coagulase-negative staphylococci, VRE, and penicillin-resistant *S pneumoniae*), it is a potentially useful rescue drug for these difficult-to-treat infections.

Linezolid is not approved for use in pediatrics, but in clinical studies has been safe and well tolerated. Gastrointestinal symptoms are the most commonly en-

countered side effect. Neutropenia and thrombocytopenia have been reported, and linezolid should therefore be used with monitoring in patients at increased risk for these problems or in patients receiving therapy for 2 weeks or longer. Linezolid is an inhibitor of monoamine oxidase (MAO) and should not be used with inpatients taking MAO inhibitors, or with patients taking phenylpropanolamine or pseudoephedrine.

Linezolid should be used only for infections due to a proven gram-positive pathogen that is known or strongly suspected to be resistant to other available agents.

QUINUPRISTIN/DALFOPRISTIN

Quinupristin and dalfopristin are two antimicrobials of the streptogramin class, which individually are bacteriostatic but in combination are synergistic and bacteriocidal. These drugs are combined in a fixed ratio of 70:30, known as Synercid. Streptogramins inhibit protein synthesis by binding to the 50s ribosomal subunit. The streptogramins were discovered many years ago, but interest has increased only recently due to the activity of these agents against some very difficult-to-treat gram-positive infections.

The quinupristin/dalfopristin combination has activity against staphylococci, streptococci, pneumococci, and some enterococci. Quinupristin/dalfopristin is primarily indicated for serious infections due to vancomycin-resistant *Enterococcus faecium* and MRSA. Quinupristin/dalfopristin is not active against *E faecalis* and, therefore, differentiation of these strains from *E faecium* is important prior to initiating therapy.

Quinupristin/dalfopristin is not approved for therapy in children. Nonetheless, therapy has been initiated under a compassionate release program in some pediatric patients seriously ill with difficult-to-treat infections due to resistant organisms.

Arthralgias and myalgias have at times been severe in adult patients. Other significant side effects include elevated bilirubin and inflammation at intravenous sites.

Quinupristin/dalfopristin is a significant inhibitor of P-450 3A4 and, therefore, must be used with caution in patients receiving drugs metabolized by this mechanism.

The use of quinupristin/dalfopristin should be limited to serious infections due to proven *E faecium* or *S aureus* or infections due to proven gram-positive cocci that are resistant to other agents.

CEPHALOSPORINS

Cephalosporin agents make up a large and often confusing group of antimicrobials. Many of these drugs are similar in antibacterial spectrum and side effects and

may have similar names. Clinicians should learn well the properties of one or two drugs in each class. Cephalosporins are often grouped as “generations” to signify their similar antimicrobial activity. First-generation cephalosporins such as cefazolin intravenously and cephalexin orally are useful mainly for *S aureus* infection and urinary tract infection due to susceptible *E coli*. Second-generation cephalosporins, such as cefuroxime intravenously and cefprozil and cefuroxime orally, have somewhat reduced but acceptable activity against gram-positive cocci but greater activity against some gram-negative rods. They are active against *H influenzae* and *Moraxella catarrhalis*, including strains that produce β -lactamase capable of inactivating ampicillin. Third-generation cephalosporins have substantially less activity against gram-positive cocci such as *S aureus* but greatly augmented activity against aerobic gram-negative rods. Cefotaxime and ceftriaxone are examples of intravenous drugs, whereas cefpodoxime and cefibuten are representative oral drugs. Cefepime is a new antimicrobial often described as fourth-generation because of its broad activity against gram-positive and gram-negative organisms, including *P aeruginosa*. Cefepime is stable to β -lactamase degradation and is a poor inducer of β -lactamase. Cefepime will be most useful for organisms resistant to other drugs. Cefepime is not approved for use in children younger than age 2 months.

No cephalosporin agent has substantial activity against *L monocytogenes*, enterococci, or MRSA. The only cephalosporins useful for treating anaerobic infections are cefoxitin and cefotetan, two second-generation cephalosporins with excellent activity against *B fragilis*. Ceftazidime is a third-generation cephalosporin with appreciable activity against *P aeruginosa*.

Allergy to β -lactam antimicrobials is reported commonly by parents, but the majority of children are not shown to be allergic when studied by skin test or oral challenge. Immediate hypersensitivity reactions, including anaphylaxis or hives, most commonly predict true allergy. In contrast, many delayed reactions and non-specific rashes are likely due to the underlying infection rather than allergy (see Chapter 34). Cephalosporins should be used with caution in children with immediate hypersensitivity reactions to penicillins or cephalosporins, because 10–15% will also be allergic to cephalosporins.

Cephalosporins are seldom the drug of choice for therapy of ambulatory infections, and despite their popularity they are often more expensive than other antimicrobials with similar side effects.

Resistance to cephalosporins is common among aerobic gram-negative rods. The presence of inducible cephalosporinases in the chromosome of some gram-negative rod organisms such as *P aeruginosa*, *Serratia*

marcescens, *Citrobacter*, and *Enterobacter* has led to clinical failures because of the emergence of resistance during therapy. Extended spectrum β -lactamases mediate broad resistance to all β -lactams. Many clinicians treat infections due to these organisms with a second effective drug to attempt to limit the emergence of resistant strains. Active laboratory-based surveillance is necessary to predict the usual susceptibility encountered in gram-negative infections.

AZTREONAM

Aztreonam is the only monobactam antimicrobial agent approved in the United States. Although it is not approved for use in children, there is considerable pediatric experience with its use, including in neonates and premature infants. Aztreonam is active against aerobic gram-negative rods, including *P aeruginosa*. Aztreonam has activity against *H influenzae* and *M catarrhalis*, including those that are β -lactamase producers. Most patients with allergy to penicillin or cephalosporins are not sensitized to aztreonam, except that children with prior reactions to ceftazidime may have reactions to aztreonam because aztreonam and ceftazidime have a common side chain.

CARBAPENEMS

Meropenem, ertapenem, and imipenem are broad-spectrum β -lactam antimicrobials. Imipenem–cilastatin is a combination of an active antibiotic and cilastatin, which inhibits the metabolism of imipenem in the kidney and thereby results in high serum and urine levels of imipenem. These carbapenems are also active against *S pneumoniae*, including many penicillin-resistant and cephalosporin-resistant strains. Carbapenems have been used successfully to treat meningitis and may be considered if vancomycin is not tolerated. An increased frequency of seizures is encountered when central nervous system infections are treated with carbapenems. These agents are broadly active against streptococci, methicillin-susceptible staphylococci, some enterococci, and gram-negative rods such as *P aeruginosa*, β -lactamase-producing *H influenzae*, and gram-negative anaerobes. Ertapenem has less activity against *P aeruginosa*, *Acinetobacter* sp., and *Enterococcus* sp. than meropenem and imipenem. Because carbapenems are active against so many species of bacteria, there is a strong temptation to use them as single-drug empiric therapy. Units that have used carbapenems heavily have encountered resistance in many different species of gram-negative rods. A more appropriate practice is to reserve carbapenems for patients who have infections that are unresponsive or resistant to other antimicrobial agents.

MACROLIDES & AZILIDES

Erythromycin is the most commonly used macrolide antimicrobial agent. It is active against many bacteria that are resistant to cell wall-active antimicrobials and is the drug of choice for *Bordetella pertussis*, *Legionella pneumophila*, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *C trachomatis* infections (in children in whom tetracycline is not an option). Erythromycin is used for outpatient therapy of streptococcal and staphylococcal infections and in patients with penicillin allergy. More serious infections due to streptococci and staphylococci are usually treated with penicillins, clindamycin, PRPs, or cephalosporins because of a significant incidence of erythromycin resistance in both species. *S pneumoniae* resistant to erythromycin and the related macrolides are now frequent in many communities. This limits the ability of macrolide antimicrobials for therapy of otitis media and sinusitis. Gastrointestinal side effects are common. Interactions with theophylline, carbamazepine, terfenadine, cycloserine, and other drugs may require dosage modifications of erythromycin and clarithromycin. Interactions with azithromycin are less common.

Erythromycin is available in many formulations, including the base, estolate, ethyl succinate, and stearate. Transient hepatic toxicity occurs in adults but is much less common in children. Erythromycin base and stearate should be taken with meals for best absorption.

Clarithromycin and azithromycin, macrolide and azilide antimicrobials, respectively, are much less likely than erythromycin to cause nausea, vomiting, and diarrhea. These agents are useful in children who cannot tolerate erythromycin. Clarithromycin is more active than erythromycin against *H influenzae*, *M catarrhalis*, and *N gonorrhoeae* and is the drug of choice, sometimes in combination, for some nontuberculous mycobacterial infections. Azithromycin has a prolonged tissue half-life that achieves a prolonged antimicrobial effect. Azithromycin is dosed once daily for 5 days but must be taken 1 hour before or 2 hours after meals because food interferes with absorption. Although azithromycin is active against *H influenzae*, some authors report delayed eradication of *H influenzae* from the middle ear. Azithromycin can be used for single-dose therapy of *C trachomatis* infections. It is beneficial in adolescents when compliance with erythromycin or tetracycline is a concern. Azithromycin is useful for therapy of *Shigella* and *Salmonella* infections including typhoid fever. Due to resistance of many strains to ampicillin and TMP-SMX, alternatives are needed in some cases. Cefixime is no longer available, and fluoroquinolones are not used generally in children. In these cases, azithromycin may be a useful alternative. Clarithromycin is effective against Lyme disease, but 7 days of azithromycin for

that indication was inferior to amoxicillin. Clarithromycin and azithromycin are alternative drugs for toxoplasmosis in sulfonamide-allergic patients and as alternatives to erythromycin in legionellosis. In vitro and limited clinical experience in providing treatment to contacts of pertussis patients suggests efficacy equal to that of erythromycin. Clarithromycin and azithromycin are considerably more expensive than most erythromycin formulations, which for that reason are usually preferred, but they are advantageous by virtue of their twice-daily and once-daily dosing, respectively. Some failures of the newer macrolides have occurred in *S pneumoniae* sepsis and meningitis, perhaps because of low serum levels despite the high tissue levels achieved. High rates of resistance to macrolides and azilides have been encountered in some communities. The frequent use of azithromycin for respiratory infections and acute otitis media has contributed to selection of resistant strains.

CLINDAMYCIN

Clindamycin is active against *Staphylococcus aureus*, *Streptococcus pyogenes*, other streptococcal species except enterococci, and both gram-positive and gram-negative anaerobes. Clindamycin or metronidazole is frequently combined with other antimicrobials for empiric therapy of suspected anaerobic or mixed anaerobic and aerobic infections. Examples are pelvic inflammatory disease, necrotizing enterocolitis, other infections in which the integrity of the gastrointestinal or genitourinary tracts is compromised, and sinusitis. Clindamycin does not achieve high levels in CSF, but brain abscesses, toxoplasmosis, and other central nervous system infections, where disruption of the blood-brain barrier occurs, may be successfully treated with clindamycin. Clindamycin may be superior for treatment of serious streptococcal infections that appear to be toxin-mediated. For the usual oral anaerobes, penicillin is more active than clindamycin. Empiric use of clindamycin is justified in suspected anaerobic infections because cultures frequently cannot be obtained and, if obtained, may be slow in confirming anaerobic infection. Clindamycin has been associated with the occurrence of pseudomembranous colitis. Although diarrhea is a frequent side effect, pseudomembranous colitis is uncommonly due to clindamycin in children.

SULFONAMIDES

Sulfonamides—the oldest class of antimicrobials—remain useful for treatment of urinary tract infections. They are used also for other infections due to *E coli* and for *Nocardia*. Although useful for rheumatic fever prophylaxis in penicillin-allergic patients, sulfonamides fail

to eradicate group A streptococci and cannot be used for treatment of acute infections.

Trimethoprim-sulfamethoxazole (TMP-SMZ) is a fixed combination that is more active than either drug alone. Gram-positive cocci, including *S pneumoniae*, many staphylococci, *Haemophilus*, and many gram-negative rods, are susceptible. Unfortunately, resistance to TMP-SMZ has developed in recent years. *S pneumoniae* resistant to penicillin and cephalosporins is often also resistant to TMP-SMZ and erythromycin. In some communities, *Shigella* and *Salmonella enteritidis* strains remain susceptible, as do most *E coli*. TMP-SMZ is therefore very useful for treatment of urinary tract infections and bacterial dysentery. TMP-SMZ is also the drug of choice for treatment or prophylaxis against *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) infection. Dermatologic and myelosuppressive side effects limit the use of TMP-SMZ in some children infected with HIV.

Sulfonamide is associated with several cutaneous reactions, including urticaria, photosensitivity, Stevens-Johnson syndrome, purpura, and maculopapular rashes. Hematologic side effects such as leukopenia, thrombocytopenia, and hemolytic anemia are uncommon. Common gastrointestinal side effects are nausea and vomiting. The dermatologic and hematologic side effects are thought to be more common and more severe with TMP-SMZ than with sulfonamide alone.

TETRACYCLINES

Tetracyclines are effective against a broad range of bacteria but are not commonly used in children because alternative effective drugs are available. Many different tetracycline formulations are available. Tetracyclines are effective against *Bordetella pertussis* and *E coli* and many species of *Rickettsia*, *Chlamydia*, and *Mycoplasma*. Doxycycline or minocycline is the drug of choice for eradication of *Chlamydia trachomatis* in pelvic inflammatory disease and nongonococcal urethritis.

Staining of permanent teeth was noted in young children given repeated courses of tetracyclines. As a result, tetracyclines are generally not given to children younger than age 9 years unless alternative drugs are unavailable. A single course of tetracycline does not pose a significant risk of tooth staining. Mucous membrane candidiasis, photosensitivity, nausea, and vomiting are other common side effects. Tetracycline should be taken on an empty stomach, either 1 hour before or 2 hours after a meal. Doxycycline is well absorbed even in the presence of food; administration with food may minimize gastrointestinal side effects. Doxycycline is often preferred because it is better tolerated than tetracycline, and twice daily administration is convenient.

Tetracycline is used for therapy of rickettsial infections such as Rocky Mountain spotted fever, ehrlichiosis, rickettsialpox, murine typhus, and Q fever; as an alternative to erythromycin for *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* infections; and for treatment of psittacosis, brucellosis, *Pasteurella multocida* infection, and relapsing fever.

AMINOGLYCOSIDES

The aminoglycosides bind to ribosomal subunits and inhibit protein synthesis. They are active against aerobic gram-negative rods, including *P aeruginosa*. Streptomycin was the first drug in this class, but today it is used only to treat tuberculosis and the occasional cases of plague and tularemia.

Aminoglycosides are used to treat serious gram-negative infections and are given intravenously or intramuscularly. They are also used to treat pyelonephritis, suspected gram-negative sepsis, and in other settings where *P aeruginosa* infections are common, such as cystic fibrosis and burns. Aminoglycosides have activity against gram-positive organisms and, combined with penicillin or ampicillin, may achieve synergistic killing of *L monocytogenes* and group B streptococci. Penicillin, ampicillin, or vancomycin combined with gentamicin is indicated for therapy of serious enterococcal infections, such as sepsis or endocarditis because of more rapid clinical improvement with combined therapy. Aminoglycosides have activity against *S aureus* but are not used for therapy except in combination with other antistaphylococcal antibiotics.

Aminoglycosides are not active in an acidic environment and may not be effective against loculated abscesses. Aminoglycosides diffuse poorly into the CSF and achieve only about 10% of serum concentrations. As a result, a third-generation cephalosporin is preferred for treatment of bacillary meningitis.

Aminoglycosides kill bacteria in a concentration-dependent manner. They also have a prolonged suppressive effect on the regrowth of susceptible organisms (postantibiotic effect). These principles have led some investigators to establish guidelines for once-daily dosing of aminoglycosides, using larger initial doses given every 24 hours. Although aminoglycosides are associated with both renal and eighth nerve toxicity, the entry of the drug into renal and cochlear cells is saturable. It therefore was predicted that once-daily dosing would result in less toxicity than traditional twice-daily or three-times-daily dosing. Studies in adult patients confirm that once-daily dosing is as efficacious as traditional dosing and is associated with less toxicity. Although there is extensive experience with dosing intervals of 18–36 hours in premature babies, small total daily doses are customarily used (2–2.5 mg/kg/dose of

gentamicin or tobramycin). A convenient and cost-effective approach in children is based on the experience with adult patients and uses larger daily doses (4–7 mg/kg/dose every 24 hours). Unfortunately, there is little published information on the efficacy and safety of this approach in children.

Accordingly, traditional twice-daily or three-times-daily dosing regimens of aminoglycosides, with monitoring of serum levels, are still widely used. Careful monitoring is necessary, particularly in children with abnormal or changing renal function, premature infants, and infants with rapidly changing volumes of distribution. Aminoglycosides are usually infused over 30–45 minutes, and the peak serum concentration is measured 30–45 minutes after the end of the infusion. A trough serum concentration is measured prior to the next dose. The efficacious and nontoxic serum concentrations for gentamicin and tobramycin are trough less than 2 µg/mL and peak 5–10 µg/mL; for amikacin, trough less than 10 µg/mL and peak 15–25 µg/mL (see Table 35–4). Aminoglycoside levels and creatinine levels should be measured in children expected to receive more than three days of therapy and weekly in children on long-term therapy even when renal function is normal and stable.

FLUOROQUINOLONES

Nalidixic acid was the prototype quinolone antimicrobial, but it is not used today. Modification of the quinolone structure has led to the introduction of many new compounds called fluoroquinolones, which are well absorbed after oral administration and possess excellent antibacterial activity against resistant gram-negative pathogens. The nine currently available fluoroquinolones vary in their activity against specific organisms. Fluoroquinolones are active against most of the Enterobacteriaceae, including *Escherichia coli*, *Enterobacter*, *Klebsiella*, in some cases *P aeruginosa*, and many other gram-negative bacteria such as *H influenzae*, *M catarrhalis*, *N gonorrhoeae*, and *N meningitidis*. Some fluoroquinolones (ofloxacin, gatifloxacin) are active against *C trachomatis*. The fluoroquinolones are active against some enterococci, *S aureus*, and coagulase-negative staphylococci but not against MRSA. The newer quinolones have good activity against penicillin and cephalosporin-resistant *Streptococcus pneumoniae*, but clinical experience in children is limited.

Quinolones (except the otic and ophthalmic preparations) are currently not FDA-approved for use in children, although they often very attractive alternatives to approved agents. The objection to quinolones is based on the recognition that nalidixic acid and other quinolones cause arthropathy when used experimentally in newborn animals of many species. The fear that

children would also be more susceptible than adults to cartilage injury has not been realized in clinical experience. Both retrospective long-term follow-up studies of children given nalidixic acid and prospective studies of children receiving treatment under protocols with fluoroquinolones have shown similar rates of toxicity compared with adult patients. Arthropathy occurs uncommonly, although tendon rupture is a reported rare, serious complication. For these reasons, quinolones should be considered for use in children when the benefit clearly outweighs the risk, when no alternative drug is available, and after discussion with the parents.

Ciprofloxacin is useful for oral therapy of resistant gram-negative urinary tract infections such as that caused by *P aeruginosa*. Ofloxacin, levofloxacin, ciprofloxacin, and gatifloxacin are useful for single-dose therapy of uncomplicated gonorrhea, and ofloxacin and levofloxacin are an alternative therapy for treating *Chlamydia* infections and pelvic inflammatory disease. Ciprofloxacin and ofloxacin are used as therapy of resistant cases of shigellosis. Levofloxacin and ciprofloxacin are usually the drugs of choice for treatment of traveler's diarrhea. Ciprofloxacin is useful for treatment of *P aeruginosa* infection in cystic fibrosis patients, and as therapy for chronic suppurative otitis media. Several quinolones are used as therapy for pneumonia due to *Legionella*, *Mycoplasma*, or *Chlamydia pneumoniae*, although a macrolide is often preferred, and as prophylactic therapy of meningococcal infection. Ofloxacin and levofloxacin are used for treatment of some cases of *Mycobacterium tuberculosis* and some atypical mycobacterial infections.

METRONIDAZOLE

Metronidazole has excellent activity against most anaerobes, particularly gram-negative anaerobes such as *Bacteroides* and *Fusobacterium*, and against gram-positive anaerobes such as *Clostridium*, *Prevotella*, and *Porphyromonas*. Gram-positive anaerobic cocci such as *Peptococcus* and *Peptostreptococcus* are often more susceptible to penicillin or to clindamycin. Because metronidazole lacks activity against aerobic organisms, it is usually given with one or more other antibiotics. Metronidazole is well absorbed after oral administration and has excellent penetration into the central nervous system. Metronidazole is the drug of choice for bacterial vaginosis and for *C difficile* enterocolitis. It is active against many parasites, including *Giardia lamblia* and *Entamoeba histolytica*.

DAPTOMYCIN

Daptomycin is a newly FDA-approved antimicrobial with bactericidal activity against gram-positive cocci.

Daptomycin is a lipopeptide that binds to bacterial cell membranes, resulting in membrane depolarization and cell death. Daptomycin is active against methicillin-sensitive and -resistant *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus agalactiae*, as well as *E faecium* (including vancomycin-resistant strains), and *E faecalis* (vancomycin-sensitive strains). Daptomycin is given as a once-daily intravenous infusion of 4 mg/kg, and is approved for therapy of complicated skin and soft tissue infections, but has not been sufficiently studied in children younger than 18 years to make recommendations for dosing and use. Daptomycin is excreted renally, so a modification of dosing is needed in patients with impaired renal function. It has significant interactions with aminoglycosides, so monitoring serum concentrations of aminoglycosides is necessary. Nausea, constipation, and headache are the most common side effects of therapy. In patients with muscle pain, monitoring creatinine phosphokinase (CPK) levels should be done.

Myron J. Levin, MD, & Adriana Weinberg, MD

I. VIRAL INFECTIONS

Viruses cause most pediatric infections. Mixed viral or viral–bacterial infections of the respiratory and intestinal tracts are rather common, as is prolonged asymptomatic shedding of some viruses in childhood. Thus the detection of a virus is not always proof that it is the cause of a given illness. Viruses are often a predisposing factor for bacterial respiratory infections (eg, otitis, sinusitis, and pneumonia).

Many respiratory and herpes viruses can now be detected within 24–48 hours by combining culture and monoclonal antibody techniques (“rapid culture technique”). Diagnosis of many viral illnesses is also possible through antigen or nucleic acid detection techniques. These techniques are more rapid than isolation of viruses in tissue culture and in many cases are equally sensitive or more so. Polymerase chain reaction (PCR) amplification of viral genes has led to recognition of previously undetected infections. New diagnostic tests have changed some basic concepts about viral diseases and made diagnosis of viral infections both more certain and more complex. Only laboratories with excellent quality-control procedures should be used, and the results of new tests must be interpreted cautiously. The availability of specific antiviral agents increases the value of early diagnosis for some serious viral infections. Table 36–1 lists viral agents associated with common clinical signs, and Table 36–2 lists diagnostic tests. The viral diagnostic laboratory should be contacted for details regarding specimen collection, handling, and shipping. Table 36–3 lists common causes of red rashes in children that should be considered in the differential diagnosis of certain viral illnesses.

RESPIRATORY INFECTIONS

Many virus infections cause upper or lower respiratory tract signs and symptoms. Those that produce a predominance of these signs and symptoms are described in the text that follows. Many so-called respiratory viruses can also produce distinct nonrespiratory disease (eg, enteritis or cystitis caused by adenoviruses; parotitis

caused by parainfluenza viruses). Respiratory viruses can cause disease in any area of the respiratory tree. Thus they can cause coryza, pharyngitis, sinusitis, tracheitis, bronchitis, bronchiolitis, and pneumonia—although certain viruses tend to be closely associated with one anatomic area (eg, parainfluenza with croup, respiratory syncytial virus [RSV] with bronchiolitis) or discrete epidemics (eg, influenza, RSV, parainfluenza). Nevertheless it is impossible on clinical grounds to be certain of the viral cause of an infection in a given child. This information is provided by the virology laboratory and is often important for epidemiologic, therapeutic, and preventive reasons.

VIRUSES CAUSING THE COMMON COLD

The common cold syndrome (also called upper respiratory infection) is characterized by combinations of runny nose, nasal congestion, sore throat, tearing, cough, and sneezing. Low-grade fever may be present. The causal agent is usually not sought or determined. Epidemiologic studies indicate that rhinoviruses, which are the most common cause (30–40%), are present throughout the year, but are more prevalent in the colder months in temperate climates. Adenoviruses also cause colds in all seasons, but epidemics are common. Respiratory syncytial, parainfluenza, and influenza viruses cause the cold syndrome during epidemics from late fall through winter. Coronaviruses (≈10%) also cause colds in winter, and enteroviruses cause the “summer cold.” One significance of these infections is morbidity continuing for 5–7 days. It is likely also that changes in respiratory epithelium, local obstruction, and altered local immunity are sometimes the precursors of more severe illnesses such as otitis media, pneumonia, and sinusitis. During and following a cold the bacterial flora changes, and bacteria are found in normally sterile areas of the upper airway. Asthma attacks are also provoked by viruses that cause the common cold. There is no evidence that antibiotics will prevent these complications, and the unjustified widespread use of antibiotics for cold symptoms has contributed to the emergence of antibiotic-resistant respiratory flora.

In 5–10% of children, symptoms from these virus infections persist for more than 10 days. This overlap

Table 36–1. Some viral causes of clinical syndromes.

Rash	Adenopathy	Arthritis
Enterovirus	Epstein–Barr virus	Parvovirus B19
Adenovirus	Cytomegalovirus	Rubella
Measles	Rubella ^e	Hepatitis B
Rubella	Human immunodeficiency virus	Congenital or perinatal infection
Human herpes virus type 6 ^a or 7	Croup	Adenovirus
Varicella	Parainfluenza	Cytomegalovirus
Parvovirus B19 ^b	Influenza	Hepatitis B
Epstein–Barr virus	Adenovirus	Hepatitis C ^l
Dengue	Measles	Rubella
Human immunodeficiency virus (acute syndrome)	Bronchiolitis	Human immunodeficiency virus
Fever	Respiratory syncytial virus ^f	Parvovirus B19
Enterovirus	Adenovirus	Enterovirus
Epstein–Barr virus	Parainfluenza	Varicella
Human herpes virus type 6 ^a or 7	Influenza	Herpes simplex virus
Cytomegalovirus	Pneumonia	Meningoencephalitis
Influenza	Respiratory syncytial virus	Enterovirus
Rhinovirus	Adenovirus	Mumps
Most others	Parainfluenza	Arthropod-borne viruses
Conjunctivitis	Hantavirus	Herpes simplex virus
Adenovirus	Measles	Cytomegalovirus
Enterovirus 70	Varicella ^h	Lymphocytic choriomeningitis virus
Measles	Cytomegalovirus ^{g,i}	Measles
Herpes simplex ^c	Influenza	Varicella
Parotitis	Severe acute respiratory syndrome (SARS)	Adenovirus
Mumps	Enteritis	Human immunodeficiency virus
Parainfluenza	Rotavirus	Epstein–Barr virus
Enterovirus	Enteric adenovirus	Influenza
Cytomegalovirus	Enterovirus	West Nile virus
Epstein–Barr virus	Astrovirus	
Human immunodeficiency virus	Calicivirus	
Pharyngitis	Cytomegalovirus	
Adenovirus	Hepatitis	
Enterovirus	Hepatitis A, ^j B, C, D, E	
Epstein–Barr virus	Epstein–Barr virus	
Herpes simplex virus ^d	Adenovirus	
Influenza	Cytomegalovirus	
Other respiratory viruses	Varicella ^k	
	Parvovirus B19	

^aRoseola agent.^bErythema infectiosum agent.^cConjunctivitis rare, only in primary infections; keratitis in older patients.^dMay cause isolated pharyngeal vesicles at any age.^eMay cause adenopathy without rash.^fOver 70% of cases.^gUsually only in young infants.^hImmunosuppressed, pregnant, rarely other adults.ⁱSeverely immunosuppressed at risk.^jAnicteric cases more common in children; these may resemble viral gastroenteritis.^kCommon, but only mild laboratory abnormalities.^lEspecially when the mother is HIV-positive.

Table 36–2. Diagnostic tests for viral infections.

Agent	Rapid Antigen Detection (Specimen)	Tissue Culture Mean Days to Positive (Range)			PCR ^a	Comments
			Acute	Paired		
Adenovirus	+ (respiratory and enteric)	10 (1–21)	–	+	+	“Enteric” strains detected by culture on special cell line, antigen detection, or PCR
Arboviruses	–	–	+	+	RL	Acute serum may diagnose many forms
Astrovirus	–	–	–	–	RL	Diagnosis by electron microscopy
Calicivirus	–	–	–	–	RL	Diagnosis by electron microscopy
Colorado tick virus	On RBC	–	–	RL, CDC	+	
Cytomegalovirus	+ (tissue biopsy, blood, respiratory secretions)	2 (2–28)	+	+	+	Diagnosis also by presence of IgM antibody
Enterovirus	–	2 (2–14)	–	+	+	
Epstein–Barr virus	–	–	+	+	+	Single serologic panel defines infection status; heterophil antibodies less sensitive
Hantavirus	–	–	+	ND	RL	Diagnosis by presence of IgM antibody
Hepatitis A virus	–	–	+	ND	RL	Diagnosis by presence of IgM antibody
Hepatitis B virus	+ (blood)	–	+	ND	+	Diagnosis by presence of surface antigen or anti-core IgM antibody
Hepatitis C virus	–	–	+	ND	+	Positive serology suggests that hepatitis C may be the causative agent. PCR is confirmatory
Herpes simplex virus	+ (mucosa, tissue biopsy, respiratory secretions skin)	1 (1–7)	+	+	+	Serology rarely used for herpes simplex. IgM antibody used in selected cases
Human herpes-virus-6	–	2	+	+	+	Roseola agent
Human immunodeficiency virus	+ (blood) (acid dissociation of immune complexes)	15 (5–28)	+	ND	+	Antibody proves infection unless passively acquired (< age 15 mos); culture not widely available; PCR definitive for early diagnosis in infant
Human metapneumovirus	—	RL	–	+	+	
Influenza virus	+ (respiratory secretions)	2 (2–14)	–	+	+	Antigen detection 70–90% sensitive
Lymphocytic choriomeningitis virus	–	–	–	+	RL	Can be isolated in suckling mice
Measles virus	+ (respiratory secretions)	–	+	+	RL	Difficult to grow; IgM serology diagnostic
Mumps virus	–	> 5	+	+	RL	Complement fixation titers may allow single-specimen diagnosis

Varicella-zoster virus	+ (skin scraping)	3 (3–21)	RL	+	+	
West Nile virus	—	RL	+	+	+	

^aUseful only when performed on selected specimens by qualified laboratories.

Key:

Plus signs signify commercially or widely available; **minus signs** signify not commercially available. **Note:** Results from some commercial laboratories are unreliable.

RL, CDC: Specific antibody titers or PCR available by arrangement with individual research laboratories or the Centers for Disease Control and Prevention.

ND: Not done.

RBC = red blood cell; PCR = polymerase chain reaction.

with the symptoms of bacterial sinusitis presents a difficult problem for clinicians, especially because colds can produce an abnormal computed tomography (CT) scan of the sinuses. Viruses that cause a minor illness in immunocompetent children, such as rhinoviruses, can cause severe lower respiratory disease in immunologically or anatomically compromised children.

There is no evidence that symptomatic relief for children can be achieved with oral antihistamines, decongestants, or cough suppressants. Topical decongestants provide temporary improvement in nasal symptoms.

INFECTIONS DUE TO ADENOVIRUSES

There are over 50 types of adenoviruses, which account for 5–10% of all respiratory illnesses in childhood, usually pharyngitis or tracheitis. Adenoviral infections are common early in life. Enteric adenoviruses are an important cause of childhood diarrhea. Epidemic respiratory disease occurs in winter and spring, especially in closed environments such as day care centers and institutions. Because of latent infection in lymphoid tissue, asymptomatic shedding from the respiratory or intestinal tract is common.

Table 36–3. Red rashes in children.

Condition	Incubation Period (Days)	Prodrome	Rash	Laboratory Tests	Comments, Other Diagnostic Features
Adenovirus	4–5	URI; cough; fever	Morbilloform (may be petechial)	Normal; may see leukopenia or lymphocytosis	Respiratory symptoms are prominent. No Koplik spots. No desquamation
Measles	9–14	Cough, rhinitis, conjunctivitis	Maculopapular; face to trunk; lasts 7–10 d; Koplik spots in mouth	Leukopenia	Toxic. Bright red rash becomes confluent, may desquamate. Fever falls after rash appears.
Rubella	14–21	Usually none	Mild maculopapular; rapid spread face to extremities; gone by day 4	Normal or leukopenia	Postauricular, occipital adenopathy common. Polyarthralgia in some older girls. Mild clinical illness.
Roseola (exanthem subitum)	10–14	Fever (3–4 d)	Pink, macular rash occurs at end of illness; transient	Normal	Fever often high; disappears when rash develops; child appears well. Usually occurs in children 6 mos to 2 y of age. Seizures may complicate.
Erythema infectiosum	13–18	None	Erythematous “slapped” cheeks; then reticular rash on extremities, trunk	Normal (reticulocytopenia)	Rash may reappear over weeks, especially with exposure to heat, sunlight. May cause arthralgia/arthritis, usually in older children or adults. Red cell maturation arrest in children with chronic hemolysis can cause aplastic crisis.
Enterovirus	2–7	Variable fever, chills, myalgia, sore throat	Usually macular, maculopapular on trunk or palms, soles; vesicles or petechiae also seen	Variable	Varied rashes may resemble those of many other infections. Pharyngeal or hand-foot-mouth vesicles may occur.
Streptococcal scarlet fever	1–7	Fever, abdominal pain, headache, sore throat	Diffuse erythema, “sandpaper” texture; neck, axillae, inguinal areas; spreads to rest of body; desquamates 7–14 d	Leukocytosis; positive group A streptococcus culture of throat or wound; positive streptococcal antigen test in pharynx	Strawberry tongue, red pharynx with or without exudate. Eyes, perioral and periorbital area, palms, and soles spared. Pastia’s lines. Brief prodrome. Cervical adenopathy. Usually occurs in children 2–10 y of age.
Staphylococcal scarlet fever	1–7	Variable fever	Diffuse erythroderma; resembles streptococcal scarlet fever except eyes may be hyperemic, no “strawberry” tongue, pharynx spared	Variable leukocytosis if infected	Focal infection usually present.

(continued)

Staphylococcal scalded skin	Variable	Irritability, absent to low fever	Painful erythroderma, followed in 1–2 d by cracking around eyes, mouth; bullae form with friction (Nikolsky sign)	Normal if only colonized by staphylococci; leukocytosis and sometimes bacteremia if infected	Normal pharynx. Look for focal staphylococcal infection. Usually occurs in infants.
Toxic shock syndrome	Variable	Fever, myalgia, headache, diarrhea, vomiting	Nontender erythroderma; red eyes, palms, soles, pharynx, lips	Leukocytosis; abnormal liver enzymes, coagulation tests; proteinuria	<i>Staphylococcus aureus</i> infection; toxin-mediated multiorgan involvement. Swollen hands, feet. Hypotension or shock.
Erythema multiforme	—	Usually none or related to underlying cause	Discrete, red maculopapular lesions; symmetrical, distal, palms and soles; target lesions classic	Normal or eosinophilia	Reaction to drugs (especially sulfonamides), or infectious agents (mycoplasma; herpes simplex virus). Urticaria, arthralgia also seen.
Stevens–Johnson syndrome	—	Pharyngitis, conjunctivitis, fever, malaise	Bullous erythema multiforme; may slough in large areas; hemorrhagic lips; purulent conjunctivitis	Leukocytosis	Classic precipitants are drugs (especially sulfonamides), <i>Mycoplasma pneumoniae</i> and herpes simplex infections. Pneumonitis and urethritis also seen.
Drug allergy	—	None, or fever alone, or with myalgia, pruritus	Macular, maculopapular, urticarial, or erythroderma	Leukopenia, eosinophilia	Rash variable. Severe reactions may resemble measles, scarlet fever; Kawasaki disease; marked toxicity possible.
Kawasaki disease	Unknown	Fever, cervical adenopathy, irritability	Polymorphous (may be erythroderma) on trunk and extremities; red palms and soles, conjunctiva, lips, tongue, pharynx. Desquamation is common	Leukocytosis, thrombocytosis, elevated ESR or C-reactive protein; pyuria; decreased albumin; negative cultures and streptococcal serology; resting tachycardia	Swollen hands, feet; prolonged illness; uveitis; aseptic meningitis; no response to antibiotics. Vasculitis and aneurysms of coronary and other arteries occur (cardiac ultrasound).
Leptospirosis	4–19	Fever (biphasic), myalgia, chills	Variable erythroderma	Leukocytosis; hematuria, proteinuria; hyperbilirubinemia	Conjunctivitis; hepatitis, aseptic meningitis may be seen. Rodent, dog contact.

URI = upper respiratory infection; ESR = erythrocyte sedimentation rate.

Specific Adenoviral Syndromes

A. PHARYNGITIS

Pharyngitis is the most common adenoviral disease in children. Fever and adenopathy are common. Tonsillitis may be exudative. Rhinitis and an influenza-like systemic illness may be present. Laryngotracheitis or bronchitis may accompany pharyngitis.

B. PHARYNGOCONJUNCTIVAL FEVER

Conjunctivitis may occur alone and be prolonged, but most often is associated with preauricular adenopathy, fever, pharyngitis, and cervical adenopathy. Foreign body sensation and other symptoms last less than a week. Lower respiratory symptoms are uncommon.

C. EPIDEMIC KERATOCONJUNCTIVITIS

Symptoms are severe conjunctivitis with punctate keratitis and occasionally visual impairment. A foreign body sensation, photophobia, and swelling of conjunctiva and eyelids are characteristic. Preauricular adenopathy and subconjunctival hemorrhage are common.

D. PNEUMONIA

Severe pneumonia may occur at all ages. It is especially common in young children (< age 3 years). Chest radiographs show bilateral peribronchial and patchy ground-glass interstitial infiltrates in the lower lobes. Symptoms persist for 2–4 weeks. Adenoviral pneumonia can be necrotizing and cause permanent lung damage, especially bronchiectasis. A pertussis-like syndrome with typical cough and lymphocytosis can occur with lower respiratory tract infection.

E. RASH

A diffuse morbilliform (rarely petechial) rash resembling measles, rubella, or roseola may be present. Koplik spots are absent.

F. DIARRHEA

Enteric adenoviruses (types 40 and 41) cause 3–5% of cases of short-lived diarrhea in afebrile children.

G. MESENTERIC LYMPHADENITIS

Fever and abdominal pain may mimic appendicitis. Pharyngitis is often associated. Adenovirus-induced adenopathy may be a factor in appendicitis and intussusception.

H. OTHER SYNDROMES

Immunosuppressed patients, including neonates, may develop severe or fatal pulmonary or gastrointestinal infections or multisystem disease. Other rare complications include encephalitis, hepatitis, and myocarditis. Adenoviruses have been implicated in the syndrome of

idiopathic myocardopathy. Hemorrhagic cystitis can be a serious problem in immunocompromised children.

Diagnosis

Diagnosis is by culture of conjunctival, respiratory, or stool specimens. Several days to weeks are required for growth in conventional cultures. Viral culture using the rapid culture technique with immunodiagnostic reagents detects virus in 48 hours. Adenovirus infection can also be diagnosed using these reagents directly on respiratory secretions. This is quicker but less sensitive than the culture methods. PCR has now become an important, relatively rapid diagnostic method for adenovirus infections. Special cells are needed to isolate enteric adenoviruses. Enzyme-linked immunosorbent assay (ELISA) tests rapidly detect enteric adenoviruses in diarrheal specimens. Respiratory adenovirus infections can be detected retrospectively by comparing acute and convalescent sera, but this is not helpful during an acute illness.

Treatment

There is no specific treatment for adenovirus infections. Intravenous immune globulin (IVIG) may be tried in immunocompromised patients with severe pneumonia. There are anecdotal reports of successful treatment of immunocompromised patients with ribavirin or cidofovir, but only cidofovir inhibits adenovirus in vitro.

INFLUENZA

Symptomatic infections are common in children because they lack immunologic experience with influenza viruses. Infection rates in children are greater than in adults and are instrumental in initiating community outbreaks. Three main types of influenza viruses (A/H1N1, A/H3N2, B) have caused most human epidemics, with the antigenic drift ensuring a supply of susceptible hosts of all ages. Recently, avian influenza A/H5N1 caused human outbreaks in Asia. Epidemics occur in fall and winter.

Clinical Findings

Spread of influenza occurs by way of airborne respiratory secretions. The incubation period is 2–7 days.

A. SYMPTOMS AND SIGNS

Influenza infection in older children and adults produces a characteristic syndrome of sudden onset of high fever, severe myalgia, headache, and chills. These symptoms overshadow the associated coryza, pharyngitis, and cough. Usually absent are rash, marked conjunctivitis, adenopathy, exudative pharyngitis, and dehydrating enteritis. Fever, diarrhea, vomiting, and abdominal pain are common in young children. Infants may develop a sepsis-like illness and apnea. Chest examination is usually unremarkable. Unusual clinical findings or variants include croup (most severe with type A influenza), exacerbation of asthma, myositis (especially calf muscles), myocarditis, parotitis, encephalopathy (distinct from Reye syndrome), nephritis, and a transient maculopapular rash. Acute illness lasts 2–5 days. Cough and fatigue may last several weeks. Viral shedding may persist for several weeks in young children.

B. LABORATORY FINDINGS

The leukocyte count is normal to low, with variable shift. Influenza infections may be more difficult to recognize in children than in adults even during epidemics, and therefore a specific laboratory test is highly recommended. The virus may be found in respiratory secretions by direct fluorescent antibody staining of nasopharyngeal epithelial cells, ELISA, optic immunoassay (OIA), or PCR. It can also be cultured within 3–7 days from pharyngeal swabs or throat washings. Many laboratories use the rapid culture technique by centrifuging specimens onto cultured cell layers and detecting viral antigen after 48 hours. Other body fluids or tissues (except lung) rarely yield the virus in culture and are more appropriately tested by PCR, which, due to its high sensitivity, can increase influenza detection in respiratory specimens. A late diagnosis may be made with paired serology, using hemagglutination inhibition assays.

C. IMAGING

The chest radiograph is nonspecific; it may show hyperaeration, peribronchial thickening, diffuse interstitial infiltrates, or bronchopneumonia in severe cases. Hilar nodes are not enlarged. Pleural effusion is rare in uncomplicated influenza.

Differential Diagnosis

The following may be considered: all other respiratory viruses, *Mycoplasma pneumoniae* or *Chlamydia pneumoniae* (longer incubation period, prolonged illness), streptococcal pharyngitis (pharyngeal exudate or petechiae, adenitis, no cough), bacterial sepsis (petechial or purpuric rash may occur), toxic shock syndrome (rash, hypotension), and rickettsial infections (rash, dif-

ferent season, insect exposure). High fever, the nature of preceding or concurrent illness in family members, and the presence of influenza in the community are distinguishing features from parainfluenza or respiratory syncytial virus infections.

Complications & Sequelae

Lower respiratory tract symptoms are most common in children younger than age 5 years. Hospitalization rates are highest in children younger than 2 years. Influenza can cause croup in these children. Secondary bacterial infections (classically staphylococcal) of the middle ear, sinuses, or lungs are most common. Of the viral infections that precede Reye syndrome, varicella and influenza (usually type B) are most notable. During an influenza outbreak, ill children who develop protracted vomiting or irrational behavior should be evaluated for Reye syndrome (see Chapter 20). Influenza can also cause a viral or postviral encephalitis, with cerebral symptoms much more prominent than those of the accompanying respiratory infection. Although the myositis is usually mild and resolves promptly, severe rhabdomyolysis and renal failure have been reported.

Children with underlying cardiopulmonary, metabolic, neuromuscular, or immunosuppressive disease may develop severe viral pneumonia.

Prevention

The inactivated influenza vaccine, which has been commercially available for many years, is moderately protective in older children (see Chapter 9). A new, live-attenuated influenza vaccine (Flumist), significantly more immunogenic in children, has been recently approved by the US Food and Drug Administration for use in immunocompetent children 5 years of age or older. All children between 6 and 23 months of age or those at high risk of developing severe complications should be immunized. Medical staff and family members should also be immunized to protect high-risk patients. Type A infections may be prevented by amantadine or rimantadine (5 mg/kg; maximum 150 mg/d < age 10 years; 200 mg/d if older). Amantadine is divided into two daily doses; rimantadine can be given in a single dose. Both influenza A and B can be prevented with the neuraminidase inhibitors zanamivir (2 inhalations bid if > 7 years of age) and oseltamivir (if child < 15 kg, 30 mg bid; 15–23 kg, 45 mg bid; 23–40 kg, 60 mg bid; > 40 kg, 75 mg bid). For outbreak prophylaxis, therapy should be maintained for 2 weeks or more and 1 week after the last case of influenza is diagnosed. Chemoprophylaxis should be considered during an epidemic for high-risk children who cannot be immunized or who

have not yet developed immunity (about 6 weeks after primary vaccination or 2 weeks after a booster dose).

Treatment & Prognosis

Treatment consists of general support and management of pulmonary complications, especially bacterial superinfections. Antivirals are of some benefit in immunocompetent hosts if begun within 48 hours after onset. Studies in lung transplant patients indicate that oseltamivir might be useful for treatment of influenza in this immunocompromised population. Resistance to amantadine and rimantadine develops within a couple of days of treatment. In contrast, neuraminidase inhibitors rarely select resistant isolates.

Recovery is usually complete unless severe cardiopulmonary or neurologic damage has occurred. Fatal cases occur in immunodeficient and anatomically compromised children.

Effective treatment or prophylaxis of influenza in children markedly reduces the incidence of acute otitis media and antibiotic usage during the flu season.

PARAINFLUENZA

Parainfluenza viruses (types 1–4) are the most important cause of croup. Most infants are infected with type 3 within the first 3 years of life, often in the first year. Infection with types 1 and 2 is experienced gradually over the first 5 years of life. Types 1 and 2 occur in the fall; type 3 appears annually, with a peak in the spring or summer. Most primary infections are symptomatic and frequently involve the lower respiratory tract.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical diseases include febrile upper respiratory infection (especially in older children with re-exposure), laryngitis, tracheobronchitis, croup, and bronchiolitis (second most common cause after respiratory syncytial virus). The relative incidence of these manifestations is type-specific. Parainfluenza viruses (especially type 1) cause 65% of cases of croup in young children, 25% of tracheobronchitis, and 50% of laryngitis. Types 1 and 2 are more likely to cause bronchiolitis. Pneumonia oc-

curs in infants and immunodeficient children, and it leads to particularly high mortality among stem cell recipients. Onset is acute. Most children are febrile. Symptoms of upper respiratory tract infection often accompany croup.

B. LABORATORY FINDINGS

Diagnosis is often based on clinical findings. These viruses can be identified by conventional or rapid culture techniques (48 hours), by direct immunofluorescence on nasopharyngeal epithelial cells in respiratory secretions (< 3 hours), or by PCR (< 48 hours).

Differential Diagnosis

Parainfluenza-induced respiratory syndromes are difficult to distinguish from those caused by other respiratory viruses. Croup must be distinguished from epiglottitis caused by *Haemophilus influenzae* (abrupt onset, toxicity, drooling, dyspnea, little cough, left shift of blood smear, and a history of inadequate immunization).

Treatment

No specific therapy or vaccine is available. Croup management is discussed in Chapter 18. Ribavirin is active in vitro and has been used in immunocompromised children, but its efficacy is unproved.

RESPIRATORY SYNCYTIAL VIRUS DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diffuse wheezing and tachypnea following upper respiratory symptoms in an infant (bronchiolitis).
- Epidemics in late fall to early spring (January–February peak).
- Hyperinflation on chest radiograph.
- RSV antigen detected in nasal secretions.

General Considerations

RSV is the most important cause of lower respiratory tract illness in young children, accounting for more than 70% of cases of bronchiolitis and 40% of cases of pneumonia. Outbreaks occur annually, and attack rates are high; 60% of children are infected in the first year of life, and 90% by age 2 years. During peak season (cold weather in temperate climates), the clinical diagnosis of RSV infection in infants with bronchiolitis is as accurate as most laboratory tests. Despite the presence of serum antibody, reinfection is common. Distinct genotypes predominate in a community. Yearly shift in these is a partial explanation for reinfection. However, reinfection generally causes only upper respiratory symptoms in anatomically normal children. No vaccine is available. Immunosuppressed patients may develop progressive severe pneumonia. Children with congenital heart disease with increased pulmonary blood flow, children with chronic lung disease (eg, cystic fibrosis), and premature infants younger than age 6 months are also at higher risk for severe illness.

Clinical Findings

A. SYMPTOMS AND SIGNS

Initial symptoms are those of upper respiratory infection. Low-grade fever may be present. The classic disease is bronchiolitis, characterized by diffuse wheezing, variable fever, cough, tachypnea, difficulty feeding, and, in severe cases, cyanosis. Hyperinflation, crackles, prolonged expiration, wheezing, and retractions are present. The liver and spleen may be palpable because of lung hyperinflation but are not enlarged. The disease usually lasts 3–7 days in previously healthy children. Fever is present for 2–4 days; it does not correlate with pulmonary symptoms and may be absent during the height of lung involvement.

Apnea may be the presenting manifestation, especially in premature infants, in the first few months of life; it usually resolves after a few days, often being replaced by obvious signs of bronchiolitis. No explanation for apnea has been found.

RSV infection in subsequent years is more likely to cause tracheobronchitis or upper respiratory tract infection. Exceptions are immunocompromised hosts and children with severe chronic lung or heart disease, who may have especially severe or prolonged primary infections and are subject to additional attacks of severe pneumonitis.

B. LABORATORY FINDINGS

Rapid detection of RSV antigen in nasal or pulmonary secretions by fluorescent antibody staining or ELISA requires only several hours and is more than 90% sensi-

tive and specific. Rapid tissue culture methods take 48 hours and have comparable sensitivity.

C. IMAGING

Diffuse hyperinflation and peribronchiolar thickening are most common; atelectasis and patchy infiltrates also occur in uncomplicated infection, but pleural effusions are rare. Consolidation (usually subsegmental) occurs in 25% of children with lower respiratory tract disease.

Differential Diagnosis

Although almost all cases of bronchiolitis are due to RSV during an epidemic, other viruses, particularly human metapneumovirus, cannot be excluded. Mixed infections with other viruses, chlamydiae, or bacteria can occur. Wheezing may be due to asthma, a foreign body, or other airway obstruction. RSV infection may closely resemble chlamydial pneumonitis when fine crackles are present and fever and wheezing are not prominent. The two may also coexist. Cystic fibrosis may resemble RSV infection; a positive family history or failure to thrive associated with hyponatremia or hypoalbuminemia should prompt a sweat chloride test. Pertussis should also be considered in this age group, especially if cough is prominent and if the infant is younger than age 6 months. A markedly elevated leukocyte count should suggest bacterial superinfection (neutrophilia) or pertussis (lymphocytosis).

Complications

RSV commonly infects the middle ear. Symptomatic otitis media is more likely when secondary bacterial infection is present (usually due to pneumococci or *H influenzae*). This is the most common complication (10–20%). However, bacterial pneumonia occurs in only 0.5–1% of hospitalized patients. Sudden exacerbations of fever and leukocytosis should suggest bacterial infection. Respiratory failure or apnea may require mechanical ventilation, but occurs in less than 2% of hospitalized previously healthy full-term infants. Cardiac failure may occur as a complication of pulmonary disease or myocarditis. Respiratory syncytial virus—as well as parainfluenza and influenza viruses—commonly causes exacerbations of asthma. Nosocomial infection is so common during outbreaks that elective hospitalization or surgery, especially for those with underlying illness, should be postponed. Well-designed hospital programs to prevent nosocomial spread are imperative (see next section).

Treatment & Prevention

Children who are very hypoxic or cannot feed because of respiratory distress must be hospitalized and given

humidified oxygen and tube or intravenous feedings. Antibiotics, decongestants, and expectorants are of no value in routine infections. Such children should be kept in respiratory isolation. Cohorting ill infants in respiratory isolation during peak season (with or without rapid diagnostic attempts) and emphasizing good hand-washing may greatly decrease nosocomial transmission.

The utility of bronchodilator therapy has not been consistently demonstrated. Often a trial of bronchodilator therapy is given to determine response and is subsequently discontinued if there is no improvement. Racemic epinephrine occasionally works when albuterol fails. The use of corticosteroids is also controversial. A meta-analysis of numerous studies indicates a significant effect on hospital stay, especially in those most ill at the time of treatment. The use of steroids in the emergency room appears to speed improvement and prevent hospitalization.

Ribavirin is the only licensed antiviral therapy used for RSV infection. It is given by continuous aerosolization (6 g in a 300-mL vial of water) by a special nebulizer for 12–18 hours of every day for 3–5 days. This agent has minimal effect on virus shedding. There is great controversy about its efficacy, and its use is infrequent in infants without significant anatomic or immunologic defects. At best, there is a very modest effect on disease severity in immunocompetent infants with no underlying anatomic abnormality. Even in high-risk infants, clinical response to ribavirin therapy was not demonstrated in several studies. Nevertheless, ribavirin is sometimes used in severely ill children who are immunologically or anatomically compromised, in those with severe cardiac disease, and in those with evidence of severe RSV infection. Bronchospasm may be exacerbated by this drug, although randomized trials do not show a deterioration of pulmonary function in patients receiving ribavirin.

Monthly intramuscular administration of humanized RSV monoclonal antibody is now recommended to prevent severe disease in high-risk patients during epidemic periods. Monthly administration should be considered during the RSV season for high-risk children, as described in Chapter 9.

Use of passive immunization for immunocompromised children is logical but not established. RSV antibody is not effective for treatment of established infection.

Prognosis

Although mild bronchiolitis does not produce long-term problems, 30–40% of patients hospitalized with this infection will wheeze later in childhood. Chronic

restrictive lung disease and bronchiolitis obliterans are rare sequelae.

HUMAN METAPNEUMOVIRUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cough, coryza, sore throat.
- Bronchiolitis.
- Positive hMPV PCR in respiratory secretion.

General Considerations

After its discovery in 2001, human metapneumovirus (hMPV) was rapidly identified as a common agent of respiratory tract infections that is very similar to RSV in epidemiologic and clinical characteristics. Like RSV, parainfluenza, mumps, and measles, hMPV belongs to the paramyxovirus family. Humans are its only known reservoir. Seroepidemiologic surveys indicate that the virus has worldwide distribution. More than 90% of children contract hMPV infection by age 5 years, typically during late autumn through early spring outbreaks. hMPV accounts for 15–25% of the cases of bronchiolitis and pneumonia in children younger than 2 years of age. Older children and adults can also develop symptomatic infection.

Clinical Characteristics

A. SIGNS AND SYMPTOMS

The most common symptoms are fever, cough, rhinorrhea, and sore throat. Bronchiolitis and pneumonia occur in 40–70% of the children who acquire hMPV before the age of 2 years. Asymptomatic infection is uncommon. Other manifestations include otitis, conjunc-

tivitis, diarrhea, and myalgia. Acute wheezing has been associated with hMPV in children of all ages, raising the possibility that this virus, like RSV, might trigger reactive airway disease. Dual infection with hMPV and RSV or other respiratory viruses seems to be a common occurrence and may increase morbidity and mortality.

B. IMAGING STUDIES

Lower respiratory tract infection frequently shows hyperinflation and patchy pneumonitis on chest radiographs.

C. LABORATORY DIAGNOSIS

The virus has very selective tissue culture tropism, which accounts for its late discovery in spite of its presence in archived specimens from the mid-1900s. The preferred method of diagnosis is PCR performed on respiratory specimens. Antibody tests are available, but are most appropriately used for epidemiologic studies.

Prognosis & Treatment

No antiviral therapies are available to treat hMPV. Children with lower respiratory tract disease may require hospitalization and ventilatory support, but less frequently than with RSV-associated bronchiolitis. Duration of hospitalization with hMPV is typically shorter than with RSV.

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Suspected case

- *Febrile illness of unknown etiology with temperature above 38°C.*

AND

- *One or more clinical findings of respiratory illness (eg, cough, SOB, difficulty breathing, hypoxia).*

AND

- *Travel within 10 days of symptom onset to an area with documented/suspected community transmission of SARS.*

OR

- *Close contact within 10 days of onset of symptoms with a person with known or suspected SARS.*

Probable Case

- *Suspected case definition plus radiographic evidence of pneumonia.*

OR

- *Autopsy evidence of acute respiratory distress syndrome or pneumonia.*

General Considerations

A new cause of atypical pneumonia arose in Asia in late 2002. Because of its severity it was named severe acute respiratory syndrome (SARS). During the following half year more than 8500 cases were documented. Many other countries reported cases from travelers, including 100 in the United States. A coronavirus (SARS-CoV) was isolated as the causative agent. This virus probably was acquired from indigenous wild animals sold in markets. Subsequent spread among close contacts, as well as within hospitals and by international travelers, extended the epidemic.

Clinical Findings

A. SYMPTOMS AND SIGNS

Initially, fever is accompanied by malaise, chills, headache, myalgia, dyspnea, and cough. Abnormal chest auscultation is noted in only 25% of cases and often is less prominent than would be expected from the chest radiograph. In two thirds of patients the pulmonary symptoms and signs progress, hypoxia occurs, and 20–30% require intensive care. Fatal respiratory failure ensues in a third to a half of these. A watery diarrhea is prominent in one quarter of the patients. The incubation period is 4–7 days (range is 2–10 days). The peak severity occurs at about 2 weeks after onset.

B. LABORATORY

Leukopenia, lymphopenia, and thrombocytopenia occur in many patients. Lactate dehydrogenase (LDH), aspartate aminotransferase, and creatinine phosphokinase are often elevated. However, none of these changes are diagnostic. Virus can be isolated from respiratory secretions, saliva, urine, and feces. An RT-PCR is useful for diagnosis within 5 days of onset. Antibody can be detected by immunofluorescence assay at 10–14 days and by EIA about a week later.

C. IMAGING

Most patients have an abnormal radiograph when first seen, typically with ground-glass opacities or focal con-

solidation. In severe cases this rapidly progresses to multiple bilateral consolidations.

Differential Diagnosis

The initial onset is similar with that of other causes of atypical pneumonia (eg, *Mycoplasma*, *Chlamydia*, Q fever, *Legionella*, *C psittaci*, other viruses [especially influenza]). SARS differs from *Mycoplasma* and *Chlamydia* infections in the absence of significant coryza and sore throat. The seasonality of some viruses will suggest their exclusion from the diagnosis. The travel and contact history is a key factor in the diagnosis of SARS.

Treatment

The management is largely supportive. Since no established therapy exists, potential approaches are still evolving. A SARS-specific immunoglobulin is under study.

Prevention

Detailed surveillance and quarantine measures have evolved. These appear to have been important in limiting outbreaks. In addition, since spread within hospitals has been prominent, infection control and patient care rules for SARS are now in place.

Prognosis

Ten to 20% of hospitalized cases are fatal. This rate is greatest in elderly people and those with other underlying illnesses. Children have milder disease and fewer radiographic abnormalities.

INFECTIONS DUE TO ENTEROVIRUSES

Enteroviruses are a major cause of illness in young children. The multiple types are physically and biochemically similar and may produce identical syndromes. The multiplicity of types makes vaccine development impractical and has hindered development of antigen detection and serologic tests. However, common RNA se-

quences and group antigens have led to diagnostic tests for viral nucleic acid and proteins. A PCR assay is available in many medical centers, but tissue culture is the most commonly used diagnostic method for echoviruses, polioviruses, and coxsackie B viruses. Because cultures may turn positive in 2–4 days, they should be inoculated promptly and may be clinically useful, particularly in cases of meningoencephalitis. Many coxsackie A viruses fail to grow.

Transmission is fecal–oral or from upper respiratory secretions. Multiple enteroviruses circulate in the community at any one time; summer–fall outbreaks are common in temperate climates, but infections are seen year-round. After poliovirus, coxsackie B virus is most virulent, followed by echovirus. Neurologic, cardiac, and overwhelming neonatal infections are the most severe forms of illness.

ACUTE FEBRILE ILLNESS

Accompanied by nonspecific upper respiratory or enteric symptoms, sudden onset of fever and irritability in infants or young children is often enteroviral in origin, especially in late summer and fall. More than 90% of enteroviral infections are not distinctive. Occasionally a petechial rash is seen; more often a diffuse maculopapular or morbilliform eruption (often prominent on palms and soles) occurs on the second to fourth day of fever. Rapid recovery is the rule. More than one febrile enteroviral illness can occur in the same patient in one season. The leukocyte count is usually normal. Infants, because of fever and irritability, may undergo an evaluation for bacteremia or meningitis and be hospitalized to rule out sepsis. Approximately one half of these infants have aseptic meningitis. In the summer months enterovirus infection is more likely than human herpesvirus 6 to cause an acute medical visit for fever. Duration of illness is 4–5 days.

RESPIRATORY TRACT ILLNESSES

1. Febrile Illness with Pharyngitis

This syndrome is most common in older children, who complain of headache, sore throat, myalgia, and abdominal discomfort. The usual duration is 3–4 days. Vesicles or papules may be seen in the pharynx. There is no exudate. Occasionally, enteroviruses are the cause of croup, bronchitis, or pneumonia. They may also exacerbate asthma.

2. Herpangina

Herpangina is characterized by an acute onset of fever and posterior pharyngeal grayish white vesicles that quickly form ulcers (< 20 in number), often linearly arranged on the posterior palate, uvula, and tonsillar pillars. Bilateral faucial ulcers may also be seen. Dysphagia, vomiting, abdominal pain, and anorexia also occur and, rarely, parotitis or vaginal ulcers. Symptoms disappear in 4–5 days. The epidemic form is due to a variety of coxsackie A viruses; coxsackie B viruses and echoviruses cause sporadic cases.

The differential diagnosis includes primary herpes simplex gingivostomatitis (ulcers are more prominent anteriorly, and gingivitis is present), aphthous stomatitis (fever absent, recurrent episodes, anterior lesions), trauma, hand-foot-and-mouth disease (see later discussion), and Vincent angina (painful gingivitis spreading from the gum line, underlying dental disease). If the enanthema is missed, tonsillitis might be incorrectly diagnosed.

3. Acute Lymphonodular Pharyngitis

Coxsackievirus A10 has been associated with a febrile pharyngitis characterized by nonulcerative yellow-white posterior pharyngeal papules in the same distribution as herpangina. The duration is 1–2 weeks; therapy is supportive.

4. Pleurodynia (Bornholm Disease, Epidemic Myalgia)

Caused by coxsackie B virus (epidemic form) or many nonpolio enteroviruses (sporadic form), pleurodynia is associated with an abrupt onset of unilateral or bilateral spasmodic pain of variable intensity over the lower ribs or upper abdomen. Associated symptoms include headache, fever, vomiting, myalgias, and abdominal and neck pain. Physical findings include fever, chest muscle tenderness, decreased thoracic excursion, and occasionally a friction rub. The chest radiograph is normal. Hematologic tests are nondiagnostic. The illness generally lasts less than 1 week.

This is a disease of muscle, but the differential diagnosis includes bacterial pneumonia, empyema, tuberculosis, and endemic fungal infections (all excluded radiographically and by auscultation), costochondritis (no fever or other symptoms), and a variety of abdominal problems, especially those causing diaphragmatic irritation.

There is no specific therapy. Potent analgesic agents and chest splinting alleviate the pain.

RASHES (Including Hand-Foot-and-Mouth Disease)

The rash may be macular, maculopapular, urticarial, scarlatiniform, petechial, or vesicular. One of the most characteristic is that of hand-foot-and-mouth disease (caused by coxsackieviruses, especially types A5, A10, and A16), in which vesicles or red papules are found on the tongue, oral mucosa, hands, and feet. Often they appear near the nails and on the heels. Associated fever, sore throat, and malaise are mild. The rash may appear when fever abates, simulating roseola.

Cardiac Involvement

Myocarditis and pericarditis may be caused by a number of nonpolio enteroviruses, particularly type B coxsackieviruses. Most commonly, upper respiratory symptoms are followed by substernal pain, dyspnea, and exercise intolerance. A friction rub or gallop may be detected. Ultrasound will define ventricular dysfunction, and electrocardiography may show pericarditis or ventricular irritability. Creatine kinase may be elevated. The disease may be mild or fatal; most children recover completely. In infants, other organs may be involved at the same time; in older patients, cardiac disease is usually the sole manifestation (see Chapter 19 for therapy). Enteroviral RNA is present in cardiac tissue in some cases of dilated cardiomyopathy or myocarditis; the significance of this finding is unknown. Epidemics of enterovirus 71, which occur in Asia, as well as sporadic cases in the United States, are associated with severe left ventricular dysfunction and pulmonary edema following typical mucocutaneous manifestations of enterovirus infection.

Severe Neonatal Infection

Sporadic and nosocomial nursery cases of severe systemic enteroviral disease occur. Clinical manifestations include combinations of fever, rash, pneumonitis, encephalitis, hepatitis, gastroenteritis, myocarditis, pancreatitis, and myositis. The infants, usually younger than 1 week old, may appear septic, with cyanosis, dyspnea, and seizures. The differential diagnosis includes bacterial and herpes simplex infections, necrotizing enterocolitis, other causes of heart or liver failure, and metabolic diseases. Diagnosis is suggested by the finding of cerebrospinal fluid (CSF) mononuclear pleocytosis and confirmed by the isolation of virus or detection of enteroviral RNA from urine, stool, CSF, or pharynx. Therapy is supportive. IVIG is often administered, but its value is uncertain. Passively acquired maternal antibody may protect newborns from severe disease. For this reason, labor should not be induced in pregnant women near term who have suspected enteroviral dis-

ease. Specific antiviral therapy (pleconaril) is being evaluated for severe enteroviral infection.

Huang F-L et al: Left ventricular dysfunction in children with fulminant enterovirus 71 infection: An evaluation of the clinical course. *Clin Infect Dis* 2002;34:1020 [PMID: 11880970].

CENTRAL NERVOUS SYSTEM ILLNESSES

1. Poliomyelitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Inadequate immunization or underlying immune deficiency.*
- *Headache, fever, muscle weakness.*
- *Aseptic meningitis.*
- *Asymmetrical, flaccid paralysis; muscle tenderness and hyperesthesia; intact sensation; late atrophy.*

General Considerations

Poliovirus infection is subclinical in 90–95% of cases; it causes nonspecific febrile illness in about 5% of cases and aseptic meningitis, with or without paralytic disease, in 1–3%. In endemic areas, most older children and adults are immune because of prior inapparent infections. Occasional cases in the United States occur in patients who have traveled to foreign countries. Most cases were in immunodeficient patients who received the oral poliovirus vaccine (OPV) or were exposed to recent vaccinees. Severe poliovirus infection was a rare complication of OPV vaccination as a result of reversion of the vaccine virus. The incidence of vaccine-associated paralytic poliomyelitis (VAPP) in the United States was 1:750,000 and 1:2.4 million doses for the first and second dose of OPV, respectively. Although rare, VAPP became more common than wild-type poliomyelitis in the United States in the 1980s. This led to change in the recommended immunization regimen, substituting inactivated poliovaccine (IPV) for OPV (see Chapter 9).

Clinical Findings

A. SYMPTOMS AND SIGNS

The initial symptoms are fever, myalgia, sore throat, and headache for 2–6 days. In less than 10% of infected

children, several symptom-free days are followed by recurrent fever and signs of aseptic meningitis: headache, stiff neck, spinal rigidity, and nausea. Mild cases resolve completely. In only 1–2% of these children does high fever, severe myalgia, and anxiety portend progression to loss of reflexes and subsequent flaccid paralysis. Sensation remains intact, although hyperesthesia of skin overlying paralyzed muscles is common and pathognomonic.

Paralysis is usually asymmetrical. Proximal limb muscles are more often involved than distal, and lower limb involvement is more common. Bulbar involvement affects swallowing, speech, and cardiorespiratory function and accounts for most deaths. Bladder distention and marked constipation characteristically accompany lower limb paralysis. Paralysis is usually complete by the time the temperature normalizes. Weakness often resolves completely. Atrophy is usually apparent by 4–8 weeks. Most improvement of muscle paralysis will take place within 6 months.

B. LABORATORY FINDINGS

In patients with meningeal symptoms, the CSF contains up to several hundred leukocytes (mostly lymphocytes) per microliter; the glucose level is normal, and protein concentration is mildly elevated. Poliovirus is easy to grow in cell culture and can be readily differentiated from other enteroviruses. It is rarely isolated from spinal fluid but is often present in the throat and stool for several weeks following infection. Paired serology is also diagnostic. Laboratory methods are available to differentiate wild from attenuated vaccine isolates.

Differential Diagnosis

Aseptic meningitis due to poliovirus is indistinguishable from that due to other viruses. Paralytic disease in the United States is usually due to nonpolio enteroviruses. Polio may resemble Guillain-Barré syndrome (variable sensory loss, symmetrical loss of function; minimal pleocytosis, high protein concentration in spinal fluid), polyneuritis (sensory loss), pseudoparalysis due to bone or joint problems (eg, trauma, infection), botulism, or tick paralysis.

Complications & Sequelae

Complications are the result of the acute and permanent effects of paralysis. Respiratory, pharyngeal, bladder, and bowel malfunction are most critical. Deaths are usually due to complications arising from respiratory dysfunction. Limbs injured near the time of infection, such as by intramuscular injections, excessive prior use, or trauma, tend to be most severely involved and have the worst prognosis for recovery (provocation

paralysis). Postpolio muscular atrophy occurs in 30–40% of paralyzed limbs 20–30 years later, characterized by increasing weakness and fasciculations in previously affected, partially recovered limbs.

Treatment & Prognosis

Therapy is supportive. Bed rest, fever and pain control (heat therapy is helpful), and careful attention to progression of weakness (particularly of respiratory muscles) are important. No intramuscular injections should be given during the acute phase. Intubation or tracheostomy for secretion control and catheter drainage of the bladder may be needed. Assisted ventilation and enteral feeding may also be needed. Pleconaril, which is an antiviral drug active against most enteroviruses, has no effect on polioviruses. Postpolio paralysis is mild in about 30%, permanent in 15%, and results in death in 5–10%. Disease is worse in adults and pregnant women than in children.

2. Nonpolio Viral Meningitis

Nonpolio enteroviruses cause over 80% of cases of aseptic meningitis at all ages. In the summer and fall, multiple cases may be seen associated with circulation of neurotropic strains. Nosocomial outbreaks also occur.

Clinical Findings

The usual enteroviral incubation period is 4–6 days. Because many enteroviral infections are subclinical or not associated with central nervous system (CNS) symptoms, a history of contact with a patient with meningitis is unusual. Neonates may acquire infection from maternal blood, vaginal secretions, or feces at birth; occasionally the mother has had a febrile illness just prior to delivery.

A. SYMPTOMS AND SIGNS

Onset is usually acute with variable fever, marked irritability, and lethargy in infants. Incidence is much greater in children younger than age 1 year. Older children also describe frontal headache, photophobia, and myalgia. Abdominal pain, diarrhea, and vomiting may occur. The incidence of rash varies with the infecting strain. If rash occurs, it is usually seen after several days of illness and is diffuse, macular or maculopapular, occasionally petechial, but not purpuric. Oropharyngeal vesicles and rash on the palms and soles suggest an enterovirus. The anterior fontanelle may be full. Meningismus may be present. The illness may be biphasic, with nonspecific symptoms and signs preceding those related to the CNS. In older children, it is easier to

demonstrate meningeal signs. Seizures are unusual, and focal neurologic findings, which are rare, should lead to a search for an alternative cause. Frank encephalitis, which is also uncommon at any age, occurs most often in neonates. Because of the overall frequency of enteroviral disease in children, 10–20% of all cases of encephalitis of proved viral origin are caused by enteroviruses. In some areas of the world epidemics of enterovirus 71 that begin with typical mucocutaneous manifestations of enteroviruses are complicated by severe brainstem encephalitis and polio-like flaccid paralysis. Enterovirus 70 outbreaks have resulted in hemorrhagic conjunctivitis together with paralytic poliomyelitis. Such cases of enterovirus are now appearing in the United States. Other nonpolio enteroviruses cause sporadic cases of acute motor weakness similar to that seen with poliovirus infection. Children with congenital immune deficiency, especially agammaglobulinemia, are subject to chronic enteroviral meningoencephalitis that is often fatal or associated with severe sequelae.

B. LABORATORY FINDINGS

Blood leukocyte counts are nonspecific and often normal. The spinal fluid leukocyte count is 100–1000/ μ L. Early in the illness, polymorphonuclear cells predominate; a shift to mononuclear cells occurs within 8–36 hours. In about 95% of cases, spinal fluid parameters include a total leukocyte count less than 3000/ μ L, protein less than 80 mg/dL, and glucose more than 60% of serum values. Marked deviation from any of these findings should prompt consideration of another diagnosis (see following section). The syndrome of inappropriate secretion of antidiuretic hormone may occur but is rarely clinically significant.

Culture of CSF may yield an enterovirus within a few days (<70%); virus may be found in acellular spinal fluids. PCR for enteroviruses is a useful diagnostic method in many centers (sensitivity > 90%). This test can give an answer within 24–48 hours. Isolation of an enterovirus from throat or stool suggests but does not prove enteroviral meningitis. Vaccine poliovirus present in feces in infants being evaluated for aseptic meningitis (outside of the United States) may confuse the diagnosis but can usually be distinguished by growth characteristics.

C. IMAGING

Cerebral imaging is not often indicated; if done, it is usually normal. Subdural effusions, infarcts, edema, or focal abnormalities seen in bacterial meningitis are absent except for the rare case of focal encephalitis.

Differential Diagnosis

In the prevaccine era, mumps and polio were leading causes of aseptic meningitis, but now this is usually caused by enteroviruses, especially in the summer and fall. Other causative viruses are mosquito-borne viruses (flavivirus, bunyavirus). These are usually considered during an investigation of encephalitis, but many of them are more likely to cause isolated meningitis and should be considered when seasonal clusters of viral meningitis occur. Primary herpes simplex infection can cause aseptic meningitis in adolescents who have a genital herpes infection. In neonates, early herpes simplex meningoencephalitis may mimic enteroviral disease (see section on Infections Due to Herpesviruses). This is an important alternative diagnosis to exclude because of the need for urgent specific therapy. Lymphocytic choriomeningitis virus causes meningitis in children in contact with rodents (pet or environmental exposure). Meningitis occurs in some patients at the time of infection with human immunodeficiency virus (HIV).

Other causes of aseptic meningitis that may resemble enteroviral infection include partially treated bacterial meningitis (recent antibiotic treatment; CSF parameters resembling those seen in bacterial disease and bacterial antigen sometimes present); parameningeal foci of bacterial infection such as brain abscess, subdural empyema, mastoiditis (predisposing factors, glucose level in CSF may be lower, focal neurologic signs, and characteristic imaging); tumors or cysts (malignant cells detected by cytologic examination, a history of neurologic symptoms, higher protein concentration or lower glucose level in CSF); trauma (presence, without exception, of red blood cells, which may be erroneously assumed to be due to traumatic lumbar puncture but are crenated and fail to clear); vasculitis (other systemic or neurologic signs, found in older children); tuberculous or fungal meningitis (see Chapters 38 and 39); cysticercosis; parainfectious encephalopathies (*Mycoplasma pneumoniae*, cat scratch disease, respiratory viruses [especially influenza]); Lyme disease; leptospirosis; and rickettsial diseases.

Treatment & Prevention

No specific therapy exists. Infants are usually hospitalized, isolated, and treated with fluids and antipyretics. Moderately to severely ill infants are given appropriate antibiotics for bacterial pathogens until cultures are negative for 48–72 hours. This practice is changing somewhat, and hospital stay shortened, in areas where the PCR assay for enteroviruses is available. If patients—especially older children—are mildly ill, antibiotics may be withheld and the child observed. The illness usually lasts less than 1 week. Codeine compounds

or other strong pain relievers may be needed. C-reactive protein and lactate levels are usually low in the CSF of children with viral meningitis; both may be elevated with bacterial infection. With clinical deterioration, repeat lumbar puncture, cerebral imaging, neurologic consultation, and more aggressive diagnostic tests should be considered. Herpesvirus encephalitis is an important consideration in such cases, particularly in infants younger than age 1 month. Newborns often receive empiric acyclovir therapy until an etiologic diagnosis is made. Specific antiviral therapy (pleconaril) is under study for the treatment of severe enteroviral infections.

Measures to prevent enteroviral infection include good hygiene, scrupulous hand washing, and proper isolation in the hospital.

Prognosis

In general, enteroviral meningitis has no significant short-term neurologic or developmental sequelae. Developmental delay may follow severe neonatal infections. Unlike mumps, enterovirus infections rarely cause hearing loss.

INFECTIONS DUE TO HERPESVIRUSES

HERPES SIMPLEX

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Grouped vesicles on an erythematous base, typically in or around the mouth or genitals.*
- *Tender regional adenopathy, especially with primary infection.*
- *Fever and malaise with primary infection.*
- *Recurrent episodes in many patients.*

General Considerations

There are two types of herpes simplex viruses. Type 1 (HSV-1) causes most cases of oral, skin, and cerebral disease. Type 2 (HSV-2) causes most (80–85%) genital and congenital infections. Latent infection in sensory ganglia routinely follows primary infection. Recurrences may be spontaneous or induced by external events (eg, fever, menstruation, or sunlight) or immunosuppression. Transmission is by direct contact with infected secretions. Herpes simplex viruses are very susceptible to antiviral drugs.

Primary infection with HSV-1 often occurs early in childhood, although many adults (20–50%) have never been infected. Primary infection with HSV-1 is subclinical in 80% of cases and causes gingivostomatitis in the remainder. HSV-2, which is transmitted sexually, is also usually (65%) subclinical or produces mild, nonspecific symptoms. Infection with one type of HSV may prevent or attenuate clinically apparent infection with the other type, but individuals can be infected at different times with both HSV-1 and HSV-2. Recurrent episodes are due to reactivation of latent HSV.

Clinical Findings

The source of primary infection is often an asymptomatic excreter. Most previously infected individuals shed HSV at irregular intervals. At any one time (point prevalence), 2–4% of normal seropositive adults excrete HSV-1 in the saliva; the percentage is higher in recently infected children. HSV-2 shedding in genital secretions occurs with a point prevalence of 8–28%, depending on the method of detection (viral isolation vs PCR). A history of contact with an active HSV infection is unusual.

A. SYMPTOMS AND SIGNS

1. Gingivostomatitis—High fever, irritability, and drooling occur in infants. Multiple oral ulcers are seen on the tongue and on the buccal and gingival mucosa, occasionally extending to the pharynx. Pharyngeal ulcers may predominate in older children and adolescents. Diffusely swollen red gums that are friable and bleed easily are typical. Cervical nodes are swollen and tender. Duration is 7–14 days. Herpangina, aphthous stomatitis, thrush, and Vincent angina should be excluded.

2. Vulvovaginitis or urethritis—Genital herpes (especially HSV-2) in a prepubertal child should suggest sexual abuse. Vesicles or painful ulcers on the vulva, vagina, or penis and tender adenopathy are seen. Systemic symptoms (fever, flu-like illness, myalgia) are common with the initial episode. Painful urination may cause retention. Primary infections last 10–21 days. Le-

sions may resemble trauma, syphilis (ulcers are painless), or chancroid (ulcers are painful and nodes are erythematous and fluctuant) in the adolescent, and bullous impetigo, trauma, and severe chemical irritation in younger children.

3. Cutaneous infections—Direct inoculation onto cuts or abrasions may produce localized vesicles or ulcers. A deep HSV infection on the fingers (called herpetic whitlow) may be mistaken for a bacterial felon or paronychia; surgical drainage is of no value and is contraindicated. HSV infection of eczematous skin may result in extensive areas of vesicles and shallow ulcers (eczema herpeticum), which may be mistaken for impetigo or varicella.

4. Recurrent mucocutaneous infection—Recurrent oral shedding is usually asymptomatic. Perioral recurrences often begin with a prodrome of tingling or burning limited to the vermilion border, followed by vesiculation, scabbing, and crusting around the lips over the next 3–5 days. Intraoral lesions rarely recur. Fever, adenopathy, and other symptoms are absent. Recurrent cutaneous herpes most closely resembles impetigo; the latter is often outside the perinasal and perioral region, responds to antibiotics, yields a positive Gram stain, and *Streptococcus pyogenes* or *Staphylococcus aureus* can be isolated. Recurrent genital disease is common after the initial infection with HSV-2. The disease is shorter (5–7 days) and milder (mean, four lesions) and is not associated with systemic symptoms.

5. Keratoconjunctivitis—Keratoconjunctivitis may be part of a primary infection due to spread from infected saliva. Most cases are caused by reactivation of virus latent in the ciliary ganglion. Keratoconjunctivitis produces photophobia, pain, and conjunctival irritation. With recurrences, dendritic corneal ulcers may be demonstrable with fluorescein staining. Stromal invasion may occur. Steroids should never be used for unilateral keratitis without ophthalmologic consultation. Other causes of these symptoms include trauma, bacterial infections, and other viral infections (especially adenovirus if pharyngitis is present; bilateral involvement makes HSV unlikely) (see Chapter 15).

6. Encephalitis—Although unusual in infants outside the neonatal period, encephalitis may occur at any age, usually without cutaneous herpes lesions. In older children, HSV encephalitis can follow a primary infection, but often represents reactivation of latent virus. HSV is the most common cause of sporadic severe encephalitis. It is the most important because it can be treated with specific antiviral therapy. Fever, headache, behavioral changes, and neurologic deficits or focal seizures occur. Mild mononuclear pleocytosis is typically present along with an elevated protein concentration, which contin-

ues to rise on repeat lumbar punctures. In older children hypodense areas with a medial and inferior temporal lobe predilection are seen on CT scan, especially after 3–5 days, but the findings in infants may be more diffuse. Magnetic resonance imaging (MRI) is more sensitive and is positive sooner. Periodic focal epileptiform discharges are seen on electroencephalograms but are not diagnostic of HSV infection. Viral cultures of CSF are rarely positive. The PCR assay to detect HSV DNA in CSF is a sensitive and specific rapid test. Without early antiviral therapy, the prognosis is poor. The differential diagnosis includes mumps, mosquito-borne and other viral encephalitis, parainfectious and postinfectious encephalopathy, brain abscess, acute demyelinating syndromes, and bacterial meningoencephalitis.

7. Neonatal infections—Infection is acquired by ascending spread prior to delivery (5–10% of cases) or at the time of vaginal delivery from a mother with genital infection. Occasionally the infection is acquired in the postpartum period from oral secretions of family members or hospital personnel. A history of genital herpes in the mother is usually absent. Within a few days and up to 4 weeks, skin vesicles (especially at sites of trauma, such as where scalp monitors were placed) appear. Some infants have infections limited to the skin, eye or mouth. Other infants are acutely ill, presenting with jaundice, shock, bleeding, or respiratory distress. Some infants appear well initially, but dissemination of the infection to the brain or other organs becomes evident during the ensuing week if it is untreated. HSV infection (and empiric therapy) should be considered in newborns with the sepsis syndrome who are unresponsive to antibiotic therapy and have negative bacterial cultures. Skin lesions may be absent at the time of presentation. Some infected infants exhibit only neurologic symptoms at 2–3 weeks after delivery: apnea, lethargy, fever, poor feeding, or persistent overt seizures. The brain infection in these children is often diffuse and is best diagnosed by MRI. The skin lesions may resemble impetigo, bacterial scalp abscesses, or miliaria; some children may fail to develop skin lesions. Skin lesions may recur over weeks or months after recovery from the acute illness. Progressive culture-negative pneumonitis is another manifestation of neonatal HSV.

B. LABORATORY FINDINGS

With multisystem disease, abnormalities in platelets, clotting factors, and liver function tests are often present. A finding of lymphocytic pleocytosis and elevated CSF protein indicates aseptic meningitis or encephalitis. Virus may be cultured from infected epithelial sites (vesicles, ulcers, or conjunctival scrapings) and from in-

fectured tissue (skin, brain) obtained by biopsy. Cultures of CSF are positive in about 50% of neonatal cases, but uncommon in older children. HSV will be detected within 2 days by rapid tissue culture methods. Isolation from throat, eye, urine, or stool of a newborn is diagnostic. Vaginal culture of the mother may offer circumstantial evidence for the diagnosis, but may be negative.

Rapid diagnostic tests include immunofluorescent stains or ELISA to detect viral antigen. The PCR assay for HSV DNA is positive ($\approx 95\%$) in the CSF when there is brain involvement. Serum is often positive in the presence of multisystem disease.

Complications, Sequelae, & Prognosis

Gingivostomatitis may result in dehydration due to dysphagia; severe chronic oral disease and esophageal involvement may occur in immunosuppressed patients. Primary vulvovaginitis may be associated with aseptic meningitis, paresthesias, autonomic dysfunction due to neuritis (urinary retention, constipation), and secondary candidal infection. Extensive cutaneous disease (as in eczema) may be associated with dissemination, and bacterial superinfection. Keratitis may result in corneal opacification or perforation. Untreated encephalitis is fatal in 70% of patients and causes severe damage in most of the remainder. When acyclovir treatment is instituted early, 20% die and 40% are neurologically impaired. Disseminated neonatal infection is often fatal in spite of therapy, and survivors are often impaired.

Treatment

A. SPECIFIC MEASURES

HSV is sensitive to antiviral therapy.

1. Topical antivirals—Antivirals are most effective for corneal disease and include 1% trifluridine, 5% acyclovir, and 3% vidarabine. Trifluridine appears superior; cure rates over 95% are reported. These agents should be used with the guidance of an ophthalmologist.

2. Mucocutaneous HSV infections—These respond to administration of oral nucleoside analogs (acyclovir, valacyclovir, or famciclovir). The main indications are severe genital HSV infection in adolescents (see Chapter 40) and severe gingivostomatitis in young children. Antiviral therapy is beneficial for primary disease when begun early. Recurrent disease rarely requires therapy. Frequent genital recurrences may be suppressed by oral administration of nucleoside analogs, but this approach should be used sparingly. Other forms of severe cutaneous disease, such as eczema herpeticum, respond to these antivirals. Intravenous acyclovir may be required

when disease is extensive in immunocompromised children (500 mg/m² every 8 hours). Oral acyclovir, which is available in suspension, is also used within 72–96 hours for severe primary gingivostomatitis in immunocompetent young children (10 mg/kg per dose four times a day for 5–7 days). Antiviral therapy does not alter the incidence or severity of subsequent recurrences of oral or genital infection. Development of resistance to antivirals is very rare after treating immunocompetent patients, but is increasingly reported in immunocompromised patients who receive frequent and prolonged therapy.

3. Encephalitis—This is treated with intravenous acyclovir 500 mg/m² every 8 hours for 21 days.

4. Neonatal infection—Newborns receive 20 mg/kg intravenous acyclovir every 8 hours for 21 days (14 days if infection is limited to skin, eye, or mouth).

B. GENERAL MEASURES

1. Gingivostomatitis—Gingivostomatitis is treated with pain relief and temperature control. Maintaining hydration is important because of the long duration of illness (7–14 days). Nonacidic, cool fluids are best. Topical anesthetic agents (eg, viscous lidocaine or an equal mixture of kaolin–attapulgate (Kaopectate), diphenhydramine, and viscous lidocaine may be used as a mouthwash for older children who will not swallow it; ingested lidocaine may be toxic to infants or may lead to aspiration. Antiviral therapy is indicated in normal hosts with severe disease. Antibiotics are not helpful.

2. Genital infections—Genital infections require pain relief, assistance with voiding (warm baths, topical anesthetics, rarely catheterization), and psychological support. Lesions should be kept clean; drying decreases the potential for spread and may shorten the duration of symptoms. Sexual contact should be avoided during the interval from prodrome to crusting stages.

3. Cutaneous lesions—Skin lesions should be kept clean, dry, and covered if possible to prevent spread. Systemic analgesics may be helpful. Secondary bacterial infection is uncommon in patients with lesions on the mucosa or involving small areas. Secondary infection should be considered and treated if necessary (usually with an antistaphylococcal agent) in patients with more extensive lesions. Candidal superinfection occurs in 10% of women with primary genital infections.

4. Recurrent cutaneous disease—Recurrent disease is usually milder than primary infection. Sun block lip balm helps prevent labial recurrences after intense sun exposure. There is no evidence that the many popular topical or vitamin therapies are efficacious.

5. Keratoconjunctivitis—An ophthalmologist should be consulted regarding the use of cycloplegics, anti-inflammatory agents, local debridement, and other therapies.

6. Encephalitis—Extensive support will be required for obtunded or comatose patients. Rehabilitation and psychological support are often needed for survivors.

7. Neonatal infection—The affected infant should be isolated and given acyclovir. Cesarean section is indicated if the mother has obvious cervical or vaginal lesions, especially if these represent primary infection (35–50% transmission rate). With infants born vaginally to mothers who have active lesions, appropriate cultures should be obtained at 24–48 hours after birth, and the infants should be observed closely. Treatment is given to babies whose culture results are positive or who have suggestive signs or symptoms. Babies born to mothers with obvious primary genital herpes should receive therapy before the culture results are known. For women with a history of genital herpes infection, but no genital lesions, vaginal delivery with peripartum cultures of maternal cervix is the standard. Clinical follow-up of the newborn is recommended when maternal culture results are positive. Repeated cervical cultures during pregnancy are not useful.

VARICELLA & HERPES ZOSTER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Varicella (chickenpox):

- Exposure to varicella or herpes zoster 10–21 days previously; no prior history of varicella.
- Widely scattered red macules and papules concentrated on the face and trunk, rapidly progressing to clear vesicles, pustules, and then crusting,

over 5–6 days. Variable fever and nonspecific systemic symptoms.

Herpes zoster (shingles):

- History of varicella.
- Local paresthesias and pain prior to eruption (more common in older children).
- Dermatomal distribution of grouped vesicles on an erythematous base.

General Considerations

Primary infection with varicella-zoster virus results in varicella, which almost always confers lifelong immunity; the virus remains latent in sensory ganglia. Herpes zoster, which represents reactivation of this latent virus, occurs in 15–20% of individuals some time in their life. The incidence of herpes zoster is highest in elderly individuals and in immunosuppressed patients. Spread of varicella from a contact is by respiratory secretions or fomites from vesicles or pustules, with a greater than 90% infection rate in susceptible persons. Herpes zoster is about one third as infectious. Over 95% of young adults with a history of varicella are immune, as are 90% of native-born Americans who are unaware of having had varicella. Many individuals from tropical or subtropical areas never have childhood exposure and are susceptible. Humans are the only reservoir.

Clinical Findings

Exposure to varicella or herpes zoster has usually occurred 14–16 days previously (range, 10–21 days). Contact may not have been recognized, since the index case is infectious 1–2 days before rash appears. Although varicella is the most distinctive childhood exanthem, inexperienced observers may mistake other diseases for varicella. A 1- to 3-day prodrome of fever, respiratory symptoms, and headache may occur, especially in older children. The preruleptive pain of herpes zoster may last several days and be mistaken for other illnesses.

A. SYMPTOMS AND SIGNS

1. Varicella—The usual case consists of mild systemic symptoms followed by crops of red macules that rapidly become small vesicles with surrounding erythema (described as a dew drop on a rose petal), form pustules, become crusted and then scab over, and leave no scar. The rash appears predominantly on the trunk and face. Lesions occur in the scalp, nose, mouth (where they are nonspecific ulcers), conjunctiva, and vagina. The magnitude of systemic symptoms usually parallels skin involvement. Up to five crops of lesions may be seen.

New crops usually stop forming after 5–7 days. Pruritus is often intense. If varicella occurs in the first few months of life, it is often mild as a result of persisting maternal antibody. Once crusting begins, the patient is no longer contagious.

2. Herpes zoster—The eruption of shingles involves a single dermatome, usually truncal or cranial. The rash does not cross the midline. Ophthalmic zoster may be associated with corneal involvement. The closely grouped vesicles, which resemble a localized version of varicella or herpes simplex, often coalesce. The duration is 7–10 days before crusting. Postherpetic neuralgia is rare in children. A few vesicles are occasionally seen outside the involved dermatome. Herpes zoster is a common problem in HIV-infected or other immunocompromised children. Herpes zoster is also common in children who had varicella in early infancy or whose mothers had varicella during pregnancy.

B. LABORATORY FINDINGS

Leukocyte counts are normal or low. Leukocytosis suggests secondary bacterial infection. The virus can be identified by fluorescent antibody staining of a lesion smear. Rapid culture methods take 48 hours. Diagnosis can be made with paired serology. Serum aminotransferase levels may be modestly elevated during normal varicella.

C. IMAGING

Varicella pneumonia classically produces numerous bilateral nodular densities and hyperinflation. This is very rare in immunocompetent children. Abnormal chest radiographs are seen more frequently in adults.

Differential Diagnosis

Varicella is usually distinctive. Similar rashes include those of coxsackievirus infection (fewer lesions, lack of crusting), impetigo (fewer lesions, smaller area, no classic vesicles, positive Gram stain, perioral or peripheral lesions), papular urticaria (insect bite history, nonvesicular rash), scabies (burrows, no typical vesicles), parapsoriasis (rare in children younger than age 10 years, chronic or recurrent, often a history of prior varicella), rickettsialpox (eschar where the mite bites, smaller lesions, no crusting), dermatitis herpetiformis (chronic, urticaria, residual pigmentation), and folliculitis. Herpes zoster is sometimes confused with a linear eruption of herpes simplex or a contact dermatitis (eg, *Rhus* dermatitis).

Complications & Sequelae

A. VARICELLA

Secondary bacterial infection with staphylococci or group A streptococci is most common, presenting as impetigo,

cellulitis or fasciitis, abscesses, scarlet fever, or sepsis. Bacterial superinfection occurs in 2–3% of children. Hospitalization rates associated with varicella are 1:750–1:1000 cases in children and 10-fold higher in adults.

Protracted vomiting or a change in sensorium suggests Reye syndrome or encephalitis. Because Reye syndrome usually occurs in patients who are also using salicylates, these should be avoided in patients with varicella. Encephalitis occurs in less than 0.1% of cases, usually in the first week of illness. It is usually limited to cerebellitis with ataxia, which resolves completely. Diffuse encephalitis can be severe.

Varicella pneumonia usually afflicts immunocompromised children (especially those with leukemia or lymphoma or those receiving high doses of steroids or chemotherapy) and adults; pregnant women may be at special risk. Cough, dyspnea, tachypnea, rales, and cyanosis occur several days after onset of rash. Varicella may be life-threatening in immunosuppressed patients. Their disease is complicated by severe pneumonitis, hepatitis, and encephalitis. Varicella exposure in such patients must be evaluated immediately for postexposure prophylaxis (see Chapter 9).

Hemorrhagic varicella lesions may be seen without other complications. This is most often caused by autoimmune thrombocytopenia, but hemorrhagic lesions can occasionally represent idiopathic disseminated intravascular coagulation (purpura fulminans).

Neonates born to mothers who develop varicella from 5 days before to 2 days after delivery are at high risk for severe or fatal (5%) disease and must be given varicella-zoster immune globulin (VZIG) and followed closely (see Chapter 9).

Varicella occurring during the first 20 weeks of pregnancy may cause (2% incidence) congenital infection associated with cicatricial skin lesions, associated limb anomalies, and cortical atrophy.

Unusual complications of varicella include optic neuritis, myocarditis, transverse myelitis, orchitis, and arthritis.

B. HERPES ZOSTER

Complications of herpes zoster include secondary bacterial infection, motor or cranial nerve paralysis (1 per 200 cases in adults), encephalitis, keratitis, and dissemination in immunosuppressed patients. These complications are rare in immunocompetent children, and they do not develop prolonged pain. Postherpetic neuralgia does occur in immunocompromised children.

Treatment

A. GENERAL MEASURES

Supportive measures include maintenance of hydration, administration of acetaminophen for discomfort, cool

soaks or antipruritics for itching (diphenhydramine, 1.25 mg/kg every 6 hours, or hydroxyzine, 0.5 mg/kg every 6 hours), and observance of general hygiene measures (keep nails trimmed and skin clean). Care must be taken to avoid overdosage with antihistaminic agents. Topical or systemic antibiotics may be needed for bacterial superinfection.

B. SPECIFIC MEASURES

Although acyclovir is more active against herpes simplex, it is the preferred drug for varicella and herpes zoster infections. Recommended parenteral acyclovir dosage for severe disease is 10 mg/kg (500 mg/m²) intravenously every 8 hours, each dose infused over 1 hour. Parenteral therapy should be started early in immunosuppressed patients or high-risk infected neonates. VZIG is of no value for established disease. The effect of oral acyclovir (80 mg/kg/d, divided in four doses) on varicella in immunocompetent children was modestly beneficial and nontoxic, but only when administered within 24 hour after the onset of varicella. Oral acyclovir should be used selectively in immunocompetent children (eg, when intercurrent illness is present; possibly when second attacks occur in the household or when the patient is an adolescent—both of which are associated with more severe disease) and in children with underlying chronic illnesses. Valacyclovir and famciclovir are superior antiviral agents because of better absorption; acyclovir is available as a pediatric suspension. Herpes zoster in an immunocompromised child should be treated with intravenous acyclovir when it is severe. Oral valacyclovir or famciclovir can be used in immunocompromised children when the nature of the illness and the immune status support this decision.

Prevention

VZIG is available for postexposure prevention of varicella in high-risk susceptible persons (see Chapter 9). Postexposure prophylaxis with acyclovir is effective when it is started at 8 or 9 days after exposure and is continued for 7 days. The live attenuated varicella vaccine should be given as part of routine childhood immunization, and “catch-up” immunization is recommended for all other susceptible children and adults. Varicella vaccine is also useful for postexposure prophylaxis when given within 3–5 days of the exposure.

Prognosis

Except for secondary bacterial infections, serious complications are rare and recovery complete in immunocompetent hosts.

Varicella-related deaths—United States, 2002. MMWR- Morb Mortal Weekly Rep 2002;52:545 [PMID: 12803193].

ROSEOLA INFANTUM (EXANTHEMA SUBITUM)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- High fever in a child age 6–36 months.
- Minimal toxicity.
- Rose-pink maculopapular rash appears when fever subsides.

General Considerations

Roseola infantum is a benign illness caused by human herpesviruses 6 (HHV-6) or 7 (HHV-7). HHV-6 is a major cause of acute febrile illness in young children. Its significance is its ability to mimic more serious causes of high fever and its role in inciting febrile seizures.

Clinical Findings

The most prominent historical feature is the abrupt onset of fever, often reaching 40.6°C, which lasts up to 8 days (mean, 4 days) in an otherwise mildly ill child. The fever then ceases abruptly, and a characteristic rash may appear. Roseola occurs predominantly in children age 6 months to 3 years, with 90% of cases occurring before the second year. HHV-7 infection tends to occur somewhat later in childhood. These viruses are the most common recognized cause of exanthematous fever in this age group and are responsible for 20% of emergency room visits by children age 6–12 months.

A. SYMPTOMS AND SIGNS

Mild lethargy and irritability may be present, but generally there is a dissociation between systemic symptoms and the febrile course. The pharynx, tonsils, and tympanic membranes may be injected. Conjunctivitis and pharyngeal exudate are notably absent. Diarrhea and vomiting occur in one third of patients. Adenopathy of the head and neck often occurs. The anterior fontanelle is bulging in one quarter of HHV-6-infected infants. If rash appears (20–30% incidence), it begins on the trunk and spreads to the face, neck, and extremities. Rose-pink macules or maculopapules, 2–3 mm in diameter, are nonpruritic, tend to coalesce, and disap-

pear in 1–2 days without pigmentation or desquamation. Rash may occur without fever.

B. LABORATORY FINDINGS

Leukopenia and lymphocytopenia are present early. Laboratory evidence of hepatitis occurs in some patients, especially adults.

Differential Diagnosis

The initial high fever may require exclusion of serious bacterial infection. The relative well-being of most children and the typical course and rash soon clarify the diagnosis. The erythrocyte sedimentation rate is normal. If the child has a febrile seizure, it is important to exclude bacterial meningitis. The CSF is normal in children with roseola. In children who receive antibiotics or other medication at the beginning of the fever, the rash may be attributed incorrectly to drug allergy.

Complications & Sequelae

Febrile seizures occur in 10% of patients (even higher percentages in those with HHV-7 infections). There is evidence that HHV-6 can directly infect the CNS, causing meningoencephalitis or aseptic meningitis. Multiorgan disease (pneumonia, hepatitis, bone marrow suppression, encephalitis) may occur in immunocompromised patients.

Treatment & Prognosis

Fever is managed readily with acetaminophen and sponge baths. Fever control should be a major consideration in children with a history of febrile seizures. Roseola infantum is otherwise entirely benign.

CYTOMEGALOVIRUS INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Primary Infection:

- Asymptomatic or minor illness in young children.
- Mononucleosis-like syndrome without pharyngitis in postpubertal individuals.

Congenital Infection:

- Intrauterine growth retardation.

- *Microcephaly with intracerebral calcifications and seizures.*
- *Retinitis and encephalitis.*
- *Hepatosplenomegaly with thrombocytopenia.*
- *“Blueberry muffin” rash.*
- *Sensorineural deafness.*

Immunocompromised Hosts:

- *Retinitis and encephalitis.*
- *Pneumonitis.*
- *Enteritis and hepatitis.*
- *Bone marrow suppression.*

General Considerations

Cytomegalovirus (CMV) is a ubiquitous herpesvirus transmitted by many routes. It can be acquired in utero following maternal viremia or postpartum from birth canal secretions or maternal milk. Young children are infected by the saliva of playmates; older individuals are infected by sexual partners (eg, from saliva, vaginal secretions, or semen). Transfused blood products and transplanted organs can be a source of CMV infection. Clinical illness is determined largely by the patient's immune competence. Immunocompetent individuals usually develop a mild self-limited illness, whereas immunocompromised children can develop severe, progressive, often multiorgan disease. In utero infection can be teratogenic.

1. In Utero Cytomegalovirus Infection

Approximately 0.5–1.5% of children are born with CMV infections acquired during maternal viremia. CMV infection is asymptomatic in over 90% of these children, who are usually born to mothers who had experienced reactivation of latent CMV infection during the pregnancy. Symptomatic infection occurs predominantly in infants born to mothers with primary CMV infection but can also result from recurrent, most likely, reinfection during pregnancy. Even when exposed to a primary maternal infection, less than 50% of fetuses are infected, and in only 10% of those infants is the infection symptomatic at birth. Primary infection in the first half of pregnancy poses the greatest risk for severe fetal damage.

Clinical Findings

A. SYMPTOMS AND SIGNS

Severely affected infants are born ill; they are often small for gestational age, floppy, and lethargic. They

feed poorly and have poor temperature control. Hepatosplenomegaly, jaundice, petechiae, seizures, and microcephaly are common. Characteristic signs are a distinctive chorioretinitis and periventricular calcification. A purpuric (so-called blueberry muffin) rash similar to that seen with congenital rubella may be present. The mortality rate is 10–20%. Survivors usually have significant sequelae, especially mental retardation, neurologic deficits, retinopathy, and hearing loss. Isolated hepatosplenomegaly or thrombocytopenia may occur. Even mildly affected children may subsequently manifest mental retardation and psychomotor delay. However, most infected infants (90%) are born to mothers with preexisting immunity who had a reactivation of latent CMV during pregnancy. These children have no clinical manifestations at birth. Of these, 10–15% develop sensorineural hearing loss, which is often bilateral and may appear several years after birth.

B. LABORATORY FINDINGS

In severely ill infants, anemia, thrombocytopenia, hyperbilirubinemia, and elevated aminotransferase levels are common. Lymphocytosis occurs occasionally. Pleocytosis and an elevated protein concentration are found in CSF. The diagnosis is readily confirmed by isolation of CMV from urine or saliva within 48 hours, using rapid culture methods combined with immunoassay. The presence in the infant of IgM-specific CMV antibodies suggests the diagnosis. Some commercial ELISA kits are 90% sensitive and specific for these antibodies.

C. IMAGING

Head radiologic exams may show microcephaly, periventricular calcifications, and ventricular dilation. These findings strongly correlate with neurologic sequelae and retardation. Long bone radiographs may show the “celery stalk” pattern characteristic of congenital viral infections. Interstitial pneumonia may be present.

Differential Diagnosis

CMV infection should be considered in any newborn who is seriously ill shortly after birth, especially once bacterial sepsis, metabolic disease, intracranial bleeding, and cardiac disease have been excluded. Other congenital infections to be considered in the differential diagnosis include toxoplasmosis (serology, more diffuse calcification of the CNS, specific type of retinitis, macrocephaly), rubella (serology, specific type of retinitis, cardiac lesions, eye abnormalities), enteroviral infections (time of year, maternal illness, severe hepatitis), herpes simplex (skin lesions, cultures, severe hepatitis), and syphilis (serology for both infant and mother, skin lesions, bone involvement).

Treatment & Prevention

Support is rarely required for anemia and thrombocytopenia. Most children with symptoms at birth have significant neurologic, intellectual, visual, or auditory impairment. Ganciclovir, 5 mg/kg every 12 hours, is recommended for children with severe, life- or sight-threatening disease if end-organ disease recurs or progresses. Duration is 2–3 weeks or until symptoms resolve. This approach decreases viral shedding and limits progression of symptoms, including hearing loss, during treatment. However, the therapeutic advantage is progressively lost over time after treatment is discontinued. Children who are asymptomatic at birth have a 10–15% incidence of hearing loss but few other sequelae. There is no evidence that early treatment prevents late-onset hearing loss. Delayed development and hearing loss should be looked for and treated as soon as possible.

2. Perinatal Cytomegalovirus Infection

CMV infection can be acquired from birth canal secretions or shortly after birth from maternal milk. In some socioeconomic groups, 10–20% of infants are infected at birth and excrete CMV for many months. Infection can also be acquired in the postnatal period from un-screened transfused blood products.

Clinical Findings

A. SYMPTOMS AND SIGNS

Ninety percent of immunocompetent infants infected by their mothers at birth develop subclinical illness (ie, virus excretion only) or a minor illness within 1–3 months. The remainder develop an illness lasting several weeks and characterized by hepatosplenomegaly, lymphadenopathy, and interstitial pneumonitis in various combinations. The severity of the pneumonitis may be increased by the simultaneous presence of *Chlamydia trachomatis*. Infants who receive blood products are often premature and immunologically impaired. If they are born to CMV-negative mothers and subsequently receive CMV-containing blood, they frequently develop severe infection and pneumonia after a 2- to 6-week incubation period.

B. LABORATORY FINDINGS

Lymphocytosis, atypical lymphocytes, anemia, and thrombocytopenia may be present, especially in premature infants. Liver function is abnormal. CMV can be isolated from urine and saliva. Secretions obtained at bronchoscopy contain CMV and epithelial cells bearing CMV antigens. Serum levels of CMV antibody rise significantly.

C. IMAGING

Chest radiographs show a diffuse interstitial pneumonitis in severely affected infants.

Differential Diagnosis

CMV infection should be considered as a cause of any prolonged illness in early infancy, especially if hepatosplenomegaly, lymphadenopathy, or atypical lymphocytosis is present. This must be distinguished from granulomatous or malignant diseases and from congenital infections (syphilis, toxoplasmosis, hepatitis B) not previously diagnosed. Other viruses (Epstein–Barr virus [EBV], HIV, adenovirus) can cause this syndrome. CMV is a recognized cause of viral pneumonia in this age group. Because asymptomatic CMV excretion is common in early infancy, care must be taken to establish the diagnosis and to rule out concomitant pathogens such as *Chlamydia* and RSV. Severe CMV infection in early infancy may indicate that the child has a congenital or acquired immune deficiency.

Treatment & Prevention

The self-limited disease of normal infants requires no therapy. Severe pneumonitis in premature infants requires oxygen administration and often intubation. Very ill infants should receive ganciclovir (6 mg/kg every 12 hours). CMV infection acquired by transfusion can be prevented by excluding CMV-seropositive blood donors. Milk donors should also be screened for prior CMV infection. It is likely that high-risk infants receiving large doses of IVIG for other reasons will be protected against severe CMV disease.

3. Cytomegalovirus Infection Acquired in Childhood & Adolescence

Young children are readily infected by playmates, especially because CMV continues to be excreted in saliva and urine for many months after infection. The cumulative annual incidence of CMV excretion by children in day care centers exceeds 75%. In fact, young children in a family are often the source of primary CMV infection of their mothers during subsequent pregnancies. An additional peak of CMV infection takes place when adolescents become sexually active. Sporadic acquisition of CMV occurs after blood transfusion and transplantation.

Clinical Findings

A. SYMPTOMS AND SIGNS

Most young children who acquire CMV are asymptomatic or have a minor febrile illness, occasionally with adenopathy. They provide an important reservoir of

virus shedders that facilitates spread of CMV. Occasionally a child may have prolonged fever with hepatosplenomegaly and adenopathy. Older children and adults, many of whom are infected during sexual activity, are more likely to be symptomatic in this fashion and can present with a syndrome that mimics the infectious mononucleosis syndrome that follows EBV infection (1–2 weeks of fever, malaise, anorexia, splenomegaly, mild hepatitis, and some adenopathy; see next section). This syndrome can also occur 2–4 weeks after transfusion of CMV-infected blood.

B. LABORATORY FINDINGS

In the CMV mononucleosis syndrome, lymphocytosis and atypical lymphocytes are common, as is a mild rise in aminotransferase levels. CMV is present in saliva and urine, and CMV DNA can be uniformly detected in plasma or blood.

Differential Diagnosis

In older children, CMV infection should be included as a possible cause of fever of unknown origin, especially when lymphocytosis and atypical lymphocytes are present. CMV infection is distinguished from EBV infection by the absence of pharyngitis, the relatively minor adenopathy, and the absence of serologic evidence of acute EBV infection. Mononucleosis syndromes are also caused by *Toxoplasma gondii*, rubella virus, adenovirus, hepatitis A virus, and HIV.

Prevention

Screening of transfused blood or filtering blood (thus removing CMV-containing white blood cells) prevents cases related to this source.

4. Cytomegalovirus Infection in Immunocompromised Children

In addition to symptoms experienced during primary infection, immunocompromised hosts develop symptoms with reinfection or reactivation of latent CMV. This is clearly seen in children with acquired immunodeficiency syndrome (AIDS), after transplantation, or with congenital immunodeficiencies. However, in most immunocompromised patients, primary infection is more likely to cause severe symptoms than is reactivation or reinfection. The severity of the resulting disease is generally proportionate to the degree of immunosuppression.

Clinical Findings

A. SYMPTOMS AND SIGNS

A mild febrile illness with myalgia, malaise, and arthralgia may occur, especially with reactivation disease. Se-

vere disease often includes subacute onset of dyspnea and cyanosis as manifestations of interstitial pneumonitis. Auscultation reveals only coarse breath sounds and scattered rales. A rapid respiratory rate may precede clinical or radiographic evidence of pneumonia. Hepatitis without jaundice or hepatomegaly is common. Diarrhea, which can be severe, occurs with CMV colitis, and CMV can cause esophagitis with symptoms of odynophagia or dysphagia. These enteropathies are most common in AIDS, as is the presence of a retinitis that often progresses to blindness. Encephalitis and polyradiculitis also occur in AIDS.

B. LABORATORY FINDINGS

Neutropenia and thrombocytopenia are common. Atypical lymphocytosis is infrequent. Serum aminotransferase levels are often elevated. The stools may contain occult blood if enteropathy is present. CMV is readily isolated from saliva, urine, buffy coat, and bronchial secretions. Results are available in 48 hours. Interpretation of positive cultures is made difficult by asymptomatic shedding of CMV in saliva and urine in many immunocompromised patients. CMV disease correlates more closely with the presence of CMV in the blood or lung lavage fluid. Monitoring for the appearance of CMV DNA in plasma or CMV antigen in blood mononuclear cells is used as a guide to early antiviral (“pre-emptive”) therapy.

C. IMAGING

Bilateral interstitial pneumonitis is present on chest radiographs.

Differential Diagnosis

The initial febrile illness must be distinguished from treatable bacterial or fungal infection. Similarly the pulmonary disease must be distinguished from intrapulmonary hemorrhage; drug-induced or radiation pneumonitis; pulmonary edema; and bacterial, fungal, parasitic, and other viruses infection in this population. CMV infection is seen bilaterally and interstitially on chest radiographs, cough is nonproductive, chest pain is absent, and the patient is not usually toxic. *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) infection may have a similar presentation. These patients may have polymicrobial disease. It is suspected that bacterial and fungal infections are enhanced by the neutropenia that can accompany CMV infection. Infection of the gastrointestinal tract is diagnosed by endoscopy. This will exclude candidal, adenoviral, and herpes simplex infections and allows tissue confirmation of CMV-induced mucosal ulcerations.

Treatment & Prevention

Blood donors should be screened to exclude those with prior CMV infection, or blood should be filtered. Ideally, seronegative transplant recipients should receive organs from seronegative donors. Severe symptoms, most commonly pneumonitis, often respond to early therapy with intravenous ganciclovir (5 mg/kg every 12 hours for 14–21 days). Neutropenia is a frequent side effect of this therapy. Foscarnet and cidofovir are alternative therapeutic agents recommended for patients with ganciclovir-resistant virus. Prophylactic use of oral or intravenous ganciclovir may prevent CMV infections in organ transplant recipients. Preemptive therapy can be used in some high-risk transplant recipients who are monitored for CMV antigen or DNA in their plasma or mononuclear cells and who receive antivirals when the test results reach a certain threshold or rapidly increase regardless of clinical signs or symptoms. CMV-seropositive children with AIDS and low CD4 counts (< 50/μL) should have funduscopic examinations and plasma CMV DNA measurements every 3 months.

INFECTIOUS MONONUCLEOSIS (Epstein–Barr Virus)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Prolonged fever.*
- *Exudative pharyngitis.*
- *Generalized adenopathy.*
- *Hepatosplenomegaly.*
- *Atypical lymphocytes.*
- *Heterophil antibodies.*

General Considerations

Mononucleosis is the most characteristic syndrome produced by EBV infection. Young children infected with

EBV have either no symptoms or a mild nonspecific febrile illness. As the age of the host increases, EBV infection is more likely to produce the typical features of the mononucleosis syndrome in 20–25% of infected adolescents. EBV is acquired readily from asymptomatic carriers (15–20% of whom excrete the virus in saliva on any given day) and from recently ill patients, who excrete virus for many months. Young children are infected from the saliva of playmates and family members. Adolescents may be infected through sexual activity. EBV can also be transmitted by blood transfusion and organ transplantation.

Clinical Findings

A. SYMPTOMS AND SIGNS

After an incubation period of 1–2 months, a 2- to 3-day prodrome of malaise and anorexia yields, abruptly or insidiously, to a febrile illness with temperatures exceeding 39°C. The major complaint is pharyngitis, which is often (50%) exudative. Lymph nodes are enlarged, firm, and mildly tender. Any area may be affected, but posterior and anterior cervical nodes are almost always enlarged. Splenomegaly is present in 50–75% of patients. Hepatomegaly is common (30%), and the liver is frequently tender. Five percent of patients have a rash, which can be macular, scarlatiniform, or urticarial. Rash is almost universal in patients taking penicillin or ampicillin. Soft palate petechiae and eyelid edema are also observed.

B. LABORATORY FINDINGS

1. Peripheral blood—Leukopenia may occur early, but an atypical lymphocytosis (comprising over 10% of the total leukocytes at some time in the illness) is most notable. Hematologic changes may not be seen until the third week of illness and may be entirely absent in some EBV syndromes (eg, neurologic ones).

2. Heterophil antibodies—These nonspecific antibodies appear in over 90% of older patients with mononucleosis but in fewer than 50% of children younger than age 5 years. They may not be detectable until the second week of illness and may persist for up to 12 months after recovery. Rapid screening tests (slide agglutination) are usually positive if the titer is significant; a positive result strongly suggests but does not prove EBV infection.

3. Anti-EBV antibodies—It may be necessary to measure specific antibody titers when heterophil antibodies fail to appear, as in young children. Acute EBV infection is established by detecting IgM antibody to the viral capsid antigen (VCA) or by detecting a fall over several weeks of IgG anti-VCA titers (IgG antibody peaks by the time symptoms appear).

4. EBV PCR—This assay detects EBV DNA. It is the method of choice for the diagnosis of CNS and ocular infections. Quantitative EBV PCR in peripheral blood mononuclear cells has been used to detect EBV-related lymphoproliferative disorders in transplant patients.

Differential Diagnosis

Severe pharyngitis may suggest group A streptococcal infection. Enlargement of only the anterior cervical lymph nodes, a neutrophilic leukocytosis, and the absence of splenomegaly suggest bacterial infection. Although a child with a positive throat culture result for streptococcus usually requires therapy, up to 10% of children with mononucleosis are asymptomatic streptococcal carriers. In this group, penicillin therapy is unnecessary and often causes a rash. Severe primary herpes simplex pharyngitis, occurring in adolescence, may also mimic infectious mononucleosis. In this type of pharyngitis, some anterior mouth ulcerations should suggest the correct diagnosis. EBV infection should be considered in the differential diagnosis of any perplexing prolonged febrile illness. Similar illnesses that produce atypical lymphocytosis include rubella (pharyngitis not prominent, shorter illness, less adenopathy and splenomegaly), adenovirus (upper respiratory symptoms and cough, conjunctivitis, less adenopathy, fewer atypical lymphocytes), hepatitis A or B (more severe liver function abnormalities, no pharyngitis, no lymphadenopathy), and toxoplasmosis (negative heterophil test, less pharyngitis). Serum sickness-like drug reactions and leukemia (smear morphology is important) may be confused with infectious mononucleosis. CMV mononucleosis is a close mimic except for minimal pharyngitis and less adenopathy; it is much less common. Serologic tests for EBV and CMV should clarify the correct diagnosis. The acute initial manifestation of HIV infection is a mononucleosis-like syndrome in many patients.

Complications

Splenic rupture is a rare complication, which usually follows significant trauma. Hematologic complications, including hemolytic anemia, thrombocytopenia, and neutropenia, are more common. Neurologic involvement can include aseptic meningitis, encephalitis, isolated neuropathy such as Bell palsy, and Guillain-Barré syndrome. Any of these may appear prior to or in the absence of the more typical signs and symptoms of infectious mononucleosis. Rare complications include myocarditis, pericarditis, and atypical pneumonia. Recurrence or persistence of EBV-associated symptoms for 6 months or longer characterizes chronic active EBV. This disease is due to continuous viral replication and warrants specific

antiviral therapy. Rarely EBV infection becomes a progressive lymphoproliferative disorder characterized by persistent fever, multiple organ involvement, neutropenia or pancytopenia, and agammaglobulinemia. Hemocytopenia is often present in the bone marrow. An X-linked genetic defect in immune response has been inferred for some patients (Duncan syndrome, X-linked lymphoproliferative disorder). Children with other congenital immunodeficiencies or chemotherapy-induced immunosuppression can also develop progressive EBV infection, EBV-associated lymphoproliferative disorder or lymphoma, and other malignancies.

Treatment & Prognosis

Bed rest may be necessary in severe cases. Acetaminophen controls high fever. Potential airway obstruction due to swollen pharyngeal lymphoid tissue responds rapidly to systemic corticosteroids. Corticosteroids may also be given for hematologic and neurologic complications, although no controlled trials have proved their efficacy in these conditions. Fever and pharyngitis disappear by 10–14 days. Adenopathy and splenomegaly can persist several weeks longer. Some patients complain of fatigue, malaise, or lack of well-being for several months. Although steroids may shorten the duration of fatigue and malaise, their long-term effects on this potentially oncogenic viral infection are unknown, and indiscriminate use is discouraged. Patients with splenic enlargement should avoid contact sports for 6–8 weeks. Acyclovir, valacyclovir, penciclovir, ganciclovir, and foscarnet are active against EBV and are indicated in the treatment of chronic active EBV.

Management of EBV-related lymphoproliferative disorders relies primarily on decreasing the immunosuppression whenever possible. Adjunctive therapy with acyclovir, ganciclovir, or another antiviral active against EBV as well as CMV hyperimmune globulin has been used without scientific evidence of efficacy.

VIRAL INFECTIONS SPREAD BY INSECT VECTORS

In the United States, mosquitoes are the most common insect vectors that spread viral infections (Table 36–4).

Table 36–4. Some virus diseases spread by insects in the United States.

Disease	Natural Reservoir (Vector)	Geographic Distribution	Incubation Period	Clinical Presentations	Laboratory Findings	Complications, Sequelae	Diagnosis, Therapy, Comments
FLAVIVIRUSES St. Louis encephalitis (SLE)	Birds (<i>Culex</i> mosquitoes)	Southern Canada, central and southern United States Caribbean, South America	2–5 d (up to 3 wk)	Abrupt onset of fever, chills, headache, nausea, vomiting; may develop generalized weakness, seizures, coma, ataxia, cranial nerve palsies. Aseptic meningitis is common in children	Modest leukocytosis, neutrophilia, elevated liver enzymes. CSF: 100–200 WBC/ μ L (PMNs predominate early).	Mortality rate 2–5% in children (especially < age 5). Neurologic sequelae in 1–20%.	20–500 cases a year, < 2% symptomatic. (Worse in elderly.) Therapy: supportive. Diagnosis: serology. Specific antibody often present within 5 d.
Dengue	Humans (<i>Aedes</i> mosquitoes)	Asia, Africa, Central and South America, Caribbean; rarely in southern United States	4–7 d (range 3–14 d)	Fever, headache, myalgia, joint and bone pain, retro-ocular pain, nausea and vomiting; maculopapular or petechial rash in 50%, sparing palms and soles; adenopathy. Meningoencephalitis in 5–10% of children.	Leukopenia, thrombocytopenia. CSF: 100–500 mononuclear cells/ μ L if neurologic signs are present.	Hemorrhagic fever, shock syndrome, prolonged weakness.	High infection rate. 50–150 cases occur in US travelers to endemic areas. Biphasic course may occur. Therapy: supportive. Diagnosis: serology; IgM-EIA antibody by day 6.
West Nile	Birds (<i>Culex</i> mosquitoes); small mammals	N. Africa, Middle East, parts of Asia, Europe, continental United States	3–12 d	Abrupt onset of fever, headache, sore throat, myalgia, retro-ocular pain, conjunctivitis; 20–50% with rash; adenopathy. Encephalitis may be accompanied by muscle weakness, flaccid paralysis, or movement disorders.	Mild leukocytosis; 10–15% lymphopenic moderate CSF pleocytosis.	Mortality rate 10%, of those with CNS symptoms, especially in elderly; weakness and myalgia may persist for an extended period.	Most important mosquito-borne encephalitis in the United States. Diagnosis: IgM-EIA serology; cross-reacts with St. Louis encephalitis; positive by 6–8 d; definitive diagnosis by PCR. Therapy: supportive
ALPHA TOGA VIRUSES Western equine encephalitis	Birds (<i>Culiseta</i> mosquitoes)	Canada, Mexico, and United States west of Mississippi River	2–5 d	Similar to that of St. Louis encephalitis. Most infections are subclinical.	Variable white counts. CSF: 10–300 WBC/ μ L.	Permanent brain damage, 10% overall; most severe in older adults.	< 50 cases a year in the United States. Case/infection is 1:1000 for older adults and 1:1 for infants. Equine illness precedes human outbreaks. Diagnosis: IgM antibody in first week. Therapy: supportive

Eastern equine encephalitis	Birds (<i>Culisata</i> mosquitoes)	Eastern seaboard United States Caribbean, South America	2–5 d	Similar to that of St. Louis encephalitis but more severe. Progresses rapidly in one third to coma and death.	Leukocytosis with neutrophilia. CSF: 500–2000 WBC/ μ L; PMNs predominate early.	Mortality rate 20–50%; neurologic sequelae in over 50% of children.	Most severe mosquito-borne encephalitis in the United States. Fewer than 20 cases a year. Only 3–10% of cases are symptomatic. Therapy: supportive. Diagnosis: serology. Titers often positive in first week. Equine deaths may signal an outbreak.
Venezuelan equine encephalitis	Horses (ten species of mosquitoes)	South and Central America, Texas	1–6 d	Similar to that of St. Louis encephalitis.	Lymphopenia, mild thrombocytopenia, abnormal liver function tests. CSF: 50–200 mononuclears/ μ L.	Severe disease more common in infants; 20% fatality rate for encephalitis.	Most infections do not cause encephalitis. Vaccination of horses will stop epidemic. Therapy: supportive. Diagnosis: IgM antibody (EIA).
BUNYAVIRUS California encephalitis (La-Crosse, Jamestown Canyon, California)	Chipmunks and other small mammals (<i>Aedes</i> mosquitoes)	Northern and mid central United States, southern Canada	3–7 d	Similar to that of St. Louis encephalitis; sore throat and respiratory symptoms are common; focal neurologic signs in up to 25%. Seizures prominent. Pre-pubertal children are most likely to have severe disease. Can mimic HSV encephalitis.	Variable white counts. CSF: 30–200 (up to 600) WBC/ μ L; variable PMNs; protein often normal.	Mortality rate < 1%. Seizure disorder may begin during acute illness.	About 100–150 cases a year in the United States, 5% symptomatic. > 10% with sequelae. Therapy: supportive. Diagnosis: serology. Up to 90% have specific IgM antibody in first week; 25% of population in certain regions has IgG antibody.
COLTIVIRUS Colorado tick fever	Small mammals (<i>Dermacentor andersoni</i> , or wood tick)	Rocky Mountain region of United States and Canada	3–4 d (range, 2–14 d)	Fever, chills, myalgia, conjunctivitis, headache, retro-orbital pain; rash in < 10%. No respiratory symptoms. Biphasic fever in 50%.	Leukopenia (maximum at 4–6 d), mild thrombocytopenia.	Rare encephalitis, coagulopathy.	Patient may have no known tick bite. Acute illness lasts 7–10 d; prolonged fatigue in adults. Therapy: supportive. Diagnosis: serology, direct FA staining of red cells for viral antigen, PCR.

CSF = cerebrospinal fluid; EIA = enzyme immunoassay; FA = fluorescent antibody; PCR = polymerase chain reaction; PMN = polymorphonuclear neutrophil; WBC = white blood cells; HSV = herpes simplex virus.

As a consequence, these infections—and others that are spread by ticks—tend to occur as summer–fall epidemics that coincide with the seasonal breeding and feeding habits of the vector, and the etiologic agent varies by region. Thus a careful travel and exposure history is critical for correct diagnostic work-up.

ENCEPHALITIS

Encephalitis presents as fever, headache, and various combinations of sensorial or behavioral change, with or without focal neurological abnormalities (see Chapter 23). Evidence of meningitis is often present. CSF is abnormal, usually with mononuclear cell pleocytosis, elevated protein level, and normal sugar level. Neutrophils may be prominent in CSF early in the illness. Encephalitis is a common severe manifestation of many infections spread by insects (see Table 36–4). With many pathogens, the infection is most often subclinical, or mild CNS disease such as meningitis is present. These infections have some distinguishing features in terms of subclinical infection rate, unique neurologic syndromes, associated non-neurologic symptoms, and prognosis. The diagnosis is generally made clinically during recognized outbreaks and is confirmed by virus-specific serology. Prevention consists of control of mosquito vectors and precautions with proper clothing and insect repellents to minimize mosquito and tick bites.

1. West Nile Virus Encephalitis

This flavivirus is the most important arbovirus infection in the United States. Since it was described in 1999 in New York, it has spread to 47 states. In 2003, West Nile virus caused more than 8500 infections and 190 deaths, the largest epidemic of arboviral meningoencephalitis ever reported. Its reservoir includes more than 160 species of birds whose migration explain the rapid growth of the epidemic. During summer–fall epidemics most infected individuals are asymptomatic. Approximately 20% develop West Nile fever, which is characterized by fever, headache, retro-orbital pain, nausea and vomiting, lymphadenopathy, and a maculopapular rash (20–50%). Less than 1% of infected patients develop meningitis or encephalitis, but 10% of these cases are fatal (0.1% of all infections). The major risk factor for severe disease is age older than 50 years and immune compromise, although children develop West Nile fever and occasionally have neurologic disease. The neurologic manifestations are most often those found with other encephalitides. However, distinguishing atypical features include polio-like flaccid paralysis, movement disorders (parkinsonism, tremor, myoclonus), brainstem symptoms, polyneuropathy,

and optic neuritis. Muscle weakness, facial palsy, and hyporeflexia are common (20% of each finding). Diagnosis is best made by detecting IgM antibody (EIA) to the virus in CSF. This will be present by 2–3 days (95%) after onset. PCR is a specific diagnostic tool, but is less sensitive than antibody detection. Antibody rise in serum can also be used for diagnosis. Treatment is supportive, although various antivirals and specific immune globulin are being studied. The infection is not spread between contacts, but is spread by donated organs and blood and breast milk and transplacentally. The coming years will indicate if this virus will become a serious endemic problem in the United States.

DENGUE

In endemic areas 50–100 million cases of dengue occur each year, often in severe forms. In the United States, 50–150 cases are diagnosed, most often in travelers from the Caribbean or Asia and less often in those visiting Central and South America. Texas has sporadic indigenous outbreaks of dengue. The spread of dengue requires the requisite species of mosquito, which transmits virus from a reservoir of viremic humans in endemic areas. Most patients have mild disease, especially young children, who may have a nonspecific fever and rash. Severity is a function of age and prior infection with other serotypes of dengue virus, a prerequisite for severe hemorrhagic complications.

Clinical Findings

A. SYMPTOMS AND SIGNS

Dengue fever begins abruptly 4–7 days after transmission (range, 3–14 days) with fever, chills, severe retro-orbital pain, severe muscle and joint pain, nausea, and vomiting. Erythema of the face and torso may occur early. After 3–4 days a centrifugal maculopapular rash appears in half of patients. The rash can become petechial, and mild hemorrhagic signs (epistaxis, gingival bleeding, microscopic blood in stool or urine) may be noted. The illness lasts 5–7 days, although rarely fever may reappear for several additional days.

B. LABORATORY FINDINGS

Leukopenia and a mild drop in platelets are common. Liver function tests are usually normal. Diagnosis is made by viral culture of plasma (50% sensitive up to the fifth day), by detecting IgM-specific ELISA anti-

bodies (90% sensitive at the sixth day), or by detecting a rise in type-specific antibody. PCR is available for diagnosis.

Differential Diagnosis

This diagnosis should be considered for any traveler to an endemic area who has symptoms suggestive of a systemic viral illness, although less than 1 in 1000 travelers to these areas develop dengue. Often the areas visited have other unique viruses circulating and are potential sources of malaria, typhoid fever, leptospirosis, and measles. EBV, influenza, enteroviruses, and acute HIV infection may produce a similar illness. An illness that starts 2 weeks after the trip ends or that lasts longer than 2 weeks is not dengue.

Complications

Rarely dengue fever is associated with meningoencephalitis (5–10%) or hepatic damage. More common in endemic areas is the appearance of dengue hemorrhagic fever, which is defined by significant thrombocytopenia, bleeding, and a plasma leak syndrome (hemoconcentration, hypoalbuminemia, and pleural or peritoneal effusions). This is the consequence of circulating antibody acquired from a prior heterotypic dengue virus infection; thus it is rarely seen in typical travelers. Failure to recognize and treat this complication may lead to dengue shock syndrome, which has a high fatality rate.

Prevention

Prevention of dengue fever involves avoiding high-risk areas and using conventional mosquito avoidance measures. The main vector is a day-time feeder.

Treatment

Dengue fever is treated by oral replacement of fluid lost from gastrointestinal symptoms. Analgesic therapy, which is often necessary, should not include drugs that affect platelet function. Recovery is complete without sequelae. The hemorrhagic syndrome requires prompt fluid therapy with plasma expanders and isotonic saline.

Gregson A, Edelman R: Dengue virus infection. *Pediatr Infect Dis J* 2003;22:179 [PMID:12586982].

COLORADO TICK FEVER

Colorado tick fever, a tick-borne illness, is endemic in the high plains and mountains of the central and northern Rocky Mountains and northern Pacific coast of the United States. The reservoir of the virus consists of

squirrels and chipmunks. Many hundreds of cases of Colorado tick fever occur each year in visitors or laborers entering this region, primarily from May through July.

Clinical Findings

A. SYMPTOMS AND SIGNS

After a 3- to 4-day incubation period (maximum, 14 days) fever begins suddenly together with chills, lethargy, headache, ocular pain, myalgia, abdominal pain, and nausea and vomiting. Conjunctivitis may be present. A nondistinctive maculopapular rash occurs in 5–10% of patients. The illness lasts 7–10 days, and half of patients have a biphasic fever curve with several afebrile days in the midst of the illness.

B. LABORATORY FINDINGS

Leukopenia is characteristic early in the illness. Platelets are modestly decreased. Specific ELISA testing is available, but 3–4 weeks may elapse before seroconversion. Fluorescent antibody staining will detect virus-infected erythrocytes during the illness and for weeks after recovery.

Differential Diagnosis

Early findings, especially if rash is present, may suggest enterovirus, measles, or rubella infection. Enteric fever may be an early consideration because of the presence of leukopenia and thrombocytopenia. A history of tick bite, which is often obtained, information about local risk, and the biphasic fever pattern will help with the diagnosis. Because of the wilderness exposure, diseases such as leptospirosis, borreliosis, tularemia, ehrlichiosis, and Rocky Mountain spotted fever will be considerations.

Complications

Meningoencephalitis occurs in 3–7% of patients. Cardiac and pulmonary complications are rare.

Prevention & Treatment

Prevention involves avoiding endemic areas and using conventional means to avoid tick bite. Therapy is supportive. Do not use analgesics that modify platelet function.

Klasco R: Colorado tick fever. *Med Clin North Am* 2002; 86:435 [PMID:11982311].

OTHER MAJOR VIRAL CHILDHOOD EXANTHEMS

See Infections Due to Herpesvirus section for a discussion of varicella and roseola, two other major childhood exanthems.

ERYTHEMA INFECTIOSUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and rash with “slapped-cheek” appearance.
- Arthritis in older children.
- Profound anemia in patients with impaired erythrocyte production.
- Nonimmune hydrops fetalis.

General Considerations

This benign exanthematous illness of school-age children is caused by the human parvovirus designated B19. Spread is respiratory, occurring in winter–spring epidemics. A nonspecific mild flu-like illness may occur during the initial viremia at 7–10 days; the characteristic rash occurring at 10–17 days represents an immune response. The patient is viremic and contagious prior to—but not after—the onset of rash.

Approximately one half of infected individuals have a subclinical illness. Most cases (60%) occur in children between ages 5 and 15 years, with an additional 40% occurring later in life. Forty percent of adults are seronegative. The disease is mildly contagious; the secondary attack rate in a school or household setting is 50% among susceptible children and 20–30% among susceptible adults.

Clinical Findings

Owing to the nonspecific nature of the exanthem and the many subclinical cases, a history of contact with an infected individual is often absent or unreliable. Recognition of the illness is easier during outbreaks.

A. SYMPTOMS AND SIGNS

Typically the first sign of illness is the rash, which begins as raised, fiery red maculopapular lesions on the cheeks that coalesce to give a “slapped-cheek” appearance. The lesions are warm, nontender, and sometimes pruritic. They may be scattered on the forehead, chin,

and postauricular areas, but the circumoral region is spared. Within 1–2 days, similar lesions appear on the proximal extensor surfaces of the extremities and spread distally in a symmetrical fashion. Palms and soles are usually spared. The trunk, neck, and buttocks are also commonly involved. Central clearing of confluent lesions produces a characteristic lace-like pattern. The rash fades in several days to several weeks but frequently reappears in response to local irritation, heat (bathing), sunlight, and stress. Almost one half of infected children have some rash remaining (or recurring) for 10 days. Fine desquamation may be present. Mild systemic symptoms occur in up to 50% of children. These symptoms include low-grade fever (38–38.5°C), mild malaise, sore throat, and coryza. They appear for 2–3 days and are followed by a week-long asymptomatic phase before the rash appears.

Purpuric stocking-glove rashes, neurologic disease, and severe disorders resembling hemolytic–uremic syndrome have also been described in association with parvovirus B19.

B. LABORATORY FINDINGS

A mild leukopenia occurs early in some patients, followed by leukocytosis and lymphocytosis. Specific IgM and IgG serum antibody tests are available, but care must be used in choosing a reliable laboratory for this test. Nucleic acid detection tests are often definitive. The disease is not diagnosed by routine viral culture.

Differential Diagnosis

In children immunized against measles and rubella, parvovirus B19 is the most frequent agent of morbilliform and rubelliform rashes. The characteristic rash and the mild nature of the illness distinguish erythema infectiosum from other childhood exanthems. It lacks the prodromal symptoms of measles and the lymphadenopathy of rubella. Systemic symptoms and pharyngitis are more prominent with enteroviral infections and scarlet fever.

Complications & Sequelae

A. ARTHRITIS

Arthritis is more common in older patients, beginning with late adolescence. Approximately 10% of children have severe joint symptoms. Girls are affected more commonly than boys. Pain and stiffness occur symmetrically in the peripheral joints. Arthritis usually follows the rash and may persist for 2–6 weeks but resolves without permanent damage.

B. APLASTIC CRISIS

Parvovirus B19 replicates primarily in erythroid progenitor cells. Consequently, reticulocytopenia occurs for approximately 1 week during the illness. This goes unnoticed in individuals with a normal erythrocyte half-life but results in severe anemia in patients with chronic hemolytic anemia. The rash of erythema infectiosum follows the hemolysis in these patients.

Pure red cell aplasia, leukopenia, pancytopenia, idiopathic thrombocytopenic purpura, and a hemophagocytic syndrome have also been described. Patients with AIDS and other immunosuppressive illnesses may develop prolonged anemia or pancytopenia. Patients with hemolytic anemia and aplastic crisis or immunosuppressed patients may still be contagious and should be isolated while in the hospital.

C. OTHER END ORGAN INFECTIONS

Parvovirus is under study as a potential cause of a variety of collagen–vascular diseases, neurologic syndromes, hepatitis, and myocarditis.

D. IN UTERO INFECTIONS

Infection of susceptible pregnant women may produce fetal infection with hydrops fetalis; fetal death occurs in about 6%, and most fatalities occur in the first 20 weeks—compared with a fetal loss of 3.5% in control subjects. The risk of fetal infection is unknown. Congenital anomalies have not been associated with parvovirus B19 infection during pregnancy.

Treatment & Prognosis

Erythema infectiosum is a benign illness for immunocompetent individuals. Patients with aplastic crisis may require blood transfusions. It is unlikely that this complication can be prevented by quarantine measures, because acute parvovirus infection in contacts is often unrecognized and is most contagious prior to the rash. Pregnant women who are exposed to erythema infectiosum or who work in a setting in which an epidemic occurs should be tested for evidence of prior infection. Susceptible pregnant women should then be followed up for evidence of parvovirus infection. Approximately 1.5% of women of childbearing age are infected during pregnancy. If maternal infection occurs, the fetus should be followed up by ultrasonography for evidence of hydrops and distress. In utero transfusion or early delivery may salvage some fetuses. Pregnancies should not be terminated because of parvovirus infection. The risk of fetal death among exposed pregnant women of unknown serologic status is less than 2.5% for homemakers and less than 1.5% for schoolteachers.

Intramuscular immune globulin is not protective. High-dose IVIG has stopped viremia and led to mar-

row recovery in some cases of prolonged aplasia. Its role in immunocompetent patients and pregnant women is unknown.

Messina MF et al: Purpuric gloves and socks syndrome caused by parvovirus B19 infection. *Pediatr Infect Dis J* 2003;22:755 [PMID: 12938681].

MEASLES (RUBEOLA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Exposure to measles 9–14 days previously.
- Prodrome of fever, cough, conjunctivitis, and coryza.
- Koplik spots (few to many small white papules on a diffusely red base on the buccal mucosa) 1–2 days prior to and after onset of rash.
- Maculopapular rash spreading down from the face and hairline to the trunk over 3 days and later becoming confluent.
- Leukopenia.

General Considerations

This childhood exanthem is rarely seen in the United States because of universal vaccination (< 50 cases in 2003, all of which were imported or related to imported cases). Sporadic clusters of cases are the result of improper immunization more so than of vaccine failures, and are usually related to imported cases. It is recommended that all children be revaccinated on entrance into primary or secondary school (see Chapter 9). The attack rate in susceptible individuals is extremely high; spread is respiratory. Morbidity and mortality rates in the developing world are substantial because of underlying malnutrition and secondary infections. Because humans are the sole reservoir of measles, there is the potential to eliminate this disease worldwide.

Clinical Findings

A history of contact with a suspected case may be absent because airborne spread is efficient and patients are contagious during the prodrome. Contact with an imported case may not be recognized. In temperate cli-

mates, epidemic measles is a winter–spring disease. Many suspected cases are misdiagnoses of other viral infections.

A. SYMPTOMS AND SIGNS

High fever and lethargy are prominent. Sneezing, eyelid edema, tearing, copious coryza, photophobia, and harsh cough ensue and worsen. Koplik spots are white macular lesions on the buccal mucosa, typically opposite the lower molars. These are almost pathognomonic for rubeola, although they may be absent. A discrete maculopapular rash begins when the respiratory symptoms are maximal and spreads quickly over the face and trunk, coalescing to a bright red. As it involves the extremities, it fades from the face and is completely gone within 6 days; fine desquamation may occur. Fever peaks when the rash appears and usually falls 2–3 days thereafter.

B. LABORATORY FINDINGS

Lymphopenia is characteristic. Total leukocyte counts may fall to 1500/ μ L. The diagnosis is usually made by detection of measles IgM antibody in serum drawn at least 3 days after the onset of rash or later by detection of a significant rise in antibody. Direct detection of measles antigen by fluorescent antibody staining of nasopharyngeal cells is a useful rapid method. PCR testing of oropharyngeal secretions or urine is extremely sensitive and specific and can detect infection up to 5 days before symptoms.

C. IMAGING

Chest radiographs often show hyperinflation, perihilar infiltrates, or parenchymal patchy, fluffy densities. Secondary consolidation or effusion may be visible.

Differential Diagnosis

Table 36–3 lists other illnesses that may resemble measles.

Complications & Sequelae

A. RESPIRATORY COMPLICATIONS

These complications occur in up to 15% of patients. Bacterial superinfections of lung, middle ear, sinus, and cervical nodes are most common. Fever that persists after the third or fourth day of rash suggests such a complication, as does leukocytosis. Bronchospasm, severe croup, and progressive viral pneumonia or bronchiolitis (in infants) also occur. Immunosuppressed patients are at much greater risk for fatal pneumonia than are immunocompetent patients.

B. CEREBRAL COMPLICATIONS

Encephalitis occurs in 1 in 2000 cases. Onset is usually within a week after appearance of rash. Symptoms include combativeness, ataxia, vomiting, seizures, and coma. Lymphocytic pleocytosis and a mildly elevated protein concentration are usual CSF findings, but the fluid may be normal. Forty percent of patients so affected die or have severe neurologic sequelae.

Subacute sclerosing panencephalitis (SSPE) is a slow measles virus infection of the brain that becomes symptomatic years later in about 1 in 100,000 previously infected children. This progressive cerebral deterioration is associated with myoclonic jerks and a typical electroencephalographic pattern. It is fatal in 6–12 months. It rarely occurs following administration of vaccine; in fact, no case has been reported in recent years. High titers of measles antibody are present in serum and CSF.

C. OTHER COMPLICATIONS

These include hemorrhagic measles (severe disease with multiorgan bleeding, fever, cerebral symptoms), thrombocytopenia, appendicitis, keratitis, myocarditis, and premature delivery or stillbirth. Mild liver function test elevation has been detected in up to 50% of cases in young adults; frank jaundice may also occur. Measles causes transient immunosuppression; thus, reactivation or progression of tuberculosis (including transient cutaneous anergy) occurs in untreated children.

Treatment, Prognosis, & Prevention

Recovery generally occurs 7–10 days after onset of symptoms. Therapy is supportive: eye care, cough relief (avoid opioid suppressants in infants), and fever reduction (acetaminophen, lukewarm baths; avoid salicylates). Secondary bacterial infections should be treated promptly; antimicrobial prophylaxis is not indicated. Ribavirin is active in vitro and may be useful in infected immunocompromised children. High-dose intravenous ribavirin in combination with intrathecal interferon- α has been successfully used in the management of SSPE. In malnourished children, vitamin A supplementation should be given to attenuate the illness.

The current two-dose active vaccination strategy is successful. Vaccine should not be withheld for concurrent mild acute illness, tuberculosis or positive tuberculin skin test, breast-feeding, or exposure to an immunodeficient contact. The vaccine is recommended for HIV-infected children without severe HIV complications and adequate CD4 cells ($\geq 15\%$).

Vaccination prevents the disease in susceptible exposed individuals if given within 72 hours (see Chapter 9). Immune globulin (0.25 mL/kg intramuscularly; 0.5 mL/kg if immunocompromised) will prevent or

modify measles if given within 6 days. Suspected cases should be diagnosed promptly and reported to the local health department.

RUBELLA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *History of rubella vaccination usually absent.*
- *Prodromal nonspecific respiratory symptoms and adenopathy (postauricular and occipital).*
- *Maculopapular rash beginning on face, rapidly spreading to the entire body, and disappearing by fourth day.*
- *Few systemic symptoms.*
- *Congenital infection.*
 - Retarded growth, development.*
 - Cataracts, retinopathy.*
 - Purpuric “blueberry muffin” rash at birth.*
 - Jaundice, thrombocytopenia.*
 - Deafness.*
 - Congenital heart defect.*

General Considerations

If it were not teratogenic, rubella would be of little clinical importance. Clinical diagnosis is difficult in some cases because of its variable expression. In one study, over 80% of infections were subclinical. Because of inadequate vaccination, outbreaks now occur in adolescents or adults. Rubella is transmitted by aerosolized respiratory secretions. Patients are infectious 5 days before until 5 days after the rash. Fewer than 10 cases were reported in the United States in 2003.

Congenital rubella, in infants both of unimmunized women and of women who have apparently been reinfectd in pregnancy, is now rare (no cases in 2003).

Clinical Findings

The incubation period is 14–21 days. The nondistinctive signs may make exposure history unreliable. A history of immunization makes rubella unlikely but still possible. Congenital rubella usually follows maternal infection in the first trimester.

A. SYMPTOMS AND SIGNS

1. Infection in children—Young children may only have rash. Older patients often have a nonspecific prodrome of low-grade fever, ocular pain, sore throat, and myalgia. Postauricular and suboccipital adenopathy (sometimes generalized) is characteristic. This often precedes the rash or may occur without rash. The rash consists of erythematous discrete maculopapules beginning on the face. A “slapped-cheek” appearance or pruritus may occur. Scarletiform or morbilliform rash variants may occur. The rash spreads quickly to the trunk and extremities after it fades from the face; it is gone by the fourth day. Enanthema is usually absent.

2. Congenital infection—More than 80% of women infected in the first 4 months of gestation are delivered of affected infants; congenital disease occurs in less than 5% of women infected later in pregnancy. Later infections can result in isolated defects, such as deafness. The main manifestations are as follows:

- a. **Growth retardation**—Between 50% and 85% of infants are small at birth and remain so.
- b. **Cardiac anomalies**—Pulmonary artery stenosis, patent ductus arteriosus, ventricular septal defect.
- c. **Ocular anomalies**—Cataracts, microphthalmia, glaucoma, retinitis.
- d. **Deafness**
- e. **Cerebral disorders**—Chronic encephalitis; retardation.
- f. **Hematologic disorders**—Thrombocytopenia, dermal nests of extramedullary hematopoiesis or purpura (“blueberry muffin” rash), lymphopenia.
- g. **Others**—Hepatitis, osteomyelitis, immune disorders, malabsorption, diabetes.

B. LABORATORY FINDINGS

Leukopenia is common, and platelet counts may be low. Congenital infection is associated with low platelet counts, abnormal liver function tests, hemolytic anemia, pleocytosis, and very high rubella IgM antibody titers. Total serum IgM is elevated, and IgA and IgG levels may be depressed.

C. IMAGING

Pneumonitis and bone metaphyseal longitudinal lucencies may be present in radiographs of children with congenital infection.

Diagnosis & Differential Diagnosis

Virus may be isolated from throat or urine from 1 week before to 2 weeks after onset of rash. Children with congenital infection are infectious for months. The virus laboratory must be notified that rubella is suspected. Serologic diagnosis is best made by demonstrating a fourfold rise in antibody titer between specimens drawn 1–2 weeks apart. The first should be drawn promptly, because titers increase rapidly after onset of rash. Both specimens must be tested simultaneously by a single laboratory. Specific IgM antibody can be measured by immunoassay. Because the decision to terminate a pregnancy is usually based on serologic results, testing must be done carefully.

Rubella may resemble infections due to enterovirus, adenovirus, measles, EBV, roseola, parvovirus, *Toxoplasma gondii*, and *Mycoplasma*. Drug reactions may also mimic rubella. Because public health implications are great, sporadic suspected cases should be confirmed serologically or virologically.

Congenital rubella must be differentiated from congenital CMV infection, toxoplasmosis, and syphilis.

Complications & Sequelae

A. ARTHRALGIA AND ARTHRITIS

Both occur more often in adult women. Polyarticular involvement (fingers, knees, wrists), lasting a few days to weeks, is typical. Frank arthritis occurs in a small percentage of patients. It may resemble acute rheumatoid arthritis.

B. ENCEPHALITIS

With an incidence of about 1:6000, this is a nonspecific parainfectious encephalitis associated with a low mortality rate. A syndrome resembling SSPE (see Measles section) has also been described in congenital rubella.

C. RUBELLA IN PREGNANCY

Infection in the mother is self-limited and not severe.

Prevention

Rubella is one of the infections that could be eradicated. See Chapter 9 for the indication and efficacy of rubella vaccine. Standard prenatal care should include rubella antibody testing. Seropositive mothers are at no risk; seronegative mothers are vaccinated after delivery.

A pregnant woman possibly exposed to rubella should be tested immediately; if seropositive, she is im-

mune and need not worry. If she is seronegative, a second specimen should be drawn in 4 weeks, and both specimens should be tested simultaneously. Seroconversion in the first trimester suggests high fetal risk; such women require counseling regarding therapeutic abortion.

When pregnancy termination is not an option, some experts recommend intramuscular administration of 20 mL of immune globulin within 72 hours after exposure in an attempt to prevent infection. (This negates the value of subsequent antibody testing.) The efficacy of this practice is unknown.

Treatment & Prognosis

Symptomatic therapy is sufficient. Arthritis may improve with administration of anti-inflammatory agents. The prognosis is excellent in all children and adults but poor in congenitally infected infants, in whom most defects are irreversible or progressive. The severe cognitive defects seem to correlate closely in these infants with the degree of growth failure.

INFECTIONS DUE TO OTHER VIRUSES

HANTAVIRUS CARDIOPULMONARY SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Influenza-like prodrome (fever, myalgia, headache, cough).*
- *Rapid onset of unexplained pulmonary edema.*
- *Residence or travel in epidemic area; exposure to aerosols from deer mouse droppings or secretions.*

General Considerations

Hantavirus cardiopulmonary syndrome is the first native bunyavirus infection endemic in this country. Hantavirus cardiopulmonary syndrome is distinctly different in mode of spread (no arthropod vector) and clinical picture from other bunyavirus diseases.

Clinical Findings

The initial cases of hantavirus pulmonary syndrome involved travel to or residence in an area where New Mexico, Colorado, Utah, and Arizona are contiguous and involved potential exposure to the habitat of the reservoir, the deer mouse. This rodent and other selected rodents that harbor related hantaviruses live in many other locales. Thus, through 2003, more than 325 cases were confirmed in 29 other states, with additional cases in Canada. Epidemics occur when environmental conditions favor large increases in the rodent population and increased prevalence of virus in this reservoir.

A. SYMPTOMS AND SIGNS

After an incubation period of 2–3 weeks, onset is sudden, with a nonspecific virus-like prodrome: fever; back, hip, and leg pain; chills; headache; and nausea and vomiting. Abdominal pain may be present. Sore throat, conjunctivitis, rash, and adenopathy are absent, and respiratory symptoms are absent or limited to a dry cough. After 1–10 days (usually 3–7), dyspnea, tachypnea, and evidence of a pulmonary capillary leak syndrome appear. This often progresses rapidly over a period of hours. Hypotension is common not only from hypoxemia but also from myocardial dysfunction. Copious, amber-colored, nonpurulent secretions are common. Decreased cardiac output and elevated systemic vascular resistance distinguish this disease from early bacterial sepsis.

B. LABORATORY FINDINGS

The hemogram shows leukocytosis with a prominent left shift and immunoblasts, thrombocytopenia, and hemoconcentration. LDH is elevated, as are liver function tests; serum albumin is low. Creatinine is elevated in some patients, and proteinuria is common. Lactic acidosis and low venous bicarbonate are poor prognostic signs. A serum IgM ELISA test is positive early in the illness. Otherwise the diagnosis is made by specific staining of tissue or PCR, usually at autopsy.

C. IMAGING

Initial chest radiographs are normal. This is followed by bilateral interstitial infiltrates with the typical butterfly pattern of acute pulmonary edema, bibasilar airspace disease, or both. Significant pleural effusions are often

present. These findings contrast with those of other causes of acute respiratory distress syndrome.

Differential Diagnosis

In some geographic areas, plague and tularemia may be possibilities. Infections with viral respiratory pathogens and *Mycoplasma* have a slower tempo, do not elevate the LDH, and do not cause the hematologic changes. Q fever, psittacosis, toxin exposure, legionellosis, and fungal infections are possibilities, but the history, tempo of the illness, and blood findings, as well as the exposure history, should be distinguishing features. Hantavirus cardiopulmonary syndrome is a consideration in previously healthy persons with a febrile illness associated with unexplained pulmonary edema.

Treatment & Prognosis

When given early for other bunyavirus infections, intravenous ribavirin has been effective, and hantaviruses are sensitive *in vitro* to ribavirin. A trial of this therapy for hantavirus cardiopulmonary syndrome is under way. Management should concentrate on oxygen therapy and mechanical ventilation as required. Because of capillary leakage, Swan–Ganz catheterization to monitor cardiac output and inotropic support—rather than fluid therapy—should be used to maintain perfusion. Venoarterial extracorporeal membrane oxygenation can provide short-term support for selected patients. The virus is not spread by person-to-person contact. No isolation is required. Thus far, the case fatality rate is approximately 50%. Guidelines are available for reduction of exposure to the infectious agent.

Peters CJ, Khan AS: Hantavirus pulmonary syndrome: The new American hemorrhagic fever. *Clin Infect Dis* 2002;34:1224 [PMID: 11941549].

MUMPS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- No prior mumps immunization.
- Parotid gland swelling.
- Aseptic meningitis with or without parotitis.

General Considerations

Mumps was one of the classic childhood infections; virus spread by the respiratory route attacked almost all unimmunized children (asymptotically in 30–40% of cases), and produced lifelong immunity. The vaccine is so efficacious that clinical disease is rare in immunized children. As a result of subclinical infections or childhood immunization, 95% of adults are immune. Infected patients can spread the infection from 1–2 days prior to the onset of symptoms and for 5 additional days. The incubation period is 14–21 days.

A history of exposure to a child with parotitis is not proof of mumps exposure. In an adequately immunized individual, parotitis is usually due to another cause. Currently in the United States less than 1 case is reported per 100,000 population.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Salivary gland disease—Tender swelling of one or more glands, variable fever, and facial lymphedema are typical. Parotid involvement is most common; signs are bilateral in 70% of patients. The ear is displaced upward and outward; the mandibular angle is obliterated. Systemic toxicity is usually absent. Parotid stimulation with sour foods may be quite painful. The orifice of the Stensen duct may be red and swollen; yellow secretions may be expressed, but pus is absent. Parotid swelling dissipates after 1 week.

2. Meningoencephalitis—Prior to widespread immunization, mumps was the most common cause of aseptic meningitis, which is usually manifested by mild headache or asymptomatic mononuclear pleocytosis. Fewer than 10% of patients have clinical meningitis or encephalitis. Cerebral symptoms do not correlate with parotid symptoms, which are absent in many patients with meningoencephalitis. Although neck stiffness, nausea, and vomiting can occur, encephalitic symptoms are rare (1:4000 cases of mumps); recovery in 3–10 days is the rule.

3. Pancreatitis—Abdominal pain may represent transient pancreatitis. Because salivary gland disease may elevate serum amylase, specific markers of pancreatic function (lipase, amylase isoenzymes) are required for assessing pancreatic involvement.

4. Orchitis, oophoritis—Involvement of the gonads is associated with fever, local tenderness, and swelling. Epididymitis is usually present. Orchitis is unusual in young children but occurs in up to one third of affected postpubertal males. Usually it is unilateral and resolves in 1–2 weeks. Although one third of infected testes atrophy, bilateral involvement and sterility are rare.

5. Other—Thyroiditis, mastitis (especially in adolescent females), arthritis, and presternal edema (occasionally with dysphagia or hoarseness) may be seen.

B. LABORATORY FINDINGS

Peripheral blood leukocyte count is usually normal. Up to 1000 cells/ μ L (predominantly lymphocytes) may be present in the CSF, with mildly elevated protein and normal to slightly decreased glucose. Viral culture of saliva, throat, urine, or spinal fluid may be positive for at least 1 week after onset. Paired sera assayed by ELISA are currently used for diagnosis. Complement-fixing antibody to the soluble antigen disappears in several months; its presence in a single specimen thus indicates recent infection.

Differential Diagnosis

Mumps parotitis may resemble the following: cervical adenitis (the jaw angle may be obliterated, but the ear does not usually protrude; the Stensen duct orifice is normal; leukocytosis and neutrophilia are observed); bacterial parotitis (pus in the Stensen duct, toxicity, exquisite tenderness); recurrent parotitis (idiopathic or associated with calculi); tumors or leukemia; and tooth infections. Many viruses, including parainfluenza, enteroviruses, EBV, CMV, and influenza virus, can cause parotitis. Parotid swelling in HIV infection is less painful and tends to be bilateral and chronic, but bacterial parotitis occurs in some children with HIV infection.

Unless parotitis is present, mumps meningitis resembles that caused by enteroviruses or early bacterial infection. An elevated amylase is a useful clue in this situation. Isolated pancreatitis is not distinguishable from many other causes of epigastric pain and vomiting. Mumps is a classic cause of orchitis, but torsion, bacterial or chlamydial epididymitis, *Mycoplasma* infection, other viral infections, hematomas, hernias, and tumors must also be considered.

Complications

The major neurologic complication is nerve deafness (usually unilateral), which can result in inability to hear high tones. It may occur without meningitis. Permanent damage is rare, occurring in less than 0.1% of cases of mumps. Aqueductal stenosis and hydrocephalus (especially following congenital infection), myocarditis, transverse myelitis, and facial paralysis are other rare complications.

Treatment & Prognosis

Treatment is supportive and includes provision of fluids, analgesics, and scrotal support for orchitis. Sys-

temic steroids have been used for orchitis, but their value is anecdotal. Surgery is not recommended.

RABIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *History of animal bite 10 days to 1 year (usually less than 90 days) previously.*
- *Paresthesias or hyperesthesia in bite area.*
- *Progressive limb and facial weakness in some patients (dumb rabies; 30%).*
- *Irritability followed by fever, confusion, combativeness, muscle spasms (especially pharyngeal with swallowing) in all patients (furious rabies).*
- *Rabies antigen detected in corneal scrapings or tissue obtained by brain or skin biopsy; Negri bodies seen in brain tissue.*

General Considerations

Rabies remains a potentially serious public health problem wherever animal immunization is not widely practiced or when humans play or work in areas with sylvan rabies. Although infection does not always follow a bite by a rabid animal (about 40% infection rate following rabid dog bites), infection is almost invariably fatal. Any warm-blooded animal may be infected, but susceptibility and transmissibility vary with different species. Bats often carry and excrete the virus in saliva or feces for prolonged periods; they are the major cause of rabies in the United States. Dogs and cats are usually clinically ill within 10 days after becoming contagious (the standard quarantine period for suspect animals). Valid quarantine periods or signs of illness are not fully known for many species. Rodents rarely transmit infection. Animal vaccines are very effective when properly

administered, but a single inoculation may fail to produce immunity in up to 20% of dogs.

The risk is assessed according to the type of animal (bats always considered rabid; raccoons, skunks, foxes in many areas); wound extent and location (infection more common after head or hand bites, or if wounds have extensive salivary contamination or are not quickly and thoroughly cleaned); geographic area (urban rabies is rare to nonexistent in US cities; rural rabies is possible, especially outside the United States); and animal vaccination history (risk low if documented). Most rabies in the United States is with genotypes found in bats, yet a history of bat bite is rarely obtained. Aerosolized virus in caves inhabited by bats has caused infection.

Clinical Findings

A. SYMPTOMS AND SIGNS

Paresthesias at the bite site are usually the first symptoms. Nonspecific anxiety, excitability, or depression follows, then muscle spasms, drooling, hydrophobia, delirium, and lethargy. Swallowing or even the sensation of air blown on the face may cause pharyngeal spasms. Seizures, fever, cranial nerve palsies, coma, and death follow within 7–14 days after onset. In a minority of patients, the spastic components are initially absent and the symptoms are primarily flaccid paralysis and cranial nerve defects. The furious components appear subsequently.

B. LABORATORY FINDINGS

Leukocytosis is common. CSF is usually normal or may show elevation of protein and mononuclear cell pleocytosis. Cerebral imaging and electroencephalography are not diagnostic.

Infection in an animal may be determined by use of the fluorescent antibody test to examine brain tissue for antigen. Rabies virus is excreted in the saliva of infected humans, but the diagnosis is usually made by antigen detection in scrapings or tissue samples of richly innervated epithelium, such as the cornea or the hairline of the neck. Classic Negri cytoplasmic inclusion bodies in brain tissue are not always present. Seroconversion occurs after 7–10 days.

Differential Diagnosis

Failure to elicit the bite history in areas where rabies is rare may delay diagnosis. Other disorders to be considered include parainfectious encephalopathy; encephalitis due to herpes simplex, mosquito-borne viruses, other viruses; and Guillain-Barré syndrome.

Prevention

See Chapter 9 for information regarding vaccination and postexposure prophylaxis. Rabies immune globulin and diploid cell vaccine have made prophylaxis more effective and minimally toxic; however, rare cases of prophylaxis failure are still being reported. Because rabies is almost always fatal, presumed exposures must be managed carefully.

Treatment & Prognosis

Survival is rare but has been reported in four patients receiving meticulous intensive care. No antiviral preparations are of proved benefit. Early diagnosis is important for the protection and prophylaxis of individuals exposed to the patient.

Messenger SL et al: Emerging epidemiology of bat-associated cryptic cases of rabies in humans in the United States. *Clin Infect Dis* 2002;35:738 [PMID: 12203172].

II. RICKETTSIAL INFECTIONS

Rickettsiae are pleomorphic, gram-negative coccobacilli which are obligate intracellular parasites. Rickettsial diseases are often included in the differential diagnosis of febrile rashes, although some (notably Q fever) are not characterized by rash. Severe headache is a prominent symptom. The endothelium is the primary target tissue, and the ensuing vasculitis is responsible for severe illness.

All rickettsioses except Q fever are transmitted by cutaneous arthropod contact, either by bite or contamination of skin breaks with tick feces. Evidence of such contact by history or physical examination may be completely lacking, especially in young children. The geographic distribution of the vector is often the primary determinant for suspicion of these infections. Therapy often must be empirical. Many new broad-spectrum antimicrobials are inactive against these cell wall-deficient organisms; tetracycline is usually effective.

HUMAN EHRLICHIOSIS

Ehrlichia species are responsible for febrile pancytopenia in animals. In humans, *Ehrlichia sennetsu* is responsible for a mononucleosis-like syndrome seen in Japan and Malaysia. One agent of North American human ehrlichiosis has been identified as *E chaffeensis*. The reservoir hosts are probably wild rodents, deer, and

sheep; ticks are the vectors. Most cases caused by this agent are reported in the south central and middle to southern Atlantic states. Arkansas, Missouri, Oklahoma, and North Carolina are high-prevalence areas. Almost all cases occur between March and October, when ticks are active. A second ehrlichiosis syndrome, seen in the upper Midwest and Northeast (Connecticut, Wisconsin, Minnesota, and New York are high-prevalence areas), is caused by an organism closely related to *E phagocytophila* or *E equi*. These are known large animal pathogens. *E chaffeensis* has a predilection for mononuclear cells, whereas intracytoplasmic inclusions in granulocytes are common with the *E phagocytophila* and *E equi* infections. Hence diseases caused by these agents are referred to as human monocytic ehrlichiosis or human granulocytic ehrlichiosis, respectively. A newly discovered agent, *E ewingii*, also causes tick-borne human granulocytic ehrlichiosis. Rocky Mountain spotted fever and human monocytic ehrlichiosis share the same vector (Lone Star tick), whereas Lyme disease and human granulocytic ehrlichiosis are both spread by the deer tick. Thus dual infections are common and should be considered in patients who fail to respond to therapy.

Clinical Findings

In approximately 75% of patients, a history of tick bite can be elicited. The majority of the remaining patients report having been in a tick-infested area. The usual incubation period is 5–21 days.

A. SYMPTOMS AND SIGNS

Fever and headache are universally present. Gastrointestinal symptoms (anorexia, nausea and vomiting) are reported in most pediatric patients. Distal limb edema may also occur in children. Chills, photophobia, conjunctivitis, myalgia, and arthralgia occur in more than half of patients. Rash occurs in one third of patients with monocytic ehrlichiosis but is less common (< 10%) in granulocytic ehrlichiosis. Rash may be erythematous, macular, papular, petechial, scarlatiniform, or vasculitic. Meningitis occurs. Interstitial pneumonitis, adult respiratory distress syndrome, and renal failure occur in severe cases. The physical examination reveals rash, mild cervical adenopathy, and hepatomegaly. Perinatal transmission has been documented. A child without a rash may present as a case of fever of unknown origin.

B. LABORATORY FINDINGS

Laboratory abnormalities include leukopenia with left shift, lymphopenia, thrombocytopenia, and elevated aminotransferase levels. Disseminated intravascular coagulation can occur in severe cases. Anemia occurs in

one third of patients. The definitive diagnosis is made serologically. The Centers for Disease Control and Prevention uses appropriate antigens in an immunofluorescent antibody test in order to distinguish between the etiologic agents. Intracytoplasmic inclusions (morulae) may occasionally be observed in mononuclear cells in monocytic ehrlichiosis and are usually observed in polymorphonuclear cells from the peripheral blood or bone marrow in granulocytic ehrlichiosis. Specific PCR is now available for diagnosis.

Differential Diagnosis

The differential diagnosis includes septic or toxic shock, other rickettsial infections (especially Rocky Mountain spotted fever), Colorado tick fever, leptospirosis, Lyme borreliosis, relapsing fever, EBV, CMV, viral hepatitis and other viral infections, Kawasaki disease, systemic lupus erythematosus, and leukemia.

Treatment & Prognosis

Although the disease may last several weeks, it is usually self-limited. Deaths do occur in children. Doxycycline, 2–4 mg/kg/d divided every 12 hours (maximum 100 mg/dose) for 7–10 days, is the treatment of choice. Fatal disease occurs in less than 3% of cases. Immune compromise is a risk factor for severe disease.

Lantos P, Krause PJ: Ehrlichiosis in children. *Semin Pediatr Infect Dis* 2002;13:249-56 [PMID: 12491230].

Singh-Behl D et al: Tick-borne infections. *Dermatol Clin* 2003;21:237 [PMID: 12757245].

RICKETTSIALPOX

Rickettsia akari is transmitted by mites from infected house mice. Most cases in the United States have occurred in northeastern cities. The bite site becomes a papule, then a pustule; it ulcerates and then forms a characteristic black eschar at about the time fever develops at 9–14 days. Local adenopathy is the rule. Headache, myalgia, and photophobia are followed in 2–4 days by a generalized maculopapular rash. Palms and soles are usually spared. Vesicles develop on the papules. The fever lasts about a week. Diagnosis is established by serology.

The differential diagnosis includes varicella, enteroviral infections, other rickettsial spotted fevers, meningococemia, and gonococemia. Mild cases require no therapy. Tetracycline for 3 to 5 days is effective.

Paddock CD et al: Rickettsialpox in New York City: A persistent urban zoonosis. *Ann NY Acad Sci* 2003;990:36 [PMID:12860597].

ROCKY MOUNTAIN SPOTTED FEVER

Rickettsia rickettsii causes one of many similar tick-borne illnesses characterized by fever and rash that occur worldwide. Most are named for their geographic area. In all except Rocky Mountain spotted fever and murine typhus, there is a characteristic eschar at the bite site, called the *tache noire*. Dogs and rodents are reservoirs of *R rickettsii*.

Rocky Mountain spotted fever is the most severe of these infections and the most important (500–1000 cases per year) in the United States. It occurs predominantly in the eastern seaboard; in the southeastern states; and in Arkansas, Texas, Missouri, Kansas, and Oklahoma—much less common to the west. Most cases occur in children exposed in rural areas from April to September. Because tick attachment lasting 6 hours or longer is needed, frequent tick removal is a preventive measure.

Clinical Findings

A. SYMPTOMS AND SIGNS

After the incubation period of 3–12 days (mean, 7 days), there is high fever (over 40°C, often hectic), usually of abrupt onset, myalgia, severe and persistent headache (retro-orbital; less obvious in infants), toxicity, photophobia, vomiting, and diarrhea. The characteristic rash occurs in 85–90% of patients and appears 2–6 days after fever onset as macules and papules, especially prominent on the palms, soles, and extremities, becoming petechial and spreading centrally. Conjunctivitis, splenomegaly, edema, meningismus, irritability, and confusion may occur.

B. LABORATORY FINDINGS

Laboratory findings are nonspecific and reflect diffuse vasculitis: thrombocytopenia, hyponatremia, early mild leukopenia, proteinuria, abnormal liver function tests, hypoalbuminemia, and hematuria. CSF pleocytosis is common. Serologic diagnosis is achieved with indirect fluorescent or latex agglutination antibody methods, but generally only 7–10 days after onset of the illness. Skin biopsy with specific fluorescent staining may give the diagnosis within the first week of the illness.

Differential Diagnosis

The differential diagnosis includes meningococemia, measles, meningitis, staphylococcal sepsis, enteroviral infection, leptospirosis, Colorado tick fever, scarlet

fever, murine typhus, Kawasaki disease, and ehrlichiosis.

Treatment & Prognosis

To be effective, therapy for Rocky Mountain spotted fever must be started early and is often based on a presumptive diagnosis in endemic areas prior to rash onset. It is important to remember that atypical presentations, such as the absence of pathognomonic rash, often lead to delay in appropriate therapy. Doxycycline is the agent of choice for children, regardless of age. Treatment should be continued for 2 or 3 days after the temperature has returned to normal for a full day. A minimum of 10 days of therapy is recommended.

Complications and death result from severe vasculitis, especially in the brain, heart, and lung. The mortality rate is 5–7%. Delay in therapy is an important determinant of mortality.

Sexton DJ, Kaye KS: Rocky mountain spotted fever. *Med Clin North Am* 2002;86:351 [PMID: 11982306].

ENDEMIC TYPHUS (MURINE TYPHUS)

Endemic typhus is present in the southern United States, mainly in southern Texas, and in Southern California. The disease is transmitted by fleas from infected rodents, from their feces in scratches, or by inhalation. Domestic cats, dogs, and opossums may play a role in the transmission of suburban cases. No eschar appears at the inoculation site, which may go unnoticed. The incubation period is 6–14 days. Headache, myalgia, and chills slowly worsen. Fever may last 10–14 days. After 3–8 days, a rash appears. Truncal macules and papules spread to the extremities; the rash is rarely petechial. The location of the rash in typhus, with sparing of the palms and soles, is a distinction from Rocky Mountain spotted fever. Rash may be absent in 20–40% of patients. Hepatomegaly may be present. Intestinal and respiratory symptoms may occur. Mild thrombocytopenia and elevated liver enzymes may be present. The illness is usually self-limited and milder than epidemic typhus. More prolonged neurologic symptoms have been described. Therapy is usually not needed. Doxycycline is the drug of choice. Therapy for 3 days is usually sufficient. Fluorescent antibody and ELISA tests are available.

Fergie JE et al: Murine typhus in south Texas children. *Pediatr Infect Dis J* 2000;19:535 [PMID: 10877169].

Q FEVER

Coxiella burnetii is transmitted by inhalation rather than by an arthropod bite. The birth tissues and excreta of domestic animals and of some rodents are the infectious source. Unpasteurized milk from infected animals may also transmit disease. Q fever is also distinguished from other rickettsial diseases by the infrequent occurrence of cutaneous manifestations and by the prominence of pulmonary disease.

Clinical Findings

A. SYMPTOMS AND SIGNS

Many patients have a self-limited flu-like syndrome of chills, fever, severe headache, and myalgia of abrupt onset occurring 10–30 days after exposure. Abdominal pain, vomiting, chest pain, and dry cough are prominent in children. Examination of the chest may produce few findings, as in other atypical pneumonias. Hepatosplenomegaly is common. The illness lasts 1–4 weeks, and frequently is associated with weight loss.

B. LABORATORY FINDINGS

Leukopenia with left shift is characteristic. Thrombocytopenia is unusual and another distinction from other symptomatic rickettsial diseases. Aminotransferase and γ -glutamyl transferase levels are elevated. Diagnosis is made by finding a complement-fixing antibody response (fourfold rise or single high titer) to the phase II organism. Chronic infection is indicated by antibody against the phase I organism. IgM ELISA and specific PCR are also available.

C. IMAGING

Pneumonitis occurs in 50% of patients. Multiple segmental infiltrates are common, but the radiographic appearance is not pathognomonic. Consolidation and pleural effusion are rare.

Differential Diagnosis

In the appropriate epidemiologic setting, Q fever should be considered in evaluating causes of atypical pneumonias such as from *Mycoplasma pneumoniae*, viruses, *Legionella*, and *Chlamydia pneumoniae*. It should also be included among the causes of mild hepatitis without rash or adenopathy in children with exposure to farm animals.

Treatment & Prognosis

Typically the illness lasts 1–2 weeks without therapy. One complication is chronic disease, which often im-

plies myocarditis or granulomatous hepatitis. Meningoencephalitis is also a rare complication.

C burnetii is also one of the causes of so-called culture-negative endocarditis. Both types of complication are rare. Endocarditis is difficult to treat; mortality approaches 50%. The course of the uncomplicated illness is shortened with tetracycline; doxycycline is preferred.

Therapy is continued for several days after the patient becomes afebrile. Quinolones are also effective.

Human Immunodeficiency Virus Infection

37

Elizabeth J. McFarland, MD

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Children younger than age 18 months:

- A child known to be HIV-seropositive or born to an HIV-infected mother.

And

- Has positive results on two separate determinations on blood or tissue (excluding cord blood) for one or more of the following HIV detection tests: HIV nucleic acid detection, HIV antigen (p24), HIV culture.

Or

- Meets criteria for AIDS diagnosis based on the 1987 Centers for Disease Control and Prevention (CDC) AIDS surveillance case (see Table 37-1 and CDC case definition, *MMWR Morb Mortal Wkly Rep*, 1994).

Or

- Has HIV antibody and evidence of cellular and humoral immunodeficiency (without another cause) and symptoms compatible with HIV infection.

Children older than age 18 months:

- HIV-seropositive by repeatedly reactive enzyme-linked immunosorbent assay and confirmatory test.

Or

- Meets any of the criteria listed for children younger than age 18 months.

General Considerations

Acquired immunodeficiency syndrome (AIDS) results from progression of human immunodeficiency virus (HIV) infection. HIV is a retrovirus that infects mainly helper T lymphocytes (CD4 lymphocytes), monocytes, and macrophages. In general, cells are infected after

binding of the glycosylated envelope protein of HIV, gp120, to both the CD4 receptor protein and a chemokine receptor, which are found on the surface of the target cells. The function and number of CD4 lymphocytes and other affected cells are diminished by HIV infection, with profound effects on both humoral and cell-mediated immunity. Without treatment, HIV infection causes generalized immune incompetence and eventually AIDS. However, combination antiretroviral treatment is highly effective at delaying disease progression.

The clinical diagnosis of AIDS is made when an HIV-infected child develops any of the opportunistic infections, malignancies, or conditions listed in category C (Table 37-1). In adults and adolescents, the criteria for a diagnosis of AIDS also include absolute CD4 lymphocyte counts of 200/ μ L or less.

Mode of Transmission

HIV is transmitted by sexual contact, percutaneous exposure to contaminated blood, and vertical transmission. Perinatal transmission may occur in utero, at the time of delivery, or via breast feeding. Indirect evidence suggests that about 30% of perinatal infections occur prior to birth. Risk factors associated with mother-to-infant transmission include high maternal plasma HIV RNA, advanced maternal disease stage, low CD4 lymphocyte count, and factors related to increased exposure to maternal blood or cervical secretions at the time of delivery (ie, duration of rupture of membranes, presence of blood in the infant's gastric secretions, first-born twin delivery).

In the United States, risk factors for HIV infection among adults include exposure to blood products from 1978 to early 1985, parenteral illicit drug use, multiple heterosexual or homosexual contacts, and a partner with any of the preceding risk factors. Casual, classroom, or household contact with an HIV-infected person poses no risk. Seroprevalence rates are highest among gay men and injecting drug users. However, the proportion of new AIDS cases in 2001 acquired by heterosexual contact was approximately equal to the proportion acquired by injecting drug use and only slightly

Table 37-1. Clinical categories of children with HIV infection.**Category N: Not symptomatic**

No signs or symptoms or only one of the conditions listed in category A

Category A: Mildly symptomatic

Having two or more of the following conditions:

- Lymphadenopathy
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Category B: Moderately symptomatic

Having symptoms attributed to HIV infections other than those in category A or C

Examples:

- Anemia, neutropenia, thrombocytopenia
- Bacterial meningitis, pneumonia, sepsis (single episode)
- Candidiasis, oropharyngeal, persisting over 2 months
- Cardiomyopathy
- Cytomegalovirus infection with onset < 1 month of age
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus recurrent stomatitis, bronchitis, pneumonitis, esophagitis at < 1 month of age
- Herpes zoster, two or more episodes or more than one dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia
- Nephropathy
- Nocardiosis
- Persistent fever
- Toxoplasmosis with onset < 1 month of age
- Varicella, complicated

Category C: Severely symptomatic

- Serious bacterial infections, multiple or recurrent
- Candidiasis, esophageal or pulmonary
- Coccidioidomycosis, disseminated
- Cryptosporidiosis or isosporiasis with diarrhea > 1 month
- Cytomegalovirus infection with onset > 1 month of age
- Encephalopathy
- Herpes simplex virus: persistent oral lesions, or bronchitis, pneumonitis, esophagitis at > 1 month of age
- Histoplasmosis
- Kaposi sarcoma
- Lymphoma
- Mycobacterium tuberculosis*, extrapulmonary
- Mycobacterium* infection, other species, disseminated
- Pneumocystis jiroveci* pneumonia
- Progressive multifocal leukoencephalopathy
- Salmonella* septicemia, recurrent
- Toxoplasmosis of the brain with onset > 1 month of age
- Wasting syndrome

less than the proportion acquired by men having sex with men. Youth (ages 13–24 years) and women of color are disproportionately represented among new cases. In developing nations, heterosexual contact is the most common mode of transmission among adults, and prevalence is similar in both genders.

Perinatal transmission accounts for over 90% of prepubertal AIDS cases in the United States and almost all new pediatric HIV infections. In the United States, the number of perinatally acquired AIDS cases declined 83% between 1992 (907 cases) and 2001 (150 cases). This decline reflects a decrease in perinatal transmission attributed primarily to zidovudine (ZDV) and other antiretroviral treatment during pregnancy. Without intervention, 15–30% of infants born to HIV-infected women will be infected. The rate of vertical transmission can be reduced to 5–8% by providing ZDV treatment to the mother during pregnancy and delivery and by providing additional prophylaxis to the infant during the first 6 weeks after birth. In the current era of combination therapy during pregnancy, transmission rates are as low as 1%. Most transmissions involve women not receiving therapy during pregnancy, either because the infection is undiagnosed or because of lack of prenatal care. Offering of HIV testing to all pregnant women is strongly recommended so that those who are HIV-infected can receive treatments to reduce perinatal transmission. Perinatal transmission rates in developing countries continue to be high. Worldwide, an estimated 3.2 million children are infected with HIV, most of them in Africa, India, Thailand, and parts of South America. In 2002, an estimated 800,000 new infections occurred in children younger than age 15 years. Studies of short-course medical treatment demonstrate reduced transmission rates, but have yet to be implemented on a wide-scale basis.

Currently, sexual activity (both heterosexual and homosexual) is the main mode of infection after puberty, with a smaller number of cases resulting from sharing of contaminated needles. The incidence among youth, especially minority youth, is increasing. As a result of careful donor screening and testing of the donated blood, HIV transmission resulting from blood products is now extremely rare (1:2,000,000 transfusions).

Pathogenesis

At the time of initial HIV infection, high levels of HIV are detected in the bloodstream. In adults, the level of viremia declines without therapy concurrent with the appearance of an HIV-specific host immune response and plasma viremia usually reaches a steady-state level about 6–12 months after primary infection. The amount of virus present in the plasma at that point and thereafter is predictive of the rate of disease progression

for the individual. Despite ongoing virus replication, a period of clinical latency occurs lasting from 1 year to more than 12 years during which the infected person is asymptomatic. The virus and anti-HIV immune responses are in a steady state, with high levels of virus production and destruction balanced against production and destruction of CD4 lymphocytes. Eventually, the balance favors the virus, and the viral burden increases as the CD4 lymphocyte count declines.

Approximately 30% of infants with vertically acquired HIV infection will have virus detectable in the blood at birth. This is thought to indicate infection acquired in utero. The remaining infected infants, probably acquiring HIV during labor and delivery, will test negative for HIV at birth but will soon have detectable virus, usually by 2–4 weeks. The level of viremia rises steeply, reaching a peak at age 1–2 months. In contrast with adults, infants will have a gradual decline in plasma viremia that extends beyond 2 years. Infants generally have plasma virus levels 10 times higher than those in adults.

Without treatment, about 20–30% of HIV-infected infants develop an AIDS-defining illness by age 1 year and die before age 2–3 years. High levels of viremia at age 1–2 months and over the first year of life characterize these infants. Other predictors of rapid progression are low absolute counts of CD4 and suppressor–killer T (CD8) lymphocytes in the first 6 months. In the remainder, the disease progresses more slowly, with a mortality rate of 3.5% per year between ages 1 and 7 years and median survival greater than 7 years. These so-called slow progressors will generally have lower virus levels and a more gradual decline in CD4 lymphocyte counts. There are rare instances of children and adults with untreated infection for 8–10 years or more with no evidence of immune suppression. Studies indicate that both viral and host genetic factors, not all fully defined, play a role in determining the rate of disease progression. The initiation of antiretroviral therapy

dramatically alters the natural history by slowing disease progression and permitting restoration of immune function.

Clinical Findings

A. SYMPTOMS AND SIGNS

The manifestations described in this section are likely to be observed in children with untreated infection or in those unresponsive to therapy. Children given effective antiretroviral therapy usually have few symptoms, most of which will be from the medications.

The CDC has developed disease staging criteria for HIV-infected children (see Tables 37–1 and 37–2). The criteria incorporate clinical symptoms ranging from no symptoms to mild, moderate, and severe symptoms (categories N, A, B, C, respectively) and age-adjusted CD4 lymphocyte counts (immunologic categories 1, 2, 3, corresponding to none, moderate, or severe immune suppression, respectively). Each child is classified both by CD4 lymphocyte count and by clinical category. Category C diagnoses are the diseases indicating an AIDS diagnosis, with the exception of lymphoid interstitial pneumonitis, which was included as an AIDS-defining illness but is not a sign of late-stage disease.

1. Primary acute infection—The incubation period is 2–4 weeks for primary infection acquired by adults and adolescents through high-risk behavior. Nonspecific symptoms occur in 30–90% of new infections (eg, flu or mild mononucleosis-like illness), and often are not brought to medical attention. Diagnosis requires a high index of suspicion. Infected persons may present with fever, fatigue, malaise, pharyngitis, enlarged lymph nodes, and hepatosplenomegaly. Signs seen less commonly but more specific to HIV are mild oral ulcerations; a diffuse macular, erythematous rash; and mild meningitis or encephalopathy. Occasionally, thrush,

Table 37–2. Immunologic categories based on age-specific CD4 lymphocyte counts and percentages of total lymphocytes.

Immunologic Category	Age of Child					
	< 12 months		1–5 years		6–12 years	
	cells/ μ L	(%)	cells/ μ L	(%)	cells/ μ L	(%)
1. No evidence of suppression	≥ 1500	(≥ 25)	≥ 1000	(≥ 25)	≥ 500	(≥ 25)
2. Evidence of moderate suppression	750–1499	(15–24)	500–999	(15–24)	200–499	(15–24)
3. Evidence of severe suppression	< 750	(< 15)	< 500	(< 15)	< 200	(< 15)

Adapted from MMWR Morb Mortal Wkly Rep 1994;43(RR-12):4.

Candida esophagitis, or genital ulcers are observed. These early symptoms of primary infection resolve spontaneously within 1–2 weeks, although some persons have fatigue and depression for weeks or months.

A primary infection syndrome is rarely recognized following perinatal acquisition. Newborns with perinatal HIV infection are rarely symptomatic (less than 7%) at birth. Size and physical features are not different from uninfected infants. However, 75–95% will demonstrate some sign (mostly nonspecific) by age 1 year.

2. Nonspecific symptoms—Nonspecific symptoms may be observed in early- or late-stage disease. Frequent illness (especially recurrent otitis media or sinusitis) is typical, in addition to poor weight gain, chronic cough, chronic diarrhea, developmental delay, unexplained fevers, night sweats, generalized lymphadenopathy, parotid swelling, or hepatosplenomegaly. Delayed growth may be observed as early as age 4 months in some infants. These common early findings may be present for years in an otherwise well child.

3. Infections related to immunodeficiency—Progressive immune dysfunction in both humoral and cell-mediated responses results in susceptibility to infections. Recurrent or serious bacterial infections are more common in children than in HIV-infected adults. Bouts of bacteremia, especially due to *Streptococcus pneumoniae*, can occur in children without suppressed CD4 T-cell counts. Infections with *Mycobacterium tuberculosis* (usually acquired from adults in the household) may be severe. Primary varicella-zoster (VZV) infections may be prolonged or severe. Recurrent herpes zoster (shingles) is common even in the era of combination therapy. Recurrent herpes simplex lesions may be large, painful, and persistent. Likewise, persistent aphthous ulcers may cause significant morbidity. Late-stage immunodeficiency is accompanied by susceptibility to a variety of opportunistic pathogens. Pneumonia caused by *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) is the most common AIDS-defining diagnosis in children with unrecognized HIV infection. The incidence is highest between ages 2 and 6 months and is often fatal during this period. Symptoms are difficult to distinguish from those of viral or atypical pneumonia. Patients typically have fever, tachypnea, intercostal retractions, progressive hypoxemia, and an elevated lactate dehydrogenase (LDH) concentration (see Chapter 39). Persistent candidal mucocutaneous infections (oral, skin, and vaginal) are common. Candidal esophagitis occurs with more advanced disease. In children with severe immunosuppression, cytomegalovirus (CMV) infections may result in disseminated disease, hepatitis, gastroenteritis, retinitis, and encephalitis.

Cryptococcal infections and histoplasmosis have been described, although much less frequently than among HIV-infected adults. Disseminated infection with *Mycobacterium avium* complex (MAC) occurs at the rate of 5 per 100 patient-years in infected children who have CD4 lymphocyte counts under 50–100/ μ L. Symptoms and signs associated with this opportunistic pathogen include fever, night sweats, weight loss, diarrhea, fatigue, lymphadenopathy, hepatomegaly, anemia, and granulocytopenia. A variety of diarrheal pathogens that cause mild, self-limited symptoms in healthy persons may result in severe, chronic diarrhea in HIV-infected persons. These include rotavirus, *Cryptosporidium parvum*, *Microsporidium*, *Cyclospora*, *Isospora belli*, *Giardia lamblia*, and bacterial pathogens. Chronic parvovirus infection manifested by anemia can occur. Reactivation of toxoplasmosis occurs rarely in children.

4. Organ system disease—HIV infection may cause a variety of organ system symptoms. In most cases, the pathogenesis is not fully understood; however, symptoms occurring in the absence of other pathogens are thought to result from HIV infection itself.

Prior to effective antiretroviral therapy, encephalopathy was a common problem, afflicting 20% or more of HIV-infected children. Following perinatal transmission, affected patients may present with acquired microcephaly, progressive motor deficit, ataxia, pseudobulbar palsy, and failure to attain (or loss of) developmental milestones. Children who are older may have symptoms similar to those observed in infected adults, such as gradual mental status changes initially affecting attention span and memory. However, other treatable causes of central nervous system disease should be sought, especially when an acute change in symptoms occurs.

Lymphoid interstitial pneumonitis is characterized by a diffuse peribronchial and interstitial infiltrate composed of lymphocytes and plasma cells. It may be asymptomatic or associated with dry cough, hypoxemia, dyspnea or wheezing on exertion, and clubbing of the digits. Auscultatory findings may be few. Children with this disorder frequently have enlargement of the parotid glands, generalized lymphadenopathy, and normal LDH (elevated in *Pneumocystis* pneumonia [PCP]). Although this diagnosis was originally classified as AIDS-defining because of specificity to HIV, the condition is associated with slow progression and is not an indicator of advanced disease.

Symptomatic cardiomyopathy is observed mainly in infants with rapid disease progression. Symptoms are those of congestive heart failure.

Mild to moderate elevation of liver enzymes is frequently observed, and, more rarely, overt clinical

hepatitis occurs due to HIV infection itself. However, patients are often taking medications with potential hepatotoxicity, and superinfection with other pathogens (CMV, Epstein–Barr virus [EBV], MAC, hepatitis C, hepatitis B) that affect the liver is common. Thus the diagnosis of HIV hepatitis should be one of exclusion. Chronic diarrhea may occur with HIV infection; however, as with hepatitis, it is commonly associated with other gastrointestinal infections. Since these may respond to specific treatment, severe diarrhea warrants an aggressive evaluation, including cultures, microscopic examinations of stool, and often colonoscopy with biopsy. Nephropathy, myopathy, and neuropathy are all recognized in children but are relatively uncommon.

5. Malignancy—Children with HIV are at increased risk of malignancy, although even prior to effective therapy, malignancy was an uncommon AIDS-defining illness. The tumors most commonly associated with pediatric HIV infection are non-Hodgkin lymphomas. Unlike non-Hodgkin lymphomas in immunocompetent persons, these tumors commonly occur at extranodal sites (central nervous system, bone, gastrointestinal tract, liver, or lungs) and are usually high-grade and of B-cell origin. Cervical infection with human papillomavirus is more likely to progress to neoplasia in adolescent females with HIV infection. Kaposi sarcoma, a common malignancy among HIV-infected homosexual males, rarely occurs in children. There is an increased frequency of leiomyosarcomas.

B. LABORATORY FINDINGS

HIV antibody is measured by enzyme-linked immunosorbent assay (ELISA). A confirmatory test, usually a Western blot, must be performed because individuals occasionally have nonviral cross-reacting antibodies, which result in a false-positive ELISA. Rarely (in less than 1% of cases) an infected person may fail to make antibody. However, they are usually obviously ill, and tests for virus or viral antigen are positive. During the early weeks after nonvertical, primary infection, HIV antibody may be absent; tests for the presence of virus (nucleic acid detection or p24 antigen) are positive.

Infants born to HIV-infected mothers will have HIV antibody—regardless of infection status—owing to transplacental passage of maternal antibody. The median time to loss of maternal HIV antibody is 10 months; all children lose maternal antibody by 18 months. A diagnosis of HIV infection can be made in over 95% by age 2–4 months by detecting HIV in blood, with nucleic acid detection.

Approximately 70% of infected infants will have negative results with assays for HIV RNA and DNA at birth, presumably because of low viral burden, perhaps

indicating that the infection was acquired at the time of birth. Hence, negative tests during this early period do not rule out infection. Over the first 8 weeks, essentially all infected infants will become positive for HIV nucleic acid. An infant who is otherwise well and has had at least two negative HIV cultures or nucleic acid detection tests, both performed after age 1 month and at least one performed after age 3 months, is very unlikely to be infected. The infant should be followed-up for clinical symptoms and retested at ages 12, 15, and 18 months for reversion to seronegative status to confirm the absence of infection. The absolute number and percentage of CD4 lymphocytes decline with disease progression; CD8 lymphocytes may be increased. CD4 lymphocyte numbers and percentages in infants are normally much higher than in adults and decline to adult levels by age 6 years. Hence, age-adjusted values must be used in evaluating these tests (see Table 37–2).

Some children will have thrombocytopenia due to autoimmune antibodies at a relatively early stage of disease. As disease progresses, anemia and granulocytopenia become common. Patients are often also taking antiretroviral or prophylactic medication, which may result in bone marrow suppression; distinguishing between effects due to HIV or drug therapy may be difficult. Hypergammaglobulinemia is characteristic and may be observed as early as age 9 months. Some children fail to make specific antibody to antigens (eg, *Haemophilus influenzae* type b, *Streptococcus pneumoniae*), which contributes to subsequent infections. With brain involvement, the cerebrospinal fluid may be normal or the protein may be elevated and a mononuclear pleocytosis may be present.

C. IMAGING

Cerebral images can demonstrate atrophy and calcification in the basal ganglia and frontal lobes in patients with encephalopathy. Chest radiographs of children with lymphoid interstitial pneumonitis show diffuse interstitial reticulonodular infiltrates, occasionally with hilar adenopathy. The chest radiograph in PCP typically demonstrates perihilar infiltrates progressing to bilateral diffuse alveolar disease.

Differential Diagnosis

Differential diagnosis of HIV infection will vary with the presenting sign or symptom. Infants with immunodeficiency may resemble infants with other types of congenital immunodeficiencies such as hypogammaglobulinemia or severe combined immunodeficiency syndrome (see Chapter 29). When poor growth is a prominent feature of the presentation, HIV infection may be confused with other causes of growth deficiency. Children or adolescents presenting with gener-

alized lymphadenopathy or hepatosplenomegaly may resemble those infected with viruses such as EBV or CMV. The symptoms of acute primary infection in the adolescent may be similar to those of mononucleosis caused by EBV or CMV, toxoplasmosis, rubella, secondary syphilis, influenza, enterovirus, or viral hepatitis.

The diagnosis can be made or excluded with HIV antibody testing in a child older than age 18 months. In younger infants, a negative result usually excludes HIV infection, but a positive result must be followed by testing for the presence of virus. HIV-infected children with hypogammaglobulinemia occasionally have falsely negative antibody tests. Any child suspected of having HIV infection who has negative serologic tests should be tested by a nucleic acid-based test. Likewise, an adolescent with symptoms of primary infection should be tested for virus by nucleic acid detection.

Prevention

The only 100% effective method of avoiding sexual transmission of HIV infection is abstinence or limiting sexual contact to a mutually monogamous partner who is not HIV-infected. However, condoms—used consistently and correctly—are highly effective in preventing transmission between stable, sexually active couples in which only one partner is HIV-infected. In two studies, seroconversions occurred in 0–2% of discordant couples using condoms consistently compared with 10–15% of couples with inconsistent condom use. A third study reported 1.1 seroconversions per 100 person-years of observation among consistent condom users compared with 9.7 seroconversions among inconsistent users. The CDC provides detailed instructions on correct condom use. Prompt treatment of other sexually transmitted diseases also reduces the risk of sexual transmission. Many experts have recently begun to offer antiretroviral medications as prophylaxis against HIV infection to people who are exposed to HIV in a circumstance that is not likely to recur (eg, sexual assault, condom rupture) although there are no official recommendations for or against this approach.

Vertical transmission can be substantially prevented by giving antiretroviral therapy to the mother during pregnancy and by providing prophylaxis of the newborn. Women with access to antiretroviral therapy should receive three-drug combination regimens during pregnancy. Zidovudine (ZDV) should be incorporated into the regimen if possible since this is the medication with the greatest amount of efficacy and safety data. Combination therapy that results in viral suppression to less than 1000 cp/mL reduces transmission rates to under 1%. Antiretroviral therapy begun later in pregnancy can also reduce transmission although less pro-

foundly. Studies have demonstrated the benefit of ZDV plus lamivudine, nevirapine plus ZDV, nevirapine alone, and even ZDV alone started as late as during labor. Short-course treatments can reduce transmission by 30–50%. Treatment of the infant for 1–2 weeks after birth is critical to preventing infection.

Elective cesarean section reduces the risk of transmission by 50% in women, with or without ZDV treatment. For women receiving combination therapy that suppresses viral load to less than 1000 cp/mL, cesarean section is unlikely to further decrease transmission appreciably.

The CDC and the American College of Obstetrics and Gynecology now recommend offering HIV testing with informed consent routinely to all pregnant women. Women found to be infected should be counseled regarding all HIV-related pregnancy care issues, including the benefits and risks of therapy with antiretroviral agents. Amniocentesis should be avoided if possible. Because breast milk can carry the virus, breastfeeding by HIV-infected mothers is contraindicated when access to safe formula can be ensured, as is the case in the United States.

Infected blood and secretions should be handled according to CDC recommendations.

The CDC recommends postexposure prophylaxis following occupational exposure. Recommended therapy is with ZDV and lamivudine (3TC), with or without a third agent, depending on the degree of risk associated with the exposure.

Treatment

HIV infection calls for specific antiretroviral treatment to prevent progressive deterioration of the immune system as well as prophylactic measures at late stages of HIV infection to prevent opportunistic infections. Whenever possible, children should be enrolled in collaborative treatment studies. Current information on clinical trials may be obtained at:

http://aidsinfo.nih.gov/clinical_trials

Guidelines for the treatment of HIV developed by a national working group of pediatric HIV specialists are published by the United States Public Health System at:

<http://aidsinfo.nih.gov/guidelines>

The treatment paradigm changes frequently; therefore, prior to initiating treatment, expert consultation should be obtained.

A. SPECIFIC MEASURES

1. Principles of HIV treatment—Treatment of HIV is aimed at suppressing viral replication. Numerous studies have demonstrated that the rate of disease progression is directly correlated with the number of HIV copies circulating in plasma. Antiretroviral treatment that reduces HIV replication is associated with increases in CD4 T-lymphocyte counts, reconstitution of immune function, and arrest of disease progression. Children have a remarkable ability to restore normal CD4 T-cell counts even when treatment is started at advanced disease stage. Highly active antiretroviral therapy (HAART) has been available for over 8 years, and, thus far, it appears that successful treatment may be able to prevent disease progression. However, it is clear that even the most potent regimens fail to eradicate virus. HIV persists in long-lived resting cells and cessation of antiretroviral treatment results in resumption of viremia and decline in CD4 lymphocytes. Therefore, treatment for HIV with currently available modalities must be continuous and lifelong.

Emergence of drug-resistant HIV during therapy is a major challenge. HIV has a high spontaneous mutation rate, and emergence of drug resistance during treatment is frequent. Many antiretroviral drugs select for resistant mutations in the virus within weeks to a few months when used as monotherapy. Prevention of resistance mutations requires complete suppression such that virus is not replicating and has no opportunity to generate new mutations. To date, achieving potent viral suppression requires a combination of at least three antiviral agents. Treatment with a combination of drugs with different mechanisms of action provides an additional barrier to resistance as the virus must be resistant to all the drugs in the combination. Finally, strict adherence to the prescribed treatment is critical. Studies demonstrate that more than 95% of the doses must be taken in order to maintain optimal viral suppression. Therefore programs and services that enhance adherence are essential adjuncts of any HAART regimen.

Determining the best time to initiate treatment is a subject of intense discussion and research. For children demonstrating HIV-related symptoms (clinical category C in Table 37-1) or evidence of immune suppression (CD4 lymphocyte counts in category 3; see Table 37-2) the consensus is that treatment should be started irrespective of age or HIV RNA level. In addition, children with a plasma HIV RNA over 100,000 copies/mL are at high risk of progression, so this is a well-accepted criterion for initiating treatment. In the United States, many experts recommend treatment for all HIV-infected infants younger than age 12 months because surrogate markers that reliably identify all infants at risk of rapid progression are lacking.

The best approach for the asymptomatic child with low or modest plasma viral load and without evidence of severe immune suppression is less clear. Such a child might live many years without HIV-related symptoms. It is possible that starting a complex medication regimen with associated toxicities and significant effect on quality of life could be delayed without detriment to the child's long-term prognosis. However, it can also be argued that early treatment will better preserve normal immune function and prevent effects on growth and development that may not be reversed when treatment is started. At present, for children older than age 12 months at diagnosis with mild to moderate clinical symptoms (clinical category A or B) or with moderate immunologic suppression (immune category 2), most experts would consider initiating therapy. For asymptomatic children, many experts favor close observation, with therapy initiated if declining CD4 lymphocyte counts or increasing HIV plasma RNA copy numbers are observed. Once therapy has been initiated, the patient should be monitored every 3 months for changes in plasma virus copy number, CD4 lymphocyte count, symptoms, and adverse drug effects.

2. Considerations in selecting antiretroviral medications—The process of selecting a combination of medications for a particular patient has become highly complex. The FDA has approved 20 drugs from four different classes for the treatment of HIV (Table 37-3). The clinician must consider the potency of the drugs, tolerability, simplicity of dosing, drug interactions, and viral resistance profiles.

Potency, the intrinsic ability of the regimen to fully suppress viral replication, is foremost because without complete suppression resistant virus will emerge. Tolerability is also critical because regimens that are poorly tolerated fail due to poor adherence. When selecting a tolerable regimen, the circumstances and priorities of each individual patient and family must be considered. Certain side effects may be acceptable to one person but for another person be intolerable. Likewise, for some patients the frequency of dosing may have the greatest effect on their compliance, whereas another may be satisfied with frequent dosing provided the number or size of pills taken is reduced. The most tolerable regimens are those with few adverse effects, simple dosing regimens, low number of different medications, few and small pills, and palatable taste. Unfortunately, many of the currently available medications lack these characteristics. However, the pharmaceutical industry is taking these characteristics into consideration in new drug development. Gradually, drugs that can be given once daily and require fewer total pills or liquids are becoming available.

Table 37-3. Antiretroviral drugs approved by the US Food and Drug Administration.

Drug Class or Drug Name	Potential Adverse Effects ¹	Mechanism of Action
Nucleoside/nucleotide reverse transcriptase inhibitors	Lactic acidosis (rare but potentially fatal)	Chain termination of HIV DNA
Abacavir (ACC; Ziagen)	Hypersensitivity reaction	
Didanosin (ddI; Videx)	Pancreatitis, peripheral neuropathy, nausea, diarrhea	
Emtricitabine (FTC; Emtriva)	Minimal toxicity	
Lamivudine (3TC; Epivir)	Minimal toxicity	
Stavudine (d4T; Zerit)	Peripheral neuropathy, lipodystrophy, pancreatitis	
Tenofovir (TDF; Viread)	Headache, nausea, diarrhea, bone demineralization, renal insufficiency (rare)	
Zalcitabine (ddC; Hivid)	Peripheral neuropathy, stomatitis	
Zidovudine (ZDV, AZT; Retrovir)	Anemia, neutropenia, gastrointestinal intolerance, headache	
Zidovudine/lamivudine (CBV, Combivir)	See individual drugs	
Zidovudine/lamivudine/abacavir (TZV, Trizavir)	See individual drugs	
Non-nucleoside reverse transcriptase inhibitors	Rash, rarely Stevens–Johnson syndrome	Synthesis of HIV DNA inhibited
Delavirdine (Rescriptor)	Increased liver transaminases, headache	
Efavirenz (Sustiva)	Central nervous system symptoms, increased transaminases, teratogenic in monkeys	
Nevirapine (Viramune)	Hepatitis	
Protease inhibitors	Glucose intolerance, risk of bleeding in hemophilia, dyslipidemia, lipodystrophy, transaminase elevation	Production of noninfectious virions
Amprenavir (Agenerase)	Rash, oral paresthesia	
Fosamprenavir (Lexiva)		
Atazanavir (Reyataz)	Increased indirect bilirubin	
Indinavir (Crixivan)	Nephrolithiasis, increased indirect bilirubin	
Lopinavir/ritonavir (Kaletra)	Gastrointestinal intolerance	
Nelfinavir (Viracept)	Diarrhea	
Ritonavir (Norvir)	Nausea, circumoral paraesthesias, hepatitis, pancreatitis, taste perversion	
Saquinavir hard gel (Invirase)	Gastrointestinal intolerance	
Saquinavir soft gel (Fortovase)		
Fusion inhibitors		Viral entry inhibited
Enfuvirtide (Fuzeon)	Injection site reactions, increased rate of bacterial pneumonias, hypersensitivity reactions (<1%)	

¹Relative incidence of adverse events depends on specific drug.

Drug interactions between different antiretroviral medications, and with other medications, are frequent and must be considered when selecting a combination of drugs. Most of the protease inhibitors and non-nucleoside reverse transcriptase inhibitors are metabolized by cytochrome P-450 isotypes and therefore can induce or inhibit the metabolism of other drugs that are me-

tabolized by that pathway. Some combinations lead to significant decreases or increases in drug levels, and combined use is contraindicated. On the other hand, drug interactions can also be advantageous. Certain combinations may inhibit metabolism, leading to increased plasma levels without requiring administration of higher doses. Drug absorption and metabolism can

vary widely between individuals, especially for the protease inhibitor class. Therefore, therapeutic drug monitoring to determine the level of drug in serum and adjust doses to achieve therapeutic levels is recommended by some experts.

The potential for viral resistance should be evaluated when selecting a combination. Optimally, an initial regimen would select viral resistance mutations that do not confer cross-resistance to a large number of other drugs. This permits an opportunity to use alternative regimens if resistance to the initial regimen develops. The process is aided by laboratory methods (genotyping and phenotyping) to determine the presence of virus with specific drug resistance mutations in the patient.

3. Specific antiretroviral medications—

a. Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)—The NRTIs act as nucleotide analogues, which are incorporated into HIV DNA during transcription by the HIV reverse transcriptase. The result is chain termination and failure to complete provirus, preventing incorporation of HIV genome into cellular DNA. The human mitochondrial DNA polymerase also has limited affinity for these analogues, the degree varying with the drug. Incorporation of the analogue into mitochondrial DNA is one mechanism thought to lead to adverse effects including pancreatitis, peripheral neuropathy, bone marrow suppression (anemia or neutropenia), and lipodystrophy (loss of peripheral fat and accumulation of visceral fat). Lactic acidosis with hepatic steatosis (fatty liver) is a rare but potentially fatal complication that may result from mitochondrial toxicity.

A hypersensitivity reaction to abacavir occurs in approximately 10% of patients. This adverse effect is not related to mitochondrial toxicity. The reaction, characterized by a flu-like syndrome with or without rash, may be fatal with continued treatment or rechallenge. The NRTIs vary widely with regard to antiviral activity, rates at which viral resistance occurs, and adverse effects. They are dosed either once or twice daily. Most NRTIs are available as liquids, and dosing recommendations for children have been determined for most.

b. Nonnucleoside reverse transcriptase inhibitors (NNRTIs)—NNRTIs also inhibit HIV DNA synthesis but act at a different site on the viral enzyme so no cross-resistance occurs with NRTI. The NNRTIs have potent antiretroviral activity, but single amino acid mutations in the viral reverse transcriptase protein often induce resistance to all three drugs in this class. The most common toxicity is rash. Stevens–Johnson syndrome has been reported, but rash is usually mild and often resolves without changing therapy. Efavirenz is associated with mild central nervous system symptoms

(ie, dizziness, confusion), which usually resolve after the initial weeks of use. Inflammation of the liver, rarely fatal, may occur with any of the drugs in the class but is more common with nevirapine. The NNRTI are dosed once or twice daily and the pill sizes are small. Pediatric dosing information is available for nevirapine and efavirenz.

c. Protease inhibitors—Protease inhibitors (PIs) are synthetic molecules designed to bind to the HIV protease. The protease is critical for the assembly of infectious virions. In the presence of PIs, progeny virus is released from the cell but cannot infect new cells. Acute adverse effects are mainly gastrointestinal intolerance as well as other effects specific to the particular drug (see Table 37–3). All PIs are associated with a risk of glucose intolerance and bleeding for hemophiliacs. Most are associated with dyslipidemia (elevated cholesterol and triglycerides) and may contribute to lipodystrophy. An exception is atazanavir, which is not associated with changes in serum lipids. As a rule, these drugs are highly potent and usually require multiple mutations for high-level resistance to develop. Cross-resistance is observed for some drugs in the class, but others have differing resistance mutations. Taste and pill burden limit tolerability of these medications. The PIs are metabolized by the hepatic P-450 cytochrome enzymes, resulting in many interactions with other drugs, including other antiretrovirals. Careful attention to drug interactions is necessary when treating a patient taking a PI. Regimens combining two PIs can take advantage of the drug interactions and improve the pharmacokinetic properties of the drugs.

d. Fusion inhibitors—Enfuvirtide is the first drug to be FDA-approved in this class. Enfuvirtide interferes with the fusion of the viral envelope and the cell plasma membrane, thereby preventing entry of the virus into the cell. Enfuvirtide must be administered parenterally, and local reactions at the injection site are common.

B. GENERAL MEASURES

1. Immunizations—Combined diphtheria–tetanus–acellular pertussis, inactivated poliovirus, conjugated *Haemophilus influenzae* type b, conjugated *Streptococcus pneumoniae*, and hepatitis B vaccines should be given as recommended for healthy children (see Chapter 9). A dose of 23-valent polysaccharide vaccine at 2 years and a booster after 3–5 years is recommended in addition to the conjugated pneumococcal vaccine series given in infancy. Infected children and their household contacts should receive inactivated influenza vaccine annually after age 6 months. In general, live virus vaccines should be avoided. However, the risk of measles is considered greater than the potential risk of the vaccine in asymptomatic children; thus measles–mumps–rubella

vaccine should be given at age 12 months, with the second dose at 1 month later, provided the child does not have evidence of severe immunosuppression (category C or category 3). Varicella vaccine, also a live virus, is recommended for asymptomatic children without prior evidence of immunosuppression. Studies in progress preliminarily suggest that VZV vaccine will be safe in children with restored CD4 T-cells counts. Because antibody titers to vaccines decline with time and progressive immunodeficiency, prophylaxis with immune globulin for measles exposure and tetanus immune globulin for tetanus-prone wounds should be given regardless of immunization status. Varicella-zoster immune globulin should be considered after each varicella exposure for HIV-infected children with progressive HIV who have not had prior varicella or VZV vaccination.

2. Prophylaxis for infections—Children with suppressed CD4 lymphocyte numbers benefit from prophylactic treatment to prevent opportunistic infections. Children who have had their CD4 counts restored to category 1 or 2 for over 3–4 months can be taken off prophylactic treatments. Antibiotic prophylaxis for PCP has been extremely effective. Because this infection has its highest incidence during the first year of life, PCP prophylaxis is given to all infants born to HIV-infected mothers beginning at age 4–6 weeks. When tests for HIV DNA or RNA are demonstrated negative at age 3–4 months, the infant may discontinue prophylaxis. HIV-infected infants should continue on prophylactic drugs until age 12 months, when further treatment is based on assessment of symptoms and age-adjusted CD4 lymphocyte counts every 3 months. Published guidelines from the CDC for PCP prophylaxis are summarized in Table 37–4 and 37–5.

Children with hypogammaglobulinemia or a history of serious or multiple bacterial infections may benefit from monthly intravenous immune globulin (IVIG) if they are not receiving trimethoprim–sulfamethoxazole. Clarithromycin or azithromycin reduces the frequency of disseminated MAC with a survival benefit for children with very low CD4 counts.

Recurrent mucocutaneous and esophageal candidiasis can be prevented with nystatin, clotrimazole, or fluconazole treatment. Some patients suffer recurrent severe herpes simplex or VZV infections. These may be prevented with oral antiviral prophylaxis (acyclovir, valacyclovir, famciclovir).

HIV-infected children have a higher risk of progression of infections due to *M tuberculosis*. Because the child’s infection is usually acquired from adult household contacts, other household members should be skin-tested for tuberculosis yearly. Adults and children found to have positive tuberculosis skin tests should be

Table 37–4. *Pneumocystis jiroveci*^a (PCP) pneumonia prophylaxis for HIV-exposed and infected infants by age and HIV infection status.

Birth to 4–6 wk	No prophylaxis
4–6 wk to 4 mos	Prophylaxis
4–12 mos	
HIV-infected or indeterminate	Prophylaxis
HIV infection reasonably excluded ^b	No prophylaxis
1–5 y, HIV-infected	Prophylaxis if CD4 count < 500/μL or CD4 < 15% ^c
6–12 y, HIV-infected	Prophylaxis if CD4 count < 200/μL or CD4 < 15% ^c

^aFormerly *Pneumocystis carinii*.

^bAmong children who have had two or more negative HIV cultures or PCR tests, both of which are performed at age 1 month and one of which is performed at age 3–4 months or older.

^cProphylaxis should be considered on a case-by-case basis for children who might otherwise be at risk for pneumocystis pneumonia, such as those with rapidly declining CD4 counts or percentages or children with category C conditions.

<http://www.aidsinfo.nih.gov/guidelines>

Table 37–5. Drug regimens for *Pneumocystis jirovac*i prophylaxis for children over age 4 weeks.

Recommended regimen

Trimethoprim–sulfamethoxazole, 150 mg TMP/m²/d plus 750 mg SMX/m²/d, administered orally, divided into two doses per day 3 days a week on consecutive days

Alternative (same total daily dosages):

Single daily dose 3 days a week on consecutive days

Divided twice-daily doses 7 days a week

Divided twice-daily doses 3 days a week on alternate days

Alternative if trimethoprim–sulfamethoxazole is not tolerated^a

Dapsone, 2 mg/kg/d (not to exceed 100 mg) orally once daily

Aerosolized pentamidine (children over age 5 years), 300 mg via Respigard II inhaler monthly

Atovaquone, age 1–3 mos and > 24 mos, 30 mg/kg orally once daily; age 4–24 mos, 45 mg/kg orally once daily

^aIf dapsone, aerosolized pentamidine, or atovaquone is not tolerated, some clinicians use intravenous pentamidine 4 mg/kg every 2–4 wk.

Adapted from 2001 USPHS/IDSA Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus.

evaluated further for disease and receive treatment according to their HIV status.

3. Infections and other conditions—Rates of bacteremia, especially pneumococcal bacteremia, and shingles are higher among HIV-infected children, even without severe suppression of CD4 counts. Therefore, blood cultures should be obtained liberally in ill-appearing or febrile HIV-infected children. VZV and herpes simplex virus infections are treated with acyclovir since symptoms may be prolonged in children with HIV. Short courses of valacyclovir or famciclovir—drugs with good bioavailability—are also effective, although not approved for children. Aphthous ulcers also occur in children, even when on suppressive antiretroviral drug therapy. Symptomatic CMV infection is treated with ganciclovir or foscarnet and requires ongoing secondary prophylaxis if CD4 lymphocytes counts remain low. MAC requires treatment with a multidrug regimen to delay the emergence of resistance. Lymphoid interstitial pneumonitis may respond to corticosteroid therapy. Chronic parvovirus as a cause of anemia should be investigated and can be treated with IVIG. Anemia and granulocytopenia, whether drug-induced or HIV-induced, may respond to epoetin alfa (erythropoietin) and filgrastim (granulocyte colony-stimulating factor, G-CSF), respectively. Rarely transfusions are needed; CMV-seronegative blood should be used.

4. General support—Growth failure (weight and height) is one of the earliest and most sensitive markers of disease progression. The cause is a combination of increased metabolic needs related to chronic infection and decreased caloric intake. Nutritional evaluation and counseling should be a part of early care before problems arise. When a child's routine diet fails to provide adequate nutrition, supplemental nutrition in the form of oral supplements and nutritious snacks is often required. Supplemental feeding by gastrointestinal tubes may be required for children who are unable to consume sufficient calories orally.

Evaluation and support for psychosocial needs of HIV-affected families is imperative. As with other chronic illnesses, HIV infection affects all family members, and it also carries an additional social stigma. Emotional concerns and financial needs are more prominent than medical needs at many stages of the disease process and influence the family's ability to comply with a medical treatment regimen. HIV-infected children often have comorbid mental health conditions. Ideally, care should be coordinated by a team of caregivers that is familiar with this disease and the newest therapies and that has access to community resources.

Prognosis

Plasma viremia and age-adjusted CD4 lymphocyte count can be used to assess the risk of progression and complications of HIV. Poor prognosis in perinatal infection is associated with encephalopathy, infections with *P jiroveci*, early development of AIDS, and a rapidly declining CD4 lymphocyte count. Without treatment, approximately 30% of infected infants will progress to severe symptoms (class C) or death by 1 year of age. Among optimally treated children rates of progression and mortality are low.

Public Health Issues

In general, the infant or child who is well enough to attend day care or school should be treated no differently from other children. The exception may be a toddler with uncontrollable biting behavior or bleeding lesions that cannot be covered adequately; in these situations, the child may be withheld from group day care. Routine good hygiene used for the prevention of transmission of other infectious diseases is appropriate for the prevention of common infections, which may be severe in the HIV-infected child. Optimally the school health care provider and teacher will be aware of the diagnosis, but there is no legal requirement that any individual at the school or day care center be informed. The parents and the child may prefer to keep the diagnosis confidential, because the stigma associated with HIV infection may be difficult to overcome. Adolescents with HIV should receive counseling on the risk of transmission through sexual activity and shared needles. Programs should be made available to encourage use of barrier protection and to develop strategies for disclosure to their partners and other friends.

Horizontal transmission (ie, in the absence of sexual contact or injecting drug use) of HIV is exceedingly rare and is associated with exposure of broken skin or mucous membranes to HIV-infected blood or bloody secretions. Because undiagnosed HIV-infected infants and children might be enrolled, all schools and day care centers should have policies with simple guidelines for using universal precautions to prevent transmission of HIV infection in these settings. Saliva, tears, urine, and stool are not contagious if there is no gross blood in these fluids. A barrier protection (eg, latex or rubber gloves, thick pads of fabric or paper) should be used when possible contact with blood or bloody body fluids may occur. Objects that might be contaminated with blood, such as razors or toothbrushes, should not be shared. No special care is required for dishes, towels, toys, or bedclothes. Blood-soiled clothing may be washed routinely with hot water and detergent. Contaminated surfaces may be disinfected easily with a vari-

ety of agents, including household bleach (1:10 dilution), some commercial disinfectants (eg, Lysol), or 70% isopropyl alcohol.

Conclusion

Pediatric HIV infection is a complex and multifaceted disease. Many aspects of care are under intense investigation, and recommendations for clinical care change frequently. Updated information should be sought whenever a child is diagnosed with HIV infection. With recognition of the longer survival time in most infected children, this disease is now approached as a chronic illness. Many children, infected from birth, are entering adolescence and young adulthood. The complexity of antiretroviral drug therapy requires care from a provider with HIV expertise. Primary care physicians are encouraged to participate in the care of HIV-infected children in collaboration with centers staffed by personnel with expertise in pediatric HIV issues.

Infections: Bacterial & Spirochetal

38

John W. Ogle, MD, & Marsha S. Anderson, MD

I. BACTERIAL INFECTIONS

GROUP A STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Streptococcal pharyngitis:

- *Clinical diagnosis based entirely on symptoms; signs and physical examination unreliable.*
- *Throat culture or rapid antigen detection test positive for group A streptococci.*

Impetigo:

- *Rapidly spreading, highly infectious skin rash.*
- *Erythematous denuded areas and honey-colored crusts.*
- *On culture, group A streptococci are grown in most (not all) cases.*

General Considerations

Group A streptococci (GAS) are common gram-positive bacteria producing a wide variety of clinical illnesses, including acute pharyngitis, impetigo, cellulitis, and scarlet fever, the generalized illness caused by strains that elaborate erythrogenic toxin. Group A streptococci can also cause pneumonia, septic arthritis, osteomyelitis, meningitis, and other less common infections. GAS infections may also produce nonsuppurative sequelae (rheumatic fever, acute glomerulonephritis).

The cell walls of streptococci contain both carbohydrate and protein antigens. The C-carbohydrate antigen determines the group, and the M- or T-protein antigens determine the specific type. In most strains, the M protein appears to confer virulence, and antibod-

ies developed against the M protein are protective against reinfection with that type.

Group A streptococci are almost all β -hemolytic. These organisms may be carried without symptoms on the skin and in the pharynx, rectum, and vagina. Between 10% and 15% of school children in some studies are asymptomatic pharyngeal carriers of group A streptococci. Streptococcal carriers are individuals who do not mount an immune response to the organism and are therefore believed to be at low risk for nonsuppurative sequelae. All group A streptococci are sensitive to penicillin. Resistance to erythromycin is common in some countries and has increased in the United States.

A. CLINICAL FINDINGS

1. Respiratory infections—

a. Infancy and early childhood (< age 3 years)—The onset of infection is insidious, with mild symptoms (eg, low-grade fever, serous nasal discharge, and pallor). Otitis media is common. Pharyngitis with exudate and cervical adenitis are uncommon in this age group.

b. Childhood type—Onset is sudden, with fever and marked malaise and often with repeated vomiting. The pharynx is sore and edematous, and the tonsillar area generally shows exudate. Anterior cervical lymph nodes are tender and enlarged. Small petechiae are frequently seen on the soft palate. In scarlet fever, the skin is diffusely erythematous and appears sunburned and roughened (so-called sandpaper rash). The rash is most intense in the axillae and groin and on the abdomen and trunk. It blanches on pressure except in the skin folds, which do not blanch and are pigmented (Pastia sign). The rash usually appears 24 hours after the onset of fever and rapidly spreads over the next 1–2 days. Desquamation begins on the face at the end of the first week and becomes generalized by the third week. Early, the surface of the tongue is coated white, with the papillae enlarged and bright red (so-called white strawberry tongue). Subsequently desquamation occurs, and the tongue appears beefy red (strawberry tongue). The face generally shows circumoral pallor. Petechiae may be seen on all mucosal surfaces.

c. **Adult type**—The adult type is characterized by exudative or nonexudative tonsillitis with fewer systemic symptoms, lower fever, and no vomiting. Scarlet fever is uncommon in adults.

2. Impetigo—Streptococcal impetigo begins as a papule that vesiculates and then breaks, leaving a denuded area covered by a honey-colored crust. Both *Staphylococcus aureus* and group A streptococci are isolated in some cases. The lesions spread readily and diffusely. Local lymph nodes may become swollen and inflamed. Although the affected child often lacks systemic symptoms, occasionally a high fever and toxicity are present. If flaccid bullae are present, the disease is called bullous impetigo and is caused by an epidermolytic toxin-producing strain of *S aureus*.

3. Cellulitis—The portal of entry is often an insect bite or superficial abrasion on an extremity. A diffuse and rapidly spreading cellulitis occurs that involves the subcutaneous tissues and extends along the lymphatic pathways with only minimal local suppuration. Local acute lymphadenitis occurs. The child is usually acutely ill, with fever and malaise. In classic erysipelas, the involved area is bright red, swollen, warm, and very tender. The infection may extend rapidly from the lymphatics to the bloodstream.

Streptococcal perianal cellulitis is an entity peculiar to young children. Pain with defecation often leads to constipation, which may be the presenting complaint. The child is afebrile and otherwise well. Perianal erythema and tenderness and painful rectal examination are the only abnormal physical findings. Scant rectal bleeding with defecation may occur. Culture of a perianal swab specimen usually yields a heavy growth of group A streptococcus. A variant of this syndrome is streptococcal vaginitis in prepubertal girls. Symptoms are dysuria and pain; marked erythema and tenderness of the introitus and blood-tinged discharge are seen.

4. Necrotizing fasciitis—This dangerous disease is being reported more frequently, particularly as a complication of varicella infection. Only 20–40% of cases are due to GAS. About 30–40% are due to *S aureus* and the rest to mixed bacterial infections. The disease is characterized by extensive necrosis of superficial fasciae, with undermining of surrounding tissue and extreme systemic toxicity. Initially the skin overlying the infection is tender and pale red without distinct borders, resembling subcutaneous cellulitis. Blisters or bullae may appear. The color deepens to a distinct purple or in some cases becomes very pale. The involved area may develop mild to massive edema. Early recognition and aggressive debridement of necrotic tissue are essential.

5. Group A streptococcal infections in newborn nurseries—GAS epidemics occur occasionally in nurs-

eries. The organism may be introduced into the nursery from the vaginal tract of a mother or from the throat or nose of a mother or a staff member. The organism then spreads from infant to infant. The umbilical stump is colonized while the infant is in the nursery. As is true also in staphylococcal infections, there may be no or few clinical manifestations while infants are still in the nursery. Most often, a colonized infant develops a chronic, oozing omphalitis days later at home. The organism may spread from the infant to other family members. More serious and even fatal infections may develop, including sepsis, meningitis, empyema, septic arthritis, and peritonitis.

6. Streptococcal sepsis—Serious illness from GAS sepsis is now more common both in children and in adults. Rash and scarlet fever may be present. Prostration and shock result in high mortality rates. Pharyngitis is uncommon as an antecedent illness. Underlying disease is a predisposing factor.

7. Streptococcal toxic shock syndrome (STSS)—A toxic shock syndrome caused by GAS has been defined. Like *S aureus*-associated toxic shock, multiorgan system involvement is a prominent part of the illness. The criteria for diagnosis include (1) isolation of GAS from a normally sterile site, hypotension or shock, and (2) at least two of the following: renal impairment (creatinine > 2 times the upper limit of normal for age), thrombocytopenia (< 100,000/mm³) or coagulopathy, liver involvement (transaminases > 2 times normal), acute respiratory distress syndrome (ARDS), generalized erythematous macular rash, soft tissue necrosis (myositis, necrotizing fasciitis, gangrene). In cases that otherwise meet clinical criteria, isolation of GAS from a nonsterile site (throat, wound, vagina) is indicative of a probable cause.

B. LABORATORY FINDINGS

Leukocytosis with a marked shift to the left is seen early. Eosinophilia regularly appears during convalescence. β -Hemolytic streptococci are cultured from the throat. The organism may be cultured from the skin and by needle aspiration from subcutaneous tissues and other involved sites such as infected nodes. Occasionally blood cultures are positive. GAS may be identified most easily by their sensitivity to bacitracin. Rapid antigen detection tests are 60–95% sensitive and over 95% specific for detecting GAS in throat swabs. The predictive value of negative tests is about 80%, meaning that one in five patients with a positive throat culture will have a negative rapid antigen test. Rapid tests may be useful when early antibiotic therapy is considered, but because the currently available tests lack sensitivity, a standard culture should be done on specimens testing negative by the rapid test.

Antistreptolysin O (ASO) titers rise about 150 units within 2 weeks after an acute infection. Elevated ASO

and anti-DNase B titers are useful in documenting prior throat infections in cases of acute rheumatic fever. The streptozyme test is a 2-minute slide test that detects antibodies to streptolysin O, hyaluronidase, streptokinase, DNase B, and NADase. It is somewhat more sensitive than the measurement of ASO titers.

Proteinuria, cylindruria, and minimal hematuria may be seen early in children with streptococcal infection. True poststreptococcal glomerulonephritis is seen 1–4 weeks after the respiratory or skin infection.

Differential Diagnosis

Streptococcal infection in early childhood must be differentiated from adenovirus and other respiratory virus infections. The pharyngitis in herpangina (coxsackie A viruses) is vesicular or ulcerative. Herpes simplex also causes ulcerative lesions, which most commonly involve the anterior pharynx, tongue, and gums. In infectious mononucleosis, the pharyngitis is also exudative, but splenomegaly and generalized adenopathy are typical, and laboratory findings are often diagnostic (atypical lymphocytes, elevated liver enzymes, and a positive heterophil or other serologic test for mononucleosis). Uncomplicated streptococcal pharyngitis improves within 24–48 hours if penicillin is given and by 72–96 hours without antimicrobials.

Group G and group C streptococci are uncommon causes of pharyngitis but have been implicated in epidemics of sore throat in college students. Acute rheumatic fever does not occur following group G or group C infection, although acute glomerulonephritis is a complication. *Arcanobacterium hemolyticum* may cause pharyngitis with scarlatina-like or maculopapular truncal rash. In diphtheria, systemic symptoms, vomiting, and fever are less marked; pharyngeal pseudomembrane is confluent and adherent; the throat is less red; and cervical adenopathy is prominent. Pharyngeal tularemia causes white rather than yellow exudate. There is little erythema, and cultures for β -hemolytic streptococci are negative. A history of exposure to rabbits and a failure to respond to antimicrobials may suggest the diagnosis. Leukemia and agranulocytosis may present with pharyngitis and are diagnosed by bone marrow examination.

Scarlet fever must be differentiated from other exanthematous diseases (principally rubella), erythema due to sunburn, drug reactions, Kawasaki disease, toxic shock syndrome, and staphylococcal scalded skin syndrome (see also Table 36–3).

Complications

Suppurative complications of GAS infections include sinusitis, otitis, mastoiditis, cervical lymphadenitis,

pneumonia, empyema, septic arthritis, and meningitis. Spread of streptococcal infection from the throat to other sites—principally the skin (impetigo) and vagina—is common and should be considered in every instance of chronic vaginal discharge or chronic skin infection, such as that complicating childhood eczema. Both acute rheumatic fever and acute glomerulonephritis are nonsuppurative complications of GAS infections.

A. ACUTE RHEUMATIC FEVER (SEE CHAPTER 19.)

B. ACUTE GLOMERULONEPHRITIS

Acute glomerulonephritis can follow streptococcal infections of either the pharynx or the skin—in contrast to rheumatic fever, which follows pharyngeal infection only. Glomerulonephritis may occur at any age, even infancy. In most reports of acute glomerulonephritis, males predominate by a ratio of 2:1, whereas acute rheumatic fever occurs with equal frequency in both sexes. Certain M types are associated strongly with poststreptococcal glomerulonephritis (nephritogenic types). The serotypes resident on or producing disease on the skin often differ from those found in the pharynx.

The incidence of acute glomerulonephritis after streptococcal infection is variable and has ranged from nil to 28%. Several outbreaks of acute glomerulonephritis in families have involved 50–75% of siblings of affected patients in 1- to 7-week periods. Second attacks of glomerulonephritis are rare. The median latent period between infection and the development of glomerulonephritis is 10 days. In contrast, acute rheumatic fever occurs after a median latent period of 18 days.

Treatment

A. SPECIFIC MEASURES

Treatment is directed toward both eradication of acute infection and prevention of rheumatic fever. In patients with pharyngitis, antibiotics should be started early to relieve symptoms and should be continued for 10 days to prevent rheumatic fever. Although early therapy has not been shown to prevent glomerulonephritis, it seems advisable to treat impetigo promptly in sibling contacts of patients with poststreptococcal nephritis. Neither sulfonamides nor trimethoprim–sulfamethoxazole (TMP–SMX) is effective in the treatment of streptococcal infections. Although topical therapy for impetigo with antimicrobial ointments (especially mupirocin) is as effective as systemic therapy, it does not eradicate pharyngeal carriage and is less practical for extensive disease.

1. Penicillin—Except for penicillin-allergic patients, penicillin V (phenoxymethyl penicillin) is the drug of choice. Penicillin resistance has never been documented. For children weighing less than 27 kg, the regimen is 250 mg, given orally bid or tid for 10 days. For heavier children, adolescents, or adults, 500 mg bid–tid is recommended. Giving penicillin V (250 mg) bid is as effective as more frequent oral administration or intramuscular therapy, and it may lead to better compliance. Another alternative for treatment of pharyngitis and impetigo is a single dose of benzathine penicillin G, given intramuscularly (0.6 million units for children weighing < 60 lb [27.2 kg] and 1.2 million units for children weighing > 60 lb [27.2 kg]). Intramuscular delivery ensures compliance, but is painful. Parenteral therapy is indicated if vomiting or sepsis is present. Mild cellulitis due to GAS may be treated orally or intramuscularly as outlined earlier.

Cellulitis requiring hospitalization should be treated with aqueous penicillin G (150,000 units/kg/d, given intravenously in four to six divided doses) or procaine penicillin (50,000 units/kg, given intramuscularly once or twice a day) until there is marked improvement. Penicillin V, 125–250 mg q6h, may then be given orally to complete a 10-day course. Acute cervical lymphadenitis may require incision and drainage. Treatment of necrotizing fasciitis requires emergency surgical debridement followed by high-dose parenteral antibiotics appropriate to the organisms cultured.

2. Other antibiotics—For penicillin-allergic patients with pharyngitis or impetigo the following alternative regimens have been used: erythromycin estolate (20–40 mg/kg/d in two to four divided doses) for 10 days, clarithromycin (15 mg/kg/d in two divided doses) for 10 days, and azithromycin (12 mg/kg/d) once daily for 5 days. Erythromycin resistance, although not currently widespread in the United States, was reported in 48% of strains tested in Pittsburgh in 2001. Penicillin-allergic patients from areas with high rates of erythromycin resistance may require an alternative antibiotic. Clindamycin, cephalexin, cefibuten, cefdinir, and cefadroxil are other effective oral antimicrobials. The dosage of clindamycin is 10–20 mg/kg/d orally in four divided doses. Each of these drugs should be given for 10 days. Patients with immediate, anaphylactic hypersensitivity to penicillin should not receive cephalosporins, because up to 15% will also be allergic to cephalosporins. In most studies, bacteriologic failures after cephalosporin therapy are less frequent than failures following penicillin. However, cephalosporins are far more expensive than penicillin. Additionally, there are few conclusive data on the ability of these agents to prevent rheumatic fever. Therefore, penicillin remains the agent of choice for nonallergic patients. Many strains are resistant to tetracycline.

For infections requiring intravenous therapy, aqueous penicillin G (250,000 units/kg in six divided doses given intravenously) is usually the drug of choice. Cefazolin (100–150 mg/kg/d intravenously or intramuscularly in three divided doses), clindamycin (25–40 mg/kg/d intravenously in four divided doses), and vancomycin (40 mg/kg/d intravenously in four divided doses) are alternatives in penicillin-allergic patients. Clindamycin is preferred by many and may be superior to penicillin for necrotizing fasciitis. Clindamycin should not be used alone empirically for severe, suspected GAS infections because a small percentage of isolates in the United States are resistant to clindamycin. Some physicians use both penicillin and clindamycin in patients with STSS.

3. Serious GAS disease—Serious GAS infections, such as pneumonia, osteomyelitis, septic arthritis, sepsis, endocarditis, meningitis, and STSS, require parenteral antimicrobial therapy. Penicillin G is the drug of choice for these invasive infections. Clindamycin, in addition to penicillin G, is advocated by many experts for STSS or necrotizing fasciitis. Necrotizing fasciitis requires prompt surgical debridement. Patients with STSS need attention given to volume status and blood pressure and evaluation for a focus of infection, if not readily apparent. Intravenous immune globulin (in addition to antibiotics) has sometimes been used in severe cases.

4. Treatment failure—Even when compliance is perfect, organisms will be found in 5–15% of children after cessation of therapy. Reculture is indicated only in the patient with pharyngitis or if the patient has a personal or family history of rheumatic fever. Repeat treatment at least once with an oral cephalosporin or clindamycin is indicated in patients with recurrent culture-positive pharyngitis.

5. Prevention of recurrences in rheumatic individuals—The preferred prophylaxis for rheumatic individuals is benzathine penicillin G, 1.2 million units intramuscularly every 4 weeks. If the risk of streptococcal exposure is high, every 3 week dosing is preferred. One of the following alternative oral prophylactic regimens may be used: sulfadiazine, 0.5 g (if < 27 kg) or 1 g (if > 27 kg)/d; penicillin V, 200,000 units bid; or erythromycin, 250 mg bid. Prophylaxis is continued for at least 5 years or until age 21 years (whichever is longer) if carditis is absent. Prophylaxis in these individuals should be continued if the risk of contact with persons with GAS is high (eg, parents of school-age children, pediatric nurses, teachers). In the presence of carditis without residual heart or valvular disease, a minimum of 10 years, (or well into adulthood, whichever is longer) is the minimum duration. If the patient has residual valvular heart disease, many recommend life-

long prophylaxis. These patients should be at least 10 years from their last episode of rheumatic disease and at least 40 years of age prior to considering discontinuation of prophylaxis. A similar approach to the prevention of recurrences of glomerulonephritis may be indicated during childhood when there is a suspicion that repeated streptococcal infections coincide with flare-ups of acute glomerulonephritis.

B. GENERAL MEASURES

Acetaminophen is useful for pain or fever. Local treatment of impetigo may promote earlier healing. Crusts should first be soaked off. Areas beneath the crusts should then be washed with soap daily.

C. TREATMENT OF COMPLICATIONS

Rheumatic fever is best prevented by early and adequate penicillin treatment of the streptococcal infection (see earlier discussion).

D. TREATMENT OF CARRIERS

Identification and treatment of GAS carriers is difficult. There are no established clinical or serologic criteria for differentiating carriers from the truly infected. Some children receive multiple courses of antimicrobials, with persistence of GAS in the throat, leading to a so-called streptococcal neurosis on the part of families.

In certain circumstances, eradication of carriage may be desirable: (1) when a family member has a history of rheumatic fever, (2) when an episode of GAS toxic shock syndrome or necrotizing fasciitis has occurred in a household contact, (3) multiple, recurring, documented episodes of GAS in family members despite adequate therapy, and (4) during an outbreak of rheumatic fever or GAS-associated glomerulonephritis. Clindamycin (20 mg/kg/d, given orally in three divided doses, to a maximum of 1.8 g/d) or a combination of rifampin (20 mg/kg/d, given orally for 4 days) and penicillin in standard dosage given orally has been used to attempt eradication of carriage.

Prognosis

Death is rare except in infants or young children with sepsis or pneumonia. The febrile course is shortened and complications eliminated by early and adequate treatment with penicillin.

GROUP B STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Early-onset neonatal infection:

- *Newborn younger than age 7 days, with rapidly progressing overwhelming sepsis, with or without meningitis.*
- *Pneumonia with respiratory failure frequently present; chest radiograph resembles that seen in hyaline membrane disease.*
- *Leukopenia with a shift to the left.*
- *Blood or CSF cultures growing group B streptococci.*

Late-onset infection:

- *Meningitis, sepsis, or other focal infection in a child age 1–16 weeks with blood or CSF cultures growing group B streptococci.*

General Considerations

Although most patients with group B streptococcal (GBS) disease are infants younger than age 3 months, cases are seen in infants age 4–5 months. Serious infection also occurs in women with puerperal sepsis, in immunocompromised patients, in patients with cirrhosis and spontaneous peritonitis, and in diabetic patients with cellulitis. GBS infections occur as frequently as gram-negative infections in the newborn period. Two distinct clinical syndromes distinguished by differing perinatal events, age at onset, and serotype of the infecting strain occur in these infants.

Risk factors for early-onset group GBS disease include maternal GBS colonization, gestational age less than 37 weeks, rupture of membranes more than 18 hours prior to presentation, young maternal age, black race, and low or absent maternal GBS anticapsular antibodies.

Clinical Findings

Early-onset illness is observed in newborns younger than 7 days old. The onset of symptoms in the majority of these infants occurs in the first 48 hours of life, and most are ill within 6 hours. Apnea is often the first sign. Sepsis, meningitis, apnea, and pneumonia are the most common clinical presentations. There is a high incidence of associated maternal obstetric complications, especially premature labor and prolonged rupture of the membranes. Newborns with early-onset disease are severely ill at the time of diagnosis, and more than 50% die. Although most infants with early-onset infections are full-term, premature infants are at increased risk for the disease. Newborns with early-onset infection acquire GBS in utero as an ascending infection or during passage through the birth canal. When early-onset infection is complicated by meningitis, as occurs in approximately 30% of patients, more than 80% of the bacterial isolates belong to serotype III. Postmortem examination of infants with early-onset disease almost always reveals pulmonary inflammatory infiltrates and hyaline membranes containing large numbers of GBS.

Late-onset infection occurs in infants between ages 7 days and 4 months (median age at onset, about 4 weeks). Maternal obstetric complications are not usually associated with late-onset infection. These infants are usually not as ill at the time of diagnosis as those with early-onset disease, and the mortality rate is lower. In recent series, about 37% of patients have meningitis and 46% have sepsis. Septic arthritis and osteomyelitis, meningitis, occult bacteremia, otitis media, ethmoiditis, conjunctivitis, cellulitis (particularly of the face or submandibular area), lymphadenitis, breast abscess, empyema, and impetigo have been described. Strains of GBS possessing the capsular type III polysaccharide antigen are isolated from more than 95% of infants with late-onset disease, regardless of clinical manifestations. The exact mode of transmission of the organisms is not well defined.

Diagnosis

Culture of GBS from a normally sterile site such as blood, pleural fluid, or cerebrospinal fluid (CSF) provides proof of diagnosis. Frequent false-positive results limit the usefulness of testing for GBS antigen in urine and CSF.

Prevention

Many women of childbearing age possess type-specific circulating antibody to the polysaccharide antigens for GBS. These antibodies are transferred to the newborn via the placental circulation. Carriers delivering healthy

infants have significant serum levels of IgG antibody to this antigen. In contrast, women delivering infants who develop GBS disease of either the early- or late-onset type rarely have detectable antibody in their sera.

Monovalent and bivalent vaccines with type II or III polysaccharide antigens have been studied in pregnant women, with 80–90% of bivalent conjugate vaccine recipients developing fourfold or greater increases in GBS capsular polysaccharide type II- or III-specific IgG. These reports are encouraging that a multivalent vaccine could be developed and given to pregnant women to prevent many cases of early-onset GBS disease.

The Centers for Disease Control (CDC) has issued culture-based maternal guidelines for the prevention of early-onset GBS disease.

CDC Recommendations for Prevention of Perinatal GBS Disease

- All pregnant women should be screened at 35–37 weeks' gestation with a vaginal and rectal culture for GBS.

Exceptions: women with known GBS bacteremia during the current pregnancy or women who have delivered a previous infant with GBS disease do not need screening—all these women need intrapartum prophylaxis.

- If GBS status is unknown at onset of labor or rupture of membranes, intrapartum chemoprophylaxis should be administered to women with any of the following:

Gestation less than 37 weeks.

Rupture of membranes more than 18 hours

Intrapartum temperature of greater than 38.0°C (> 100.4°F)

- Women with GBS colonization and a planned cesarean delivery done prior to labor and rupture of membranes do not routinely need intrapartum antibiotics
- Intrapartum antibiotic recommendations (Table 38–1).
- Empiric treatment of a neonate whose mother received intrapartum antibiotics (IAP) for prevention of GBS (Figure 38–1).

Treatment of GBS Disease

Intravenous ampicillin and an aminoglycoside is the initial regimen of choice for newborns with presumptive invasive GBS disease. For neonates younger than 7 days of age with meningitis, the recommended ampicillin dosage is 200–300 mg/kg/d, given intravenously in 3 divided doses. For infants older than 7 days of age,

Table 38–1. CDC recommended regimens for intrapartum prophylaxis for perinatal GBS disease.^a

Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 million units IV q4h until delivery
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV q4h until delivery
If penicillin allergic ^b	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV q8h until delivery
Patients at high risk for anaphylax ^c	
GBS susceptible to clindamycin and erythromycin ^d	Clindamycin, 900 mg IV q8h until delivery
	OR
	Erythromycin, 500 mg IV q6h until delivery
GBS resistant to clindamycin or erythromycin or susceptibility unknown	Vancomycin, ^e 1 g IV q12h until delivery

^aBroader-spectrum agents, including an agent active against GBS, may be necessary for treatment of chorioamnionitis.

^bHistory of penicillin allergy should be assessed to determine whether a high risk for anaphylaxis is present. Penicillin-allergic patients at high risk for anaphylaxis are those who have experienced immediate hypersensitivity to penicillin including a history of penicillin-related anaphylaxis; other high-risk patients are those with asthma or other diseases that would make anaphylaxis more dangerous or difficult to treat, such as persons being treated with beta-adrenergic-blocking agents.

^cIf laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing should be performed on prenatal GBS isolates from penicillin allergic women at high risk for anaphylaxis.

^dResistance to erythromycin is often but not always associated with clindamycin resistance. If a strain is resistant to erythromycin but appears susceptible to clindamycin, it may have inducible resistance to clindamycin.

^eCefazolin is preferred over vancomycin for women with a history of penicillin allergy other than immediate hypersensitivity reactions, and pharmacologic data suggest it achieves effective intraamniotic concentrations. Vancomycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.

Reprinted, with permission, from Schrag S et al: Prevention of perinatal Group B streptococcal disease, revised guidelines from CDC. *MMWR* 2002;51(RR11);1.

the recommended ampicillin dosage is 300 mg/kg/d, given intravenously in 4–6 divided doses. Penicillin G can be used once GBS is identified and clinical and microbiologic responses have occurred. GBS are less susceptible than other streptococci to penicillin, and high doses are recommended, especially for meningitis. In infants with meningitis, the recommended dosage of penicillin G varies with age: for infants age 7 days or younger, 250,000–450,000 units/kg/d, given intravenously in 3 divided doses; for infants older than age 7 days, 450,000–500,000 units/kg/d, given intravenously in 4–6 divided doses.

A second lumbar puncture after 24–48 hours of therapy is recommended by some experts to assess efficacy. Duration of therapy is 2–3 weeks for meningitis; at least 4 weeks for osteomyelitis, cerebritis, ventriculitis, or endocarditis; and 10–14 days for most other infections. Therapy does not eradicate carriage of the organism. Ceftriaxone is active in vitro against GBS, and because of its long serum half-life it may be given once or twice daily intramuscularly or intravenously.

Ceftriaxone is sometimes used to complete a course of therapy when intravenous access has become difficult. Ceftriaxone is usually not used in newborns because of associated cholestasis.

STREPTOCOCCAL INFECTIONS WITH ORGANISMS OTHER THAN GROUP A OR B

Streptococci of groups other than A and B are part of the normal flora of humans and can occasionally cause disease. Group C or group G organisms occasionally produce pharyngitis (with an ASO rise) but without risk of subsequent rheumatic fever. Acute glomerulonephritis may occasionally occur. Group D streptococci and *Enterococcus* species are normal inhabitants of the gastrointestinal tract and may produce urinary tract infections, meningitis, and sepsis in the newborn, as well as endocarditis. Nosocomial infections caused by *Enterococcus* are frequent in neonatal and oncology units and in patients with central venous catheters.

^a If no maternal intrapartum prophylaxis for GBS was administered despite an indication being present, data are insufficient on which to recommend a single management strategy.

^b Includes complete blood cell count and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.

^c Duration of therapy varies depending on results of blood culture, cerebrospinal fluid findings, if obtained, and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 h.

^d CBC with differential and blood culture.

^e Applies only to penicillin, ampicillin, or celazoin and assumes recommended dosing regimens.

^f A healthy-appearing infant who was ≥ 38 weeks gestation at delivery and whose mother received ≥ 4 h of intrapartum prophylaxis before delivery may be discharged home after 24 h if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 h and until criteria for discharge are achieved.

Figure 38–1. Algorithm for treatment of a newborn whose mother received intrapartum antimicrobial prophylaxis for prevention of GBS or suspected chorioamnionitis. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstance or institutional preferences may be appropriate.

(Reprinted, with permission, from Schrag S et al: Prevention of perinatal group B streptococcal disease, revised guidelines from CDC. *MMWR* 2002;51 (RR11):1.)

Nonhemolytic aerobic streptococci and β -hemolytic streptococci are normal flora of the mouth. They are involved in the production of dental plaque and probably dental caries and are the most common cause of subacute infective endocarditis. Finally, there are numerous anaerobic and microaerophilic streptococci, normal flora of the mouth, skin, and gastrointestinal tract, which alone or in combination with other bacteria may cause sinusitis, dental abscesses, brain abscesses, and intra-abdominal or lung abscesses.

Treatment

A. ENTEROCOCCAL INFECTIONS

1. Infections with ampicillin-susceptible enterococci—Lower tract urinary infections can be treated with oral amoxicillin alone. Pyelonephritis should be treated intravenously with ampicillin and gentamicin (gentamicin dosing may need to be adjusted for altered renal function). Sepsis or meningitis in the newborn should be treated intravenously with a combination of

ampicillin (100–200 mg/kg/d in three divided doses) and gentamicin (6–7.5 mg/kg/d in three divided doses). Monitoring of aminoglycoside levels is done to avoid toxicity and to ensure therapeutic levels. Endocarditis requires 4–6 weeks of intravenous treatment. Penicillin G (250,000 units/kg/d in six to eight divided doses) plus streptomycin (30 mg/kg/d) or gentamicin (6–7.5 mg/kg/d in three divided doses) is most often used. Cephalosporins are not effective.

2. Infections with ampicillin-resistant enterococci—Ampicillin-resistant enterococci are often susceptible to vancomycin (40–60 mg/kg/d in four divided doses). Two agents are effective against vancomycin-resistant enterococci and approved for use in adults. Quinipristin/dalfopristin (Synercid) has been approved for infections with vancomycin-resistant *Enterococcus faecium* (not effective against *E faecalis*). Linezolid (Zyvox) is approved for vancomycin-resistant *E faecalis* and *E faecium* infections. Resistance to these newer agents has been rarely reported. Infectious disease consultation is recommended when use of these drugs is entertained.

B. VIRIDANS STREPTOCOCCAL INFECTIONS (SUBACUTE INFECTIVE ENDOCARDITIS)

It is important to determine the penicillin sensitivity of the infecting strain as early as possible in the treatment of viridans streptococcal endocarditis. Resistant organisms are most commonly seen in patients receiving penicillin prophylaxis for rheumatic heart disease. Strains sensitive to penicillin G (minimum inhibitory concentration [MIC] < 0.1 µg/mL) may be treated for 4 weeks with penicillin, 150,000–200,000 units/kg/d intravenously, with gentamicin added during the first 2 weeks. There is considerable experience with 2-week therapy in adult patients using penicillin and gentamicin. Similarly, excellent results have been obtained with ceftriaxone once daily for 4 weeks. If the MIC is 0.5 µg/mL or higher, longer therapy and higher doses of penicillin G must be used (200,000–300,000 units/kg/d intravenously in combination with streptomycin or gentamicin for 4–6 weeks). If the MIC is 0.1–0.5 µg/mL, penicillin G at the higher dose for a minimum of 4 weeks is recommended, with gentamicin added for the first 2 weeks. Vancomycin, 40 mg/kg/d, is usually preferred for resistant strains and patients allergic to penicillin.

PNEUMOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Bacteremia:

- High fever (> 39.4°C).
- Leukocytosis (> 15,000/µL).
- Age 6–24 months.

Pneumonia:

- Fever, leukocytosis, and tachypnea.
- Localized chest pain.
- Localized or diffuse rales. Chest radiograph may show lobar infiltrate (with effusion).

Meningitis:

- Fever, leukocytosis.
- Bulging fontanelle, neck stiffness.
- Irritability and lethargy.

All types:

- Diagnosis confirmed by cultures of blood, CSF, pleural fluid, or other body fluid.

General Considerations

Sepsis, sinusitis, otitis media, pneumonitis, meningitis, osteomyelitis, cellulitis, arthritis, vaginitis, and peritonitis are all part of a spectrum of pneumococcal infection. Clinical findings that correlate with occult bacteremia in ambulatory patients include age (6–24 months), degree of temperature elevation (> 39.4°C), and leukocytosis (>15,000/µL). Although each of these findings is in itself nonspecific, a combination of them should arouse suspicion. This constellation of findings in a child who has no focus of infection may be an indication for blood cultures and antibiotic therapy. The cause of most of such bacteremic episodes is pneumococci.

Streptococcus pneumoniae is the most common cause of acute purulent otitis media. Pneumococci are the or-

ganisms responsible for most cases of acute bacterial pneumonia in children. The disease is indistinguishable on clinical grounds from other bacterial pneumonias. Effusions are common, although frank empyema is less common. Abscesses also occasionally occur.

Pneumococcal meningitis is still more common than *H influenzae* type b meningitis. Pneumococcal meningitis, sometimes recurrent, may complicate serious head trauma, particularly if there is persistent leakage of CSF. This has led some physicians to recommend the prophylactic administration of penicillin or other antimicrobials in such cases.

Children with sickle cell disease, other hemoglobinopathies, congenital or acquired asplenia, and some immunoglobulin and complement deficiencies are unusually susceptible to pneumococcal sepsis and meningitis. These children often have a catastrophic illness with shock and disseminated intravascular coagulation (DIC). Even with excellent supportive care, the mortality rate is 20–50%. The spleen is important in the control of pneumococcal infection by clearing organisms from the blood and producing an opsonin that enhances phagocytosis. Aut splenectomy may explain why children with sickle cell disease are at increased risk for developing serious pneumococcal infections. Children with cochlear implants are at higher risk for pneumococcal meningitis. Children who have, or who are planning to receive, a cochlear implant should receive age-appropriate pneumococcal vaccination (> 2 weeks prior to surgery if possible).

S pneumoniae rarely causes serious disease in the neonate. Although *S pneumoniae* does not normally colonize the vagina, transient colonization does occur. Serious neonatal disease—including pneumonia, sepsis, and meningitis—may occur and clinically is similar to GBS infection.

Since being introduced in clinical medicine, penicillin has been the agent of choice for pneumococcal infections. Many strains are still highly susceptible to penicillin, and in those cases, penicillin is still the drug of choice. However, pneumococci with moderately increased resistance to penicillin are found in most communities, and reports of treatment failure, particularly in meningitis, are common. The prevalence of these relatively penicillin-resistant strains in North America varies geographically. Pneumococci with high-level resistance to penicillin and multiple other drugs are increasingly encountered throughout the United States. Pneumococci from normally sterile body fluids should be routinely tested for susceptibility to penicillin as well as other drugs.

Pneumococci have been classified into 90 serotypes based on capsular polysaccharide antigens. The frequency distribution of serotypes varies at different times, in different geographic areas, and with different

sites of infection. Serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F cause about 80–85% of invasive pneumococcal infections in young children. Similar serotypes, 6B, 9V, 14, 19A, 19F, and 23F, are responsible for most of the penicillin-resistant isolates. In February 2000, the first protein conjugate pneumococcal vaccine (Pnevnar) received FDA approval for immunization of young children. It includes polysaccharide or oligosaccharide of seven different *S pneumoniae* serotypes conjugated to a protein carrier. The serotypes in the vaccine are those listed earlier, which cause the bulk of pediatric invasive pneumococcal disease. The development of this vaccine is important in the prevention of pneumococcal disease because young children (< age 2 years), who are most at risk for the disease, are unable to immunologically mount a predictable response to the 23-valent polysaccharide vaccine. This vaccine is discussed further in Chapter 9. For older children and adults, the 23-valent pneumococcal vaccine is generally recommended.

Clinical Findings

A. SYMPTOMS AND SIGNS

In pneumococcal sepsis, fever usually appears abruptly, often accompanied by chills. There may be no respiratory symptoms. In pneumococcal sinusitis, mucopurulent nasal discharge may occur. In infants and young children with pneumonia, fever and tachypnea without auscultatory changes are the usual presenting signs. Respiratory distress is manifested by nasal flaring, chest retractions, and tachypnea. Abdominal pain is common. In older children, the adult form of pneumococcal pneumonia with signs of lobar consolidation may occur, but sputum is rarely bloody. Thoracic pain resulting from pleural involvement is sometimes present, but less often in children than in adults. With involvement of the right hemidiaphragm, pain may be referred to the right lower quadrant, suggesting appendicitis. Vomiting is common at onset but seldom persists. Convulsions are relatively common at onset in infants.

Meningitis is characterized by fever, irritability, convulsions, and neck stiffness. The most important sign in very young infants is a tense, bulging anterior fontanelle. In older children, fever, chills, headache, and vomiting are common symptoms. Classic signs are nuchal rigidity associated with positive Brudzinski and Kernig signs. With progression of untreated disease, the child may develop opisthotonos, stupor, and coma.

B. LABORATORY FINDINGS

Leukocytosis is often pronounced (20,000–45,000/ μ L), with 80–90% polymorphonuclear neutrophils. Neutropenia may be seen early in very serious infections. The presence of pneumococci in the nasopharynx is not a helpful finding, because up to 40%

of normal children carry pneumococci in the upper respiratory tract. Large numbers of organisms are seen on gram-stained smears of endotracheal aspirates from patients with pneumonia. In meningitis, CSF usually shows an elevated white blood cell (WBC) count of several thousand, chiefly polymorphonuclear neutrophils, with decreased glucose and elevated protein levels. Gram-positive diplococci are seen on stained smears of CSF sediment in 70–90% of cases in young children but are positive in only 50–65% of cases in adolescents and adults. Antigen detection tests are not useful.

Differential Diagnosis

There are many causes of high fever and leukocytosis in young infants; 90% of children presenting with these features have a disease other than pneumococcal bacteremia such as herpesvirus 6, enterovirus, or other viral infection; urinary tract infection; unrecognized focal infection elsewhere in the body; or early acute shigellosis.

Infants with upper respiratory tract infection who subsequently develop signs and symptoms of lower respiratory disease are most likely to be infected with a respiratory virus. Hoarseness or wheezing is often present. A radiograph of the chest typically shows perihilar infiltrates and increased bronchovascular markings. Viral respiratory infection often precedes pneumococcal pneumonia; therefore, the clinical picture may be mixed.

Staphylococcal pneumonia may be indistinguishable early in its course from pneumococcal pneumonia. Later, pulmonary cavitation and empyema occur. Staphylococcal pneumonia is most common in infants.

In primary pulmonary tuberculosis, children do not have a toxic appearance, and radiographs show a primary focus associated with hilar adenopathy and often with pleural involvement. Miliary tuberculosis presents a classic radiographic appearance.

Pneumonia caused by *Mycoplasma pneumoniae* is most common in children age 5 years and older. Onset is insidious, with infrequent chills, low-grade fever, prominent headache and malaise, cough, and, often, striking radiographic changes. Marked leukocytosis ($> 18,000/\mu\text{L}$) is unusual.

Pneumococcal meningitis is diagnosed by lumbar puncture. Without a gram-stained smear and culture of CSF, it is not distinguishable from other types of acute bacterial meningitis.

Complications

Complications of sepsis include meningitis and osteomyelitis; complications of pneumonia include empyema, parapneumonic effusion, and, rarely, lung abscess. Mastoiditis, subdural empyema, and brain ab-

cess may follow untreated pneumococcal otitis media. Both pneumococcal meningitis and peritonitis are more likely to occur independently without coexisting pneumonia. Shock, DIC, and Waterhouse–Friderichsen syndrome resembling meningococcemia are occasionally seen in pneumococcal sepsis, particularly in asplenic patients. Hemolytic–uremic syndrome may occur as a complication of pneumococcal pneumonia or sepsis.

Treatment

A. SPECIFIC MEASURES

All *S pneumoniae* isolated from normally sterile sites should be tested for susceptibility to penicillin. Susceptible strains should be treated with penicillin, ampicillin, or amoxicillin. Penicillin-intermediate or penicillin-resistant strains should be tested for susceptibility to cephalosporins, vancomycin, and selected other drugs. Therapy with penicillin, amoxicillin, or cephalosporins will usually succeed in cases of bacteremia or pneumonia due to intermediate-resistant isolates because serum levels in excess of the MIC can be achieved. Therapy of meningitis, empyema, osteomyelitis, and endocarditis due to nonsusceptible *S pneumoniae* is more difficult, because penetration of antimicrobials to these sites is limited. Vancomycin and third-generation cephalosporins are indicated in these and other serious or life-threatening infections pending susceptibility test results.

1. Bacteremia—In studies done prior to immunization of young children with conjugated pneumococcal vaccine, 3–5% of blood cultures in patients younger than 2 years of age yielded *S pneumoniae*. These percentages are expected to decrease now that an effective vaccine is available. However, pneumococcal disease will not disappear, as the vaccine prevents only 85% of invasive disease. Many experts treat suspected bacteremia with ceftriaxone (50 mg/kg, given intramuscularly or intravenously). Compared with oral amoxicillin (80–90 mg/kg/d), ceftriaxone may reduce fever and the need for hospitalization. However, meningitis occurs with the same frequency despite presumptive therapy. The widespread use of ceftriaxone among young children has contributed significantly to antibiotic resistance in *S pneumoniae*. All children with blood cultures that grow pneumococci must be reexamined as soon as possible. The child who has a focal infection such as meningitis or who appears septic should be admitted to the hospital to receive parenteral antimicrobials. If the child is afebrile and appears well or mildly ill, management on an ambulatory basis is appropriate. If the physician is confident that close follow-up can be achieved, lumbar puncture is not mandatory.

2. Pneumonia—For infants, severely ill patients, and immunocompromised hosts, appropriate regimens include aqueous penicillin G (150,000–200,000 units/kg/d, given intravenously in four to six divided doses), cefotaxime (50 mg/kg, q8h), or cefuroxime (50 mg/kg, q8h). Mild pneumonia may be treated with amoxicillin (80–90 mg/kg/d) for 7–10 days. Alternative regimens include oral macrolides and cephalosporins.

3. Otitis media—Most experts recommend oral amoxicillin (80–90 mg/kg/d, divided in two doses) as first line therapy. The standard course of therapy is 10 days; however, many physicians have been treating uncomplicated cases for just 5 days, based on recent studies. Treatment failures may be treated with amoxicillin/clavulanate (80–90 mg/kg/d of the amoxicillin component in the 7:1 formulation), intramuscular ceftriaxone, cefuroxime, axetil, or cefdinir. Clarithromycin or azithromycin can also be used.

4. Meningitis—Until bacteriologic confirmation and susceptibility testing are completed, patients should receive vancomycin (60 mg/kg/d, given intravenously in four divided doses) and cefotaxime (225–300 mg/kg/d intravenously in four divided doses), or vancomycin (see previous dosage) and ceftriaxone (100 mg/kg/d, given intravenously in two divided doses). Corticosteroids (dexamethasone, 0.6 mg/kg/d, in four divided doses for 4 days) are recommended by many experts as adjunctive therapy for pneumococcal meningitis. But they are controversial because they may reduce the entry of vancomycin into the CSF. Repeated lumbar puncture at 24–48 hours should be considered to ensure sterility of the CSF if dexamethasone is given or if resistant pneumococci are isolated.

If the isolate is determined to be penicillin-susceptible, aqueous penicillin G can be administered (300,000–400,000 units/kg/d, given intravenously in four to six divided doses for 10–14 days). Use of ceftriaxone or cefotaxime is acceptable alternative therapy in penicillin and cephalosporin-susceptible isolates. Consult an infectious disease specialist or the *Red Book* (American Academy of Pediatrics, 2003) for therapeutic options for isolates that are nonsusceptible to penicillin or cephalosporins.

Prognosis

In children, case fatality rates of less than 1% should be achieved except in meningitis, in which rates of 5–20% still prevail. The presence of large numbers of organisms without a prominent CSF inflammatory response or meningitis due to a penicillin-resistant strain indicates a poor prognosis. Serious neurologic sequelae, particularly hearing loss, are frequent following pneumococcal meningitis.

STAPHYLOCOCCAL INFECTIONS

Staphylococcal infections are common in childhood. Staphylococcal skin infections range from minor furuncles to the varied syndromes now collectively referred to as scalded skin syndrome. Staphylococci are the major cause of osteomyelitis and of septic arthritis as well as an uncommon but important cause of bacterial pneumonia. A toxin produced by certain strains causes staphylococcal food poisoning. Staphylococci are responsible for most infections of artificial heart valves. They cause toxic shock syndrome (see later discussion). Finally, they are found in infections at all ages and in multiple sites, particularly when infection is introduced from the skin or upper respiratory tract or when closed compartments become infected (pericarditis, sinusitis, cervical adenitis, surgical wounds, abscesses in the liver or brain, and abscesses elsewhere in the body).

Staphylococci that do not produce the enzyme coagulase are termed “coagulase-negative” and are seldom speciated in the clinical microbiology laboratory. Most *Staphylococcus aureus* strains produce coagulase. *S aureus* and coagulase-negative staphylococci are normal flora of the skin and respiratory tract. The latter rarely cause disease except in compromised hosts, the newborn, or patients with plastic indwelling lines.

Most strains of *S aureus* elaborate β -lactamase that confers penicillin resistance. This can be overcome in clinical practice by the use of a cephalosporin or a penicillinase-resistant penicillin such as methicillin, oxacillin, nafcillin, cloxacillin, or dicloxacillin. Methicillin-resistant strains of *S aureus* (MRSA) are found worldwide and are now common in certain hospitals and, increasingly, in community-acquired infections in some areas of the United States. Most MRSA retain β -lactamase production, and many are resistant to other

antibiotics as well. MRSA are also resistant in vivo to all of the penicillinase-resistant penicillins and cephalosporins. Strains with intermediate susceptibility to vancomycin have been recovered in the United States and Japan. In addition there have been two reports of vancomycin-resistant strains. The existence of such strains is of concern because of the inherent virulence of most strains of *S aureus* and because of the limited choices for therapy. *S aureus* produces a variety of exotoxins, most of which are of uncertain importance. Two toxins are recognized as playing a central role in specific diseases: exfoliatin and staphylococcal enterotoxin. The former is largely responsible for the various clinical presentations of scalded skin syndrome. Most strains that elaborate exfoliatin are of phage group II. Enterotoxin causes staphylococcal food poisoning. The exoprotein toxin most commonly associated with toxic shock syndrome has been termed TSST-1.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Staphylococcal skin diseases—Dermal infection with *S aureus* causes furuncles or cellulitis. *S aureus* are often found along with streptococci in impetigo. If the strains produce exfoliatin, localized lesions become bullous (bullous impetigo).

Scalded skin syndrome is thought to be a systemic effect of exfoliatin. The initial infection may begin at any site but is in the respiratory tract in most cases. There is a prodromal phase of erythema, often beginning around the mouth, accompanied by fever and irritability. The involved skin becomes tender, and a sick infant will cry when picked up or touched. A day or so later, exfoliation begins, usually around the mouth. The inside of the mouth is red, and a peeling rash is present around the lips, often in a radial pattern. Generalized, painful peeling may follow, involving the limbs and trunk but often sparing the feet. More commonly, peeling is confined to areas around body orifices. If erythematous but unpeeled skin is rubbed sideways, superficial epidermal layers separate from deeper ones and slough (Nikolsky sign). In the newborn, the disease is termed Ritter disease and may be fulminant. If there is tender erythema but not exfoliation, the disease is termed nonstreptococcal scarlet fever. The scarlatiniform rash is sandpaper-like, but strawberry tongue is not seen, and cultures grow *S aureus* rather than streptococcus.

2. Osteomyelitis and septic arthritis—(See Chapter 24).

3. Staphylococcal pneumonia—Staphylococcal pneumonia in infancy is characterized by abdominal distention, high fever, respiratory distress, and toxemia.

It often occurs without predisposing factors or after minor skin infections. The organism is necrotizing, producing bronchoalveolar destruction. Pneumatoceles, pyopneumothorax, and empyema are frequently encountered. Rapid progression of disease is characteristic. Frequent chest radiographs to monitor the progress of disease are indicated. Presenting symptoms may be typical of paralytic ileus, suggestive of an abdominal catastrophe.

Staphylococcal pneumonia usually is peribronchial, beginning with a focal infiltrative lesion progressing to patchy consolidation. Most often only one lung is involved (80%), more often the right. Purulent pericarditis occurs by direct extension in about 10% of cases, with or without empyema.

4. Staphylococcal food poisoning—Staphylococcal food poisoning is a result of ingestion of enterotoxin produced by staphylococci growing in uncooked and poorly refrigerated food. The disease is characterized by vomiting, prostration, and diarrhea occurring 2–6 hours after ingestion of contaminated foods.

5. Staphylococcal endocarditis—*S aureus* may produce infection of normal heart valves, of valves or endocardium in children with congenital or rheumatic heart disease, or of artificial valves. About 25% of all cases of endocarditis are due to *S aureus*. The great majority of artificial heart valve infections involve either *S aureus* or coagulase-negative staphylococci. Infection usually begins in an extracardiac focus, often the skin. Involvement of the endocardium must be suspected in every case of *S aureus* bacteremia, regardless of initial signs. Suspicion must be highest in the presence of congenital heart disease, particularly ventricular septal defects with aortic insufficiency but also simple ventricular septal defect, patent ductus arteriosus, and tetralogy of Fallot.

The presenting symptoms in staphylococcal endocarditis are fever, weight loss, weakness, muscle pain or diffuse skeletal pain, poor feeding, pallor, and cardiac decompensation. Signs include splenomegaly, cardiomegaly, petechiae, hematuria, and a new or changing murmur. The course of *S aureus* endocarditis is rapid, although subacute disease occurs occasionally. Peripheral septic embolization and uncontrollable cardiac failure are common, even when optimal antibiotic therapy is administered, and may be indications for surgical intervention (see later discussion).

6. Toxic shock syndrome—Toxic shock syndrome (TSS) is characterized by fever, blanching erythroderma, diarrhea, vomiting, myalgia, prostration, hypotension, and multiorgan dysfunction. It is due to *S aureus* focal infection, usually without bacteremia. Large numbers of cases have been described in menstruating adolescents and young women using vaginal tampons. TSS has also been reported in boys and girls with

focal staphylococcal infections and in individuals with wound infections due to *S aureus*. Additional clinical features include sudden onset; conjunctival suffusion; mucosal hyperemia; desquamation of skin on the palms, soles, fingers, and toes during convalescence; DIC in severe cases; renal and hepatic functional abnormalities; and myolysis. The mortality rate with early treatment is now about 2%. Recurrences are seen during subsequent menstrual periods in as many as 60% of untreated women who continue to use tampons. Recurrences occur in up to 15% of women given antistaphylococcal antibiotics who stop using tampons. The disease is caused by strains of *S aureus* that produce TSST-1 or one of the related enterotoxins.

7. Coagulase-negative staphylococcal infections—

Localized and systemic coagulase-negative staphylococcal infections occur primarily in immunocompromised patients, high-risk newborns, and patients with plastic prostheses or catheters. Coagulase-negative staphylococci are the most common nosocomial pathogen in hospitalized low-birth-weight neonates in the United States. Intravenous administration of lipid emulsions and indwelling central venous catheters are risk factors contributing to coagulase-negative staphylococcal bacteremia in newborn infants. In patients with an artificial heart valve, a Dacron patch, a ventriculoperitoneal shunt, or a central venous catheter, coagulase-negative staphylococci are a common cause of sepsis or catheter infection, often necessitating removal of the foreign material and protracted antibiotic therapy. Because blood cultures are frequently contaminated by this organism, diagnosis of genuine localized or systemic infection is often difficult.

B. LABORATORY FINDINGS

Moderate leukocytosis (15,000–20,000/ μ L) with a shift to the left is occasionally found, although normal counts are common, particularly in infants. The sedimentation rate is elevated. Blood cultures are frequently positive in systemic staphylococcal disease and should always be obtained when it is suspected. Similarly, pus from sites of infection should always be aspirated or obtained surgically, examined with Gram stain, and cultured both aerobically and anaerobically. There are no useful serologic tests for staphylococcal disease.

Differential Diagnosis

Staphylococcal skin disease takes many forms; therefore, the differential list is long. Bullous impetigo must be differentiated from chemical or thermal burns, from drug reactions, and, in the very young, from the various congenital epidermolytic syndromes or even herpes simplex infections. Staphylococcal scalded skin syndrome may resemble scarlet fever, Kawasaki disease,

Stevens–Johnson syndrome, erythema multiforme, and other drug reactions. A skin biopsy may be critical in establishing the correct diagnosis. The skin lesions of varicella may become superinfected with exfoliatin-producing staphylococci and produce a combination of the two diseases (bullous varicella).

Severe, rapidly progressing pneumonia with formation of abscesses, pneumatoceles, and empyemas is typical of *S aureus* infection and GAS but may occasionally be produced by pneumococci, *Haemophilus influenzae*, and GAS.

Staphylococcal food poisoning is often epidemic. It is differentiated from other common-source gastroenteritis syndromes (*Salmonella*, *Clostridium perfringens*, *Vibrio parahaemolyticus*) by the short incubation period (2–6 hours), the prominence of vomiting (as opposed to diarrhea), and the absence of fever.

Endocarditis must be suspected in any instance of *S aureus* bacteremia, particularly when a significant heart murmur or preexisting cardiac disease is present (see Chapter 19).

Newborn infections with *S aureus* can resemble infections with streptococci and a variety of gram-negative organisms. Umbilical and respiratory tract colonization occurs with many pathogenic organisms (GBS, *Escherichia coli*, *Klebsiella*), and both skin and systemic infections occur with virtually all of these organisms.

TSS must be differentiated from Rocky Mountain spotted fever, leptospirosis, Kawasaki disease, drug reactions, adenovirus, and measles (see also Table 36–3).

Treatment

A. SPECIFIC MEASURES

Community-acquired MRSA infections are on the rise. The incidence of community-acquired MRSA isolates varies greatly geographically. If the prevalence of MRSA isolates in the community is high or if the patient is seriously ill, vancomycin should be part of the empiric coverage in sick patients until culture results and susceptibility data are known. Currently, most community-acquired MRSA strains are susceptible to TMP–SMX and some are susceptible to clindamycin. Less serious infections in nontoxic patients may be initially treated using one of these agents while awaiting cultures and susceptibility data.

For methicillin-susceptible strains, a β -lactamase-resistant penicillin is the drug of choice (oxacillin, nafcillin, methicillin). In serious systemic disease, in osteomyelitis, and in the treatment of large abscesses, intravenous therapy is indicated initially (oxacillin or nafcillin, 100–150 mg/kg/d in four divided doses, or methicillin, 200–300 mg/kg/d in four divided doses). When high doses over a long period are required, it is

preferable not to use methicillin, because of the frequency with which interstitial nephritis occurs. In life-threatening illness, an aminoglycoside antibiotic (gentamicin or tobramycin) or rifampin may be used in addition for its possible synergistic action.

Cephalosporins may be considered for patients with a history of penicillin sensitivity unless there is a history of type 1 hypersensitivity reaction (ie, anaphylaxis, wheezing, edema, hives: [cefazolin, 100–150 mg/kg/d, given intravenously in three divided doses] or cephalexin [50–100 mg/kg/d, given orally in four divided doses]) can be used once a child is able to take oral antibiotics. The third-generation cephalosporins should not generally be used for staphylococcal infections.

For nonmeningeal, suspected nosocomially acquired MRSA infections, vancomycin (40 mg/kg/d intravenously in three or four divided doses) should be used until susceptibilities are available (these isolates are more frequently clindamycin- and TMP–SMX-resistant). Infections due to MRSA frequently do not respond to cephalosporins despite *in vitro* testing that suggests susceptibility. For treatment of meningitis, vancomycin must be given in higher doses (60 mg/kg/d divided into four doses). Combinations including rifampin may be either synergistic or antagonistic.

1. Skin infections—(See Chapter 14.)

2. Osteomyelitis and septic arthritis—Treatment should be begun intravenously, with antibiotics selected to cover the most likely organisms (staphylococci in hematogenous osteomyelitis; meningococci, pneumococci, staphylococci in children younger than age 3 years with septic arthritis; staphylococci and gonococci in older children with septic arthritis). Antibiotic levels should be kept high at all times.

In osteomyelitis, clinical studies support the use of intravenous treatment until fever and local symptoms and signs have subsided—usually after at least 3–5 days—followed by oral therapy (for susceptible strains, dicloxacillin, 100–150 mg/kg/d in four divided doses; or cephalexin, 100–150 mg/kg/d in four divided doses) for at least 3 additional weeks. Longer treatment may be required, particularly when radiographs show extensive involvement. Treatment of community acquired MRSA osteomyelitis should be based on susceptibility results; however, isolates are frequently susceptible to TMP–SMX or clindamycin. Vancomycin can be used as part of an empiric regimen while awaiting susceptibilities in seriously ill patients or in areas where MRSA is likely as a pathogen. In arthritis, where drug diffusion into synovial fluid is good, intravenous therapy need be given only for a few days, followed by adequate oral therapy for at least 3 weeks. In all instances, oral therapy should be administered with careful attention to

compliance, either in the hospital or at home with frequent support and reinforcement from physicians or visiting nurses. The erythrocyte sedimentation rate (ESR) is a good indicator of response to therapy. Surgical drainage of osteomyelitis or septic arthritis is often required (see Chapter 24).

3. Staphylococcal pneumonia—In areas of the country where MRSA is not prevalent, nafcillin and oxacillin are the usual drugs of choice. In sick patients, vancomycin should be used empirically until cultures and susceptibility results are obtained. Linezolid has recently been reported to be as efficacious as vancomycin in the treatment of resistant gram-positive pneumonia and soft tissue infections (cure rates: 95% linezolid vs 94% vancomycin).

Empyema and pyopneumothorax require drainage. The choice of chest tube drainage versus thoracoscopic drainage depends on the practitioner's experience and skill. If staphylococcal pneumonia is treated promptly and empyema drained promptly, resolution in children is almost always complete—despite evidence of widespread parenchymal destruction and the persistence of bullae, blebs, and even pockets of empyema or abscess fluid well into convalescence.

4. Staphylococcal food poisoning—Therapy is supportive and usually not required except in severe cases or for small infants with marked dehydration.

5. Staphylococcal endocarditis—As outlined earlier, high-dose, prolonged parenteral treatment is indicated. Methicillin-susceptible isolates are often treated with oxacillin or nafcillin. Some experts also recommend addition of gentamicin or rifampin for the first 5 days to 2 weeks. In penicillin-allergic patients (type 1 hypersensitivity, anaphylaxis) or patients with MRSA isolates, vancomycin should be used. With penicillin-sensitive organisms, penicillin G is the drug of choice. Therapy lasts in all instances for at least 6 weeks.

In some patients, medical treatment may fail. Signs of treatment failure are (1) recurrent fever without apparent treatable other cause (eg, thrombophlebitis, incidental respiratory or urinary tract infection, drug fever), (2) persistently positive blood cultures, (3) intractable and progressive congestive heart failure, and (4) recurrent (septic) embolization. In such circumstances—particularly (2), (3), and (4)—valve replacement becomes necessary. Antibiotics are continued for at least another 4 weeks. Persistent or recurrent infection may require a second surgical procedure.

6. Toxic shock syndrome—Treatment is aimed at expanding volume, maintaining perfusion pressure with inotropic agents as needed, prompt drainage of a focus of infection (or removal of tampons or foreign bodies), and giving intravenous antibiotics.

Vancomycin, in addition to a β -lactam antibiotic (oxacillin, nafcillin), can be used for empiric therapy. Some experts would use vancomycin and clindamycin, since clindamycin is a protein synthesis inhibitor and may turn off toxin production. Clindamycin should not be used empirically as a single agent until susceptibilities (if an isolate grows) are known; some strains of *S aureus* are clindamycin-resistant.

Intravenous immune globulin has been used as adjunctive therapy. Some experts believe that corticosteroid therapy may be effective if given to patients with severe illness early in the course of their disease. Antibiotic treatment reduces risk of recurrence.

7. Coagulase-negative staphylococcal infections—

Bacteremia and other serious coagulase-negative staphylococcal infections are treated initially with vancomycin. Coagulase-negative staphylococci are uncommonly resistant to vancomycin (see Chapter 35 for dosing). Strains susceptible to methicillin are treated with methicillin, oxacillin, or ceftazolin.

MENINGOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, headache, vomiting, convulsions, shock (meningitis).
- Fever, shock, petechial or purpuric skin rash (meningococcemia).
- Diagnosis confirmed by culture of normally sterile body fluids.

General Considerations

Meningococci (*Neisseria meningitidis*) may be carried asymptomatically for many months in the upper respiratory tract. Fewer than 1% of carriers develop disease. Meningitis and sepsis are the two most common forms of illness, but septic arthritis, pericarditis, pneumonia, chronic meningococcemia, otitis media, conjunctivitis, and vaginitis also occur. The highest attack rate for meningococcal meningitis is in the first year of life. The incidence in the United States is about 1.2 cases per 100,000 people. An estimated 2400–3000 cases occur in the United States annually.

Meningococci are gram-negative organisms containing endotoxin in their cell walls. Endotoxins may cause capillary vascular injury and leak and may also cause DIC. The development of irreversible shock with multiorgan failure is a significant factor in the fatal outcome of acute meningococcal infections. Meningococci are classified serologically into groups: A, B, C, Y, and W-135 are the groups most commonly implicated in systemic disease. The serologic groups serve as markers for studying outbreaks and transmission of disease. Currently in the United States, serogroups B, C, and Y each account for about one third of cases. Serogroup A, which causes periodic epidemics in developing countries, is responsible for only occasional cases of meningococcal disease in the United States. Sulfonamide resistance is common in non-serotype-A strains. *N meningitidis* with increased MICs to penicillin G are reported from South Africa and Spain. A small number of these isolates are reported in the United States. The resistance in these strains is low-level and not due to β -lactamase. Resistant isolates are susceptible to third-generation cephalosporins. Few isolates are resistant to rifampin.

Children develop immunity from asymptomatic carriage of meningococci (usually nontypable, nonpathogenic strains) or other cross-reacting bacteria. Patients deficient in one of the late components of complement (C6, C7, C8, or C9) are uniquely susceptible to meningococcal infection, particularly group A meningococci. Deficiencies of early and alternate pathway complement components are also associated with increased susceptibility.

Clinical Findings

A. SYMPTOMS AND SIGNS

Many children with clinical meningococcemia also have meningitis, and some have other foci of infection. All children with suspected meningococcemia should have a lumbar puncture.

1. Meningococcemia—A prodrome of upper respiratory infection is followed by high fever, headache, nau-

sea, marked toxicity, and hypotension. Purpura, petechiae, and occasionally bright pink, tender macules or papules over the extremities and trunk are seen. The rash usually progresses rapidly. Occasional cases lack rash. Fulminant meningococemia (Waterhouse–Friedrichsen syndrome) progresses rapidly and is characterized by DIC, massive skin and mucosal hemorrhages, and shock. This syndrome also may be due to *H influenzae*, *S pneumoniae*, or other bacteria. Chronic meningococemia is characterized by periodic bouts of fever, arthralgia or arthritis, and recurrent petechiae. Splenomegaly is often present. Patients may be free of symptoms between bouts. Chronic meningococemia occurs primarily in adults and mimics Henoch–Schönlein purpura.

2. Meningitis—In many children, meningococemia is followed within a few hours to several days by symptoms and signs of acute purulent meningitis, with severe headache, stiff neck, nausea, vomiting, and stupor. Children with meningitis generally fare better than children with meningococemia alone, probably because they have survived long enough to develop clinical signs of meningitis.

B. LABORATORY FINDINGS

The peripheral WBC count may be either low or elevated. Thrombocytopenia may be present with or without DIC (see Chapter 27). If petechial or hemorrhagic lesions are present, meningococci can sometimes be demonstrated on smear by puncturing the lesions and expressing a drop of tissue fluid. Organisms may be demonstrated by Gram stain of buffy coat preparations of blood. CSF is generally cloudy and contains more than 1000 WBCs per microliter, with many polymorphonuclear neutrophils and gram-negative intracellular diplococci. A total hemolytic complement assay may reveal absence of late components as an underlying cause.

Differential Diagnosis

The skin lesions of *H influenzae* or pneumococci, enterovirus infection, endocarditis, leptospirosis, Rocky Mountain spotted fever, other rickettsial diseases, Henoch–Schönlein purpura, and blood dyscrasias may be similar to meningococemia. Other causes of sepsis and meningitis are distinguished by appropriate Gram stain and cultures.

Complications

Meningitis may lead to permanent central nervous system (CNS) damage, with deafness, convulsions, paralysis, or impairment of intellectual function. Hydrocephalus may develop and requires ventriculoperitoneal shunt. Subdural collections of fluid are common but

usually resolve spontaneously. Extensive skin necrosis, loss of digits or extremities, intestinal hemorrhage, and late adrenal insufficiency may complicate fulminant meningococemia.

Prevention

Household contacts, day care center contacts, and hospital personnel directly exposed to the respiratory secretions of patients are at increased risk for developing meningococcal infection and should be given chemoprophylaxis with rifampin. The secondary attack rate among household members is 1–5% during epidemics and less than 1% in nonepidemic situations. Children age 3 months to 2 years are at greatest risk, presumably because they lack protective antibodies. Secondary cases may occur in day care centers and in classrooms. Hospital personnel are not at increased risk unless they have had contact with a patient's oral secretions, for example, during mouth-to-mouth resuscitation, intubation, or suctioning procedures. Approximately 50% of secondary cases in households have their onset within 24 hours of identification of the index case. Exposed contacts should be examined promptly. If they are febrile, they should be fully evaluated and given high doses of penicillin or another effective antimicrobial pending the results of blood cultures.

All intimate contacts should receive chemoprophylaxis for meningococcal disease. The most commonly used agent is rifampin, given orally in the following dosages twice daily for 2 days: 600 mg for adults; 10 mg/kg for children younger than 1 month old (maximum dosage 600 mg); and 5 mg/kg for infants younger than 1 month. Rifampin may stain a patient's tears (and contact lenses), sweat, and urine orange; it may also affect the reliability of oral contraceptives, and alternative contraceptive measures should therefore be employed when rifampin is administered. Rifampin should not be given to pregnant women. Instead, intramuscular ceftriaxone is the preferred agent—125 mg given as a single dose if the patient is younger than 15 years; 250 mg given as a single dose if older than 15 years of age. Penicillin and most other antibiotics (even with parenteral administration) are not effective chemoprophylactic agents, because they do not eradicate upper respiratory tract carriage of meningococci. Ciprofloxacin effectively eradicates nasopharyngeal carriage in adults and children but is not approved for use in children or in pregnant women. Throat cultures to identify carriers are not useful. Meningococcal vaccine has been used increasingly for control of outbreaks. Patients with functional or anatomic asplenia, complement deficiencies, or properidin deficiency should be vaccinated.

Treatment

Blood cultures should be obtained for all children with fever and purpura or other signs of meningococemia, and antibiotics should be administered immediately as an emergency procedure. There is a good correlation between survival rates and prompt initiation of antibiotic therapy. Purpura and fever should be considered a medical emergency.

Children with meningococemia or meningococcal meningitis should be treated as though shock were imminent even if their vital signs are stable when they are first seen. If hypotension already is present, supportive measures should be aggressive, because the prognosis is grave in such situations. It is optimal to initiate treatment in an intensive care setting. Treatment should not be delayed for the sake of transporting the patient. Shock may worsen following antimicrobial therapy due to endotoxin release. To minimize the risk of nosocomial transmission, patients should be placed in respiratory isolation for the first 24 hours of antibiotic treatment.

A. SPECIFIC MEASURES

Antibiotics should be begun promptly. Because other bacteria, such as *S pneumoniae*, *S aureus*, or other gram-negative organisms, can cause identical syndromes, initial therapy should be broadly effective. Vancomycin and cefotaxime (or ceftriaxone) are preferred initial coverage. Once *N meningitidis* has been isolated, penicillin G, cefotaxime, and ceftriaxone intravenously for 7 days are the drugs of choice. Relative penicillin resistance is uncommon but has been reported in the United States.

B. GENERAL MEASURES

Most cases of invasive meningococcal disease are treated with intravenous antibiotics for 7 days.

1. Cardiovascular—See Chapter 11 for management of septic shock. Corticosteroids are not beneficial. Sympathetic blockade and topically applied nitroglycerin have been used locally to improve perfusion.

2. Hematologic—Adjunctive therapy with heparin is controversial. Because hypercoagulability is frequently present in patients with meningococemia, some experts believe heparin should be considered for those with DIC. A loading dose of 50 units/kg is followed by 15 units/kg/h as a continuous drip. The patient is monitored by following the partial thromboplastin time and heparin assay. Recombinant tissue plasminogen activator, concentrated antithrombin III, and recombinant protein C infusions have been tried experimentally to reverse coagulopathy. See Chapter 27 for the management of DIC.

Prognosis

Unfavorable prognostic features include shock, DIC, and extensive skin lesions. The case fatality rate in fulminant meningococemia is over 30%. In uncomplicated meningococcal meningitis, the fatality rate is much lower (10–20%).

Vaccine

A quadrivalent vaccine prepared from purified meningococcal polysaccharides (A, C, Y, and W-135) is available in the United States for children younger than 2 years of age. This vaccine has been used for controlling outbreaks (ie, schools) and in special high-risk groups, such as patients with functional or anatomic asplenia and patients with complement or properdin deficiency. College students who will be residing in dormitories for the first time are at increased risk for meningococcal disease. Some states have mandated the meningococcal vaccine for new college students. College students and their parents should be educated about the availability of the meningococcal vaccine and immunized if they elect to receive it (see Chapter 9).

GNOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purulent urethral discharge with intracellular gram-negative diplococci on smear in male patient (usually adolescent).
- Purulent, edematous, sometimes hemorrhagic conjunctivitis with intracellular gram-negative diplococci in infant age 2–4 days.
- Fever, arthritis (often polyarticular) or tenosynovitis, and maculopapular peripheral rash that may be vesiculopustular or hemorrhagic.

- Positive culture of blood, pharyngeal, or genital secretions.

General Considerations

Neisseria gonorrhoeae is a gram-negative diplococcus. Although morphologically similar to other neisseriae, it differs in its ability to grow on selective media and to ferment carbohydrates. The cell wall of *N gonorrhoeae* contains endotoxin, which is liberated when the organism dies and is responsible for the production of a cellular exudate. The incubation period is short, usually 2–5 days.

Antimicrobial-resistant gonococci are a serious problem. *N gonorrhoeae* resistant to tetracyclines, penicillins, or both are common. Fluoroquinolone-resistant strains are also increasing.

Gonococcal disease in children may be transmitted sexually or nonsexually. Prepubertal gonococcal infection outside the neonatal period should be considered presumptive evidence of sexual contact or child abuse. Prepubertal girls usually manifest gonococcal vulvovaginitis because of the neutral to alkaline pH of the vagina and thin vaginal mucosa.

In the adolescent or adult, the work-up of every case of gonorrhea should include a careful and accurate inquiry into the patient's sexual practices, because pharyngeal infection must be detected if present and may be difficult to eradicate. Efforts should be made to identify and provide treatment to all sexual contacts. When prepubertal children are infected, cultures should be obtained from family members, and epidemiologic investigation should be thorough.

Over 310,000 cases of gonorrhea were reported in 2003; increasing rates for the last several years are a source of concern because other sexually transmitted diseases often mirror changes in gonococcal incidence.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Asymptomatic gonorrhea—The ratio of asymptomatic to symptomatic gonorrheal infections in adolescents and adults is probably 3–4:1 in women and 0.5–1:1 in men. Asymptomatic infections are as infectious as symptomatic ones.

2. Uncomplicated genital gonorrhea—

a. Male with urethritis—Urethral discharge is sometimes painful and bloody and may be white, yellow, or green. There may be associated dysuria. The patient is usually afebrile.

b. Prepubertal female with vaginitis—The only clinical findings initially may be dysuria and polymorphonuclear neutrophils in the urine. Vulvitis characterized by erythema, edema, and excoriation accompanied by a purulent discharge may follow.

c. Postpubertal female with cervicitis—Symptomatic disease is characterized by a purulent, foul-smelling vaginal discharge, dysuria, and occasionally dyspareunia. Fever and abdominal pain are absent. The cervix is frequently hyperemic and tender when touched. This tenderness is not worsened by moving the cervix, nor are the adnexa tender to palpation.

d. Rectal gonorrhea—Rectal gonorrhea is often asymptomatic. There may be purulent discharge, edema, and pain during evacuation.

3. Pharyngeal gonorrhea—Pharyngeal infection is usually asymptomatic. There may be some sore throat and, rarely, acute exudative tonsillitis with bilateral cervical lymphadenopathy and fever.

4. Conjunctivitis and iridocyclitis—Copious exudate is characteristic of gonococcal conjunctivitis. Newborns are symptomatic on days 2–4 of life. In the adolescent or adult, infection probably is spread from infected genital secretions by the fingers.

5. Pelvic inflammatory disease (salpingitis)—The interval between initiation of genital infection and its ascent to the uterine tubes is variable and may range from days to months. Menses frequently are the initiating factor. With the onset of a menstrual period, gonococci invade the endometrium, causing transient endometritis. Subsequently salpingitis may occur, resulting in pyosalpinx or hydrosalpinx. Rarely infection progresses to peritonitis or perihepatitis. Gonococcal salpingitis occurs in an acute, subacute, or chronic form. All three forms have in common tenderness on gentle movement of the cervix and bilateral tubal tenderness during pelvic examination.

Gonococci or *Chlamydia trachomatis* are the cause of about 50% of cases of pelvic inflammatory disease. A mixed infection caused by enteric bacilli, *Bacteroides fragilis*, or other anaerobes occurs in the other 50%.

6. Gonococcal perihepatitis (Fitz-Hugh and Curtis syndrome)—In the typical clinical pattern, the patient presents with right upper quadrant tenderness in association with signs of acute or subacute salpingitis. Pain may be pleuritic and referred to the shoulder. Hepatic friction rub is a valuable but inconstant sign.

7. Disseminated gonorrhea—Dissemination follows asymptomatic more often than symptomatic genital infection and often results from gonococcal pharyngitis or anorectal gonorrhea. The most common form of disseminated gonorrhea is polyarthritis or polytenosynovitis, with or without dermatitis. Monarticular arthritis is

less common, and gonococcal endocarditis and meningitis are fortunately rare.

a. Polyarthritis—Disease usually begins with the simultaneous onset of low-grade fever, polyarthralgia, and malaise. After a day or so, joint symptoms become acute. Swelling, redness, and tenderness occur, frequently over the wrists, ankles, and knees but also in the fingers, feet, and other peripheral joints. Skin lesions may be noted at the same time. Discrete, tender, maculopapular lesions 5–8 mm in diameter appear that may become vesicular, pustular, and then hemorrhagic. They are few in number and noted on the fingers, palms, feet, and other distal surfaces and may be single or multiple. In patients with this form of the disease, blood cultures are often positive, but joint fluid rarely yields organisms. Skin lesions often are positive by Gram stain but rarely by culture. Genital, rectal, and pharyngeal cultures must be performed.

b. Monarticular arthritis—In this somewhat less common form of disseminated gonorrhea, fever is often absent. Arthritis evolves in a single joint. Dermatitis usually does not occur. Systemic symptoms are minimal. Blood cultures are negative, but joint aspirates may yield gonococci on smear and culture. Genital, rectal, and pharyngeal cultures must be performed.

B. LABORATORY FINDINGS

Demonstration of gram-negative, kidney-shaped diplococci in smears of urethral exudate in males is presumptive evidence of gonorrhea. Positive culture confirms the diagnosis. Negative smears do not rule out gonorrhea. Gram-stained smears of cervical or vaginal discharge in girls are more difficult to interpret because of normal gram-negative flora, but they may be useful when technical personnel are experienced. In girls with suspected gonorrhea, both the cervical os and the anus should be cultured. Gonococcal pharyngitis requires culture for diagnosis.

Cultures for *N gonorrhoeae* are plated on a selective chocolate agar containing antibiotics (eg, Thayer–Martin agar) to suppress normal flora. If bacteriologic diagnosis is critical, suspected material should be cultured on chocolate agar as well. Because gonococci are labile, agar plates should be inoculated immediately and placed without delay in an atmosphere containing CO₂ (candle jar). When transport of specimens is necessary, material should be inoculated directly into Transgrow medium prior to shipment to an appropriate laboratory. In cases of possible sexual molestation, notify the laboratory that definite speciation is needed, because nongonococcal *Neisseria* species can grow on the selective media.

Nucleic acid amplification tests on urine specimens now enable detection of *N gonorrhoeae* and *C trachoma-*

tis. These tests have excellent sensitivity and are replacing culture in some settings. All children or adolescents with a suspected or established diagnosis of gonorrhea should have serologic tests for syphilis and HIV.

Differential Diagnosis

Urethritis in the male may be gonococcal or nongonococcal (NGU). NGU is a syndrome characterized by discharge (rarely painful), mild dysuria, and a subacute course. The discharge is usually scant or moderate in amount but may be profuse. *C trachomatis* is the only proven cause of NGU. Doxycycline (100 mg orally bid for 7 days) is efficacious. Single-dose azithromycin, 1 g orally, may achieve better compliance. *C trachomatis* has been shown to cause epididymitis in males and salpingitis in females.

Vulvovaginitis in a prepubertal female may be due to infection caused by miscellaneous bacteria, including *Shigella* and GAS, *Candida*, and herpes simplex. Discharges may be caused by trichomonads, *Enterobius vermicularis* (pinworm), or foreign bodies. Symptom-free discharge (leukorrhea) normally accompanies rising estrogen levels.

Cervicitis in a postpubertal female, alone or in association with urethritis and involvement of Skene and Bartholin glands, may be due to infection caused by *Candida*, herpes simplex, *Trichomonas*, or discharge resulting from inflammation caused by foreign bodies (usually some form of contraceptive device). Leukorrhea may be associated with birth control pills.

Salpingitis may be due to infection with other organisms. The symptoms must be differentiated from those of appendicitis, urinary tract infection, ectopic pregnancy, endometriosis, or ovarian cysts or torsion.

Disseminated gonorrhea presents a differential diagnosis that includes meningococcemia, acute rheumatic fever, Henoch–Schönlein purpura, juvenile rheumatoid arthritis, lupus erythematosus, leptospirosis, secondary syphilis, certain viral infections (particularly rubella, but also enteroviruses and parvovirus), serum sickness, type B hepatitis (in the prodromal phase), infective endocarditis, and even acute leukemia and other types of cancer. The fully evolved skin lesions of disseminated gonorrhea are remarkably specific, and genital, rectal, or pharyngeal cultures, plus cultures of blood and joint fluid, usually yield gonococci from at least one source.

Prevention

Prevention of gonorrhea is principally a matter of sex education, condom use, and identification and treatment of contacts.

Treatment

A. UNCOMPLICATED URETHRAL, ENDOCERVICAL, OR RECTAL GONOCOCCAL INFECTIONS IN ADOLESCENTS

Ceftriaxone (125 mg intramuscularly in a single dose), ciprofloxacin (500 mg orally in a single dose), ofloxacin (400 mg orally in a single dose), or levofloxacin (250 mg orally in a single dose) is preferred therapy. Doxycycline (100 mg orally bid for 7 days) or azithromycin (1 g orally in a single dose) is recommended unless *C trachomatis* is ruled out. Ceftizoxime, cefotaxime, and cefotetan parenterally are alternative single-dose therapies.

Quinolones and tetracyclines should be avoided in pregnancy. Quinolones are not approved for use in children, and repeated doses of tetracyclines may stain the teeth of young children. Erythromycin or amoxicillin is recommended for therapy of *C trachomatis* in pregnant women; azithromycin is an alternative regimen. Repeat testing 3 weeks after completion of therapy is recommended in pregnant women.

Spectinomycin (2 g intramuscularly in a single dose) is used for penicillin- and cephalosporin-allergic patients. Quinolone resistance is increasing and is common in Hawaii, Asia, and the Pacific. Quinolones are not recommended for therapy of patients or travelers from these areas. A repeat culture after completion of therapy is not necessary in asymptomatic adolescents after the ceftriaxone–doxycycline regimen. A repeat culture after completion of therapy should be obtained from infants and children.

B. PHARYNGEAL GONOCOCCAL INFECTION

Ceftriaxone (125 mg intramuscularly in a single dose) should be used; ciprofloxacin (0.5 g orally in a single dose) is an alternative for adults and older adolescents. Neither spectinomycin nor amoxicillin is recommended. A repeat culture is recommended 4–7 days after therapy.

C. DISSEMINATED GONORRHEA

Recommended regimens include ceftriaxone (1 g intramuscularly or intravenously once daily), cefotaxime (1 g intravenously q8h), ciprofloxacin (400 IV q12h), Ofloxacin (500 IV q12h), or levofloxacin (250 IV q24h). Oral therapy may follow parenteral therapy 24–48 hours after improvement. Recommended regimens include ciprofloxacin (0.5 g bid), ofloxacin (0.4 g bid), or levofloxacin (0.25 g orally once day) to complete 7 days of therapy. Fluoroquinolones are not used for pregnant patients. If concurrent infection with *Chlamydia* is present or has not been excluded, a course of doxycycline, azithromycin, or erythromycin should also be prescribed. Total duration of therapy is 7 days for disseminated infections.

D. PELVIC INFLAMMATORY DISEASE

Doxycycline (100 mg bid orally) and either cefoxitin (2 g intramuscularly or intravenously q6h) or cefotetan (2 g intramuscularly or intravenously q12h) are given until the patient is clinically improved, then doxycycline is administered by mouth to complete 14 days of therapy. Clindamycin and gentamicin given intravenously until the patient is clinically improved may be used rather than cefoxitin. Many other regimens have been used for therapy of pelvic inflammatory disease, although comparative efficacy data is limited.

E. PREPUBERTAL GONOCOCCAL INFECTIONS

1. Uncomplicated genitourinary, rectal, or pharyngeal infections—These infections may be treated with ceftriaxone (25–50 mg/kg/d to a maximum of 125 mg intramuscularly in a single dose). Children older than age 8 years should also receive doxycycline (100 mg orally bid for 7 days). The physician should evaluate all children for evidence of sexual abuse and coinfection with syphilis, *Chlamydia*, and HIV.

2. Disseminated gonorrhea—This should be treated with ceftriaxone (50 mg/kg once daily parenterally for 7 days).

BOTULISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Dry mucous membranes.
- Nausea and vomiting.
- Diplopia; dilated, unreactive pupils.
- Descending paralysis.
- Difficulty in swallowing and speech occurring within 12–36 hours after ingestion of toxin-contaminated food.
- Multiple cases in a family or group.
- Hypotonia and constipation in infants.
- Diagnosis by clinical findings and identification of toxin in blood, stool, or implicated food.

General Considerations

Botulism is a paralytic disease caused by *Clostridium botulinum*, an anaerobic, gram-positive, spore-forming bacillus normally found in soil. The organism produces an extremely potent neurotoxin. Of the seven types of toxin (A–G), types A, B, and E cause most human diseases. The toxin, a polypeptide, is so potent that 0.1 mg is lethal for humans.

Food-borne botulism usually results from ingestion of toxin-containing food. Preformed toxin is absorbed from the gut and produces paralysis by preventing acetylcholine release from cholinergic fibers at myoneural junctions. In the United States, home-canned vegetables are usually the cause. Commercially canned foods rarely are responsible. Virtually any food will support the growth of *C botulinum* spores into vegetative toxin-producing bacilli if an anaerobic, nonacid environment is provided. The food may not appear or taste spoiled. The toxin is heat-labile, but the spores are heat-resistant. Inadequate heating during processing (temperature < 115°C) allows the spores to survive and later resume toxin production. Boiling of foods for 10 minutes or heating at 80°C for 30 minutes before eating will destroy the toxin.

Infant botulism is seen in infants younger than age 6 months (median, 10 weeks). The initial symptoms are usually constipation and severe hypotonia. Infants younger than age 2 weeks rarely develop botulism. The toxin appears to be produced by *C botulinum* organisms residing in the gastrointestinal tract. In some instances, honey has been the source of spores. Clinical findings include constipation, weak suck and cry, pooled oral secretions, cranial nerve deficits, generalized weakness, and, on occasion, apnea. The characteristic electromyographic pattern of brief, small, abundant motor-unit action potentials (BSAP) may help confirm the diagnosis.

Ten to 15 cases of wound botulism are reported yearly. Most cases occur in drug abusers with infection in intravenous or intramuscular injection sites.

Botulism, as a result of aerosolization of botulinum toxin, could also occur as the result of a bioterrorism event. Only three such cases of botulism have been reported; therefore, the incubation period is not well-defined, but was about 72 hours in the reported cases.

Clinical Findings

A. SYMPTOMS AND SIGNS

The incubation period for food-borne botulism is 8–36 hours. The initial symptoms are lethargy and headache. These are followed by double vision, dilated pupils, ptosis, and, within a few hours, difficulty with swallowing and speech. Pharyngeal paralysis occurs in some cases, and food may be regurgitated. The mucous membranes often are very dry. Descending skeletal

muscle paralysis may be seen. Death usually results from respiratory failure.

Botulism patients present with a “classic triad”: (1) afebrile; (2) symmetrical, flaccid, descending paralysis with prominent bulbar palsies; and (3) clear sensorium. Botulism is caused by a toxin, thus there is no fever unless secondary infection (eg, aspiration pneumonia) occurs. Common bulbar palsies seen include dysphonia, dysphagia, dysarthria, and diplopia (4 “D’s”). Recognition of this triad is important in making the clinical diagnosis.

B. LABORATORY FINDINGS

The diagnosis is made by demonstration of *C botulinum* toxin in stool, gastric aspirate/vomit, or serum. Serum and stool samples can be sent for toxin confirmation (done by toxin neutralization mouse bioassay at CDC or state health departments). Foods that are suspected to be contaminated should be kept refrigerated and given to public health personnel for testing. Laboratory findings, including CSF examination, are usually normal. Electromyography suggests the diagnosis if the characteristic BSAP abnormalities are seen. A nondiagnostic electromyogram does not exclude the diagnosis.

Differential Diagnosis

Guillain–Barré syndrome is characterized by ascending paralysis, sensory deficits, and elevated CSF protein without pleocytosis.

Other illnesses that should be considered include poliomyelitis, postdiphtheritic polyneuritis, certain chemical intoxications, tick paralysis, and myasthenia gravis. The history and elevated CSF protein characterize postdiphtheritic polyneuritis. Tick paralysis is characterized by a flaccid ascending motor paralysis. An attached tick should be sought. Myasthenia gravis usually occurs in adolescent girls. It is characterized by ocular and bulbar symptoms, with normal pupils, fluctuating weakness, absence of other neurologic signs, and clinical response to cholinesterase inhibitors.

Complications

Difficulty in swallowing leads to aspiration pneumonia. Serious respiratory paralysis may be fatal despite assisted ventilation and intensive supportive measures.

Treatment

A. SPECIFIC MEASURES

Early treatment of botulism with antitoxin (food-borne or wound botulism) or passive human botulism immune globulin (infant botulism) is beneficial. Treatment should begin as soon as the clinical diagnosis is made (prior to microbiologic or toxin confirmation).

The current form of equine, trivalent antitoxin (types A, B, and E) is given by slow intravenous infusion. All patients need to be screened for hypersensitivity to the product prior to initiating the infusion; small challenge doses are given (see package insert). Patients who have reactions to the challenge doses are desensitized prior to receiving antitoxin infusion. The antitoxin, 24-hour diagnostic consultation, epidemic assistance, and laboratory testing services are available from the CDC through state and local health departments.

For treatment of infant botulism, intravenous human botulism immune globulin (BIG-IV) is available in California under a study protocol from the Infant Botulism Prevention Program (510-540-2646). Results of a placebo-controlled clinical trial of use in infant botulism showed reduction in the mean hospital stay in the BIG-IV-treated group (2.5 weeks) as compared with the placebo group (5.5 weeks). Equine botulinum antitoxin should not be used to treat infant botulism. BIG-IV is not available for use in any form of botulism (wound, food-borne) other than infant botulism.

B. GENERAL MEASURES

General and supportive therapy consists of bed rest, ventilatory support (if necessary), fluid therapy, enteral or parenteral nutrition, and administration of purgatives and high enemas. Aminoglycoside antimicrobials and clindamycin may exacerbate neuromuscular blockade and should be avoided.

Prognosis

The mortality rate has declined substantially in recent years and is currently at 6%. In nonfatal cases, symptoms subside over 2–3 months and recovery is usually complete.

TETANUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Unimmunized or partially immunized patient.
- History of skin wound.

- Spasms of jaw muscles (trismus).
- Stiffness of neck, back, and abdominal muscles, with hyperirritability and hyperreflexia.
- Episodic, generalized muscle contractions.
- Diagnosis is based on clinical findings and the immunization history.

General Considerations

Tetanus is caused by *Clostridium tetani*, an anaerobic, gram-positive bacillus that produces a potent neurotoxin. In unimmunized or incompletely immunized individuals, infection follows contamination of a wound by soil containing clostridial spores from animal manure. The toxin reaches the CNS by retrograde axon transport, is bound to cerebral gangliosides, and is thought to increase reflex excitability in neurons of the spinal cord by blocking function of inhibitory synapses. Intense muscle spasms result. Two thirds of cases in the United States follow minor puncture wounds of the hands or feet. In many cases, no history of a wound can be obtained. In the newborn, usually in underdeveloped countries, infection generally results from contamination of the umbilical cord. The incubation period typically is 4–14 days but may be longer. Although 14 cases of tetanus were reported in the United States in 2003, an estimated 1 million cases per year occur globally. In the United States, cases in young children are due to failure to immunize. Eighty-five percent of cases occur in adults older than 25 years.

Clinical Findings

A. SYMPTOMS AND SIGNS

The first symptom is often mild pain at the site of inoculation, followed by hypertonicity and spasm of the regional muscles. Characteristically, difficulty in opening the mouth (trismus) is evident within 48 hours. In newborns, the first signs are irritability and inability to nurse. The infant may then develop stiffness of the jaw and neck, increasing dysphagia, and generalized hyperreflexia with rigidity and spasms of all muscles of the abdomen and back (opisthotonos). The facial distortion resembles a grimace (risus sardonicus). Difficulty in swallowing and convulsions triggered by minimal stimuli such as sound, light, or movement may occur. Individual spasms may last seconds or minutes. Recurrent spasms are seen several times each hour, or they may be almost continuous. In most cases, the temperature is normal or only mildly elevated. A high or subnormal temperature is a bad prognostic sign. Patients are fully conscious and lucid. A profound circulatory

disturbance associated with sympathetic overactivity may occur on the second to fourth day, which may contribute to the mortality rate. This is characterized by elevated blood pressure, increased cardiac output, tachycardia (> 20 beats/min), and arrhythmia.

B. LABORATORY FINDINGS

The diagnosis is made on clinical grounds. There may be a mild polymorphonuclear leukocytosis. The CSF is normal with the exception of mild elevation of opening pressure. Serum muscle enzymes may be elevated. Transient electrocardiographic and electroencephalographic abnormalities may occur. Anaerobic culture and microscopic examination of pus from the wound can be helpful, but *C tetani* is difficult to grow, and the drumstick-shaped gram-positive bacilli often cannot be found.

Differential Diagnosis

Poliomyelitis is characterized by asymmetrical paralysis in an incompletely immunized child. The history of an animal bite and the absence of trismus may suggest rabies. Local infections of the throat and jaw should be easily recognized. Bacterial meningitis, phenothiazine reactions, decerebrate posturing, narcotic withdrawal, spondylitis, and hypocalcemic tetany may be confused with tetanus.

Complications

Complications include sepsis, malnutrition, pneumonia, atelectasis, asphyxial spasms, decubitus ulcers, and fractures of the spine due to intense contractions. They can be prevented in part by skilled supportive care.

Prevention

A. TETANUS TOXOID

Active immunization with tetanus toxoid prevents tetanus (see Chapter 9). Immunity is almost always achieved after the third dose of vaccine. A booster at the time of injury is needed if none has been given in the past 10 years—or within 5 years in case of a heavily contaminated wound. Nearly all cases of tetanus (99%) in the United States are in unimmunized or incompletely immunized individuals. Many adolescents and adults lack protective antibody.

B. TETANUS ANTITOXIN

Human tetanus immune globulin (TIG) should be used in children with fewer than three previous tetanus toxoid immunizations (DPT, DP_aT, DT, Td, etc) who have “tetanus-prone wounds.” These include (1) wounds contaminated with soil, saliva, debris, or feces;

(2) crush wounds, puncture wounds, or wounds with avulsed or devitalized tissue; and (3) wounds due to thermal burns or frostbite. TIG should be administered to HIV-infected children with tetanus-prone wounds, regardless of their immunization history. When TIG is indicated, 250 units is given intramuscularly. If tetanus immunization is incomplete, a dose of age-appropriate vaccine should be given. When both are indicated, tetanus toxoid and TIG should be administered concurrently at different sites using different syringes.

C. TREATMENT OF WOUNDS

Proper surgical cleansing and debridement of contaminated wounds will decrease the risk of tetanus.

D. PROPHYLACTIC ANTIMICROBIALS

Prophylactic antimicrobials are useful if the child is unimmunized and TIG is not available.

Treatment

A. SPECIFIC MEASURES

Serotherapy lowers the mortality rate from tetanus, but not dramatically. Human TIG in a single dose of 3000–6000 units, intramuscularly, is given to children and adults. Doses of 500 units have been used in infants. Surgical debridement of wounds is indicated, but more extensive surgery or amputation to eliminate the site of infection is not necessary. Antibiotics are given to attempt to decrease the number of vegetative forms of the bacteria to decrease toxin production: oral metronidazole (30 mg/kg/d in four divided doses) for 10–14 days is the preferred agent.

B. GENERAL MEASURES

The patient is kept in a quiet room with minimal stimulation. Control of spasms and prevention of hypoxic episodes are crucial. Diazepam or another anxiolytic is useful (0.6–1.2 mg/kg/d intravenously in six divided doses). In the newborn, two or three divided doses should be given. Large doses (up to 25 mg/kg/d) may be required for older children. Diazepam is given intravenously until muscular spasms become infrequent and the generalized muscular rigidity much less prominent. The drug may then be given orally and the dosage reduced as the child improves. Mechanical ventilation and muscle paralysis are necessary in severe cases. Nasogastric or intravenous feedings should be used to limit stimulation of feedings and prevent aspiration.

Prognosis

The fatality rate in newborns and heroin-addicted individuals is high. The overall mortality rate in the United States is 11%. The fatality rate depends on the quality

of supportive care, the patient's age, and the patient's vaccination history. Many deaths are due to pneumonia or respiratory failure. If the patient survives 1 week, recovery is likely.

GAS GANGRENE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Contamination of a wound with soil or feces.
- Massive edema, skin discoloration, bleb formation, and pain in an area of trauma.
- Serosanguineous exudate from wound.
- Crepitation of subcutaneous tissue.
- Rapid progression of signs and symptoms.
- Clostridia cultured or seen on stained smears.

General Considerations

Gas gangrene (clostridial myonecrosis) is a necrotizing infection that follows trauma or surgery and is caused by several anaerobic, gram-positive, spore-forming bacilli of the genus *Clostridium*. The spores are found in soil, feces, and vaginal secretions. In devitalized tissue, the spores germinate into vegetative bacilli that proliferate and produce toxins, causing thrombosis, hemolysis, and tissue necrosis. *Clostridium perfringens*, the species causing approximately 80% of cases of gas gangrene, produces at least eight such toxins. The areas involved most often are the extremities, abdomen, and uterus. *Clostridium septicum* may also cause myonecrosis and causes septicemia in patients with neutropenia. Nonclostridial infections with gas formation can mimic clostridial infections and are more common.

Clinical Findings

A. SYMPTOMS AND SIGNS

The onset of gas gangrene is sudden, usually 1–20 days (mean, 3–4 days) after trauma or surgery. The skin around the wound becomes discolored, with hemorrhagic bullae, serosanguineous exudate, and crepitation

in the subcutaneous tissues. Pain and swelling are usually intense. Systemic illness appears early and progresses rapidly to intravascular hemolysis, jaundice, shock, toxic delirium, and renal failure.

B. LABORATORY FINDINGS

Isolation of the organism requires anaerobic culture. Gram-stained smears may demonstrate many gram-positive rods and few inflammatory cells.

C. IMAGING

Radiographs may demonstrate gas in tissues, but this is a late finding and is also seen in infections with other gas-forming organisms or may be due to air introduced into tissues during trauma or surgery.

D. OPERATIVE FINDINGS

Direct visualization of the muscle at surgery may be necessary to diagnose gas gangrene. Early, the muscle is pale and edematous and does not contract normally; later, the muscle may be frankly gangrenous.

Differential Diagnosis

Gangrene and cellulitis caused by other organisms and clostridial cellulitis (not myonecrosis) must be distinguished. Necrotizing fasciitis may resemble gas gangrene.

Prevention

Gas gangrene can be prevented by the adequate cleansing and debridement of all wounds. It is essential that foreign bodies and dead tissue be removed. A clean wound does not provide a suitable anaerobic environment for the growth of clostridial species.

Treatment

A. SPECIFIC MEASURES

Penicillin G (300,000–400,000 units/kg/d intravenously in six divided doses) should be given, usually combined with clindamycin or metronidazole. Clindamycin, metronidazole, meropenem and imipenem–cilastatin are alternatives for penicillin-allergic patients.

B. SURGICAL MEASURES

Surgery should be prompt and extensive, with removal of all necrotic tissue.

C. HYPERBARIC OXYGEN

Hyperbaric oxygen therapy has been shown to be effective, but it is not a substitute for surgery. A patient may be exposed to 2–3 atm in pure oxygen for 1- to 2-hour periods for as many sessions as necessary until clinical remission occurs.

Prognosis

Clostridial myonecrosis is fatal if untreated. With early diagnosis, antibiotics, and surgery, the mortality rate is 20–60%. Involvement of the abdominal wall, leukopenia, intravascular hemolysis, renal failure, and shock are ominous prognostic signs.

DIPHTHERIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A gray, adherent pseudomembrane, most often in the pharynx but also in the nasopharynx or trachea.
- Sore throat, serosanguineous nasal discharge, hoarseness, and fever in a nonimmunized child.
- Peripheral neuritis or myocarditis.
- Positive culture.
- Treatment should not be withheld pending culture results.

General Considerations

Diphtheria is an acute infection of the upper respiratory tract or skin caused by toxin-producing *Corynebacterium diphtheriae*. Diphtheria in the United States is rare; one case was reported in 2003, and only 48 cases were reported from 1980 to 1997. However, significant numbers of elderly adults and unimmunized children are susceptible to infection. Diphtheria still occurs in epidemics in countries where immunization is not universal. Travelers to these areas may acquire the disease. *Corynebacteria* are gram-positive club-shaped rods with a beaded appearance on Gram stain.

The capacity to produce exotoxin is conferred by a lysogenic bacteriophage and is not present in all strains of *C diphtheriae*. In immunized communities, infection probably occurs through spread of the phage among carriers of susceptible bacteria rather than through

spread of phage-containing bacteria themselves. Diphtheria toxin kills susceptible cells by irreversible inhibition of protein synthesis.

The toxin is absorbed into the mucous membranes and causes destruction of epithelium and a superficial inflammatory response. The necrotic epithelium becomes embedded in exuding fibrin and red and white blood cells, forming a grayish pseudomembrane over the tonsils, pharynx, or larynx. Any attempt to remove the membrane exposes and tears the capillaries, resulting in bleeding. The diphtheria bacilli within the membrane continue to produce toxin, which is absorbed and may result in toxic injury to heart muscle, liver, kidneys, and adrenals, and is sometimes accompanied by hemorrhage. The toxin also produces neuritis, resulting in paralysis of the soft palate, eye muscles, or extremities. Death may occur as a result of respiratory obstruction or toxemia and circulatory collapse. The patient may succumb after a somewhat longer time as a result of cardiac damage. The incubation period is 2–7 days.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Pharyngeal diphtheria—Early manifestations of diphtheritic pharyngitis are mild sore throat, moderate fever, and malaise, followed fairly rapidly by prostration and circulatory collapse. The pulse is more rapid than the fever would seem to justify. A pharyngeal membrane forms and may spread into the nasopharynx or the trachea, producing respiratory obstruction. The membrane is tenacious and gray and is surrounded by a narrow zone of erythema and a broader zone of edema. The cervical lymph nodes become swollen, and swelling is associated with brawny edema of the neck (so-called bull neck). Laryngeal diphtheria presents with stridor, which can progress to obstruction of the airway.

2. Other forms—Cutaneous, vaginal, and wound diphtheria account for up to one third of cases and are characterized by ulcerative lesions with membrane formation.

B. LABORATORY FINDINGS

Diagnosis is clinical. Direct smears are unreliable. Material is obtained from the nose, throat, or skin lesions, if present, for culture, but specialized culture media is required. Between 16 and 48 hours is required before identification of the organism. A toxigenicity test is then performed. Cultures may be negative in individuals who have received antibiotics. The WBC count is usually normal, but hemolytic anemia and thrombocytopenia are frequent.

Differential Diagnosis

Pharyngeal diphtheria resembles pharyngitis secondary to β -hemolytic streptococcus, Epstein–Barr virus, or other viral respiratory pathogens. A nasal foreign body or purulent sinusitis may mimic nasal diphtheria. Other causes of laryngeal obstruction include epiglottitis and viral croup. Guillain–Barré syndrome, poliomyelitis, or acute poisoning may mimic the neuropathy of diphtheria.

Complications

A. MYOCARDITIS

Diphtheritic myocarditis is characterized by a rapid, thready pulse; indistinct heart sounds, ST-T wave changes, conduction abnormalities, dysrhythmias, or cardiac failure; hepatomegaly; and fluid retention. Myocardial dysfunction may occur from 2 to 40 days after the onset of pharyngitis.

B. POLYNEURITIS

Neuritis of the palatal and pharyngeal nerves occurs during the first or second week. Nasal speech and regurgitation of food through the nose are seen. Diplopia and strabismus occur during the third week or later. Neuritis may also involve peripheral nerves supplying the intercostal muscles, diaphragm, and other muscle groups. Generalized paresis usually occurs after the fourth week.

C. BRONCHOPNEUMONIA

Secondary pneumonia is common in fatal cases.

Prevention

A. IMMUNIZATION

Immunization with diphtheria toxoid combined with pertussis and tetanus toxoids (DTP) should be used routinely for infants and children (see Chapter 9).

B. CARE OF EXPOSED SUSCEPTIBLES

Children exposed to diphtheria should be examined, and nose and throat cultures obtained. If signs and symptoms of early diphtheria are found, antibiotic treatment should be instituted. Immunized asymptomatic individuals should receive diphtheria toxoid if a booster has not been received within 5 years. Unimmunized close contacts should receive either erythromycin orally (40 mg/kg/d in four divided doses) for 7 days or benzathine penicillin G intramuscularly (25,000 units/kg), active immunization with diphtheria toxoid, and observation daily.

Treatment

A. SPECIFIC MEASURES

1. Antitoxin—To be effective, diphtheria antitoxin should be administered within 48 hours (see Chapter 9).

2. Antibiotics—Penicillin G (150,000 units/kg/d intravenously) should be given for 10 days. For penicillin-allergic patients, erythromycin (40 mg/kg/d) is given orally for 10 days.

B. GENERAL MEASURES

Bed rest in the hospital for 10–14 days is usually required. All patients must be strictly isolated for 1–7 days until respiratory secretions are noncontagious. Isolation may be discontinued when three successive nose and throat cultures at 24-hour intervals are negative. These cultures should not be taken until at least 24 hours have elapsed since the cessation of antibiotic treatment.

C. TREATMENT OF CARRIERS

All carriers should receive treatment. Erythromycin (40 mg/kg/d orally in three or four divided doses), penicillin V potassium (50 mg/kg/d for 10 days), or benzathine penicillin G (600,000–1,200,000 units intramuscularly) should be given. All carriers must be quarantined. Before they can be released, carriers must have three negative cultures of both the nose and the throat taken 24 hours apart and obtained at least 24 hours after the cessation of antibiotic therapy.

Prognosis

Mortality varies from 3% to 25% and is particularly high in the presence of early myocarditis. Neuritis is reversible; it is fatal only if an intact airway and adequate respiration cannot be maintained. Permanent damage due to myocarditis occurs rarely.

INFECTIONS DUE TO ENTEROBACTERIACEAE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Diarrhea by several different mechanisms due to Escherichia coli.*
- *Hemorrhagic colitis and hemolytic–uremic syndrome.*
- *Neonatal sepsis or meningitis.*

- *Urinary tract infection.*
- *Opportunistic infections.*
- *Diagnosis confirmed by culture.*

General Considerations

Enterobacteriaceae are a family of gram-negative bacilli that are normal flora in the gastrointestinal tract and are also found in water and soil. They cause gastroenteritis, urinary tract infections, neonatal sepsis and meningitis, and opportunistic infections. *Escherichia coli* is the organism in this family that most commonly causes infection in children, but *Klebsiella*, *Morganella*, *Enterobacter*, *Serratia*, *Proteus*, and other genera are also important, particularly in the compromised host. *Shigella* and *Salmonella* are discussed in separate sections.

E coli strains capable of causing diarrhea were originally termed enteropathogenic (EPEC) and were recognized by serotype. It is now known that *E coli* may cause diarrhea by several distinct mechanisms. Classic EPEC strains cause a characteristic histologic injury in the small bowel termed “adherence and effacement.” Enterotoxigenic *E coli* (ETEC) causes a secretory, watery diarrhea. ETEC adheres to enterocytes and secretes one or more plasmid-encoded enterotoxins. One of these, heat-labile toxin, resembles cholera toxin in structure, function, and mechanism of action. Enteroinvasive *E coli* (EIEC) is very similar to *Shigella* in pathogenetic mechanism. Enterohemorrhagic *E coli* (EHEC) is the cause of hemorrhagic colitis and the hemolytic–uremic syndrome. The most common EHEC serotype is O157:H7, although several other serotypes cause the same syndrome. These strains elaborate one of several cytotoxins, closely related to Shiga toxin produced by *S dysenteriae*. Outbreaks of hemolytic–uremic syndrome associated with EHEC have followed consumption of inadequately cooked ground beef. Thorough heating to 68–71°C is necessary. Unpasteurized fruit juice, various uncooked vegetables, and contaminated water have also caused infections and epidemics. The common source for EHEC in all of these foods and water is the feces of cattle. Person-to-person spread including spread in day care centers by the fecal–oral route has been reported.

E coli that aggregate on the surface of hep cells in tissue culture are termed enteroaggregative (EAggEC) *E coli*. EAggEC cause diarrhea by a distinct but unknown mechanism.

Eighty percent of *E coli* strains causing neonatal meningitis possess specific capsular polysaccharide (K1 antigen), which, alone or in association with spe-

cific somatic antigens, confers virulence. K1 antigen is also present on approximately 40% of strains causing neonatal septicemia. The *E coli* K1 organisms do not appear to cause gastrointestinal disease.

Approximately 90% of urinary tract infections in children are caused by *E coli*. *E coli* binds to the uroepithelium by P-fimbriae, which are present in greater than 90% of *E coli* that cause pyelonephritis. Other bacterial cell surface structures, such as O and K antigens, and host factors are also important in the pathogenesis of urinary tract infections.

Klebsiella, *Enterobacter*, *Serratia*, and *Morganella* are normally found in the gastrointestinal tract and in soil and water. *Klebsiella* may cause a bronchopneumonia with cavity formation. *Klebsiella*, *Enterobacter*, and *Serratia* are often hospital-acquired opportunists associated with antibiotic usage, debilitated states, and chronic respiratory conditions. They frequently cause urinary tract infection or sepsis. In many newborn nurseries, nosocomial outbreaks caused by antimicrobial-resistant *Klebsiella* or *Enterobacter* sp. are a major problem.

Many of these infections are difficult to treat because of antibiotic resistance. Antibiotic susceptibility tests are necessary. Parenteral third-generation cephalosporins are usually more active than ampicillin, but resistance due to high-level production of chromosomal cephalosporinase may occur. *Enterobacter* and *Serratia* strains broadly resistant to cephalosporins also cause infections in hospitalized newborns and children. Aminoglycoside antibiotics are usually effective but require monitoring of serum levels to ensure therapeutic and nontoxic levels.

Clinical Findings

A. SYMPTOMS AND SIGNS:

1. *E coli* gastroenteritis—*E coli* may cause diarrhea of varying types and severity. ETEC usually produce mild, self-limiting illness without significant fever or systemic toxicity, often known as traveler’s diarrhea. However, diarrhea may be severe in newborns and infants, and occasionally an older child or adult will have a cholera-like syndrome. EIEC strains cause a shigellosis-like illness, characterized by fever, systemic symptoms, blood and mucus in the stool, and leukocytosis, but currently are uncommon in the United States. EHEC strains cause hemorrhagic colitis. Diarrhea is initially watery, and fever is usually absent. Abdominal pain and cramping occur, and diarrhea progresses to blood streaking or grossly bloody stools. Hemolytic–uremic syndrome occurs within a few days of diarrhea in 2–5% of children and is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure (see Chapter 22).

2. Neonatal sepsis—Findings include jaundice, hepatosplenomegaly, fever, temperature lability, apneic

spells, irritability, and poor feeding. Meningitis is associated with sepsis in 25–40% of cases. Other metastatic foci of infection may be present, including pneumonia and pyelonephritis. Sepsis may lead to severe metabolic acidosis, shock, DIC, and death.

3. Neonatal meningitis—Findings include high fever, full fontanelles, vomiting, coma, convulsions, pareses or paralysis, poor or absent Moro reflex, opisthotonos, and occasionally hypertonia or hypotonia. Sepsis coexists or precedes meningitis in most cases. Thus signs of sepsis often accompany those of meningitis. CSF usually shows a cell count of over 1000/μL, mostly polymorphonuclear neutrophils, and bacteria on Gram stain. CSF glucose concentration is low (usually less than half that of blood), and the protein is elevated above the levels normally seen in newborns and premature infants (> 150 mg/dL).

4. Acute urinary tract infection—Symptoms include dysuria, increased urinary frequency, and fever in the older child. Nonspecific symptoms such as anorexia, vomiting, irritability, failure to thrive, and unexplained fever are seen in children younger than age 2 years. Young infants may present with jaundice. As many as 1% of girls of school age and 0.05% of boys have asymptomatic bacteriuria. Screening for and treatment of asymptomatic bacteriuria is not recommended.

B. LABORATORY FINDINGS

Because *E coli* are normal flora in the stool, a positive stool culture alone does not prove that the *E coli* in the stool are causing disease. Serotyping, tests for enterotoxin production or invasiveness, and tests for P-fimbriae are performed in research laboratories. MacConkey agar with sorbitol substituted for lactose (SMAC agar) is useful to screen stool for enterohemorrhagic *E coli*. Serotyping and testing for enterotoxin are available at many state health departments. Blood cultures are positive in neonatal sepsis. Cultures of CSF and urine should also be obtained. The diagnosis of urinary tract infections is discussed in Chapter 22.

Differential Diagnosis

The clinical picture of EPEC infection may resemble that of salmonellosis, shigellosis, or viral gastroenteritis.

Neonatal sepsis and meningitis caused by *E coli* can be differentiated from other causes of neonatal infection only by blood and CSF culture.

Treatment

A. SPECIFIC MEASURES

1. *E coli* gastroenteritis—Gastroenteritis due to EPEC seldom requires antimicrobial treatment. Fluid and electrolyte therapy, preferably given orally, may be

required to avoid dehydration. Bismuth subsalicylate reduces stool volume by about one-third in infants with watery diarrhea, probably including ETEC. In nursery outbreaks, *E coli* gastroenteritis has been treated with neomycin (100 mg/kg/d orally in three divided doses for 5 days). Clinical efficacy is not established. Traveler's diarrhea may be treated with TMP-SMX in children and with fluoroquinolones in adults. The risk of hemolytic-uremic syndrome increases following treatment of EHEC colitis, and antimicrobials should be withheld in suspected cases.

2. *E coli* sepsis, pneumonia, or pyelonephritis—The drugs of choice are ampicillin (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses q4–6h), cefotaxime (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses q6–8h), ceftriaxone (50–100 mg/kg/d, given intramuscularly as single dose or in two divided doses), and gentamicin (5–7.5 mg/kg/d, given intramuscularly or intravenously in divided doses q8h). Treatment is continued for 10–14 days. Amikacin or tobramycin may be used instead of gentamicin if the strain is susceptible. Third-generation cephalosporins are often an attractive alternative as single-drug therapy and do not require monitoring for toxicity.

3. *E coli* meningitis—Third-generation cephalosporins such as cefotaxime (200 mg/kg/d intravenously in four divided doses) are given for a minimum of 3 weeks. Ampicillin (200–300 mg/kg/d intravenously in four to six divided doses) and gentamicin (5–7.5 mg/kg/d intramuscularly or intravenously in three divided doses) are also effective. Treatment with intrathecal and intraventricular aminoglycosides does not improve outcome. Serum levels need to be monitored.

4. Acute urinary tract infection—See Chapter 22.

Prognosis

Death due to gastroenteritis leading to dehydration can be prevented by early fluid and electrolyte therapy. Neonatal sepsis with meningitis is still associated with a mortality rate of over 50%. Most children with recurrent urinary tract infections do well if they have no underlying anatomic defects. The mortality rate in opportunistic infections usually depends on the severity of infection and the underlying condition.

PSEUDOMONAS INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Opportunistic infection.*
- *Confirmed by cultures.*

General Considerations

Pseudomonas aeruginosa is an aerobic gram-negative rod with versatile metabolic requirements. *P aeruginosa* may grow in distilled water and in commonly used disinfectants, complicating infection control in medical facilities. *P aeruginosa* is both invasive and destructive to tissue, and toxigenic due to secreted exotoxins, all factors that contribute to virulence. Other genera previously classified as *Pseudomonas* occasionally cause nosocomial infections. *Stenotrophomonas maltophilia* (previously *P maltophilia*) and *Burkholderia cepacia* (previously *P cepacia*) are the most frequent.

P aeruginosa is an important cause of infection in children with cystic fibrosis, neoplastic disease, neutropenia, or extensive burns and in those receiving antibiotic therapy. Infections of the urinary and respiratory tracts, ears, mastoids, paranasal sinuses, eyes, skin, meninges, and bones are seen. *Pseudomonas* pneumonia is a common nosocomial infection in patients receiving assisted ventilation.

P aeruginosa sepsis may be accompanied by characteristic peripheral lesions called ecthyma gangrenosum. Ecthyma gangrenosum also may occur by direct invasion through intact skin in the groin, axilla, or other skinfolds. *P aeruginosa* is an infrequent cause of sepsis in previously healthy infants and may be the initial sign of underlying medical problems. *P aeruginosa* osteomyelitis often complicates puncture wounds of the feet. *P aeruginosa* is a frequent cause of malignant exter-

nal otitis media and of chronic suppurative otitis media. Outbreaks of vesiculopustular skin rash have been associated with exposure to contaminated water in whirlpool baths and hot tubs.

P aeruginosa infects the tracheobronchial tree of nearly all patients with cystic fibrosis. Mucoid exopolysaccharide, an exuberant capsule, is characteristically overproduced by isolates from patients with cystic fibrosis. Although bacteremia seldom occurs, patients with cystic fibrosis ultimately succumb to chronic lung infection with *P aeruginosa*. Infection due to *B cepacia* has caused a rapidly progressive pulmonary disease in some colonized patients and may be spread by close contact.

Clinical Findings

The clinical findings depend on the site of infection and the patient's underlying disease. Sepsis with these organisms resembles gram-negative sepsis with other organisms, although the presence of ecthyma gangrenosum suggests the diagnosis. The diagnosis is made by culture. *Pseudomonas* infection should be suspected in neonates and neutropenic patients with clinical sepsis. A severe necrotizing pneumonia occurs in patients on ventilators.

Patients with cystic fibrosis have a persistent bronchitis that progresses to bronchiectasis and ultimately to respiratory failure. During exacerbations of illness, cough and sputum production increase with low-grade fever, malaise, and diminished energy.

The purulent aural drainage without fever in patients with chronic suppurative otitis media is not distinguishable from that due to other cause.

Prevention

A. INFECTIONS IN DEBILITATED PATIENTS

Colonization of extensive second- and third-degree burns by *P aeruginosa* can lead to fatal septicemia. Aggressive debridement and topical treatment with 0.5% silver nitrate solution, 10% mafenide cream, or silver sulfadiazine will greatly inhibit *P aeruginosa* contamination of burns. (See Chapter 11 for a discussion of burn wound infections and prevention.)

B. NOSOCOMIAL INFECTIONS

Faucet aerators, communal soap dispensers, disinfectants, improperly cleaned inhalation therapy equipment, infant incubators, and back rub lotions have all been associated with *Pseudomonas* epidemics. Infant-to-infant transmission by nursery personnel carrying *Pseudomonas* on the hands is frequent in neonatal units. Careful maintenance of equipment and enforcement of

infection control procedures are essential to minimize nosocomial transmission.

C. PATIENTS WITH CYSTIC FIBROSIS

Chronic infection of the lower respiratory tract occurs in nearly all patients with cystic fibrosis. The infecting organism is seldom cleared from the respiratory tract, even with intensive antimicrobial therapy, and the resultant injury to the lung eventually leads to pulmonary insufficiency. Treatment is aimed at controlling signs and symptoms of the infection.

Treatment

P. aeruginosa is inherently resistant to many antimicrobials and may develop resistance during therapy. Mortality rates in hospitalized patients exceed 50%, owing both to the severity of underlying illnesses in patients predisposed to *Pseudomonas* infection and to the limitations of therapy. Antibiotics effective against *Pseudomonas* include the aminoglycosides, ureidopenicillins (ticarcillin and piperacillin), β -lactamase inhibitor with a ureidopenicillin (ticarcillin-clavulanate and piperacillin-tazobactam), expanded-spectrum cephalosporins (ceftazidime and cefepime), imipenem, meropenem, and ciprofloxacin. Antimicrobial susceptibility patterns vary from area to area, and resistance tends to appear as new drugs become popular. Treatment of infections is best guided by clinical response and susceptibility tests.

Gentamicin or tobramycin (5–7.5 mg/kg/d, given intramuscularly or intravenously in three divided doses) or amikacin (15–22 mg/kg/d, given in two or three divided doses) in combination with ticarcillin (200–300 mg/kg/d, given intravenously in six divided doses) or with another antipseudomonal β -lactam antibiotic is recommended for treatment of serious *Pseudomonas* infections. Ceftazidime (150–200 mg/kg/d, given in four divided doses) or cefepime (150 mg/kg/d, given in three divided doses) has excellent activity against *P. aeruginosa*. Treatment should be continued for 10–14 days. Treatment with two active drugs is recommended for all serious infections.

Pseudomonas osteomyelitis requires thorough surgical debridement and antimicrobial therapy for 2 weeks. *Pseudomonas* folliculitis does not require antibiotic therapy.

Oral or intravenous ciprofloxacin is also effective against susceptible *P. aeruginosa*, but is not approved by the Food and Drug Administration for use in children because of concerns about skeletal toxicity. Nonetheless, in some circumstances of antimicrobial resistance, or when the benefits clearly outweigh the small risks, ciprofloxacin may be used.

Chronic suppurative otitis media responds to intravenous ceftazidime (150–200 mg/kg/d in three or four

divided doses) given until the drainage has ceased for 3 days. Twice-daily ceftazidime with aural debridement and cleaning given on an outpatient basis has also been successful. Swimmer's ear may be caused by *P. aeruginosa* and responds well to topical drying agents (alcohol-vinegar mix) and cleansing.

Prognosis

Because debilitated patients are most frequently affected, the mortality rate is high. These infections may have a protracted course, and eradication of the organisms may be difficult.

SALMONELLA GASTROENTERITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Nausea, vomiting, headache, meningismus.
- Fever, diarrhea, abdominal pain.
- Culture or organism from stool, blood, or other specimens.

General Considerations

Salmonellae are gram-negative rods that frequently cause food-borne gastroenteritis and occasionally bacteremic infection of bone, meninges, and other foci. Three species—*Salmonella typhi*, *Salmonella choleraesuis*, and *Salmonella enteritidis*—and approximately 2000 serotypes are recognized. *S. typhimurium* is the most frequently isolated serotype in most parts of the world. An estimated 4 million cases of salmonellosis occur yearly in the United States, but only 45,000 are reported.

Salmonellae are able to penetrate the mucin layer of the small bowel and attach to epithelial cells. Organisms penetrate the epithelial cells and multiply in the submucosa. Infection results in fever, vomiting, watery diarrhea, and occasionally mucus and polymorphonuclear neutrophils in the stool. Although the small intestine is generally regarded as the principal site of infection, colitis also occurs. *S typhimurium* frequently involves the large bowel.

Salmonella infections in childhood occur in two major forms: (1) gastroenteritis (including food poisoning), which may be complicated by sepsis and focal suppurative complications; and (2) enteric fever (typhoid fever and paratyphoid fever) (see next section). Although the incidence of typhoid fever has decreased in the United States, the incidence of *Salmonella* gastroenteritis has greatly increased in the past 15–20 years. The highest attack rates occur in children younger than age 6 years, with a peak in the age group from 6 months to 2 years.

Salmonellae are widespread in nature, infecting domestic and wild animals. Fowl and reptiles have a particularly high carriage rate. Transmission results primarily from ingestion of contaminated food. Transmission from human to human occurs by the fecal–oral route via contaminated food, water, and fomites. Numerous foods, including meats, milk, cheese, ice cream, and chocolate, are associated with outbreaks. Contaminated egg powder and frozen whole egg preparations used to make ice cream, custards, and mayonnaise are responsible for outbreaks. Eggs with contaminated shells that are consumed raw or undercooked have been incriminated in outbreaks and sporadic cases.

Because salmonellae are susceptible to gastric acidity, the elderly, infants, and patients taking antacids or H₂-blocking drugs are at increased risk for infection. Most cases of *Salmonella* meningitis (80%) and bacteremia occur in infancy. Newborns may acquire the infection from their mothers during delivery and may precipitate outbreaks in nurseries. Newborns are at special risk for developing meningitis.

Clinical Findings

A. SYMPTOMS AND SIGNS

Infants usually develop fever, vomiting, and diarrhea. The older child may also complain of headache, nausea, and abdominal pain. Stools are often watery or may contain mucus and, in some instances, blood, suggesting shigellosis. Drowsiness and disorientation may be associated with meningismus. Convulsions occur less frequently than with shigellosis. Splenomegaly is occasionally noted. In the usual case, diarrhea is moderate and subsides after 4–5 days, but it may be protracted.

B. LABORATORY FINDINGS

Diagnosis is made by isolation of the organism from stool, blood, or, in some cases, from urine, CSF, or pus from a suppurative lesion. The WBC count usually shows a polymorphonuclear leukocytosis but may show leukopenia. Typing of isolates is done with specific antisera. *Salmonella* isolates should be reported to public health authorities for epidemiologic purposes. Stool cultures are rarely positive when obtained from children who develop diarrhea after 3 days of hospitalization.

Differential Diagnosis

In staphylococcal food poisoning, the incubation period is shorter (2–4 hours) than in *Salmonella* food poisoning (12–24 hours). Fever is absent, and vomiting rather than diarrhea is the main symptom. In shigellosis, many pus cells are likely to be seen on a stained smear of stool and there is more apt to be a marked shift to the left in the peripheral white count, although some cases of salmonellosis are indistinguishable from shigellosis. *Campylobacter* gastroenteritis commonly resembles salmonellosis clinically. Culture of the stools is necessary to distinguish the causes of bacterial gastroenteritis.

Complications

Unlike most types of infectious diarrhea, salmonellosis is frequently accompanied by bacteremia, especially in newborns and infants. Septicemia with extraintestinal infection is seen, most commonly with *S choleraesuis* but also with *S enteritidis*, *S typhimurium*, and *S paratyphi* B and C. The organism may localize in any tissue and may cause arthritis, osteomyelitis, cholecystitis, endocarditis, meningitis, pericarditis, pneumonia, or pyelonephritis. Patients with sickle cell anemia or other hemoglobinopathies have a predilection for the development of osteomyelitis. Severe dehydration and shock are more likely to occur with shigellosis but may occur with *Salmonella* gastroenteritis.

Prevention

Measures for the prevention of *Salmonella* infections include thorough cooking of foodstuffs derived from contaminated sources, adequate refrigeration, control of infection among domestic animals, and meticulous meat and poultry inspections. Raw and undercooked fresh eggs should be avoided. Food handlers and child care workers with salmonellosis should have three negative stool cultures before resuming work. Asymptomatic children, who have recovered from salmonella infection, do not need exclusion.

Treatment

A. SPECIFIC MEASURES

In uncomplicated *Salmonella* gastroenteritis, antibiotic treatment does not shorten the course of the clinical illness and may prolong convalescent carriage of the organism. Colitis or secretory diarrhea due to *Salmonella* may improve with antibiotic therapy.

Because of the higher risk of sepsis and focal disease, antibiotic treatment is recommended in infants younger than age 3 months; in severely ill children; and in children with sickle cell disease, liver disease, recent gastrointestinal surgery, cancer, depressed immunity, or chronic renal or cardiac disease. Infants younger than age 3 months with positive stool cultures or suspected salmonellosis sepsis should be admitted to hospital, evaluated for focal infection including cultures of blood and CSF, and given treatment intravenously. A third-generation cephalosporin is recommended due to frequent resistance to ampicillin and TMP-SMX. Older patients developing bacteremia during the course of gastroenteritis should receive parenteral treatment initially, and a careful search should be made for additional foci of infection. After signs and symptoms subside, these patients should receive oral medication. Parenteral and oral treatment should last a total of 7–10 days. Longer treatment is indicated for specific complications. If susceptibility tests indicate resistance to ampicillin, third-generation cephalosporins or TMP-SMX should be given. Fluoroquinolones also are efficacious but are not approved for administration to children. Fluoroquinolones are used for strains resistant to multiple other drugs.

Salmonella meningitis is best treated with ampicillin (200–300 mg/kg/d intravenously in four to six divided doses) and a third-generation cephalosporin (cefotaxime, ceftriaxone) for 3 weeks. If the child improves rapidly and the CSF is sterile, treatment may be completed with a single drug, the choice guided by results of susceptibility tests.

Outbreaks on pediatric wards are difficult to control. Strict hand washing, cohorting of patients and personnel, and ultimately closure of the unit may be necessary.

B. TREATMENT OF THE CARRIER STATE

About half of patients may have positive stool cultures after 4 weeks. Infants tend to remain convalescent carriers for up to a year. Antibiotic treatment of carriers is not effective.

C. GENERAL MEASURES

Careful attention must be given to maintaining fluid and electrolyte balance, especially in infants.

Prognosis

In gastroenteritis, the prognosis is good. In sepsis with focal suppurative complications, the prognosis is more guarded. The case fatality rate of *Salmonella* meningitis is high in infants. There is a strong tendency to relapse if treatment is not continued for at least 14–21 days.

TYPHOID FEVER & PARATYPHOID FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Insidious or acute onset of headache, anorexia, vomiting, constipation or diarrhea, ileus, and high fever.*
- *Meningismus, splenomegaly, and rose spots.*
- *Leukopenia; positive blood, stool, bone marrow, and urine cultures.*

General Considerations

Typhoid fever is caused by the gram-negative bacillus *Salmonella typhi*. Paratyphoid fevers, which are usually milder but may be clinically indistinguishable, are caused by *Salmonella paratyphi* A, *Salmonella schottmuelleri*, or *Salmonella hirschfeldii* (formerly *Salmonella paratyphi* A, B, and C). Children have a shorter incubation period than do adults (usually 5–8 days instead of 8–14 days). The organism enters the body through the walls of the intestinal tract and, following a transient bacteremia,

multiplies in the reticuloendothelial cells of the liver and spleen. Persistent bacteremia and symptoms then follow. Reinfection of the intestine occurs as organisms are excreted in the bile. Bacterial emboli produce the characteristic skin lesions (rose spots). Symptoms in children may be mild or severe, but children younger than age 5 years rarely have severe typhoid fever.

Typhoid fever is transmitted by the fecal–oral route and by contamination of food or water. Unlike other *Salmonella* species, there are no animal reservoirs of *S typhi*; each case is the result of direct or indirect contact with the organism or with an individual who is actively infected or a chronic carrier.

About 350–450 cases per year are reported in the United States, 80% of which are acquired during foreign travel.

Clinical Findings

A. SYMPTOMS AND SIGNS

In children, the onset of typhoid fever is apt to be sudden rather than insidious, with malaise, headache, crampy abdominal pains and distention, and sometimes constipation followed within 48 hours by diarrhea, high fever, and toxemia. An encephalopathy may be seen with irritability, confusion, delirium, and stupor. Vomiting and meningismus may be prominent in infants and young children. The classic lengthy three-stage disease seen in adult patients is often shortened in children. The prodrome may last only 2–4 days, the toxic stage only 2–3 days, and the defervescence stage 1–2 weeks.

During the prodromal stage, physical findings may be absent, or there may merely be some abdominal distention and tenderness, meningismus, mild hepatomegaly, and minimal splenomegaly. The typical typhoidal rash (rose spots) is present in 10–15% of children. It appears during the second week of the disease and may erupt in crops for the succeeding 10–14 days. Rose spots are erythematous maculopapular lesions 2–3 mm in diameter that fade on pressure. They are found principally on the trunk and chest, and they generally disappear within 3–4 days. The lesions usually number fewer than 20.

B. LABORATORY FINDINGS

Typhoid bacilli can be isolated from many sites, including blood, stool, urine, and bone marrow. Blood cultures are positive in 50–80% of cases during the first week and less often later in the illness. Stool cultures are positive in about 50% of cases after the first week. Urine and bone marrow cultures are also valuable. Most patients will have negative cultures (including stool) by the end of a 6-week period. Serologic tests (Widal reaction) are not as useful as cultures because

both false-positive and false-negative results occur. A fourfold rise in titer of O (somatic) agglutinins is suggestive but not diagnostic of infection.

Leukopenia is common in the second week of the disease, but in the first week, leukocytosis may be seen. Proteinuria, mild elevation of liver enzymes, thrombocytopenia, and DIC are common.

Differential Diagnosis

Typhoid and paratyphoid fevers must be distinguished from other serious prolonged fevers. These include typhus, brucellosis, malaria, tularemia, miliary tuberculosis, psittacosis, vasculitis, lymphoma, mononucleosis, and Kawasaki disease. The diagnosis of typhoid fever is often made clinically in developing countries, but the accuracy of clinical diagnosis is variable. In developed countries, where typhoid fever is uncommon and physicians are unfamiliar with the clinical picture, the diagnosis is often not suspected until late. Positive cultures confirm the diagnosis.

Complications

The most serious complications of typhoid fever are gastrointestinal hemorrhage (2–10%) and perforation (1–3%). They occur toward the end of the second week or during the third week of the disease.

Intestinal perforation is one of the principal causes of death. The site of perforation generally is the terminal ileum or cecum. The clinical manifestations are indistinguishable from those of acute appendicitis, with pain, tenderness, and rigidity in the right lower quadrant. The radiographic finding of free air in the peritoneal cavity is diagnostic.

Bacterial pneumonia, meningitis, septic arthritis, abscesses, and osteomyelitis are uncommon complications, particularly if specific treatment is given promptly. Shock and electrolyte disturbances may lead to death.

About 1–3% of patients become chronic carriers of *S typhi*. Chronic carriage is defined as excretion of typhoid bacilli for more than a year, but carriage is often lifelong. Adults with underlying biliary or urinary tract disease are much more likely than children to become chronic carriers.

Prevention

Routine typhoid vaccine is not recommended in the United States but should be considered for foreign travel to endemic areas. An attenuated oral typhoid vaccine produced from strain Ty21a has better efficacy and causes minimal side effects but is not approved for children younger than age 6 years. A capsular polysaccharide

ride vaccine (ViCPS) requires one intramuscular injection and may be given to children age 2 years and older (see Chapter 9).

Treatment

A. SPECIFIC MEASURES

Antimicrobial susceptibility testing and local experience are used to guide therapy. Equally effective regimens for susceptible strains include the following: TMP–SMX (10 mg/kg trimethoprim and 50 mg/kg sulfamethoxazole per day orally in two or three divided doses), amoxicillin (100 mg/kg/d orally in four divided doses), and ampicillin (100–200 mg/kg/d intravenously in four divided doses). Aminoglycosides and first- and second-generation cephalosporins are clinically ineffective regardless of in vitro susceptibility results. Third-generation cephalosporins are used for resistant strains. Ceftriaxone and cefotaxime may be used parenterally. Ciprofloxacin or other fluoroquinolones are efficacious but not approved in children, but may be used for multiply resistant strains. Occasionally the presence of multiply resistant strains requires the use of chloramphenicol (50–100 mg/kg/d orally or intravenously in four doses). Treatment duration is 14–21 days. Patients remain febrile for 3–5 days even with appropriate therapy.

B. GENERAL MEASURES

General support of the patient is exceedingly important and includes rest, good nutrition, and careful observation, with particular regard to evidence of intestinal bleeding or perforation. Blood transfusions may be needed even in the absence of frank hemorrhage.

Prognosis

A prolonged convalescent carrier stage may occur in children. Three negative cultures after all antibiotics have been stopped are required before contact precautions are stopped. With early antibiotic therapy, the prognosis is excellent, and the mortality rate is less than 1%. Relapse occurs 1–3 weeks later in 10–20% of patients despite appropriate antibiotic treatment.

SHIGELLOSIS (BACILLARY DYSENTERY)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cramps and bloody diarrhea.
- High fever, malaise, convulsions.
- Pus and blood in diarrheal stools examined microscopically.
- Diagnosis confirmed by stool culture.

General Considerations

Shigellae are nonmotile gram-negative rods of the family Enterobacteriaceae and are closely related to *Escherichia coli*. The genus *Shigella* is divided into four major groups, A–D, representing *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*, respectively. Approximately 30,000 cases of shigellosis are reported each year in the United States. *S sonnei* followed by *S flexneri* are the most common isolates.

S dysenteriae, which causes the most severe diarrhea of all species and the greatest number of extraintestinal complications, accounts for fewer than 1% of all *Shigella* infections in the United States.

Shigellosis may be a serious disease, particularly in young children, and without supportive treatment an appreciable mortality rate results. In older children and adults, the disease tends to be self-limited and milder. Shigellosis is unusual in infants younger than age 3 months, although in rare cases shigellae may be transmitted from the mother to the newborn during delivery. Diarrhea and refusal to take feedings are the most common symptoms in neonatal shigellosis, and bloody diarrhea and fever occur less frequently. Vomiting, convulsions, or high fever is uncommon.

Shigella is usually transmitted by the fecal–oral route. Food- and water-borne outbreaks are increasing in occurrence, but are less important overall than person-to-person transmission. The disease is very communicable—as few as 200 bacteria can produce illness in an adult. The secondary attack rate in families is high, and shigellosis is a serious problem in day care centers and custodial institutions. *Shigella* organisms

produce disease by invading the colonic mucosa, causing mucosal ulcerations and microabscesses. A plasmid-encoded gene is required for enterotoxin production, chromosomal genes are required for invasiveness, and smooth lipopolysaccharide are required for virulence. An experimental vaccine is under development and is safe and immunogenic in young children.

Clinical Findings

A. SYMPTOMS AND SIGNS

The incubation period of shigellosis is usually 2–4 days. Onset is abrupt, with abdominal cramps, urgency, tenesmus, chills, fever, malaise, and diarrhea. Hallucinations and seizures sometimes accompany high fever. In severe forms, blood and mucus are seen in small volume in the stool (dysentery), and meningismus and convulsions may occur. In older children, the disease may be mild and may be characterized by watery diarrhea without blood. In young children, a fever of 39.4–40°C is common. Rarely there is rectal prolapse. Symptoms generally last 3–7 days.

B. LABORATORY FINDINGS

The total WBC count varies, but often there is a marked shift to the left. The stool may contain gross blood and mucus, and many neutrophils are seen if mucus from the stool is examined microscopically. Stool cultures are usually positive; however, they may be negative because the organism is somewhat fragile and present in small numbers late in the disease, and because laboratory techniques are suboptimal for the recovery of shigellae.

Differential Diagnosis

Diarrhea due to rotavirus infection is a winter rather than a summer disease. Usually children with rotavirus infection are not as febrile or toxic as those with shigellosis, and in rotavirus infection, stool does not contain gross blood or neutrophils. Intestinal infections caused by *Salmonella* or *Campylobacter* are differentiated by culture. Grossly bloody stools in a patient without fever or stool leukocytes suggest *E coli* O:157 infection. Amebic dysentery is diagnosed by microscopic examination of fresh stools or sigmoidoscopy specimens. Intussusception is characterized by an abdominal mass, so-called currant jelly stools without leukocytes, and absence of fever. Mild shigellosis is not distinguishable clinically from other forms of infectious diarrhea.

Complications

Dehydration, acidosis, shock, and renal failure are the major complications. In some cases, a chronic form of dysentery occurs, characterized by mucoid stools and

poor nutrition. Bacteremia and metastatic infections are rare but serious complications. Febrile seizures are common. Fulminating fatal dysentery and hemolytic-uremic syndrome occur rarely.

Treatment

A. SPECIFIC MEASURES

Resistance to TMP–SMX (10 mg/kg/d trimethoprim and 50 mg/kg/d sulfamethoxazole, given in two divided doses orally for 5 days) is now commonly encountered in many communities and limits the use of this otherwise effective drug to cases where results of susceptibility testing are known. Amoxicillin is not effective. Ampicillin (100 mg/kg/d, given in four divided doses) is also efficacious if the strain is sensitive. Parenteral ceftriaxone and oral cefixime are both effective, although cefixime is now unavailable, and experience with other third-generation oral cephalosporins is limited. Azithromycin (12 mg/kg/d on day 1, then 6 mg/kg/d for four days) was superior to cefixime in one study. Ciprofloxacin (500 mg, given bid for 5 days) is efficacious in adults but is not approved for use in children. However, it may be used in children who remain symptomatic and in need of therapy, and when multiply resistant strains limit other preferred choices. Successful treatment reduces the duration of fever, cramping, and diarrhea and terminates fecal excretion of *Shigella*. Tetracycline and chloramphenicol are also effective, but resistance to them is common. Presumptive therapy should be limited to children with classic shigellosis or known outbreaks. Afebrile children with bloody diarrhea are more commonly infected with EHEC. Antimicrobial therapy of EHEC may increase the likelihood of hemolytic uremic syndrome.

B. GENERAL MEASURES

In severe cases, immediate rehydration is critical. A mild form of chronic malabsorption syndrome may supervene and require prolonged dietary control.

Prognosis

The prognosis is excellent if vascular collapse is treated promptly by adequate fluid therapy. The mortality rate is high in very young, malnourished infants who do not receive fluid and electrolyte therapy. Convalescent fecal excretion of *Shigella* lasts 1–4 weeks in patients not receiving antimicrobial therapy. Long-term carriers are rare.

CHOLERA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of severe watery diarrhea.
- Persistent vomiting without nausea or fever.
- Extreme and rapid dehydration and electrolyte loss, with rapid development of vascular collapse.
- Contact with a case of cholera or with shellfish, or the presence of cholera in the community.
- Diagnosis confirmed by stool culture.

General Considerations

Cholera is an acute diarrheal disease caused by the gram-negative organism *Vibrio cholerae*. It is transmitted by contaminated water or food, especially contaminated shellfish. Typical disease is generally so dramatic that in endemic areas the diagnosis is obvious. Individuals with mild illness and young children may play an important role in transmission of the infection.

Asymptomatic infection is far more common than clinical disease. In endemic areas, rising titers of vibriocidal antibody are seen with increasing age. Infection occurs in individuals with low titers. The age-specific attack rate is highest in children younger than age 5 years and declines with age. Cholera is unusual in infancy.

Cholera toxin is a protein enterotoxin that is primarily responsible for symptoms. Cholera toxin binds to a regulatory subunit of adenylyl cyclase in enterocytes, causing increased cAMP and an outpouring of NaCl and water into the lumen of the small bowel.

Nutritional status is an important factor determining the severity of the diarrhea. Duration of diarrhea is prolonged in adults and children with severe malnutrition.

Cholera is endemic in India and southern and Southeast Asia and in parts of Africa. The most recent pandemic, caused by the El Tor biotype of *V cholerae*

01, began in 1961 in Indonesia. Epidemic cholera spread in Central and South America, with a total of 1 million cases and 9500 deaths reported through 1994. Cases in the United States occurred in the course of foreign travel or as a result of consumption of contaminated imported food. Cholera is increasingly associated with consumption of shellfish. Interstate shipment of oysters has resulted in cholera in several inland states.

Several recent studies provide evidence that *V cholerae* is a natural inhabitant of shellfish and copepods in estuarine environments. Seasonal multiplication of *V cholerae* may provide a source of outbreaks in endemic areas. Chronic cholera carriers are rare. The incubation period is short, usually 1–3 days.

Clinical Findings

A. SYMPTOMS AND SIGNS

Many patients infected with *V cholerae* have mild disease, with 1–2% developing severe diarrhea. During severe cholera, there is a sudden onset of massive, frequent, watery stools, generally light gray in color (so-called rice-water stools) and containing some mucus but no pus. Vomiting may be projectile and is not accompanied by nausea. Within 2–3 hours, the tremendous loss of fluids results in life-threatening dehydration, hypochloremia, and hypokalemia, with marked weakness and collapse. Renal failure with uremia and irreversible peripheral vascular collapse will occur if fluid therapy is not administered. The illness lasts 1–7 days and is shortened by appropriate antibiotic therapy.

B. LABORATORY FINDINGS

Markedly elevated hemoglobin (20 g/dL) and marked acidosis, hypochloremia, and hyponatremia are seen. Stool sodium concentration may range from 80 mEq/L to 120 mEq/L. Cultural confirmation using thiosulfate-citrate-bile salt-sucrose (TCBS) agar takes 16–18 hours for a presumptive diagnosis and 36–48 hours for a definitive bacteriologic diagnosis.

Prevention

Cholera vaccine is available and provides 50% efficacy. Protection lasts 3–6 months. Cholera vaccine is not generally recommended for travelers. Tourists visiting endemic areas are at little risk if they exercise caution in what they eat and drink and maintain good personal hygiene. In endemic areas, all water and milk must be boiled, food protected from flies, and sanitary precautions observed. Simple filtration of water is highly effective in reducing cases. Thorough cooking of shellfish prevents transmission. All patients with cholera should be isolated.

Chemoprophylaxis is indicated for household and other close contacts of cholera patients. It should be initiated as soon as possible after the onset of the disease in the index patient. Tetracycline (500 mg/d for 5 days) is effective in preventing infection. TMP–SMX may be substituted in children.

Treatment

Physiologic saline or lactated Ringer solution should be administered intravenously in large amounts to restore blood volume and urine output and prevent irreversible shock. Potassium supplements are required. Sodium bicarbonate, given intravenously, may also be needed initially to overcome profound acidosis. Moderate dehydration and acidosis can be corrected in 3–6 hours by oral therapy alone, because the active glucose transport system of the small bowel is normally functional. The optimal composition of the oral solution (in mEq/L) is as follows: Na⁺, 90; Cl⁻, 80; and K⁺, 20 (with glucose, 110 mmol/L).

Treatment with tetracycline (50 mg/kg/d orally in four divided doses for 2–5 days) or azithromycin (10 mg/kg/d in one dose for 1–5 days) shortens the duration of the disease in children and prevents clinical relapse but is not as important as fluid and electrolyte therapy. Tetracycline resistance occurs in some regions, and ciprofloxacin may be used depending on local resistance patterns. TMP–SMX should be used in children younger than age 9 years.

Prognosis

With early and rapid replacement of fluids and electrolytes, the case fatality rate is 1–2% in children. If significant symptoms appear and no treatment is given, the mortality rate is over 50%.

CAMPYLOBACTER INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, vomiting, abdominal pain, diarrhea.
- Presumptive diagnosis by darkfield or phase contrast microscopy of stool wet mount or modified Gram stain.
- Definitive diagnosis by stool culture.

General Considerations

Campylobacter species are small gram-negative, curved or spiral bacilli that are commensals or pathogens in many animals. *Campylobacter jejuni* frequently causes acute enteritis in humans. In the 1990s, *C jejuni* was responsible for 3–11% of cases of acute gastroenteritis in North America and Europe. In many areas, enteritis due to *C jejuni* is more common than that due to *Salmonella* or *Shigella*. *Campylobacter fetus* causes bacteremia and meningitis in immunocompromised patients. *C fetus* may cause maternal fever, abortion, stillbirth, and severe neonatal infection. *Helicobacter pylori* (previously called *Campylobacter pylori*) causes most cases of gastritis and peptic ulcer disease in both adults and children (see Chapter 20).

Campylobacter colonizes domestic and wild animals, especially poultry. Numerous cases have been associated with sick puppies or other animal contacts. Contaminated food and water, improperly cooked poultry, and person-to-person spread by the fecal–oral route are common routes of transmission. Outbreaks associated with day care centers, contaminated water supplies, and raw milk have been reported. Newborns may acquire the organism from their mothers at delivery.

Clinical Findings

A. SYMPTOMS AND SIGNS

C jejuni enteritis can be mild or severe. In tropical countries, asymptomatic stool carriage is common. The incubation period is usually 1–7 days. The disease usually begins with sudden onset of high fever, malaise, headache, abdominal cramps, nausea, and vomiting. Diarrhea follows and may be watery or bile-stained, mucoid, and bloody. The illness is self-limiting, lasting 2–7 days, but relapses occur in 15–25% of cases. Without antimicrobial treatment, the organism remains in the stool for 1–6 weeks.

B. LABORATORY FINDINGS

The peripheral WBC count generally is elevated, with many band forms. Microscopic examination of stool reveals erythrocytes and pus cells, and darkfield or phase contrast microscopic examination of wet mounts may reveal darting bacilli characteristic of *Campylobacter*. Other bacteria, particularly *Vibrio* species, may exhibit similar motility, but in areas where cholera and *Vibrio parahaemolyticus* diarrhea are rare, a positive darkfield examination has a predictive value of about 90%. Isolation of *C jejuni* from stool is not difficult but requires selective agar, incubation at 42°C rather than 35°C, and incubation in an atmosphere of about 5% oxygen and 5% CO₂ (candle jar is satisfactory).

Differential Diagnosis

Campylobacter enteritis may resemble viral gastroenteritis, salmonellosis, shigellosis, amebiasis, or other infectious diarrheas. Because it also mimics ulcerative colitis, Crohn disease, intussusception, and appendicitis, mistaken diagnosis can lead to unnecessary surgery.

Complications

The most common complication is dehydration. Other uncommon complications include erythema nodosum, convulsions, reactive arthritis, bacteremia, urinary tract infection, and cholecystitis. Guillain-Barré syndrome may follow *C jejuni* infection by 1–3 weeks.

Prevention

No vaccine is available. Hand washing and adherence to basic food sanitation practices help prevent disease. Hand washing and cleaning of kitchen utensils after contact with raw poultry are important.

Treatment

Treatment of fluid and electrolyte disturbances is important. Antimicrobial treatment with erythromycin in children (30–50 mg/kg/d orally in four divided doses for 5 days) or with ciprofloxacin in adults terminates fecal excretion and may prevent relapses. Fluoroquinolone-resistant *C jejuni* are now common worldwide. Therapy given early in the course of the illness will shorten the duration of symptoms but is unnecessary if given later. Antimicrobials used for shigellosis, such as TMP–SMX and ampicillin, are inactive against *Campylobacter*. Supportive therapy is sufficient in most cases.

Prognosis

The outlook is excellent if dehydration is corrected and misdiagnosis does not lead to inappropriate diagnostic or surgical procedures.

Sails AD et al: Utility of multilocus sequence typing as an epidemiological tool for investigation of outbreaks of gastroenteritis caused by *Campylobacter jejuni*. *J Clin Microbiol* 2003; 41(10):4733 [PMID: 14532212].

www.cdc.gov/ncidod/dbmd/diseaseinfo/campylobacter_g.htm

TULAREMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A cutaneous or mucous membrane lesion at the site of inoculation and regional lymph node enlargement.
- Sudden onset of fever, chills, and prostration.
- History of contact with infected animals, principally wild rabbits, or history of tick exposure.
- Positive culture or immunofluorescence from mucocutaneous ulcer or regional lymph nodes.
- High serum antibody titer.

General Considerations

Tularemia is caused by *Francisella tularensis*, a gram-negative organism usually acquired directly from infected animals, principally wild rabbits. Occasionally infection is acquired from infected domestic dogs or cats; by contamination of the skin or mucous membranes with infected blood or tissues; by inhalation of infected material; by bites of ticks, fleas, or deer flies that have been in contact with infected animals; or by ingestion of contaminated meat or water. The incubation period is short, usually 3–7 days, but may vary from 2 to 25 days.

Ticks are the most important vector. Rabbits are the classic vectors of tularemia. It is important to seek a history of rabbit hunting, skinning, or food preparation in any patient who has a febrile illness with tender lymphadenopathy, often in the region of a draining skin ulcer.

Clinical Findings

A. SYMPTOMS AND SIGNS

Several clinical types of tularemia occur in children. Sixty percent of infections are of the ulceroglandular form and start as a reddened papule that may be pruritic, quickly ulcerates, and is not very painful. Shortly thereafter, the regional lymph nodes become large and tender. Fluctuance quickly follows. At the same time, there may be marked systemic symptoms, including high fever, chills, weakness, and vomiting. Pneumonitis occasionally accompanies the ulceroglandular form or may be seen as the sole manifestation of infection (pneumonic form). A detectable skin lesion is occasionally absent, and localized lymphoid enlargement exists alone (glandular form). Oculoglandular and oropharyngeal forms also occur in children. The latter is characterized by tonsillitis, often with membrane formation, cervical adenopathy, and high fever. In the absence of any primary ulcer or localized lymphadenitis, a prolonged febrile disease reminiscent of typhoid fever can occur (typhoidal form). Splenomegaly is common in all forms.

B. LABORATORY FINDINGS

F. tularensis can be recovered from ulcers, regional lymph nodes, and sputum of patients with the pneumonic form. However, the organism grows only on an enriched medium (blood-cystine-glucose agar), and laboratory handling is dangerous owing to the risk of airborne transmission to laboratory personnel. Immunofluorescent staining of biopsy material or aspirates of involved lymph nodes is diagnostic, although it is not widely available.

The WBC count is not remarkable. Agglutinins are present after the second week of illness, and in the absence of a positive culture their development confirms the diagnosis. An agglutination titer of 1:160 or higher is considered positive.

Differential Diagnosis

The typhoidal form of tularemia may mimic typhoid, brucellosis, miliary tuberculosis, Rocky Mountain spotted fever, and infectious mononucleosis. Pneumonic tularemia resembles atypical or mycotic pneumonitis. The ulceroglandular type of tularemia resembles pyoderma caused by staphylococci or streptococci, rat-bite fever, plague, anthrax, and cat-scratch fever. The oropharyngeal type must be distinguished from streptococcal or diphtheritic pharyngitis, infectious mononucleosis, herpangina, or other viral pharyngitides.

Prevention

Children should be protected from insect bites, especially those of ticks, fleas, and deer flies, by the use of

proper clothing and repellents. Because rabbits are the source of most human infections, the dressing and handling of such game should be performed with great care. If contact occurs, thorough washing with soap and water is indicated.

Treatment

A. SPECIFIC MEASURES

Historically, streptomycin was the drug of choice (30 mg/kg/d, given intramuscularly in two divided doses, to a maximum dose of 1 g). Gentamicin and amikacin are also efficacious, more available, and familiar to clinicians. Doxycycline is effective, but relapse rates are higher. Chloramphenicol therapy is also associated with a higher relapse rate. Failures occur with ceftriaxone.

B. GENERAL MEASURES

Antipyretics and analgesics may be given as necessary. Skin lesions are best left open. Glandular lesions occasionally require incision and drainage.

Prognosis

The prognosis is excellent in cases of tularemia that are recognized early and treated appropriately.

PLAGUE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of fever, chills, and prostration.
- Regional lymphadenitis with suppuration of nodes (bubonic form).
- Hemorrhage into skin and mucous membranes and shock (septicemia).
- Cough, dyspnea, cyanosis, and hemoptysis (pneumonia).
- History of exposure to infected animals.

General Considerations

Plague is an extremely serious acute infection caused by a gram-negative bacillus, *Yersinia pestis*. It is a disease of

rodents that is transmitted to humans by flea bites. Plague bacilli have been isolated from rodents in 15 of the western states in the United States. Direct contact with rodents, rabbits, or domestic cats may transmit fleas infected with plague bacilli. Most cases occur from June through September. Human plague in the United States appears to occur in cycles that reflect cycles in wild animal reservoirs.

Clinical Findings

A. SYMPTOMS AND SIGNS

Plague assumes several clinical forms, the two most common being bubonic and septicemic. Pneumonic plague, the form that occurs when organisms enter the body through the respiratory tract, is uncommon.

1. Bubonic plague—Bubonic plague begins after an incubation period of 6 days with a sudden onset of high fever, chills, headache, vomiting, and marked delirium or clouding of consciousness. A less severe form also exists, with a less precipitous onset, but with progression over several days to severe symptoms. Although the flea bite is rarely seen, the regional lymph node, usually inguinal and unilateral, is painful and tender, 1–5 cm in diameter. The node usually suppurates and drains spontaneously after 1 week. The plague bacillus produces endotoxin that causes vascular necrosis. Bacilli may also overwhelm regional lymph nodes and enter the circulation to produce septicemia. Severe vascular necrosis results in widely disseminated hemorrhage in skin, mucous membranes, liver, and spleen. Myocarditis and circulatory collapse may result from damage by the endotoxin. Plague meningitis or pneumonia may occur following bacteremic spread from an infected lymph node.

2. Septicemic plague—Plague may initially present as septicemia without evidence of lymphadenopathy. In some series, 25% of cases are initially septicemic. Septicemic plague carries a worse prognosis than bubonic plague, largely because it is not recognized and treated early. Patients may present initially with a nonspecific febrile illness characterized by fever, myalgia, chills, and anorexia. Plague is frequently complicated by secondary seeding of the lung causing plague pneumonia.

3. Primary pneumonic plague—Inhalation of *Y. pestis* bacilli causes primary plague pneumonia. This form of plague has been transmitted to humans from cats with pneumonic plague and would be the form of plague most likely seen after aerosolized release of *Y. pestis* in a bioterrorist incident. After an incubation of 1–6 days, the patient develops fever, cough, shortness of breath, and the production of bloody, watery, or purulent sputum. Gastrointestinal symptoms are sometimes prominent. Because the initial focus of infection

is the lung, buboes are usually absent; occasionally cervical buboes may be seen.

B. LABORATORY FINDINGS

Aspirate from a bubo contains bipolar staining gram-negative bacilli. Pus, sputum, and blood all yield the organism. Laboratory infections are common enough to make isolation dangerous. A buffy coat Gram stain may reveal the organism, and blood-agar cultures yield positive results in 48 hours. The WBC count is markedly elevated, with a shift to the left. Paired acute and convalescent sera may be tested for an antibody rise in those cases with negative cultures.

Differential Diagnosis

The septic phase of the disease may be confused with illnesses such as meningococcemia, sepsis, and rickettsioses. The bubonic form resembles tularemia, anthrax, cat-scratch fever, streptococcal adenitis, and cellulitis. Primary gastroenteritis and appendicitis may have to be distinguished.

Prevention

Proper disposal of household and commercial wastes and chemical control of rats are basic elements of plague prevention. Flea control is instituted and maintained with liberal use of insecticides. Children vacationing in remote camping areas should be warned not to handle dead or dying animals. Domestic cats that roam freely in suburban areas may contact infected wild animals and acquire infected fleas. There is no commercially available vaccine for plague.

Treatment

A. SPECIFIC MEASURES

Streptomycin (20–40 mg/kg/d intramuscularly) or gentamicin (7.5 mg/kg/d) in three divided doses for 7–10 days after defervescence is effective. For patients not requiring parenteral therapy, doxycycline may be given. Doxycycline is not usually recommended for children younger than 8 years of age unless benefits of use outweigh the risk of dental staining. Plague bacilli that are multiply resistant to antimicrobials are uncommon but of serious concern.

Mortality is extremely high in septicemic and pneumonic plague if specific antibiotic treatment is not started in the first 24 hours of the disease.

Every effort should be made to effect resolution of buboes without surgery. Pus from draining lymph nodes should be handled with gloves.

B. GENERAL MEASURES

Pneumonic plague is highly infectious, and droplet isolation is required until the patient has been on effective antimicrobial therapy for 48 hours. All contacts should receive prophylaxis with oral doxycycline 2.2 mg/kg/dose (maximum dose 100 mg) given bid for 7 days. State health officials should be notified immediately about suspected plague cases.

Prognosis

The mortality rate in untreated bubonic plague is about 50%. The mortality rate for treated pneumonic plague is 50–60%. Recent mortality rates in New Mexico were 3% for bubonic plague and 71% for the septicemic form.

HAEMOPHILUS INFLUENZAE TYPE B INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Purulent meningitis in children younger than age 4 years with direct smears of CSF showing gram-negative pleomorphic rods.*
- *Acute epiglottitis: High fever, drooling, dysphagia, aphonia, and stridor.*
- *Septic arthritis: Fever, local redness, swelling, heat, and pain with active or passive motion of the involved joint in a child age 4 months to 4 years.*
- *Cellulitis: Sudden onset of fever and distinctive cellulitis in an infant, often involving the cheek or periorbital area.*
- *In all cases, a positive culture from the blood, CSF, or aspirated pus confirms the diagnosis.*

General Considerations

H influenzae type b (Hib) has become uncommon because of widespread immunization in early infancy.

The 99% reduction in incidence seen in many parts of the United States is due to high rates of vaccine coverage and reduced nasopharyngeal carriage after vaccination. Forty percent of cases occur in children younger than 6 months who are too young to have completed a primary immunization series. Hib may cause meningitis, bacteremia, epiglottitis (supraglottic croup), septic arthritis, periorbital and facial cellulitis, pneumonia, and pericarditis.

Disease due to *H influenzae* types A, C, D, E, F, or unencapsulated strains is rare, but it now accounts for a larger proportion of positive culture results. Third-generation cephalosporins are preferred for initial therapy of Hib infections. Ampicillin is adequate for culture-proved Hib susceptible strains.

Unencapsulated, nontypable *H influenzae* frequently colonizes the mucous membranes and causes otitis media, sinusitis, bronchitis, and pneumonia in children and adults. Bacteremia is uncommon. Neonatal sepsis similar to early-onset GBS is recognized. Obstetric complications of chorioamnionitis and bacteremia are usually the source of neonatal cases.

Ampicillin resistance occurs in 25–40% of nontypable *H influenzae*.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Meningitis—Infants usually present with fever, irritability, lethargy, poor feeding with or without vomiting, and a high-pitched cry.

2. Acute epiglottitis—The most useful clinical finding in the early diagnosis of Hib epiglottitis is evidence of dysphagia, characterized by a refusal to eat or swallow saliva and by drooling. This finding, plus the presence of a high fever in a “toxic” child—even in the absence of a cherry-red epiglottis on direct examination—should strongly suggest the diagnosis and lead to prompt intubation. Stridor is a late sign. (See Chapter 17 for details.)

3. Septic arthritis—Hib is a common cause of septic arthritis in unimmunized children younger than age 4 years in the United States. The child is febrile and refuses to move the involved joint and limb because of pain. Examination reveals swelling, warmth, redness, tenderness on palpation, and severe pain on attempted movement of the joint.

4. Cellulitis—Cellulitis due to Hib occurs almost exclusively in the age group from 3 months to 4 years but is now uncommon as a result of immunization. Fever is usually noted at the same time as the cellulitis, and many infants appear toxic. The cheek or periorbital (preseptal) area is usually involved.

B. LABORATORY FINDINGS

The WBC count in Hib infections may be high or normal with a shift to the left. Blood culture is frequently positive. Positive culture of aspirated pus or fluid from the involved site proves the diagnosis. In untreated meningitis, CSF smear may show the characteristic pleomorphic gram-negative rods.

C. IMAGING

A lateral view of the neck may suggest the diagnosis in suspected acute epiglottitis, but misinterpretation is common. Intubation should not be delayed to obtain radiographs. Haziness of maxillary and ethmoid sinuses occurs with orbital cellulitis.

Differential Diagnosis**A. MENINGITIS**

Meningitis must be differentiated from head injury, brain abscess, tumor, lead encephalopathy, and other forms of meningoencephalitis, including mycobacterial, viral, fungal, and bacterial agents.

B. ACUTE EPIGLOTTITIS

In croup caused by viral agents (parainfluenza 1, 2, and 3, respiratory syncytial virus, influenza A, adenovirus), the child has more definite upper respiratory symptoms, cough, hoarseness, slower progression of obstructive signs, and lower fever. Spasmodic croup occurs typically at night in a child with a history of previous attacks. A history of sudden onset of choking and paroxysmal coughing suggests aspiration of a foreign body. Retropharyngeal abscess may have to be differentiated from epiglottitis.

C. SEPTIC ARTHRITIS

Differential diagnosis includes acute osteomyelitis, prepatellar bursitis, cellulitis, rheumatic fever, and fractures and sprains.

D. CELLULITIS

Erysipelas, streptococcal cellulitis, insect bites, and trauma (including Popsicle panniculitis or other types of freezing injury) may mimic Hib cellulitis. Periorbital cellulitis must be differentiated from paranasal sinus disease without cellulitis, allergic inflammatory disease of the lids, conjunctivitis, and herpes zoster infection.

Complications**A. MENINGITIS (SEE CHAPTER 23.)****B. ACUTE EPIGLOTTITIS**

The disease may rapidly progress to complete airway obstruction with complications owing to hypoxia. Mediastinal emphysema and pneumothorax may occur.

C. SEPTIC ARTHRITIS

Septic arthritis may result in rapid destruction of cartilage and ankylosis if diagnosis and treatment are delayed. Even with early treatment, the incidence of residual damage and disability after septic arthritis in weight-bearing joints may be as high as 25%.

D. CELLULITIS

Bacteremia may lead to meningitis or pyarthrosis.

Prevention

The risk of invasive Hib disease is highest in unimmunized, or partially immunized, household contacts who are younger than 4 years of age. The following situations require rifampin chemoprophylaxis of all household contacts to eradicate potential nasopharyngeal colonization with Hib and limit risk of invasive disease: (1) families where at least one household contact is younger than 4 years of age and either unimmunized or incompletely immunized against Hib, (2) an immunocompromised child (of any age or immunization status) resides in the household, or (3) a child younger than 12 months of age resides in the home and has not received three doses of the Hib vaccine. Preschool and day care center contacts may need prophylaxis if more than one case has occurred in the center in the previous 60 days (discuss with state health officials). The index case also needs chemoprophylaxis unless treated with ceftriaxone or cefotaxime (both are effective in eradication of Hib from the nasopharynx). Household contacts and index cases who are younger than 1 month of age needing chemoprophylaxis should be given rifampin, 20 mg/kg/dose (maximum adult dose 600 mg), orally, once daily for 4 successive days. Persons younger than 1 month of age should be given oral rifampin 10 mg/kg/dose once daily for 4 days. Rifampin should not be used in pregnant females.

Treatment

All patients with bacteremic or potentially bacteremic Hib diseases require hospitalization for treatment. The drugs of choice in hospitalized patients are a third-generation cephalosporin (cefotaxime or ceftriaxone) until the sensitivity of the organism is known.

A. MENINGITIS

Therapy is begun as soon as bacterial meningitis has been identified and CSF, blood, and other appropriate cultures have been obtained. Therapy is begun with cefotaxime (50 mg/kg intravenously q6h) or ceftriaxone (50 mg/kg intravenously q12h). If the organism is sensitive to ampicillin, it is the drug of choice. Therapy should preferably be given intravenously for the entire

course. Ceftriaxone may be given intramuscularly if venous access becomes difficult.

Duration of therapy is 10 days. Longer treatment is reserved for children who respond slowly or in whom septic complications have occurred.

Repeated lumbar punctures are usually not necessary in Hib meningitis. They should be obtained in the following circumstances: unsatisfactory or questionable clinical response, seizure occurring after several days of therapy, and prolonged (7 days) or recurrent fever if the neurologic examination is abnormal or difficult to evaluate. Dexamethasone given immediately after diagnosis and continued for 2–4 days may reduce the incidence of hearing loss in children with Hib meningitis. The use of dexamethasone is controversial, but when it is used the dosage is 0.6 mg/kg/d in four divided doses for 4 days.

B. ACUTE EPIGLOTTITIS (SEE CHAPTER 17.)

C. SEPTIC ARTHRITIS

Initial therapy should include nafcillin (or another effective antistaphylococcal antibiotic), 150 mg/kg/d in four divided doses, and cefotaxime or ceftriaxone (dosage as for meningitis). If the isolate is sensitive to ampicillin, it is given in a dosage of 200–300 mg/kg/d intravenously in four divided doses. If a child is improved following initial intravenous therapy, oral amoxicillin (75–100 mg/kg/d in four divided doses q6h) may be administered under careful supervision to complete a 2-week course. Alternative oral agents for ampicillin-resistant organisms include amoxicillin-clavulanic acid or second- or third-generation cephalosporins. Ideally, susceptibility to these agents should be proved prior to use. Drainage of infected joint fluid is an essential part of treatment. In joints other than the hip, this can often be accomplished by one or more needle aspirations. In hip infections—and in arthritis of other joints where treatment is delayed or clinical response is slow—surgical drainage is advised. The joint should be immobilized.

D. CELLULITIS, INCLUDING ORBITAL CELLULITIS

Initial therapy should include an agent effective against staphylococci in combination with cefotaxime or ceftriaxone. Ampicillin may be used if the isolate is shown to be susceptible. Therapy is given parenterally for 3–7 days, followed by oral treatment as for septic arthritis, and supportive and symptomatic treatment as required. There is usually marked improvement after 72 hours of treatment. Antibiotics should be given for 10–14 days.

Prognosis

The case fatality rate for Hib meningitis is less than 5%. Young infants have the highest mortality rate. One of the most common neurologic sequelae, developing in 5–10% of patients with Hib meningitis, is sensorineural hearing loss. All patients with Hib meningitis should have their hearing checked during the course of the illness or shortly after recovery. Children in whom invasive Hib infection develops despite appropriate immunization should have tests to investigate immune function and to rule out HIV. The case fatality rate in acute epiglottitis is 2–5%. Deaths are associated with bacteremia and the rapid development of airway obstruction. The prognosis for the other diseases requiring hospitalization is good with the institution of early and adequate antibiotic therapy.

Vaccines

There are currently four separate carbohydrate protein conjugate Hib vaccines available (see Chapter 9).

PERTUSSIS (WHOOPIING COUGH)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Prodromal catarrhal stage (1–3 weeks) characterized by mild cough, coryza, without fever.*
- *Persistent staccato, paroxysmal cough ending with a high-pitched inspiratory “whoop.”*
- *Leukocytosis with absolute lymphocytosis.*
- *Diagnosis confirmed by PCR or culture of nasopharyngeal secretions.*

General Considerations

Pertussis is an acute, highly communicable infection of the respiratory tract caused by *Bordetella pertussis* and characterized by severe bronchitis. Children usually acquire the disease from symptomatic family contacts.

Adults who have mild respiratory illness, not recognized as pertussis, frequently are the source of infection. Asymptomatic carriage of *B pertussis* is not recognized. Infectivity is greatest during the catarrhal and early paroxysmal cough stage (for about 4 weeks after onset).

Pertussis cases have increased in the United States since 1980. In 2003, about 8000 cases were reported with 30% in older children and adolescents age 10–19 years. The morbidity and mortality of pertussis is greatest in young children. Fifty percent of children younger than age 1 year with a diagnosis of pertussis are hospitalized. Of 17 deaths reported in 1996 and 1997, 11 were in children younger than age 6 months.

Active immunity follows natural pertussis. Reinfections occur years to decades later but are usually milder. Immunity following vaccination wanes in 5–10 years. The majority of young adults in the United States are susceptible to pertussis infection, and disease is probably common but unrecognized.

Bordetella parapertussis causes a similar but milder syndrome and is reported frequently in Central Europe.

B pertussis organisms attach to the ciliated respiratory epithelium and multiply there; deeper invasion does not occur. Disease is due to several bacterial toxins, the most potent of which is pertussis toxin, which is responsible for lymphocytosis and many of the symptoms of pertussis.

Clinical Findings

A. SYMPTOMS AND SIGNS

The onset of pertussis is insidious, with catarrhal upper respiratory tract symptoms (rhinitis, sneezing, and an irritating cough). Slight fever may be present; temperature greater than 38.3°C suggests bacterial superinfection or another cause of respiratory tract infection. After about 2 weeks, cough becomes paroxysmal, characterized by 10–30 forceful coughs ending with a loud inspiration (the whoop). Infants and adults with otherwise typical severe pertussis often lack characteristic whooping. Vomiting commonly follows a paroxysm. Coughing is accompanied by cyanosis, sweating, prostration, and exhaustion. This stage lasts for 2–4 weeks, with gradual improvement. Cough suggestive of chronic bronchitis lasts for another 2–3 weeks. Paroxysmal coughing may continue for some months and may worsen with intercurrent viral respiratory infection. In adults, older children, and partially immunized individuals, symptoms may consist only of irritating cough lasting 1–2 weeks. In the younger unimmunized child, symptoms of pertussis last about 8 weeks or longer. Clinical pertussis is milder in immunized children.

B. LABORATORY FINDINGS

WBC counts of 20,000–30,000/μL with 70–80% lymphocytes typically appear near the end of the catarrhal

stage. Many older children and adults with mild infections never demonstrate lymphocytosis. The blood picture may resemble lymphocytic leukemia or leukemoid reactions. Identification of *B pertussis* by culture or polymerase chain reaction (PCR) from nasopharyngeal swabs or nasal wash specimens proves the diagnosis. The organism may be found in the respiratory tract in diminishing numbers beginning in the catarrhal stage and ending about 2 weeks after the beginning of the paroxysmal stage. After 4–5 weeks of symptoms, cultures and fluorescent antibody tests are almost always negative. Charcoal agar containing an antimicrobial should be inoculated as soon as possible; *B pertussis* does not tolerate drying or prolonged transport. PCR detection is replacing culture in most pediatric centers because of improved sensitivity, decreased time to diagnosis, and cost. Enzyme-linked immunosorbent assays (ELISA) for detection of antibody to pertussis toxin or filamentous hemagglutinin may be useful for diagnosis but are currently not widely available, and interpretation of antibody titers may be difficult in previously immunized patients. The chest radiograph reveals thickened bronchi and sometimes shows a “shaggy” heart border.

Differential Diagnosis

The differential diagnosis of pertussis includes bacterial, tuberculous, chlamydial, and viral pneumonia. Cystic fibrosis and foreign body aspiration may be considerations. Adenoviruses and respiratory syncytial virus may cause paroxysmal coughing with an associated elevation of lymphocytes in the peripheral blood, mimicking pertussis.

Complications

Bronchopneumonia due to superinfection is the most common serious complication. It is characterized by abrupt clinical deterioration during the paroxysmal stage, accompanied by high fever and sometimes a striking leukemoid reaction with a shift to predominantly polymorphonuclear neutrophils. Atelectasis is a second common pulmonary complication. Atelectasis may be patchy or extensive and may shift rapidly to involve different areas of lung. Intercurrent viral respiratory infection is also a common complication and may provoke worsening or recurrence of paroxysmal coughing. Otitis media is common. Residual chronic bronchiectasis is infrequent despite the severity of the illness. Apnea and sudden death may occur during a particularly severe paroxysm. Seizures complicate 1.5% of cases, and encephalopathy occurs in 0.1%. The encephalopathy frequently is fatal. Anoxic brain damage, cerebral hemorrhage, or pertussis neurotoxins are hy-

pothesized, but anoxia is most likely the cause. Epistaxis and subconjunctival hemorrhages are common.

Prevention

Active immunization (see Chapter 9) with DTP vaccine should be given in early infancy. Acellular pertussis (DTaP) vaccines cause less fever and fewer local and febrile systemic reactions and have replaced the former whole cell vaccines. The recent increase in incidence of pertussis is primarily due to increased recognition of disease in adolescents and adults.

Chemoprophylaxis with erythromycin should be given to exposed family and hospital contacts, particularly those younger than age 2 years. Hospitalized children with pertussis should be isolated because of the great risk of transmission to patients and staff. Several large hospital outbreaks have been reported.

Treatment

A. SPECIFIC MEASURES

Antibiotics may ameliorate early infections but have no effect on clinical symptoms in the paroxysmal stage. Erythromycin is the drug of choice because it promptly terminates respiratory tract carriage of *B pertussis*. Resistance to macrolides has been rarely reported. Patients should be given erythromycin estolate (40–50 mg/kg/24 h in four divided doses for 14 days). Erythromycin ethylsuccinate is efficacious, but the higher dose recommended causes considerable gastrointestinal intolerance. A recent study suggests that 7 days and 14 days of treatment are equally effective. Treatment with clarithromycin for 7 days and azithromycin for 5 days was equal to erythromycin for 14 days, with fewer gastrointestinal side effects. Ampicillin (100 mg/kg/d in four divided doses) may also be used for erythromycin-intolerant patients. Household or other close contacts (eg, in day care centers) should be given erythromycin to reduce secondary transmission. This prophylaxis should be used regardless of age or immunization status.

Corticosteroids reduce the severity of disease but may mask signs of bacterial superinfection. Albuterol (0.3–0.5 mg/kg/d in four doses) has reduced the severity of illness, but tachycardia is common when the drug is given orally, and aerosol administration may precipitate paroxysms.

B. GENERAL MEASURES

Nutritional support during the paroxysmal phase is important. Frequent small feedings, tube feeding, or parenteral fluid supplementation may be needed. Minimizing stimuli that trigger paroxysms is probably the

best way of controlling cough. In general, cough suppressants are of little benefit.

C. TREATMENT OF COMPLICATIONS

Respiratory insufficiency due to pneumonia or other pulmonary complications should be treated with oxygen and assisted ventilation if necessary. Convulsions are treated with oxygen and anticonvulsants. Bacterial pneumonia or otitis media requires additional antibiotics.

Prognosis

The prognosis for patients with pertussis has improved in recent years because of excellent nursing care, treatment of complications, attention to nutrition, and modern intensive care. However, the disease is still very serious in infants younger than age 1 year; most deaths occur in this age group. Children with encephalopathy have a poor prognosis.

LISTERIOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Early-onset neonatal disease:

- Signs of sepsis a few hours after birth in an infant born with fetal distress and hepatosplenomegaly; maternal fever.

Late-onset neonatal disease:

- Meningitis, sometimes with monocytosis in the CSF and peripheral blood. Onset at age 9–30 days.

General Considerations

Listeria monocytogenes is a gram-positive, non-spore-forming aerobic rod distributed widely in the animal

kingdom and in food, dust, and soil. It causes systemic infections in newborn infants and immunosuppressed older children. In pregnant women, infection is relatively mild, with fever, aches, and chills, but is accompanied by bacteremia and sometimes results in intrauterine or perinatal infection with grave consequences for the fetus or newborn. One fourth of cases occur in pregnant women, and 20% of their pregnancies end in stillbirth or neonatal death. *Listeria* is present in the stool of approximately 10% of the healthy population. Persons in contact with animals are at greater risk. Outbreaks of listeriosis have been traced to contaminated cabbage in coleslaw, soft cheese, hot dogs, luncheon meats, and milk. *Listeria* infections have decreased since the adoption of strict regulations for ready-to-eat foods.

Like GBS infections, listeria infections in the newborn can be divided into early and late forms. Early infections are more common, leading to a severe congenital form of infection. Later infections are often characterized by meningitis.

Clinical Findings

A. SYMPTOMS AND SIGNS

In the early neonatal form, symptoms of listeriosis usually appear on the first day of life and always by the third day. Fetal distress is common, and infants frequently have signs of severe disease at birth. Respiratory distress, diarrhea, and fever occur. On examination, hepatosplenomegaly and a papular rash are found. A history of maternal fever is common. Meningitis may accompany the septic course. The late neonatal form usually occurs after age 9 days and can occur as late as 5 weeks. Meningitis is common, characterized by irritability, fever, and poor feeding.

Listeria infections are rare in older children and are usually associated with immunodeficiency. Several recent cases are associated with tumor necrosis factor- α neutralizing agents. Signs and symptoms are those of meningitis, usually with insidious onset.

B. LABORATORY FINDINGS

In all patients except those receiving white cell depressant drugs, the WBC count is elevated, with 10–20% monocytes. When meningitis is found, the characteristic CSF cell count is high ($> 500/\mu\text{L}$) with a predominance of polymorphonuclear neutrophils in 70% of cases. Monocytes may predominate in up to 30% of cases. Gram-stained smears of CSF are usually negative, but short gram-positive rods may be seen. The chief pathologic feature in severe neonatal sepsis is miliary granulomatosis with microabscesses in liver, spleen, CNS, lung, and bowel.

Cultures are frequently positive from multiple sites, including blood from the infant and the mother. The organisms form small, weakly hemolytic colonies on blood agar and may be mistaken for streptococci.

Differential Diagnosis

Early-onset neonatal disease resembles hemolytic disease of the newborn, GBS sepsis or severe cytomegalovirus infection, rubella, or toxoplasmosis. Late-onset disease must be differentiated from meningitis due to echovirus and coxsackievirus, GBS, and gram-negative enteric bacteria.

Prevention

Immunosuppressed, pregnant, and elderly patients can decrease the risk of *Listeria* infection by avoiding soft cheeses, by thoroughly reheating or avoiding delicatessen and ready-to-eat foods, by avoiding raw meat and milk, and by thoroughly washing fresh vegetables.

Treatment

Ampicillin (150–300 mg/kg/d q6h intravenously) is the drug of choice in most cases of listeriosis. Gentamicin (2.5 mg/kg q8h intravenously) has a synergistic effect with ampicillin and should be given in serious infections and to patients with immune deficits. If ampicillin cannot be used, TMP–SMX is also effective. Cephalosporins are not effective. Treatment of severe disease should continue for at least 2 weeks.

Prognosis

In a recent outbreak of early-onset neonatal disease, the mortality rate was 27% despite aggressive and appropriate management. Meningitis in older infants has a good prognosis. In immunosuppressed children, prognosis depends to a great extent on that of the underlying illness.

TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *All types: Positive tuberculin test in patient or members of household, suggestive chest radiograph, history of contact, and demonstration of organism by stain and culture.*
- *Pulmonary: Fatigue, irritability, and undernutrition, with or without fever and cough.*
- *Glandular: Chronic cervical adenitis.*
- *Miliary: Classic snowstorm appearance of chest radiograph; choroidal tubercles.*
- *Meningitis: Fever and manifestations of meningeal irritation and increased intracranial pressure. Characteristic CSF.*

General Considerations

Tuberculosis is a granulomatous disease caused by *Mycobacterium tuberculosis*. It is a leading cause of death throughout the world. Children younger than age 3 years are most susceptible. Lymphohematogenous dissemination through the lungs to extrapulmonary sites, including the brain and meninges, eyes, bones and joints, lymph nodes, kidneys, intestines, larynx, and skin, is more likely to occur in infants. Increased susceptibility occurs again in adolescence, particularly in girls within 2 years of menarche. Following substantial increases in disease during the 1980s, tuberculosis incidence has decreased since 1992 due to increased control measures. Eleven thousand three hundred new cases were reported in 2003. High-risk groups include ethnic minorities, foreign-born persons, prisoners, residents of nursing homes, indigents, migrant workers, and health care providers. However, 50% of cases in 2001 occurred in United States-born persons. HIV infection is an important risk factor for both development and spread of disease. Pediatric tuberculosis incidence mirrors the trends seen in adults.

Exposure to an infected adult is the most common risk factor in children. The primary complex in infancy and childhood consists of a small parenchymal lesion in any area of the lung with caseation of regional nodes and calcification. Postprimary tuberculosis in adolescents and adults occurs in the apices of the lungs and is likely to cause chronic progressive cavitary pulmonary disease with less tendency for hematogenous dissemination. *Mycobacterium bovis* infection is clinically identi-

cal to *M. tuberculosis*. *M. bovis* may be acquired from unpasteurized dairy products obtained outside the United States.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. **Pulmonary**—See Chapter 18.
2. **Miliary**—Diagnosis is usually based on the classic “snowstorm” or “millet seed” appearance of lung fields on radiograph, although early in the course of disseminated tuberculosis, the chest radiograph may show no or only subtle abnormalities. The majority of patients have a fresh primary complex and pleural effusion. Choroidal tubercles are sometimes seen on fundoscopic examination. Other lesions may be present and produce osteomyelitis, arthritis, meningitis, tuberculomas of the brain, enteritis, or infection of the kidneys and liver.
3. **Meningitis**—Symptoms include fever, vomiting, headache, lethargy, and irritability, with signs of meningeal irritation and increased intracranial pressure, cranial nerve palsies, convulsions, and coma.
4. **Lymphatic**—The primary complex may be associated with a skin lesion drained by regional nodes or chronic cervical node enlargement or infection of the tonsils. Involved nodes may become fixed to the overlying skin, suppurate, and drain.

B. LABORATORY FINDINGS

The Mantoux test (0.1 mL of intermediate-strength purified protein derivative [PPD] [5 TU] inoculated intradermally) is positive at 48–72 hours if there is significant induration (Table 38–2). Parental reporting of skin test results is often inaccurate. All tests should be read by professionals trained to interpret Mantoux tests. False-negative results occur in malnourished patients, in those with overwhelming disease, and in 10% of children with isolated pulmonary disease. Temporary suppression of tuberculin reactivity may be seen with viral infections (eg, measles, influenza, varicella, mumps), after live virus immunization, and during corticosteroid or other immunosuppressive drug therapy. For these reasons, a negative Mantoux test does not exclude the diagnosis of tuberculosis. When tuberculosis is suspected in a child, household members and adult contacts (eg, teachers, caregivers) should also be tested immediately. Multiple puncture tests (tine tests) should not be used because they are associated with false-negative and false-positive reactions, and because standards for interpretation of positive results do not exist. The ESR is usually elevated. Cultures of pooled early morning gastric aspirates from three successive days will yield *M. tuberculosis* in about 40% of cases. Biopsy may be necessary to establish the diagnosis. Therapy should not

Table 38–2. Interpretation of tuberculin skin test reactions.^a

Degree of Risk	Risk Factors	Positive Reaction
High	Recent close contact with a case of active tuberculosis; chest x-ray compatible with tuberculosis; immunocompromise; HIV infection	≥ 5 mm induration
Medium	Current or previous residence in high-prevalence area (Asia, Africa, Latin America); skin test converters within past 2 years; intravenous drug use; homelessness or residence in a correctional institution; recent weight loss or malnutrition; leukemia, Hodgkin disease, diabetes mellitus; age < 4 years	≥ 10 mm induration
Low	Children ≥ 4 years without any risk factor	≥ 15 mm induration

^aStandard intradermal Mantoux test, 5 test units.

be delayed in suspected cases. The CSF in tuberculous meningitis shows slight to moderate pleocytosis (50–300 WBCs/μL, predominantly lymphocytes), decreased glucose, and increased protein.

The direct detection of mycobacteria in body fluids or discharges is best done by staining specimens with auramine-rhodamine and examining them with fluorescence microscopy; this method is superior to the Ziehl–Neelsen method.

C. IMAGING

Chest radiograph should be obtained in all children with suspicion of tuberculosis at any site or with a positive skin test. Segmental consolidation with some volume loss and hilar adenopathy are common findings in children. Pleural effusion also occurs with primary infection. Cavities and apical disease are unusual in children but are common in adolescents and adults.

Differential Diagnosis

Pulmonary tuberculosis must be differentiated from fungal, parasitic, mycoplasmal, and bacterial pneumonias; lung abscess; foreign body aspiration; lipoid pneumonia; sarcoidosis; and mediastinal cancer. Cervical lymphadenitis is most likely due to streptococcal or staphylococcal infections. Cat-scratch fever and infection with atypical mycobacteria may need to be distin-

guished from tuberculous lymphadenitis. Viral meningoencephalitis, head trauma (child abuse), lead poisoning, brain abscess, acute bacterial meningitis, brain tumor, and disseminated fungal infections must be excluded in tuberculous meningitis. The skin test in the patient or family contacts is frequently valuable in differentiating these conditions from tuberculosis.

Prevention

A. BCG VACCINE

Bacille Calmette–Guérin (BCG) vaccines are live attenuated strains of *M. bovis*. Although neonatal and childhood administration of BCG is carried out in countries with a high prevalence of tuberculosis, protective efficacy varies greatly with vaccine potency and method of delivery. Because the great majority of children who have received BCG still have negative Mantoux tests, the past history of BCG vaccination should be ignored in interpreting the skin test. In the United States, BCG vaccination is given only to tuberculin-negative children and neonates in high-risk situations who are HIV-negative, who are unlikely to receive isoniazid prophylaxis or close follow-up, or who are at high risk for exposure to persons infected with *M. tuberculosis* resistant to isoniazid and rifampin (see Chapter 9).

B. ISONIAZID CHEMOPROPHYLAXIS

Daily administration of isoniazid (10 mg/kg/d orally; maximum 300 mg) is advised for children who cannot avoid intimate household contact with adolescents or adults with active disease. Isoniazid is given until 3 months after last contact. At the end of this time, a Mantoux test should be done, and therapy should be continued for an additional 6 months if the test is positive.

C. OTHER MEASURES

Tuberculosis in infants and young children is evidence of recent exposure to active infection in an adult, usually a family member or household contact. The source contact (index case) should be identified, isolated, and given treatment to prevent other secondary cases. Reporting cases to local health departments is essential for contact tracing. Exposed tuberculin-negative children should usually receive isoniazid chemoprophylaxis. If a repeated skin test is negative 2–3 months following the last exposure, isoniazid may be stopped. Routine tuberculin skin testing is no longer recommended for children without risk factors who reside in communities with a low incidence of tuberculosis. Children with no personal risk for tuberculosis but who reside in communities with a high incidence of tuberculosis should be given a skin test at school entry and then again at age 11–16 years. Children with a risk factor for acquiring tuberculosis should

be tested every 2–3 years. Incarcerated adolescents and children living in a household with HIV-infected persons should have annual skin tests.

Children who immigrate from a country with a high incidence of infection should receive a skin test on entry to the United States or upon presentation to health care providers. A past history of BCG vaccine should not delay skin testing.

Treatment

A. SPECIFIC MEASURES

Most children with tuberculosis in the United States are hospitalized initially. If the infecting organism has not been isolated from the presumed contact for susceptibility testing, reasonable attempts should be made to obtain it from the child using morning gastric aspirates, sputum, bronchoscopy, thoracentesis, or biopsy when appropriate. Unfortunately, cultures are frequently negative in children, and the risk of these procedures must be weighed against the yield. Therapy is given daily for 2–4 weeks and then reduced to 2–3 times per week for the duration of the course. Directly observed administration of all doses of antituberculosis therapy by a trained health care professional is essential to ensure compliance with therapy.

All children with positive skin tests (see Table 38–2) without evidence of active disease have latent tuberculosis and should receive 9 months of isoniazid (10 mg/kg/d orally; maximum 300 mg) therapy. In children with active pulmonary disease, therapy for 6 months using isoniazid (10 mg/kg/d), rifampin (15 mg/kg/d), and pyrazinamide (25–30 mg/kg/d) in a single daily oral dose for 2 months, followed by isoniazid plus rifampin (either in a daily or twice-weekly regimen) for 4 months appears effective for eliminating isoniazid-susceptible organisms. For more severe disease, such as miliary or CNS infection, duration is increased to 12 months or more, and a fourth drug (streptomycin or ethambutol) is added for the first 2 months. In communities with resistance rates greater than 4%, initial therapy should usually include four drugs.

1. Isoniazid—The hepatotoxicity from isoniazid seen in adults and some adolescents is rare in children. Transient elevation of aminotransferases (up to three times normal) may be seen at 6–12 weeks, but therapy is continued unless clinical illness occurs. Routine monitoring of liver function tests is unnecessary unless prior hepatic disease is known or the child is severely ill. Peripheral neuropathy associated with pyridoxine deficiency is rare in children, and it is not necessary to add pyridoxine unless significant malnutrition coexists.

2. Rifampin—Although it is an excellent bactericidal agent, rifampin is never used alone owing to rapid de-

velopment of resistance. Hepatotoxicity may occur but rarely with recommended doses. The orange discoloration of secretions is benign but may stain contact lenses or clothes.

3. Pyrazinamide—This excellent sterilizing agent is most effective during the first 2 months of therapy. With the recommended duration and dosing, it is well tolerated. Although pyrazinamide elevates the uric acid level, it rarely causes symptoms of hyperuricemia in children. Use of this drug is now common for tuberculous disease in children, and resistance is almost unknown. Oral acceptance and CNS penetration are good.

4. Ethambutol—Because optic neuritis is the major side effect in adults, ethambutol has usually been given only to children whose vision can be reliably tested for loss of color differentiation. Optic neuritis is rare and usually occurs in those receiving more than the recommended dosage of 25 mg/kg/d. Documentation of optic toxicity in children is lacking despite considerable worldwide experience. Therefore, many four-drug regimens for children now include ethambutol.

5. Streptomycin—Streptomycin (20–30 mg/kg/d, given intramuscularly in one or two doses) should be given for 1 or 2 months in severe disease. The child's hearing should be tested periodically during use.

B. CHEMOTHERAPY FOR DRUG-RESISTANT TUBERCULOSIS

The incidence of drug resistance is increasing and reaches 10–20% in some areas of the United States. Transmission of multiply drug-resistant strains to contacts has occurred in some epidemics. All patients with resistant strains should be given at least two effective drugs. In areas with rates of resistance greater than 4%, initial therapy should include four drugs pending susceptibility testing. Consultation with local experts in treating tuberculosis is important in these difficult cases. Therapy should continue for 12 months or longer.

C. GENERAL MEASURES

1. Corticosteroids—These drugs may be used for suppressing inflammatory reactions in meningeal, pleural, and pericardial tuberculosis and for the relief of bronchial obstruction due to hilar adenopathy. Prednisone is given orally, 1 mg/kg/d for 6–8 weeks, with gradual withdrawal at the end of that time. The use of corticosteroids may mask progression of disease. Accordingly, the clinician needs to be sure that an effective regimen is being used.

2. Bed rest—Rest in bed is indicated only while the child feels ill. Isolation is necessary only for children with draining lesions or renal disease and for those with

chronic pulmonary tuberculosis. Most children with tuberculosis are noninfectious and can attend school while receiving treatment.

Prognosis

If bacteria are sensitive and treatment is completed, most children are cured with minimal sequelae. Repeat treatment is more difficult and less successful. With antituberculosis chemotherapy (especially isoniazid), there should now be nearly 100% recovery in miliary tuberculosis. Without treatment, the mortality rate in both miliary tuberculosis and tuberculous meningitis is almost 100%. In the latter form, about two thirds of patients receiving treatment survive. There may be a high incidence of neurologic abnormalities among survivors if treatment is started late.

INFECTIONS WITH NONTUBERCULOUS MYCOBACTERIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic unilateral cervical lymphadenitis.
- Granulomas of the skin.
- Chronic bone lesion with draining sinus (chronic osteomyelitis).
- Reaction to PPD-S (standard) of 5–8 mm, negative chest radiograph, and negative history of contact with tuberculosis.
- Diagnosis by positive acid-fast stain or culture.
- Disseminated infection in patients with AIDS.

General Considerations

Various species of acid-fast mycobacteria other than *Mycobacterium tuberculosis* may cause subclinical infections and occasionally clinical disease resembling tuberculosis. Strains of nontuberculous mycobacteria are common in soil, food, and water. Organisms enter the host by small abrasions in skin, oral mucosa, or gastrointestinal mucosa. Strain cross-reactivity with *M tuberculosis* can be demonstrated by simultaneous skin testing (Mantoux) with PPD-S (standard) and PPD prepared from one of the atypical antigens. Unfortunately, reagents prepared for routine non-tuberculosis skin testing are not available to clinicians.

The Runyon classification of mycobacteria includes the following:

Group I. Photochromogens (PPD-Y): (*M kansasii* and *M marinum*) Yellow color develops on exposure to light in previously white colony grown 2–4 weeks in the dark.

Group II. Scotochromogens (PPD-G): (*M scrofulaceum*) Colonies are definitely yellow-orange after incubation in the dark. Organisms may be found in small numbers in the normal flora of some human saliva and gastric contents. Subclinical infection is widespread in the United States, but clinical disease appears rarely.

Group III. Nonphotochromogens (PPD-B): “Battey avian-swine group” grows as small white colonies after incubation in the dark, with no significant development of pigment on exposure to light. Infection with *Mycobacterium avium* complex (MAC) is prevalent on the East Coast of the United States, particularly the Southeast, and in patients with AIDS.

Group IV. “Rapid growers”: (*M fortuitum*, *M chelonae*) Within 1 week after inoculation they form colonies closely resembling *M tuberculosis* morphologically.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Lymphadenitis—In children, the most common form of infection due to mycobacteria other than *M tuberculosis* is cervical lymphadenitis. MAC is the most common organism. A submandibular or cervical node swells slowly and is firm and initially somewhat tender. Low-grade fever may occur. Over time, the node suppurates and may drain chronically. Nodes in other areas of the head and neck and elsewhere are sometimes involved.

2. Pulmonary disease—In the western United States, pulmonary disease is usually due to *M kansasii*. In the eastern United States, it may be due to MAC. In other countries, disease is usually caused by MAC. In adults, there is usually underlying chronic pulmonary disease. Immunologic deficiency may be present. Presentation is clinically indistinguishable from that of tuberculosis.

Adolescents with cystic fibrosis may be infected with nontuberculous mycobacteria.

3. Swimming pool granuloma—This is due to *M marinum*. A solitary chronic granulomatous lesion with satellite lesions develops after minor trauma in infected swimming pools. Minor trauma in home aquariums or other aquatic environments also may lead to infection.

4. Chronic osteomyelitis—Osteomyelitis is caused by *M kansasii*, *M fortuitum*, or other rapid growers. Findings include swelling and pain over a distal extremity, radiolucent defects in bone, fever, and clinical and radiographic evidence of bronchopneumonia. Such cases are rare.

5. Meningitis—Disease is due to *M kansasii* and may be indistinguishable from tuberculous meningitis.

6. Disseminated infection—Rarely, apparently immunologically normal children develop disseminated infection due to nontuberculous mycobacteria. Children are ill, with fever and hepatosplenomegaly, and organisms are demonstrated in bone lesions, lymph nodes, or liver. Chest radiographs are usually normal. Between 60% and 80% of patients with AIDS will acquire MAC infection, characterized by fever, night sweats, weight loss, and diarrhea. Infection usually indicates severe immune dysfunction and is associated with CD4 lymphocyte counts less than 50/ μ L.

B. LABORATORY FINDINGS

In most cases, there is a small reaction (<10 mm) when Mantoux testing is done. Larger reactions may be seen. The chest radiograph is negative, and there is no history of contact with tuberculosis. Needle aspiration of the node excludes bacterial infection and may yield acid-fast bacilli on stain or culture. Fistulization should not be a problem because total excision is usually recommended for infection due to atypical mycobacteria. Cultures of any normally sterile body site will yield MAC in immunocompromised patients with disseminated disease. Blood cultures are positive, with a large density of bacteria.

Differential Diagnosis

See section on differential diagnosis in the previous discussion of tuberculosis and in Chapter 18.

Treatment

A. SPECIFIC MEASURES

The usual treatment of lymphadenitis is complete surgical excision. Occasionally excision is impossible because of proximity to branches of the facial nerve. Chemotherapy may then be necessary. Response of extensive adenopathy or other forms of infection varies according to the infecting species and susceptibility. Usually, com-

binations of two to four medications administered for months are required. Isoniazid, rifampin, ethambutol (depending on sensitivity to isoniazid) will result in a favorable response in almost all patients with *M kansasii* infection. Chemotherapeutic treatment of MAC is much less satisfactory because resistance to isoniazid, rifampin, and pyrazinamide is common. Susceptibility testing is necessary to optimize therapy. Most clinicians favor surgical excision of involved tissue if possible and treatment with at least three drugs to which the organism has been shown to be sensitive. Disseminated disease in patients with AIDS calls for a combination of three or more active drugs. Clarithromycin or azithromycin and ethambutol, in addition to one or more of the following drugs, is started: ethionamide, capreomycin, amikacin, rifabutin, or ciprofloxacin. *M fortuitum* and *M chelonae* are usually susceptible to amikacin plus cefoxitin followed by erythromycin, clarithromycin, azithromycin, or doxycycline and may be successfully treated with such combinations. Swimming pool granuloma due to *M marinum* is usually treated with doxycycline (in children > age 9 years) or rifampin, plus ethambutol, clarithromycin, or TMP-SMX for a minimum of 3 months. Surgery may also be beneficial.

B. GENERAL MEASURES

Isolation of the patient is usually not necessary. General supportive care is indicated for the child with disseminated disease.

Prognosis

The prognosis is good for localized disease, although fatalities occur in immunocompromised children who have disseminated disease.

LEGIONELLA INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Severe progressive pneumonia in a child with compromised immunity.

- *Diarrhea and neurologic signs are common.*
- *Positive culture requires buffered charcoal yeast extract media and proves infection.*
- *Direct fluorescent antibody staining of respiratory secretions proves infection.*

General Considerations

Legionella pneumophila is a ubiquitous gram-negative bacillus that causes two distinct clinical syndromes: Legionnaire disease and Pontiac fever. Usually Legionnaire disease is an acute, severe pneumonia that is frequently fatal in immunocompromised patients. Pontiac fever is a mild, flu-like illness that spares the lungs and is characterized by fever, headache, myalgia, and arthralgia. The disease is self-limited and is described in outbreaks in otherwise healthy adults.

Over forty species of *Legionella* have been discovered, but not all cause disease in humans. *L pneumophila* causes most infections. *Legionella* is present in many natural water sources as well as domestic water supplies (faucets, showers). Contaminated cooling towers and heat exchangers have been implicated in several large institutional outbreaks. Person-to-person transmission has not been documented.

Few cases of Legionnaire disease have been reported in children. Most were in children with compromised cellular immunity. In adults, risk factors include smoking, underlying cardiopulmonary or renal disease, alcoholism, and diabetes.

L pneumophila is thought to be acquired by inhalation of a contaminated aerosol. The bacteria are phagocytosed but proliferate within macrophages. Cell-mediated immunity is necessary to activate macrophages to kill intracellular bacteria.

Clinical Findings

A. SYMPTOMS AND SIGNS

Onset of fever, chills, anorexia, and headache is abrupt. Pulmonary symptoms appear within 2–3 days and progress rapidly. The cough is nonproductive early. Purulent sputum occurs late. Hemoptysis, diarrhea, and neurologic signs (including lethargy, irritability, tremors, and delirium) are seen.

B. LABORATORY FINDINGS

The WBC count is usually elevated. Chest radiographs show rapidly progressive patchy consolidation. Cavitation and large pleural effusions are uncommon. Cultures from sputum, tracheal aspirates, or bronchoscopic specimens, when grown on buffered yeast charcoal extract

media, are positive in 70–80% of patients at 3–7 days. Direct fluorescent antibody staining of sputum or other respiratory specimens is only 50–70% sensitive but 95% specific. Thus a negative culture or direct fluorescent antibody staining of sputum or tracheal secretions does not rule out Legionnaire disease. A urine test for Legionella antigen detects 80% of infecting species. Serologic tests are available and aid in diagnosis, but a maximum rise in titer may require 6–8 weeks.

Differential Diagnosis

Legionnaire disease is usually a rapidly progressive pneumonia in a patient who appears very ill with unremitting fevers. Other bacterial pneumonias, viral pneumonias, *Mycoplasma pneumoniae*, and fungal disease are all possibilities and may be difficult to differentiate on clinical grounds in an immunocompromised patient.

Complications

In sporadic untreated cases, mortality rates are 5–25%. In immunocompromised patients with untreated disease, mortality approaches 80%. Hematogenous dissemination may result in extrapulmonary foci of infection, including pericardium, myocardium, and kidneys. *Legionella* may be the cause of culture-negative endocarditis.

Prevention

No vaccine is available. Hyperchlorination and periodic superheating of water supplies in hospitals have been shown to reduce the number of organisms and the risk of infection.

Treatment

Intravenous azithromycin 10 mg/kg/d given as a once daily intravenous dose (maximum dose 500 mg) is the drug of choice. Rifampin (20 mg/kg/d divided in two doses) may be added to the regimen in gravely ill patients. Ciprofloxacin and levofloxacin are also effective in adults, but are not approved for use in children. Duration of therapy is 5–10 days if azithromycin is used; for other antibiotics a 14–21-day course is recommended. Oral therapy may be substituted for intravenous therapy as the patient's condition improves.

Prognosis

Mortality rate is high if treatment is delayed. Malaise, problems with memory, and fatigue are common problems after recovery.

PSITTACOSIS (ORNITHOSIS) & CHLAMYDIA PNEUMONIAE INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, cough, malaise, chills, headache.
- Diffuse rales; no consolidation.
- Long-lasting radiographic findings of bronchopneumonia.
- Isolation of the organism or rising titer of complement-fixing antibodies.
- Exposure to infected birds (ornithosis).

General Considerations

Psittacosis is caused by *Chlamydia psittaci*. When the agent is transmitted to humans from psittacine birds (parrots, parakeets, cockatoos, and budgerigars), the disease is often called psittacosis or parrot fever. However, other avian genera (pigeons, turkeys) are common sources of infection in the United States, and the general term “ornithosis” is often used. The agent is an obligate intracellular parasite. Human-to-human spread occurs rarely. The incubation period is 5–14 days. The bird from which the disease was transmitted may not be clinically ill.

C. pneumoniae may cause atypical pneumonia similar to that due to *Mycoplasma pneumoniae*. Transmission is by respiratory spread. Infection appears to be most prevalent during the second decade; half of surveyed adults are seropositive. Only a small percentage of infections result in clinical pneumonia. The disease may be more common than atypical pneumonia due to *M. pneumoniae*. Lower respiratory tract infection due to *C. pneumoniae* is uncommon in infants and young children.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. *C. psittaci*—The disease is extremely variable but tends to be mild in children. The onset is rapid or insidious, with fever, chills, headache, backache, malaise, myalgia, and dry cough. Signs include pneumonitis, alteration of percussion note and breath sounds, and rales. Pulmonary findings may be absent early. Dyspnea

and cyanosis may occur later. Splenomegaly, epistaxis, prostration, and meningismus are occasionally seen. Delirium, constipation or diarrhea, and abdominal distress may occur.

2. *C. pneumoniae*—Clinically, *C. pneumoniae* infection is similar to *M. pneumoniae* infection. Most are mild upper respiratory infections. Lower respiratory tract infection is characterized by fever, sore throat (perhaps more severe with *C. pneumoniae*), cough, and bilateral pulmonary findings and infiltrates.

B. LABORATORY FINDINGS

1. *C. psittaci*—In psittacosis, the WBC count is normal or decreased, often with a shift to the left. Proteinuria is frequently present. *C. psittaci* is present in the blood and sputum during the first 2 weeks of illness and can be isolated by inoculation of specimens into mice or embryonated eggs, but culture is available only in research laboratories. A fourfold rise in complement fixation titers in specimens obtained at least 2 weeks apart or a single titer above 1:32 is considered evidence of infection. The rise in titer may be minimized or delayed by therapy. Infection with *C. pneumoniae* may lead to diagnostic confusion because cross-reactive antibody may cause falsely positive *C. psittaci* titers. Microimmunofluorescence and PCR assays are specific but usually not commercially available for *C. psittaci*.

2. *C. pneumoniae*—A fourfold rise in IgG titer (microimmunofluorescence antibody test) or an IgM above 16 is evidence of infection. IgG antibody peaks 6–8 weeks after infection. *C. pneumoniae* can be isolated from nasal wash or throat swab specimens after inoculation into cell culture. A PCR assay is also available.

C. IMAGING

The radiographic findings in psittacosis are those of central pneumonia, which later becomes widespread or migratory. Psittacosis is indistinguishable from viral pneumonias by radiograph. Signs of pneumonitis may appear on radiograph in the absence of clinical suspicion of pulmonary involvement.

Differential Diagnosis

Psittacosis can be differentiated from acute viral or mycoplasmal pneumonias only by the history of contact with potentially infected birds. In severe or prolonged cases with extrapulmonary involvement, the differential diagnosis includes a wide spectrum of diseases including typhoid fever, brucellosis, and rheumatic fever.

Complications

Complications of psittacosis include myocarditis, endocarditis, hepatitis, pancreatitis, and secondary bacterial

pneumonia. *C. pneumoniae* infection may be prolonged or may recur.

Treatment

Doxycycline should be given for 14 days after defervescence to patients older than age 8 years with psittacosis. Alternatively, erythromycin, azithromycin, or clarithromycin may be used in children younger than age 8 years. Supportive oxygen may be needed. The patient should be kept in isolation. *C. pneumoniae* responds to macrolides or doxycycline: a 14-day course is recommended.

Centers for Disease Control and Prevention: Compendium of measures to control *Chlamydia psittaci* infection among humans (psittacosis) and pet birds (avian chlamydiosis), 2000. MMWR 2000;49(RR-8):3.

File TM Jr et al: The role of atypical pathogens: *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella pneumophila* in respiratory infection. Infect Dis Clin North Am 1998; 12:569.

CAT-SCRATCH DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of a cat scratch or cat contact.
- Primary lesion (papule, pustule, conjunctivitis) at site of inoculation.
- Acute or subacute regional lymphadenopathy.
- Aspiration of sterile pus from a node.
- Laboratory studies excluding other causes.
- Biopsy of node or papule showing histopathologic findings consistent with cat-scratch disease and occasionally characteristic bacilli on Warthin–Starry stain.
- Positive cat-scratch serology (antibody to *Bartonella henselae*).

General Considerations

The causative agent of cat-scratch disease is *Bartonella henselae*, a gram-negative bacillus that also causes bacillary angiomatosis. Cat-scratch disease is a benign, self-limited form of lymphadenitis. Patients often report a cat scratch (67%) or contact with a cat or kitten (90%). The cat almost invariably is healthy. The clinical picture is that of a regional lymphadenitis associated with

an erythematous papular skin lesion without intervening lymphangitis. The disease occurs worldwide and is more common in the fall and winter. It is estimated that more than 20,000 cases per year occur in the United States. The most common systemic complication is encephalitis.

Clinical Findings

A. SYMPTOMS AND SIGNS

About 50% of patients with cat-scratch disease develop a primary lesion at the site of inoculation. The lesion usually is a papule or pustule that appears 3–10 days after injury and is located most often on the arm or hand (50%), head or leg (30%), or trunk or neck (10%). The lesion may be conjunctival (10%). Regional lymphadenopathy appears 10–50 days later and may be accompanied by mild malaise, lassitude, headache, and fever. Multiple sites are seen in about 10% of cases. Involved nodes may be hard or soft and 1–6 cm in diameter. They are usually tender, and 10–20% of them suppurate. The overlying skin may be inflamed. Lymphadenopathy usually resolves in about 2 months but may persist for up to 8 months.

Unusual manifestations include erythema nodosum, thrombocytopenic purpura, conjunctivitis (Parinaud oculoglandular fever), parotid swelling, pneumonia, osteolytic lesions, mesenteric and mediastinal adenitis, neuroretinitis, peripheral neuritis, hepatitis, granulomata of the liver and spleen, and encephalitis.

Immunocompetent patients may develop an atypical systemic form of cat-scratch disease. These patients have prolonged fever, fatigue, and malaise. Lymphadenopathy may be present. Hepatosplenomegaly or low-density hepatic or splenic lesions visualized by ultrasound or computed tomography scan are seen in some patients.

Infection in immunocompromised individuals may take the form of bacillary angiomatosis, presenting as vascular tumors of the skin and subcutaneous tissues. Immunocompromised patients may also have bacteremia or infection of the liver (peliosis hepatis).

B. LABORATORY FINDINGS

Serologic evidence of *Bartonella* infection by indirect fluorescent antibody or enzyme-linked immunosorbent assay with a titer above 1:64 is supportive of the diagnosis. PCR assays are available commercially. Cat-scratch skin test antigens are not recommended.

Histopathologic examination of involved tissue may show pyogenic granulomas or bacillary forms demonstrated by Warthin–Starry silver stain. There is usually some elevation in the ESR. In patients with CNS involvement, the CSF is usually normal but may show a slight pleocytosis and modest elevation of protein.

Differential Diagnosis

Cat-scratch disease must be distinguished from pyogenic adenitis, tuberculosis (typical and atypical), tularemia, plague, brucellosis, lymphoma, primary toxoplasmosis, infectious mononucleosis, lymphogranuloma venereum, and fungal infections.

Treatment

Treatment of cat-scratch disease adenopathy is controversial because the disease usually resolves without therapy and the patient is typically not exceedingly ill. Treatment of typical cat-scratch disease with a 5-day course of azithromycin has been shown to speed resolution of lymphadenopathy in some patients. The best therapy is reassurance that the adenopathy is benign and will subside spontaneously with time (mean duration of illness is 14 weeks). In cases of suppuration, node aspiration under local anesthesia with an 18- to 19-gauge needle relieves the pain. Excision of the involved node is indicated in cases of chronic adenitis. In some reports, gentamicin, ciprofloxacin, and TMP-SMX have been useful. Immunocompromised patients with evidence of infection should be treated with antibiotics: long-term therapy (months) in these patients with azithromycin, erythromycin, or doxycycline is often needed to prevent relapses.

Prognosis

The prognosis is good if complications do not occur.

II. SPIROCHETAL INFECTIONS

SYPHILIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Congenital:

- *All types: History of untreated maternal syphilis, a positive serologic test, and a positive darkfield examination.*

- *Newborn: Hepatosplenomegaly, characteristic radiographic bone changes, anemia, increased nucleated red cells, thrombocytopenia, abnormal spinal fluid, jaundice, edema.*
- *Young infant (3–12 weeks): Snuffles, maculopapular skin rash, mucocutaneous lesions, pseudoparalysis (in addition to radiographic bone changes).*
- *Children: Stigmata of early congenital syphilis, interstitial keratitis, saber shins, gummas of nose and palate.*

Acquired:

- *Chancre of genitals, lip, or anus in child or adolescent. History of sexual contact.*

General Considerations

Syphilis is a chronic, generalized infectious disease caused by a spirochete, *Treponema pallidum*. In the acquired form, the disease is transmitted by sexual contact. Primary syphilis is characterized by the presence of an indurated painless chancre, which heals in 7–10 days. A secondary eruption involving the skin and mucous membranes appears in 4–6 weeks. After a long latency period, late lesions of tertiary syphilis involve the eyes, skin, bones, viscera, CNS, and cardiovascular system.

Congenital syphilis results from transplacental infection. Infection may result in stillbirth or produce illness in the newborn, in early infancy, or later in childhood. First-trimester fetal infection has been found in the products of conception in therapeutic abortions. Syphilis occurring in the newborn and young infant is comparable to secondary disease in the adult but is more severe and life-threatening. Late congenital syphilis (developing in childhood) is comparable to tertiary disease.

Congenital syphilis is increasing in the United States due to increasing primary and secondary syphilis in women of childbearing age, and perhaps due to inadequate diagnosis and treatment of syphilis in prenatal care programs.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Congenital syphilis—

a. **Newborns**—Most newborns with congenital syphilis are asymptomatic. If not detected and treated, symptoms develop within weeks to months. When clin-

ical signs are present, they usually consist of jaundice, anemia with or without thrombocytopenia, increase in nucleated red blood cells, hepatosplenomegaly, and edema. Overt signs of meningitis (bulging fontanelle, opisthotonos) may be present, but subclinical infection with CSF abnormalities is more likely.

b. Young infants (3–12 weeks)—The infant may appear normal for the first few weeks of life only to develop mucocutaneous lesions and pseudoparalysis of the arms or legs. Shotty lymphadenopathy may be felt. Hepatomegaly is universal, with splenomegaly in 50% of patients. Other signs of disease similar to those seen in the newborn may be present. Anemia has been reported as the only presenting manifestation of congenital syphilis in this age group. “Snuffles” (rhinitis), characterized by a profuse mucopurulent discharge that excoerates the upper lip, is present in 25% of patients. A syphilitic rash is common on the palms and soles but may occur anywhere on the body. The rash consists of bright red, raised maculopapular lesions that gradually fade. Moist lesions occur at the mucocutaneous junctions (nose, mouth, anus, genitals) and lead to fissuring and bleeding.

Syphilis in the young infant may lead to stigmata recognizable in later childhood, such as rhagades (scars) around the mouth or nose, a depressed bridge of the nose (saddle nose), and a high forehead (secondary to mild hydrocephalus associated with low-grade meningitis and frontal periostitis). The permanent upper central incisors may be peg-shaped with a central notch (Hutchinson teeth), and the cusps of the sixth-year molars may have a lobulated mulberry appearance.

c. Children—Bilateral interstitial keratitis (at age 6–12 years) is characterized by photophobia, increased lacrimation, and vascularization of the cornea associated with exudation. Chorioretinitis and optic atrophy may also be seen. Meningovascular syphilis (at age 2–10 years) is usually slowly progressive, with mental retardation, spasticity, abnormal pupillary response, speech defects, and abnormal CSF. Deafness sometimes occurs. Thickening of the periosteum of the anterior tibiae produces saber shins. A bilateral effusion into the knee joints (Clutton joints) may occur but is not associated with sequelae. Gummas may develop in the nasal septum, palate, long bones, and subcutaneous tissues.

2. Acquired syphilis—The primary chancre of the genitals, mouth, or anus may occur as a result of intimate sexual contact. If the chancre is missed, signs of secondary syphilis, such as rash, fever, headache, and malaise, may be the first manifestation of the disease.

B. LABORATORY FINDINGS

1. Darkfield microscopy—Treponemes can be seen in scrapings from a chancre and from moist lesions.

2. Serologic tests for syphilis—There are two general types of serologic tests for syphilis: treponemal and nontreponemal. The latter (Venereal Disease Research Laboratory, or VDRL) is useful for screening and follow-up of known cases. A rapid test (the rapid plasma reagin, or RPR) is useful for screening, but positive sera should be examined further by quantitative nontreponemal and treponemal tests. Positive nontreponemal tests are confirmed with more specific fluorescent treponemal antibody absorbed, or FTA-ABS test. False-positive FTA-ABS tests are uncommon except with other spirochetal disease.

One or two weeks after the onset of primary syphilis (chancre), the FTA-ABS test becomes positive. The VDRL or a similar nontreponemal test usually turns positive a few days later. By the time the secondary stage has been reached, virtually all patients show both positive FTA-ABS and positive nontreponemal tests. During latent and tertiary syphilis, the VDRL may become negative, but the FTA-ABS test usually remains positive. The quantitative VDRL or a similar nontreponemal test should be used to follow-up treated cases (see following discussion).

Positive serologic tests in cord sera may represent passively transferred antibody rather than congenital infection and therefore must be supplemented by a combination of clinical and laboratory data. Elevated total cord IgM is a helpful but nonspecific finding. A specific IgM-FTA-ABS is available, but negative results are not conclusive and should not be relied on. Demonstration of characteristic treponemes by darkfield examination of material from a moist lesion (skin; nasal or other mucous membranes) is definitive. Serial measurement of quantitative VDRL is also very useful, because passively transferred antibody in the absence of active infection should decay with a normal half-life of about 18 days.

In one study, 15% of infants with congenital syphilis had negative cord blood serology, presumably due to maternal infection late in pregnancy.

C. IMAGING

Radiographic abnormalities are present in 90% of infants with symptoms of congenital syphilis and in 20% of asymptomatic infants. Metaphyseal lucent bands, periostitis, and a widened zone of provisional calcification may be present. Bilateral symmetrical osteomyelitis with pathologic fractures of the medial tibial metaphyses (Wimberger sign) is almost pathognomonic.

Differential Diagnosis

A. CONGENITAL SYPHILIS

1. Newborns—Sepsis, congestive heart failure, congenital rubella, toxoplasmosis, disseminated herpes simplex, cytomegalovirus infection, and hemolytic disease

of the newborn have to be differentiated. A positive Coombs test and blood group incompatibility distinguish hemolytic disease.

2. Young infants—Injury to the brachial plexus, poliomyelitis, acute osteomyelitis, and septic arthritis must be differentiated from pseudoparalysis. Coryza due to viral infection often responds to symptomatic treatment. Rash (ammoniacal diaper rash) and scabies may be confused with a syphilitic eruption.

3. Children—Interstitial keratitis and bone lesions of tuberculosis are distinguished by positive tuberculin reaction and chest radiograph. Arthritis associated with syphilis is unaccompanied by systemic signs, and joints are nontender. Mental retardation, spasticity, and hyperactivity are shown to be of syphilitic origin by strongly positive serologic tests.

B. ACQUIRED SYPHILIS

Herpes genitalis, traumatic lesions, and other venereal diseases must be differentiated.

Prevention

A serologic test for syphilis should be performed at the initiation of prenatal care and repeated at delivery. In mothers at high risk for syphilis, repeated tests may be necessary. Serologic tests for syphilis may be negative on both the mother and the baby at the time of birth if the mother acquires syphilis near term. Adequate treatment of mothers with secondary syphilis before the last month of pregnancy reduces the incidence of congenital syphilis from 90% to less than 2%. Examination and serologic testing of sexual partners and siblings should also be done.

Treatment

A. SPECIFIC MEASURES

Penicillin is the drug of choice for *T pallidum* infection. If the patient is allergic to penicillin, erythromycin or one of the tetracyclines may be used.

1. Congenital syphilis—Infants born to seropositive mothers require careful examination and quantitative antitreponemal (VDRL, RPR) syphilis testing. The same quantitative antitreponemal test should be done on the infant as the one done on the mother so the titers can be compared. Maternal records regarding the diagnosis of syphilis, treatment, and follow-up titers should be reviewed. Infants should be further evaluated for congenital syphilis for any of the following circumstances:

- The maternal titer has increased fourfold.
- The infant's titer is at least fourfold greater than the maternal titer.

- Signs of syphilis are found on examination.
- Maternal syphilis was not treated or inadequately treated during pregnancy.
- Maternal treatment of syphilis with a nonpenicillin regimen, or the regimen or dose of medication is undocumented.
- Maternal syphilis treated during pregnancy, but therapy completed less than 4 weeks prior to delivery.
- Maternal syphilis treated appropriately during pregnancy, but without the appropriate decrease in maternal nontreponemal titers after treatment.

The complete evaluation of an infant for possible congenital syphilis includes complete blood count, liver function tests, long bone radiographs, CSF examination (cell counts, glucose, protein), CSF VDRL, and quantitative serologic tests. In addition, the placenta and umbilical cord should be examined pathologically using fluorescent antitreponemal antibody.

Treatment for congenital syphilis is indicated for infants with physical signs, umbilical cord or placenta positive for DFA-TP staining or darkfield examination, abnormal radiographs, elevated CSF protein or cell counts, reactive CSF VDRL, or serum quantitative nontreponemal titer that is more than fourfold higher than the maternal titer (using same test). Infants with proved or suspected congenital syphilis should receive either (1) aqueous crystalline penicillin G, 50,000 units/kg/dose intravenously q12h (if <1 week old) or q8h (if 1–4 weeks old) for 10 days; or (2) aqueous procaine penicillin G, 50,000 units/kg/dose intramuscularly once daily for 10 days. All infants diagnosed after age 4 weeks receive 50,000–60,000 units/kg/dose aqueous crystalline penicillin intravenously q6h for 10 days.

Additionally, treatment should be given to infants whose mothers have inadequately treated syphilis, to those whose mothers received treatment less than 1 month before delivery, to those whose mothers have undocumented or inadequate serologic response to therapy, and to those whose mothers were given nonpenicillin drugs to treat syphilis. In these instances, if the infant is asymptomatic, has a normal physical exam, normal CSF parameters, nonreactive CSF VDRL, normal bone films, quantitative nontreponemal titer less than fourfold of the mother's titer, and good follow-up is certain, some experts would give a single dose of penicillin G benzathine 50,000 units/kg intramuscularly. If there is any abnormality in the preceding evaluation or if the CSF testing is not interpretable, the full 10 days of intravenous penicillin should be given. Close clinical and serologic follow-up monthly is necessary.

Asymptomatic, seropositive, infants with normal physical examinations born to mothers who received adequate syphilis treatment (completed > 4 weeks prior

to delivery) and whose mothers have an appropriate serologic response (fourfold or greater decrease in titer) to treatment may be at lower risk for congenital syphilis. Some experts believe complete laboratory and radiographic evaluation in these infants (CSF, long bone films) is not necessary. Those infants who meet the preceding criteria, have nontreponemal titers less than fourfold higher than maternal titers, and for whom follow-up is certain can be given benzathine penicillin G, 50,000 units/kg, administered intramuscularly in a single dose. Subsequently, the infants should be followed with quantitative serologic tests and physical examinations until the nontreponemal serologic test is negative (see follow-up). Rising titers or clinical signs usually occur within 4 months in infected infants, requiring a full evaluation (including CSF studies and long bone radiographs) and institution of intravenous penicillin therapy.

a. Follow-up for congenital syphilis—Children treated for congenital syphilis need physical examinations at 1 and 2 months after completion of therapy, and both physical examinations and quantitative VDRL or RPR tests should be performed at 3, 6, and 12 months after the end of therapy or until the tests become nonreactive. Repeat CSF examination, including a CSF VDRL test, every 6 months until normal is indicated for infants with a positive CSF VDRL reaction. A reactive CSF VDRL test at the 6-month interval is an indication for retreatment. Titers decline with treatment and are usually negative by 6 months. Repeat treatment is indicated for children with rising titers or stable titers that do not decline.

2. Acquired syphilis of less than one year's duration—Benzathine penicillin G (50,000 units/kg, given intramuscularly, to a maximum of 2.4 million units) is given to adolescents with primary, secondary, or latent disease of less than 1 year's duration. All children should have a CSF examination (with CSF VDRL) prior to commencing therapy, to exclude neurosyphilis. Adolescents and adults need a CSF examination if clinical signs or symptoms suggest neurologic involvement.

3. Syphilis of more than one year's duration (late latent disease)—Syphilis of more than 1 year's duration (without evidence of neurosyphilis) requires weekly intramuscular benzathine penicillin G therapy for 3 weeks. CSF examination and VDRL test should be done on all children and patients with coexisting HIV infection or neurologic symptoms. In addition, patients who have failed treatment or who were previously treated with an agent other than penicillin need a CSF examination and CSF VDRL.

4. Neurosyphilis—Aqueous crystalline penicillin G is recommended, 200,000–300,000 U/kg/d in four to six

divided doses, given intravenously for 10–14 days. The maximum adult dose is 4 million units/dose. This regimen should possibly be followed by an intramuscular course of benzathine G penicillin, 50,000 U/kg given once a week for 3 consecutive weeks, to a maximum dose of 2.4 million units.

B. GENERAL MEASURES

Penicillin treatment of early congenital or secondary syphilis may result in a febrile Jarisch–Herxheimer reaction. Treatment is symptomatic, with careful follow-up and aspirin or acetaminophen, although transfusion may be necessary in infants with severe hemolytic anemia.

Prognosis

Severe disease, if undiagnosed, may be fatal in the newborn. Complete cure can be expected if the young infant is given penicillin. Serologic reversal usually occurs within 1 year. Treatment of primary syphilis with penicillin is curative. Permanent neurologic sequelae may occur in meningovascular syphilis.

Centers for Disease Control and Prevention: Congenital syphilis—United States, 2000. JAMA 2001;286(5):529 [PMID: 11508285].

Guidelines for treatment of sexually transmitted diseases. MMWR 1998;47(RR-1):28.

RELAPSING FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Episodes of fever, chills, malaise.
- Occasional rash, arthritis, cough, hepatosplenomegaly, conjunctivitis.
- Diagnosis confirmed by direct microscopic identification of spirochetes in smears of peripheral blood.

General Considerations

Relapsing fever is a vector-borne disease caused by spirochetes of the genus *Borrelia*. Epidemic relapsing fever is transmitted to humans by body lice (*Pediculus humanus*) and endemic relapsing fever by soft-bodied ticks (genus *Ornithodoros*). Tick-borne relapsing fever is endemic in the western United States. Transmission usually takes place during the warm months, when ticks are active and recreation or work brings people into

contact with *Ornithodoros* ticks. Infection is often acquired in mountain camping areas and cabins. The ticks are nocturnal feeders and remain attached for only 5–20 minutes. Consequently the patient seldom remembers a tick bite. Rarely, neonatal relapsing fever results from transplacental transmission of *Borrelia*. Both louse-borne and tick-borne relapsing fever may be acquired during foreign travel.

Clinical Findings

A. SYMPTOMS AND SIGNS

The incubation period is 4–18 days. The attack is sudden, with high fever, chills, tachycardia, nausea and vomiting, headache, myalgia, arthralgia, bronchitis, and a dry, nonproductive cough. Hepatomegaly and splenomegaly appear later. Meningeal irritation may be present. An erythematous rash may be seen over the trunk and extremities, and petechiae may be present. After 3–10 days, the fever falls by crisis. Jaundice, iritis, conjunctivitis, cranial nerve palsies, and hemorrhage occur more commonly during relapses.

The disease is characterized by relapses at intervals of 1–2 weeks and lasting 3–5 days. The relapses duplicate the initial attack but become progressively less severe. In louse-borne relapsing fever, there is usually a single relapse. In tick-borne infection, two to six relapses occur.

B. LABORATORY FINDINGS

During febrile episodes, the patient's urine contains protein, casts, and occasionally erythrocytes; a marked polymorphonuclear leukocytosis is present; and, in about 25% of cases, the patient has a false-positive serologic test for syphilis. Examination of the peripheral blood smear is the diagnostic test of choice. Spirochetes can be found in the peripheral blood by direct microscopy in approximately 70% of cases by darkfield examination or by Wright, Giemsa, or acridine orange staining of thick and thin smears. Spirochetes are not found during afebrile periods. Immunofluorescent antibody (or ELISA confirmed by Western blot) can sometimes help establish the diagnosis serologically. However, high titers of *Borrelia hermsii* can cross-react with *Borrelia burgdorferi* (the agent in Lyme disease) in immunofluorescent antibody assay, ELISA, and Western blots. Serologic specimens can be sent to the Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, CO 80522.

Differential Diagnosis

Relapsing fever may be confused with malaria, leptospirosis, dengue, typhus, rat-bite fever, Colorado tick

fever, Rocky Mountain spotted fever, collagen vascular disease, or any fever of unknown origin.

Complications

Complications include facial paralysis, iridocyclitis, optic atrophy, hypochromic anemia, pneumonia, nephritis, myocarditis, endocarditis, and seizures. CNS involvement occurs in 10–30% of patients.

Treatment

For children younger than age 8 years who have tick-borne relapsing fever, standard dosages of penicillin or erythromycin should be given for 10 days. Older children may be given doxycycline. Chloramphenicol is also efficacious. Patients who are unable to take oral medications may be given intravenous penicillin G. In louse-borne relapsing fever, a single dose of tetracycline or erythromycin has been effective.

Severely ill patients should be hospitalized. Antibiotic treatment should be started after the fever has dropped, to reduce the risk of severe Jarisch–Herxheimer reaction. Isolation precautions are not necessary for relapsing fever. Contact precautions are recommended for patients with louse infestations.

Prognosis

The mortality rate in treated cases of relapsing fever is very low, except in debilitated or very young children. With treatment, the initial attack is shortened and relapses prevented. The response to antimicrobial therapy is dramatic.

Tickborne relapsing fever outbreak after a family gathering—New Mexico, August 2002. *MMWR* 2003;52(34):809.

LEPTOSPIROSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Biphasic course lasting 2 or 3 weeks.
- Initial phase: high fever, headache, myalgia, and conjunctivitis.
- Apparent recovery for 2–3 days.
- Return of fever associated with meningitis.

- Jaundice, hemorrhages, and renal insufficiency (severe cases).
- Culture of organism from blood and CSF (early) and from urine (later), or direct microscopy of urine or CSF.
- Positive leptospiral agglutination test.

General Considerations

Leptospirosis is a zoonosis caused by many antigenically distinct but morphologically similar spirochetes. The organism enters through the skin or respiratory tract. Classically the severe form (Weil disease), with jaundice and a high mortality rate, was associated with infection with *Leptospira icterohaemorrhagiae* after immersion in water contaminated with rat urine. It is now known that a variety of animals (eg, dogs, rats, cattle) may serve as reservoirs for pathogenic *Leptospira*, that a given serogroup may have multiple animal species as hosts, and that severe disease may be caused by many different serogroups.

In the United States, leptospirosis usually occurs after contact with dogs. Cattle, swine, or rodents may transmit the organism. Sewer workers, farmers, abattoir workers, animal handlers, and soldiers are at risk for occupational exposure. Outbreaks have resulted from swimming in contaminated streams and harvesting field crops. In the United States, about 100 cases are reported yearly, and about one third are in children.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Initial phase—The incubation period is 4–19 days (mean, 10 days). Chills, fever, headache, myalgia, conjunctivitis (episcleral injection), photophobia, cervical lymphadenopathy, and pharyngitis occur commonly. The initial leptospiremic phase lasts for 3–7 days.

2. Phase of apparent recovery—Symptoms typically (but not always) subside for 2–3 days.

3. Systemic phase—Fever reappears and is associated with headache, muscular pain and tenderness in the abdomen and back, and nausea and vomiting. Lung, heart, and joint involvement occasionally occurs. These manifestations are due to extensive vasculitis.

a. Central nervous system involvement—The CNS is involved in 50–90% of cases. Severe headache and mild nuchal rigidity are usual, but delirium, coma, and focal neurologic signs may be seen.

b. Renal and hepatic involvement—In about 50% of cases, the kidney or liver is affected. Gross hematuria

and oliguria or anuria is sometimes seen. Jaundice may be associated with an enlarged and tender liver.

c. Gallbladder involvement—Leptospirosis may cause acalculous cholecystitis in children, demonstrable by abdominal ultrasound as a dilated, nonfunctioning gallbladder. Pancreatitis is unusual.

d. Hemorrhage—Petechiae, ecchymoses, and gastrointestinal bleeding may be severe.

e. Rash—A rash is seen in 10–30% of cases. It may be maculopapular and generalized or may be petechial or purpuric. Occasionally erythema nodosum is seen. Peripheral desquamation of the rash may occur. Gangrenous areas are sometimes noted over the distal extremities. In such cases, skin biopsy demonstrates the presence of severe vasculitis involving both the arterial and the venous circulations.

B. LABORATORY FINDINGS

Leptospire are present in the blood and CSF only during the first 10 days of illness. They appear in the urine during the second week, where they may persist for 30 days or longer. The organism can be isolated from blood inoculated into Fletcher's semisolid medium or Ellinghausen–McCullough–Johnson–Harris (EMJH) semisolid medium, but culture techniques are slow (7–10 days), difficult, and not generally available.

The WBC count is often elevated, especially when there is liver involvement. Serum bilirubin levels usually remain below 20 mg/dL. Other liver function tests may be abnormal, although the aspartate transaminase (AST) usually is elevated only slightly. An elevated serum creatine kinase is frequently found. CSF shows moderate pleocytosis (<500/ μ L)—predominantly mononuclear cells—increased protein (50–100 mg/dL), and normal glucose. Urine often shows microscopic pyuria, hematuria, and, less often, moderate proteinuria (++ or greater). The ESR is elevated markedly. Chest radiograph may show pneumonitis.

Serologic antibodies measured by enzyme immunoassay may be demonstrated during or after the second week of illness. The serologic test of choice is a microscopic agglutination test using live organisms (performed at the CDC, Atlanta, GA 30333). Leptospiral agglutinins generally reach peak levels by the third to fourth week. A 1:100 titer is considered suspicious; a fourfold or greater rise is diagnostic. A PCR assay may be available at specialized research centers or through the CDC.

Differential Diagnosis

Fever and myalgia associated with the characteristic episcleral injection should suggest leptospirosis. During the prodrome, malaria, typhoid fever, typhus, rheuma-

toid arthritis, brucellosis, and influenza may be suspected. Later, depending on the organ systems involved, a variety of other diseases need to be distinguished, including encephalitis, viral or tuberculous meningitis, viral hepatitis, glomerulonephritis, viral or bacterial pneumonia, rheumatic fever, subacute infective endocarditis, acute surgical abdomen, and Kawasaki disease (see Table 36–3).

Prevention

Preventive measures include avoidance of contaminated water and soil, rodent control, immunization of dogs and other domestic animals, and good sanitation. Immunization or antimicrobial prophylaxis with doxycycline may be of value to certain high-risk occupational groups.

Treatment

A. SPECIFIC MEASURES

Aqueous penicillin G (150,000 units/kg/d, given in four to six divided doses intravenously for 7–10 days) should be given when the diagnosis is suspected. Studies in severely ill patients indicate a benefit even if treatment is started 4 days after onset. A Jarisch–Herxheimer reaction may occur. Oral doxycycline may be used for mildly ill patients.

B. GENERAL MEASURES

Symptomatic and supportive care is indicated, particularly for renal and hepatic failure and hemorrhage.

Prognosis

Leptospirosis is usually self-limiting and not characterized by jaundice. The disease usually lasts 1–3 weeks but may be more prolonged. Relapse may occur. There are usually no permanent sequelae associated with CNS infection, although headache may persist. The mortality rate in reported cases in the United States is 5%, usually from renal failure. The mortality rate may reach 20% or more in elderly patients who have severe kidney and hepatic involvement.

LYME DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Characteristic skin lesion (erythema migrans) 3–30 days after tick bite.
- Arthritis, usually pauciarticular, occurring about 4 weeks after appearance of skin lesion. Headache, chills, and fever.
- Residence or travel in an endemic area during the late spring to early fall.

General Considerations

Lyme disease is a subacute or chronic spirochetal infection caused by *Borrelia burgdorferi* and transmitted by the bite of an infected deer tick (*Ixodes* species). The disease was known in Europe for many years as tick-borne encephalomyelitis, often associated with a characteristic rash (erythema migrans). Discovery of the agent and vector followed investigation of an outbreak of pauciarticular arthritis in Lyme, Connecticut, in 1977.

Although cases are reported from many countries, the most prominent endemic areas in the United States include the Northeast, upper Midwest, and West Coast. The northern European countries also have high rates of infection. More than 17,000 cases were reported in the United States in 2003. The disease is spreading as a result of increased infection in and distribution of the tick vector. Most cases with rash are recognized in spring and summer, when most tick bites occur; however, because the incubation period for joint and neurologic disease may be months, cases may present at any time. *Ixodes* ticks are very small, and their bite is often unrecognized.

Clinical Findings

A. SYMPTOMS AND SIGNS

Erythema migrans, the most characteristic feature of Lyme disease, develops in 60–80% of patients. Between 3 and 30 days after the bite, a ring of erythema develops at the site and spreads over days. It may attain a diameter of 20 cm. The center of the lesion may clear (resembling tinea corporis), remain red, or become raised (suggesting a chemical or infectious cellulitis). Many patients are otherwise asymptomatic. Some have fever (usually low-grade), headache, and myalgias. Multiple

satellite skin lesions, urticaria, or diffuse erythema may occur. Untreated, the rash lasts days to 3 weeks.

In up to 50% of patients, arthritis develops several weeks to months after the bite. Recurrent attacks of migratory, monoarticular, or pauciarticular arthritis involving the knees and other large joints occur. Each attack lasts for days to a few weeks. Fever is common and may be high. Complete resolution between attacks is typical. Chronic arthritis develops in less than 10% of patients, more often in those with the DR4 haplotype.

Neurologic manifestations develop in up to 20% of patients and usually consist of Bell palsy, aseptic meningitis (which may be indistinguishable from viral meningitis), or polyradiculitis. Peripheral neuritis, Guillain-Barré syndrome, encephalitis, ataxia, chorea, and other cranial neuropathies are less common. Seizures suggest another diagnosis. Untreated, the neurologic symptoms are usually self-limited but may be chronic or permanent. Although the fatigue and non-specific neurologic symptoms may be prolonged in a few patients, Lyme disease is not proved to be a cause of chronic fatigue syndrome.

Self-limited heart block or myocardial dysfunction occurs in about 5% of patients.

B. LABORATORY FINDINGS

Most patients with only rash have normal laboratory tests. Children with arthritis may have moderately elevated ESRs and WBC counts; the antinuclear antibodies and rheumatoid factor tests are negative or nonspecific; streptococcal antibodies are not elevated. Circulating IgM cryoglobulins may be present. Joint fluid may show up to 100,000 cells with a polymorphonuclear predominance, normal glucose, and elevated protein and immune complexes; Gram stain and culture are negative. In patients with CNS involvement, the CSF may show lymphocytic pleocytosis and elevated protein; the glucose and all cultures and stains are normal or negative. Abnormal nerve conduction may be present with peripheral neuropathy.

Diagnosis

Lyme disease is a clinical diagnosis. History, physical examination, and laboratory features are important to consider. The causative organism is difficult to culture. Serologic testing may support the clinical diagnosis. Antibody testing should be performed in experienced laboratories. Serologic diagnosis of Lyme disease is based on a two-test approach: an ELISA and an immunoblot to confirm a positive or indeterminate ELISA. Antibodies may not be detectable until several weeks after infection has occurred; therefore, serologic testing in children with a typical rash is not recommended. Therapy early in disease may blunt antibody

titers. Recent studies have shown considerable intralaboratory and interlaboratory variability in titers reported. Overdiagnosis of Lyme disease based on atypical symptoms and positive serology appears to be common. Sera from patients with syphilis, HIV, and leptospirosis may give false-positive results for Lyme disease. Patients who receive appropriate treatment for Lyme disease may remain seropositive for several years. Diagnosis of CNS disease requires objective abnormalities of the neurologic examination, laboratory or radiographic studies, and consistent positive serology.

Differential Diagnosis

Aside from the disorders already mentioned, the rash may resemble pityriasis, erythema multiforme, a drug eruption, or erythema nodosum. Erythema migrans is nonscaly, minimally tender or nontender, and persists longer in the same place than many of the more common childhood erythematous rashes. The arthritis may resemble juvenile rheumatoid arthritis, reactive arthritis, septic arthritis, reactive effusion from a contiguous osteomyelitis, rheumatic fever, leukemic arthritis, systemic lupus erythematosus, and Henoch-Schönlein purpura. Spontaneous resolution in a few days to weeks helps differentiate Lyme disease from juvenile rheumatoid arthritis, in which arthritis lasting a minimum of 6 weeks is required for diagnosis. The neurologic signs may suggest idiopathic Bell palsy, viral or parainfectious meningitis or meningoencephalitis, lead poisoning, psychosomatic illness, and many other conditions.

Prevention

Prevention consists of avoidance of endemic areas, wearing long sleeves and pants, frequent checks for ticks, and application of tick repellents. Ticks usually are attached for 24–48 hours before transmission of Lyme disease occurs. Ticks should be removed with a tweezer by pulling gently without twisting or excessive squeezing of the tick. Permethrin sprayed on clothing decreases tick attachment. Repellents containing high concentrations of DEET may be neurotoxic and should be used cautiously and washed off when tick exposure ends. The CDC does not recommend prophylactic antibiotics for tick bites in asymptomatic individuals.

A Lyme vaccine was licensed for use in persons age 15–70 years, but was withdrawn and is not available.

Treatment

Antimicrobial therapy is beneficial in most cases of Lyme disease. It is most effective if started early. Prolonged treatment is important for all forms. Relapses occur in some patients on all regimens.

A. RASH, OTHER EARLY INFECTIONS

Amoxicillin, 25–50 mg/kg/d, given orally in two divided doses (to a maximum of 2 g/d) for 14–21 days can be used for children of all ages. Doxycycline (100 mg, given orally bid) for 14–21 days may be used for children older than age 8 years. Erythromycin (30 mg/kg/d) or cefuroxime is used in penicillin-allergic children, although erythromycin may be less effective than amoxicillin.

B. ARTHRITIS

The amoxicillin or doxycycline regimen (same dosage as for the rash) should be used, but treatment should continue for 4 weeks. Parenteral ceftriaxone (75–100 mg/kg/d) or penicillin G (300,000 units/kg/d, given intravenously in four divided doses for 2–4 weeks) is used for persistent arthritis.

C. BELL PALS

The same oral drug regimens may be used for 3–4 weeks.

D. OTHER NEUROLOGIC DISEASE OR CARDIAC DISEASE

Parenteral therapy for 2–3 weeks is recommended with either ceftriaxone (75–100 mg/kg/d in one daily dose) or

penicillin G (300,000 units/kg/d intravenously in four divided doses).

I. INFECTIONS: PARASITIC

Parasitic diseases are common and may present clinically in a variety of ways (Table 39–1). Although travel to endemic areas suggests particular infections, many are transmitted through fomites or acquired from contact with human carriers and can occur anywhere. Some of the less common parasitic infections and those seen primarily in the developing world are presented in abbreviated form in Table 39–2.

Selection of Patients for Evaluation

The incidence of parasitic infections varies greatly with geographic area. Children who have traveled or lived in areas where parasitic infections are endemic are at risk for infection with a variety of intestinal and tissue parasites. Children who have resided only in developed countries are usually free of tissue parasites (except *Toxoplasma*). Searching for intestinal parasites is expensive for the patient and time-consuming for the laboratory. More than 90% of ova and parasite examinations performed in most hospital laboratories in the United States are negative; many have been ordered inappropriately. An approach to determining which children with diarrhea need such examinations is presented in Figure 39–1. It can be more cost-effective to treat symptomatic US immigrants with albendazole or nitazoxanide, broad-spectrum antiparasitic drugs, and to investigate only those whose symptoms persist.

Immunodeficient children are very susceptible to protozoal intestinal infections. Multiple opportunists are frequently identified, and the threshold for ordering tests should be low for these children.

Specimen Processing

For tissue parasites, contact the laboratory for proper collection procedures. Diarrheal stools may contain

trophozoites that die rapidly during transport. The specimen should be either examined immediately or placed in a stool fixative such as polyvinyl alcohol. Fixative vials for home collection of stool are available. They may contain toxic compounds, so they should be stored safely. Fixed specimens are stable at room temperature. Formed stools usually contain cysts that are more stable. It is best to fix these also after collection, but they may be reliably examined after transport at room temperature.

Eosinophilia & Parasitic Infections

Although parasites commonly cause eosinophilia, in developed countries other causes are much more common and include allergies, drugs, and other infections. Heavy intestinal nematode infections cause eosinophilia; they are easily detected on a single ova and parasite examination. Light nematode infections and common protozoal infections—giardiasis, cryptosporidiosis, and amebiasis—rarely cause eosinophilia. Eosinophilia is also unusual or minimal in more serious infections such as amebic liver abscess, toxoplasmosis, and malaria.

The most common parasitic infection in the United States that causes significant eosinophilia with negative stool examination is toxocariasis. In a young child with unexplained eosinophilia and a negative stool examination, a serologic test for *Toxocara* may be the next appropriate test. Trichinosis is a rare cause of marked eosinophilia; strongyloidiasis is a cause of eosinophilia that may be difficult to diagnose with stool examinations. The differential diagnosis of eosinophilia is broad for patients who have been in developing countries.

Table 39–1. Symptoms of parasitic infection.

Sign	Agent	Comments ^a
Abdominal pain	<i>Anisakis</i>	Shortly after raw fish ingestion.
	<i>Ascaris</i>	Heavy infection may obstruct bowel, biliary tract.
	<i>Clonorchis</i>	Heavy, early infection. Hepatomegaly later.
	<i>Entamoeba histolytica</i>	Hematochezia, variable fever, diarrhea.
	<i>Fasciola hepatica</i>	Diarrhea, vomiting.
	Hookworm	Iron deficiency anemia with heavy infection.
	<i>Strongyloides</i>	Eosinophilia, pruritus. May resemble peptic disease.
	<i>Trichinella</i>	Myalgia, periorbital edema, eosinophilia.
Cough	<i>Trichuris</i>	Diarrhea, dysentery with heavy infection.
	<i>Ascaris</i>	Wheezing, eosinophilia during migration phase.
	<i>Paragonimus westermani</i>	Hemoptysis; chronic. May mimic tuberculosis.
	<i>Strongyloides</i>	Wheezing, pruritus, eosinophilia during migration or dissemination.
	<i>Toxocara</i>	Affects ages 1–5 y; hepatosplenomegaly; eosinophilia.
Diarrhea	Tropical eosinophilia	Pulmonary infiltrates, eosinophilia.
	<i>Blastocystis</i>	Possibly with heavy infection in immunosuppressed or immunocompetent individuals.
	<i>Cryptosporidium</i>	Watery; prolonged in normals, chronic in immunosuppressed individuals.
	<i>Dientamoeba fragilis</i>	Only with heavy infection.
	<i>Entamoeba histolytica</i>	Hematochezia, variable fever; no eosinophilia.
	<i>Giardia</i>	Afebrile, chronic; anorexia; no hematochezia or eosinophilia.
	<i>Schistosoma</i>	Chronic; hepatosplenomegaly (some types).
	<i>Strongyloides</i>	Abdominal pain; eosinophilia.
Dysentery	<i>Trichinella</i>	Myalgia, periorbital edema, eosinophilia.
	<i>Trichuris</i>	With heavy infection.
	<i>Balantidium coli</i>	Swine contact.
	<i>Entamoeba histolytica</i>	Few to no leukocytes in stool; fever; hematochezia.
Dysuria	<i>Schistosoma</i>	During acute infection.
	<i>Trichuris</i>	With heavy infection.
	<i>Enterobius</i>	Usually girls with worms in urethra, bladder; nocturnal, perianal pruritus.
Headache (and other cerebral symptoms)	<i>Schistosoma</i>	Hematuria. Exclude bacteriuria, stones (some types).
	<i>Angiostrongylus</i>	Eosinophilic meningitis.
	<i>Naegleria</i>	Fresh-water swimming; rapidly progressive meningoencephalitis.
	<i>Plasmodium</i>	Fever, chills, jaundice, splenomegaly. Cerebral ischemia (with <i>P falciparum</i>).
	<i>Taenia solium</i>	Cysticercosis. Focal seizures, deficits; hydrocephalus, aseptic meningitis.
	<i>Toxoplasma</i>	Meningoencephalitis (especially in the immunosuppressed); hydrocephalus in infants.
	<i>Trypanosoma</i>	African forms. Chronic lethargy (sleeping sickness).

(continued)

Table 39–1. Symptoms of parasitic infection. (continued)

Sign	Agent	Comments ^a
Pruritus	<i>Ancylostoma braziliense</i>	Creeping eruption; dermal serpiginous burrow.
	<i>Enterobius</i>	Perianal, nocturnal.
	Filaria	Variable; seen in many filarial diseases.
	Hookworm	Local at penetration site in heavy exposure.
	<i>Strongyloides</i>	Diffuse with migration; may be recurrent.
	<i>Trypanosoma</i>	African forms; one of many nonspecific symptoms.
Fever	<i>Entamoeba histolytica</i>	With acute dysentery or liver abscess.
	<i>Leishmania donovani</i>	Hepatosplenomegaly, anemia, leukopenia.
	<i>Plasmodium</i>	Chills, headache, jaundice; periodic.
	<i>Toxocara</i>	Cough, hepatosplenomegaly, eosinophilia.
	<i>Toxoplasma</i>	Generalized adenopathy; splenomegaly.
	<i>Trichinella</i>	Myalgia, periorbital edema, eosinophilia.
	<i>Trypanosoma</i>	Early stage, African forms; lymphadenopathy.
Anemia	<i>Diphyllobothrium</i>	Megaloblastic due to B ₁₂ deficiency; rare.
	Hookworm	Iron deficiency.
	<i>Leishmania donovani</i>	Fever, hepatosplenomegaly, leukopenia (kala-azar).
	<i>Plasmodium</i>	Hemolysis.
	<i>Trichuris</i>	Heavy infection due to iron loss.
Eosinophilia	<i>Angiostrongylus</i>	Eosinophilic meningitis.
	<i>Fasciola</i>	Abdominal pain.
	Filaria	Microfilariae in blood. Lymphadenopathy.
	<i>Onchocerca</i>	Skin nodules, keratitis.
	<i>Schistosoma</i>	Chronic; intestinal or genitourinary symptoms.
	<i>Strongyloides</i>	Abdominal pain, diarrhea.
	<i>Toxocara</i>	Hepatosplenomegaly, cough; affects ages 1–5 y.
	<i>Trichinella</i>	Myalgia, periorbital edema.
	Tropical pulmonary eosinophilia	Cough.
Hematuria	<i>Schistosoma</i>	<i>S haematobium</i> . Bladder, urethral granulomas. Exclude stones, bacteriuria.
Hemoptysis	<i>Paragonimus westermani</i>	Lung fluke. Variable chest pain; chronic.
Hepatomegaly	<i>Clonorchis</i>	Heavy infection. Tenderness early; cirrhosis late.
	<i>Echinococcus</i>	Chronic; cysts.
	<i>Entamoeba histolytica</i>	Toxic hepatitis or abscess. No eosinophilia.
	<i>Leishmania donovani</i>	Splenomegaly, fever, pancytopenia.
	<i>Schistosoma</i>	Chronic; hepatic fibrosis, splenomegaly (some types).
	<i>Toxocara</i>	Splenomegaly, eosinophilia, cough; no adenopathy.

(continued)

Table 39–1. Symptoms of parasitic infection. (continued)

Sign	Agent	Comments ^a
Splenomegaly	<i>Leishmania donovani</i>	Hepatomegaly, fever, anemia.
	<i>Plasmodium</i>	Fever, chills, jaundice, headache.
	<i>Schistosoma</i>	Hepatomegaly.
	<i>Toxocara</i>	Eosinophilia, hepatomegaly.
	<i>Toxoplasma</i>	Lymphadenopathy, other symptoms.
Lymphadenopathy	Filaria	Inguinal typical; chronic.
	<i>Leishmania donovani</i>	Hepatosplenomegaly, pancytopenia, fever.
	<i>Schistosoma</i>	Acute infection; fever, rash, arthralgia, hepatosplenomegaly.
	<i>Toxoplasma</i>	Cervical common; may involve single site; splenomegaly.
	<i>Trypanosoma</i>	Localized near bite or generalized hepatosplenomegaly (Chagas disease); generalized (especially posterior cervical) in African forms.

^aSymptoms usually related to degree of infestation. Infestation with small numbers of organisms is often asymptomatic.

PROTOZOAL INFECTIONS

SYSTEMIC INFECTIONS

1. Malaria

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in or travel to an endemic area.
- Cyclic paroxysms of chills, fever, and intense sweating.
- Headache, backache, cough, abdominal pain, nausea, vomiting, diarrhea.
- Coma, seizures.
- Splenomegaly, anemia.
- Malaria parasites in peripheral blood smear.

General Considerations

Malaria kills a million children worldwide each year and is undergoing a resurgence in areas where it was previously controlled. Approximately 1000 imported cases are diagnosed in the United States each year, but local transmission may also occasionally take place. The female anopheline mosquito transmits the parasites—*Plasmodium vivax* (most common), *P falciparum* (most virulent), *P ovale* (similar to *P vivax*), and *P malariae*.

The gametocytes ingested from an infected human form sporozoites in the mosquito; when inoculated into a susceptible host, these sporozoites infect hepatocytes. The preerythrocytic phase (hepatic) is about 1–2 weeks for all but *P malariae* infection (3–5 weeks), but the initial symptoms may be delayed for up to a year in *P falciparum*, 4 years in *P vivax*, and decades in *P malariae* infections. Merozoites released into the circulation from hepatocytes infect red cells (young cells by *P vivax* and *P ovale*, old cells by *P malariae*, and all cells by *P falciparum*) and begin the synchronous erythrocytic cycles—rupturing the infected cells at regular 48- or 72-h intervals. Asynchronous cycles causing daily fevers are most common in early stages of infection. Survival is associated with a progressive decrease in intensity of cycles; relapses years later may occur from persistent hepatic infection, which occurs in *P vivax* and *P ovale* infections. Infection acquired congenitally or from transfusions or needle sticks does not result in a hepatic phase.

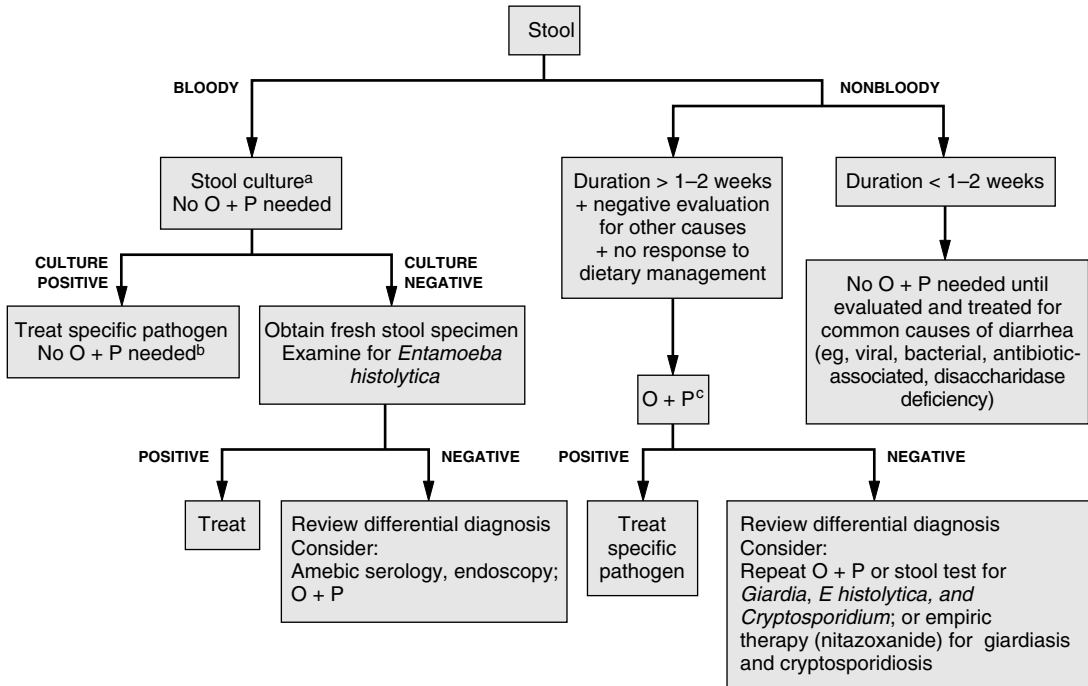

Susceptibility varies genetically; certain red cell phenotypes are partially resistant to *P falciparum* infection (hemoglobin S, hemoglobin F, thalassemia, and possibly glucose-6-phosphate dehydrogenase deficiency). The worldwide distribution of the four species is determined, to some extent, by host genetic factors. The absence of *P vivax* from Africa reflects the lack of specific Duffy blood group substances among most native Africans. Recurrent infections result in some natural species-specific immunity; this does not prevent infection but does decrease parasitemia and symptoms. Normal splenic function is an important factor because of

Table 39–2. Some parasitic infections seen less commonly in developed regions.

Agent (Disease)	Geographic Region	Vector	Symptoms and Signs	Laboratory Findings	Diagnosis	Therapy and Comments
<i>Trypanosoma cruzi</i> (Chagas disease)	South and Central America, Mexico	Reduviid bug	Acute: painful red nodule at bite site, conjunctivitis, periorbital edema (Romaña sign), fever, local ± generalized adenitis. Late: myocarditis, megaesophagus, megacolon.	Mononuclear leukocytosis	Organisms in peripheral blood. Positive serology.	Nifurtimox or benznidazole may help early. No therapy for late disease. May be transmitted by blood transfusion or congenitally.
<i>Trypanosoma brucei</i> (sleeping sickness)	Africa	Tsetse fly	Hepatosplenomegaly, adenopathy. Nodule at bite site (resolves). Recurrent fever, headache, myalgia, progressive encephalitis.	Elevated ESR, anemia, CSF pleocytosis	Organisms in blood, CSF, marrow, nodes. Positive serology.	Suramin, eflornithine, fentamidine, Melortopol.
<i>Leishmania donovani</i> (kala-azar)	Mideast, India, Mediterranean, South and Central America	Sandfly	Fever, generalized adenopathy, hepatosplenomegaly weeks to months after infection.	Pancytopenia, hypergammaglobulinemia	Organisms in marrow, nodes, spleen. Positive serology.	Sodium stibogluconate, meglumine antimonate, pentamidine, amphotericin B.
<i>Leishmania tropica</i> (Oriental sore)	Asia, India, North Africa	Sandfly	Papule at bite site (usually on face, limbs) develops after weeks to months, then ulcerates and scars.	—	Organisms in skin biopsy. Positive skin test, serology.	Same as for <i>L. donovani</i> .
<i>Leishmania braziliensis</i> , <i>L. mexicana</i> (chiclero ulcer)	South America	Sandfly	Painful mucocutaneous ulcers or granulomas. Nasolabial lesions common.	—	Skin biopsy. Positive skin test, serology.	Same as for <i>L. donovani</i> ; ketoconazole.

<i>Wuchereria, Brugia</i> (filariasis)	Tropics, subtropics	Mosquito	Chronic adenopathy, often inguinal. Obstructive lymphedema.	Eosinophilia	Concentrated blood smears for larvae. Positive serology.	Ivermectin, diethylcarbamazine kill larvae. Surgery for lymphatic obstruction.
<i>Angiostrongylus cantonensis</i> (eosinophilic meningitis)	Hawaii, Asia, Pacific Islands	Snails, slugs	Ingestion (usually inadvertent) followed in 1–4 wk by meningitis of variable severity. Paresthesias.	Eosinophils in CSF and blood	Positive serology. Larvae may be present in CSF.	Fever absent or low. No focal lesions on CNS imaging. No specific therapy. Steroids may be beneficial. Mebendazole may help.
<i>Paragonimus westermani</i> (lung fluke infection)	Asia, South America, Africa	Raw crabs, crustaceans	Cough, hemoptysis. Rarely seizures, other CNS signs if migration to brain occurs.	—	Large ova in concentrated specimens, feces. Cystic nodular lesions on chest radiograph or CNS imaging.	Resembles pulmonary tuberculosis. Praziquantel very effective.
<i>Clonorchis sinensis</i> (liver fluke infection)	Asia	Raw fish	Adult flukes obstruct biliary tree. Acute: hepatomegaly, fever, jaundice, urticaria. Late: cirrhosis, carcinoma.	Variable liver function abnormalities	Ova in feces.	Praziquantel. Advanced disease not treatable. Liver transplant.

CNS = central nervous system; ESR = erythrocyte sedimentation rate.

O + P = Ova and parasite examination.

^a *Shigella*, *Salmonella*, *Campylobacter*, *E. coli* (*Escherichia coli*) 0157, *Yersinia*; assay for *Clostridium difficile* toxin if recent antimicrobial use.

^b Unless critically ill, from endemic area for amebiasis, or unresponsive to standard therapy.

^c Include examination for *Cryptosporidium* and *Cyclospora*; immediate stool fixation needed if stool is diarrheal.

Figure 39–1. Parasitologic evaluation of acute diarrhea.

the immunologic and filter function of the spleen. Asplenic persons develop rapidly progressive malaria with many circulating infected erythrocytes (including mature forms of *P falciparum*). Maternal immunity protects the neonate.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical manifestations vary according to species, strain, and host immunity. The infant presents with recurrent bouts of fever, irritability, poor feeding, vomiting, jaundice, and splenomegaly. Rash is usually absent, which helps distinguish malaria from viral infections in patients presenting with similar symptoms. In older children, the pathognomonic constellation of headache, backache, chills, myalgia, and fatigue is more easily elicited. Fever may be cyclic (every 48 hours for all but *P malariae* infection, in which it occurs every 72 hours) or irregular (most commonly observed with *P falciparum*). Between attacks, patients may look quite well. If the disease is untreated, relapses cease within a year in

P falciparum and within several years in *P vivax* infections but may recur decades later with *P malariae* infection. Infection during pregnancy often causes intrauterine growth retardation or premature delivery but rarely true fetal infection.

Physical examination in patients with uncomplicated cases may show only mild splenomegaly and anemia.

B. LABORATORY FINDINGS

The diagnosis of malaria relies on detection of one or more of the four human plasmodia in blood smears. Most acute infections are caused by *P vivax*, *P ovale*, or *P falciparum*, although 5–7% are due to multiple species. Giemsa-stained thick smears offer the highest diagnostic accuracy for malaria parasites. Identification of the *Plasmodium* species relies on morphologic criteria (Table 39–3) and requires an experienced observer.

Alternative techniques of similar or higher diagnostic accuracy for *P falciparum* include enzyme-linked immunosorbent assay (ELISA), DNA hybridization, and polymerase chain reactors (PCR). A unique feature of

Table 39–3. Differentiation of malaria parasites on blood smears.

	<i>Plasmodium falciparum</i>	<i>P vivax, P ovale</i>
Multiple infected erythrocytes	Common	Rare
Mature trophozoites or schizonts	Absent ^a	Common
Schüffner dots	Absent	Common
Enlarged erythrocytes	Absent	Common
Banana-shaped gametocytes	Common	Absent

^aUsually sequestered in the microcirculation. Rare cases with circulating forms have extremely high parasitemia and a poor prognosis.

the microscopic examination is the semiquantitative estimate of the parasitemia, which is best done on thin smears. This information is particularly useful in the management of infections caused by *P falciparum*, in which high parasitemia (more than 10% infected erythrocytes or more than 500,000 infected erythrocytes/ μ L) is associated with high morbidity and mortality and requires hospitalization. Treatment response of *P falciparum* and chloroquine-resistant *P vivax* infections is best monitored by daily parasitemia assays: Constant or increased number of infected erythrocytes after 48 hours of treatment or after the second hemolytic crisis suggests an inadequate therapeutic response. Other laboratory findings that reflect the severity of hemolysis include decreased hematocrit, hemoglobin, and haptoglobin levels; increased reticulocyte count; and hyperbilirubinemia and increased lactate dehydrogenase (LDH). Thrombocytopenia is common, but the incidence of leukocytosis is variable.

Differential Diagnosis

Relapsing fever may be associated with borreliosis, brucellosis, sequential common infections, Hodgkin disease, juvenile rheumatoid arthritis, rat-bite fever, or one of the idiopathic periodic fevers. Other common causes of high fever and headache include influenza, *Mycoplasma pneumoniae* or enteroviral infection, sinusitis, meningitis, enteric fever, tuberculosis, occult pneumonia, or bacteremia. Fever, headache, and jaundice in a patient returning from tropical areas indicate that leptospirosis and yellow fever should be included in the differential diagnosis. Malaria may also coexist with other diseases.

Complications & Sequelae

Severe complications are limited to *P falciparum* infection and result from microvascular obstruction and tissue ischemia. Impaired consciousness and seizures are the most common complications of malaria in children. In addition, respiratory failure, renal impairment, severe bleeding, and shock are associated with a poor prognosis. Among the laboratory abnormalities, hypoglycemia, acidosis, elevated aminotransferases, and parasitemia greater than 10% characterize severe malaria.

Prevention

Malaria chemoprophylaxis should be instituted 2 weeks (weekly regimens) to 2 days (daily regimens) before traveling to an area of endemic infection to permit changes if the drug is not tolerated. Because the antimalarial drugs recommended for prophylaxis do not kill sporozoites, therapy should be continued for 1 week (atovaquone/proguanil) or 4 weeks (all other regimens) after returning from an endemic area to cover infection acquired at departure.

Chloroquine is the drug of choice for prophylaxis of *P vivax*, *P ovale*, *P malariae*, and chloroquine-sensitive *P falciparum* (Table 39–4). Chloroquine is safe for all ages and during pregnancy. Side effects (dizziness, blurred vision, headache) can be reduced by administering half of the weekly dose twice per week. Effects of chloroquine on heart rhythm are infrequent and are typically associated with rapid intravenous infusion or overdosage. Chloroquine has immunosuppressive properties and has been reported to impair immunization against rabies but not against yellow fever.

For chloroquine-resistant *P falciparum*, the regimens of choice are weekly mefloquine, daily doxycycline, or daily atovaquone/proguanil. The side effects of mefloquine are headache, dizziness, and blurred vision. This drug is now considered safe during pregnancy but is not used in children weighing less than 15 kg. Daily doxycycline is recommended for patients older than age 8 years who are unable to tolerate mefloquine. Women on prolonged doxycycline therapy tend to develop yeast vaginitis, and it is advisable to supply them with nystatin suppositories. Atovaquone/proguanil is better tolerated than mefloquine. For optimal absorption, this drug should be administered with food or no later than 45 minutes after a meal. Daily primaquine is also effective. Primaquine is also used to prevent relapse of *P vivax* or *P ovale* infections. Primaquine is contraindicated for patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, in whom it induces hemolysis. Less effective alternatives include chloroquine plus proguanil or chloroquine alone, with one therapeutic dose of pyrimethamine/sulfadoxine made available for

Table 39–4. Chemoprophylaxis of malaria.^a

Drug	Dosage
Chloroquine-sensitive areas^b	
Chloroquine	5 mg base/kg/wk up to 300 mg (adult dose)
Chloroquine-resistant areas	
Mefloquine	0.25 tablet (62.5 mg) once a week (15–19 kg) 0.5 tablet (125 mg) (20–30 kg) 0.75 tablet (187.5 mg) (31–45 kg) 1 tablet (250 mg) (> 45 kg)
Doxycycline	2 mg/kg/d (age > 8 years) up to 100 mg (adult dose)
Atovaquone/proguanil	11–20 kg: 62.5 mg/25 mg daily 21–30 kg: 125 mg/50 mg 31–40 kg: 187.5 mg/75 mg > 40 kg: 250 mg/100 mg
Primaquine	0.5 mg/kg base daily up to 30 mg (adult dose)
Chloroquine	As above
plus	
Proguanil	50 mg daily (age < 2 y) 100 mg (age 2–6 y) 150 mg (age 7–10 y) 200 mg (age > 10 y)
or	
Pyrimethamine-sulfadoxine for presumptive treatment (carry a single dose for self-treatment of febrile illness when medical care is not immediately available)	< 1 y: 1/4 tablet 1–3 y: 1/2 tablet 4–8 y: 1 tablet 9–14 y: 2 tablets > 14 y: 3 tablets
Relapse of <i>P vivax</i> or <i>P ovale</i>^c	
Primaquine	0.3 mg base/kg/d up to 15 mg (adult dose) during the last 2 wk of prophylaxis

^aUpdated malaria chemoprophylaxis information may be obtained by calling the Centers for Disease Control and Prevention Hot Line at 404-332-4555 or on the web at www.cdc.gov.

^bChloroquine-resistant *Plasmodium falciparum* has not yet been identified in Central America west of the Panama Canal zone, Haiti, Dominican Republic, Mexico, and most of the Middle East.

^cOptional. Observation and prompt initiation of treatment when relapse occurs is sufficient.

self-treatment in the advent of potential breakthrough, signaled by fever, in areas where medical attention is not readily available.

No drug regimen guarantees protection against malaria. If fever develops within 1 year (particularly within 2 months) after travel to an endemic area, patients should be advised to seek medical attention. Insect repellents, insecticide-impregnated bed nets, and proper clothing are important adjuncts for malaria prophylaxis.

Treatment

Treatment for malaria includes a variety of supportive strategies in addition to the antimalarial drugs. It is advisable to hospitalize nonimmune patients infected with *P falciparum* until a decrease in parasitemia is demonstrated, indicating that treatment is effective and severe complications are unlikely to occur.

Partially immune patients with uncomplicated *P falciparum* infection and nonimmune persons infected with *P vivax*, *P ovale*, or *P malariae* can receive treatment as outpatients if follow-up is reliable. For children, hydration and treatment of hypoglycemia are of utmost importance. Anemia, seizures, pulmonary edema, and renal failure require conventional management. Corticosteroids are contraindicated for cerebral malaria because of increased mortality. In severe malaria, exchange transfusion can be life-saving, particularly in nonimmune persons with parasitemia greater than 15%.

Chloroquine is the drug of choice for treatment of infection with chloroquine-sensitive plasmodia (Table 39–5). For patients unable to take oral medication, intravenous chloroquine or quinidine can be administered with careful monitoring for potential arrhythmogenic effects. Therapy can later be converted to oral chloroquine. For chloroquine-resistant *P falciparum* infection, oral therapy includes quinine with pyrimethamine/sulfadoxine, tetracycline, doxycycline, or clindamycin. Two-drug treatment shortens the quinine course from 7 to 3 days unless the malaria is severe or was acquired in areas of multidrug-resistant *P falciparum* (South America and Southeast Asia). Other options are mefloquine, halofantrine, and atovaquone/proguanil. Artemether* and artesunate* are very effective against *P falciparum*, including quinine-resistant strains. However, cardiovascular toxicity might be a limiting factor. If chemoprophylaxis failed to protect the patient, the same drug should not be used for treatment. Halofantrine should not be used as treatment for persons who failed mefloquine chemoprophylaxis, because the two drugs exhibit cross-resistance. Patients in-

*Not licensed in USA

Table 39–5. Treatment of malaria.

Drug	Dosage
Chloroquine-sensitive plasmodia	
Chloroquine	10 mg base/kg up to 600 mg, followed either by 5 mg base/kg after 6, 24, and 48 h, or 5 mg base/kg after 12, 24, and 36 h
Chloroquine-resistant <i>P falciparum</i>	
A. Oral regimens	
1. Quinine sulfate	25 mg/kg/d up to 2g/d in three doses for 3–7 d
plus	
Pyrimethamine-sulfadoxine	¼ tablet on the last day of quinine (age < 1 y) ½ tablet (age 1–3 y) 1 tablet (age 4–8 y) 2 tablets (age 9–14 y) 3 tablets (age > 15 y)
or	
Tetracycline	20 mg/kg/d up to 1 g/d in four doses for 7 d
or	
Doxycycline	3 mg/kg/d up to 100 mg as single daily dose for 7 d
or	
Clindamycin	20–40 mg/kg/d up to 2700 mg in three doses for 3 d
2. Mefloquine	25 mg/kg up to 1250 mg as a single dose
3. Halofantrine	8 mg/kg up to 500 mg every 6 h for three doses; repeat in 1 wk
4. Atovaquone/proguanil	11–20 kg: 1 tablet (250 mg/100 mg) daily for 3 d 21–30 kg: 2 tablets 31–40 kg: 3 tablets > 40 kg: 4 tablets
B. Parenteral regimen	
Quinidine gluconate	10 mg/kg up to 600 mg as loading dose IV in normal saline slowly over 1–2 h followed by continuous infusion of 0.02 mg/kg/min until oral therapy can be started
Chloroquine-resistant <i>P vivax</i>	
Mefloquine	25 mg/kg up to 1250 mg in a single dose
Halofantrine	8 mg/kg up to 500 mg/kg every 6 h for three doses; repeat in 1 week
Prevention of relapse with <i>P vivax</i> or <i>P ovale</i>	
Primaquine phosphate ^a	0.3 mg base/kg/d up to 15 mg base/d for 14 d

^aScreen for glucose-6-phosphate dehydrogenase deficiency.

ected with chloroquine-resistant *P falciparum* who cannot take oral medication should receive intravenous quinidine, which is two or three times more active than quinine. Serum levels of quinidine can be measured in most North American hospitals. Chloroquine-resistant *P vivax* infection, which has been identified in Papua New Guinea, Irian Jaya (in Indonesia), India, Brazil, and Colombia, can be treated with mefloquine or halofantrine. *P vivax* or *P ovale* infections in persons living in nonendemic areas are usually treated with primaquine to prevent late relapse.

2. Babesiosis

Babesia microti is a malaria-like protozoan that infects and lyses erythrocytes of wild and domestic animals in North America and Europe. In the United States, human babesiosis occurs in the coastal areas of Massachusetts, Rhode Island, and New York. Humans accidentally enter the cycle when bitten by *Ixodes scapularis*, one of the intermediate hosts and vectors of *B microti*. After inoculation, the protozoan penetrates the erythrocytes and starts an asynchronous cycle that causes hemolysis.

Clinical Findings

The incubation period is 1–3 weeks but may extend up to 6 weeks. Many times the tick bite is unnoticed. Symptoms are nonspecific and include sustained or cyclic fever up to 40°C, shaking chills, malaise, myalgias, headache, and dark urine. Hepatosplenomegaly is an uncommon finding. The disease is usually self-limited, but severe cases have been described in asplenic patients and immunocompromised hosts. Because *Babesia* and *Borrelia burgdorferi* share another vector, *Ixodes dammini*, dual infection may occur.

Diagnosis

Microscopic evaluation of thin or thick blood smears reveals the intraerythrocytic organisms that resemble *P falciparum* ring forms. Specific serology is also available through the Centers for Disease Control and Prevention. IgG titers greater than or equal to 1:1024 are diagnostic of acute infection.

Treatment

Clindamycin (20 mg/kg/d, up to 600 mg every 6 hours) or azithromycin (500 mg on the first day, followed by 250 mg/d) in combination with quinine (25 mg/kg/d, up to 650 mg every 6–8 hours) or azithromycin and atovaquone (750 mg bid) for 7–10 days is the treatment of choice. Other antimalarial drugs, including chloroquine, have been unsuccessful.

3. Toxoplasmosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Congenital toxoplasmosis: chorioretinitis, microphthalmia, strabismus, microcephaly, hydrocephaly, convulsions, psychomotor retardation, intracranial calcifications, jaundice, hepatosplenomegaly, abnormal blood cell counts.*
- *Acquired toxoplasmosis in an immunocompetent host: lymphadenopathy, hepatosplenomegaly, rash.*
- *Acquired or reactivated toxoplasmosis in an immunocompromised host: encephalitis, chorioretinitis, myocarditis, and pneumonitis.*
- *Ocular toxoplasmosis: chorioretinitis.*
- *Serologic evidence of infection with Toxoplasma gondii or demonstration of the agent in tissue or body fluids.*

General Considerations

Toxoplasma gondii is a worldwide parasite of animals and birds. Felines, the definitive hosts, excrete oocysts in their feces. Ingested mature oocysts or tissue cysts lead to tachyzoite invasion of the intestinal cells. Intracellular replication of the tachyzoites cause cell lysis and spread of the infection to adjacent cells or to other tissues via the bloodstream. In chronic infection, *T gondii* appears as bradyzoite-containing tissue cysts that do not trigger an inflammatory reaction. In immunocompromised hosts, tachyzoites are released from the cysts and begin a new cycle of infection. The two major routes of *Toxoplasma* transmission to humans are oral (including pica

and congenital). Oocysts survive for up to 18 months in moist soil. Oral infection occurs after ingestion of cyst-containing undercooked meat or other food products. Oocyst survival is limited in dry, very cold, or very hot conditions, and at high altitude, which probably accounts for the lower incidence of toxoplasmosis in these climatic regions. In the United States, less than 1% of cattle and 25% of sheep and pigs are infected with toxoplasmosis. In humans, depending on geographic area, seropositivity increases with age from nil–10% in children younger than age 10 years to 3–70% in adults. Congenital transmission occurs during acute infection of pregnant women; this occurs in 0.2–1% of all pregnancies in the United States. Rarely, fetal infection has been documented in immunocompromised mothers who have chronic toxoplasmosis. The rate of vertical transmission in patients with untreated toxoplasmosis increases from 10% in the first trimester to 60% in the third. Symptomatic disease, however, is more likely to follow infection in early gestation (20–25%) compared with late gestation (less than 11%). Treatment during pregnancy decreases transmission by 60%.

Clinical Findings

A. CONGENITAL TOXOPLASMOSIS

Congenital toxoplasmosis has a variety of manifestations, including miscarriage, prematurity, and stillbirth. Most frequently, symptomatic infants present with a combination of fever, microcephaly or hydrocephaly, hepatosplenomegaly, jaundice, chorioretinitis, convulsions, abnormal cerebrospinal fluid (CSF) (xanthochromia and mononuclear pleocytosis), and cerebral calcifications. Other findings include strabismus, eye palsy, maculopapular rash, pneumonitis, myocarditis, thrombocytopenia, lymphocytosis and monocytosis, and an erythroblastosis-like syndrome. The overall mortality rate for congenital toxoplasmosis, which is approximately 10%, is higher in neonates who are symptomatic at birth. Congenital toxoplasmosis must be differentiated from cytomegalovirus infection, rubella, herpes simplex infection, syphilis, Lyme disease, listeriosis, erythroblastosis, and the encephalopathies that accompany degenerative diseases.

B. ACQUIRED TOXOPLASMA INFECTION IN THE IMMUNOCOMPETENT HOST

Only 10–20% of acute *Toxoplasma* infections produce symptoms. Patients usually present with lymphadenopathy without fever. The nodes are discrete, variably tender, and do not suppurate. Cervical lymph nodes are most frequently involved, but any nodes may be enlarged. Less common findings include fever, malaise, myalgias, fatigue, hepatosplenomegaly, low lymphocyte counts (usually less than 10%), and liver enzyme eleva-

tions. Unilateral chorioretinitis may occur. The disease is self-limited, although lymph node enlargement may persist or may wax and wane for a few months to 1 or even more years. Rarely, an apparently healthy child may develop severe disseminated disease associated with myocarditis, pneumonitis, or encephalitis.

Toxoplasmic lymphadenitis must be distinguished from other causes of infectious mononucleosis-like syndromes (< 1% are caused by *Toxoplasma*).

C. ACUTE TOXOPLASMOSIS IN THE IMMUNODEFICIENT HOST

Patients with human immunodeficiency virus (HIV), lymphoma, leukemia, or transplantation are at high risk for developing severe disease (encephalitis, chorioretinitis, myocarditis, or pneumonitis) following acute infection or reactivation. Children born to HIV- and *Toxoplasma*-infected mothers may acquire both pathogens in utero.

D. OCULAR TOXOPLASMOSIS

In active congenital toxoplasmosis, chorioretinitis is usually bilateral and shows acute inflammatory foci on funduscopic examination. This generally resolves, leaving depigmented scars of the retina surrounded by areas of hyperpigmentation. Chorioretinitis may reactivate in a single eye later in life. The appearance of the ocular lesion is not specific and mimics other granulomatous ocular diseases.

Diagnosis

Active infection is diagnosed by demonstration of *T gondii* or its DNA in blood or body fluids; seeing tachyzoites in histologic sections or cytology preparations; cysts in placenta or fetal tissues; characteristic lymph node histology; or typical serology (most commonly used). IgG antibodies, measured by the Sabin–Feldman dye test, immunofluorescence, ELISA, or particle agglutination, become detectable 1–2 weeks after infection, peak at 1–2 months, and, after decreasing at variable speed, persist for life. IgM antibodies, measured by ELISA or particle agglutination, appear earlier and decline faster than IgG antibodies. Absence of both serum IgG and IgM virtually rules out the diagnosis of toxoplasmosis. Acute toxoplasmosis in an immunocompetent host is best documented by analyzing IgG and IgM in paired blood samples drawn 3 weeks apart. Because high antibody titers (IgM or IgG) can persist for several months after acute infection, a single high-titer determination is nonspecific. However, seroconversion or a fourfold increase in titer confirms the diagnosis.

In the immunocompromised host, serology is not sensitive, and active infection is documented by PCR or finding tachyzoites by histologic examination.

Patients with *Toxoplasma* chorioretinitis typically have low levels of specific IgG and absent IgM. The diagnosis can be confirmed by demonstrating high anti-body titers in aqueous fluid.

Congenital infection is documented by anti-*Toxoplasma* IgM or IgA antibodies in the blood of the neonate. Prenatal diagnosis of congenital infection requires a combination of ultrasonography (to detect ventricle enlargement) and amniotic fluid PCR or cord blood serology. Amniotic fluid PCR is highly sensitive and carries fewer risks than cord puncture.

Differential Diagnosis

Congenital infection may resemble that due to cytomegalovirus, syphilis, rubella, or herpes simplex. Acquired infection mimics viral, bacterial, or lymphoproliferative disorders.

Prevention

Pregnant women and immunocompromised patients should wash hands thoroughly after handling raw meat, cook meat to 66°C or greater, wash fruits and vegetables before consumption, and avoid contact with cat feces. Serologic screening of pregnant women is warranted in areas of high prevalence. A first test should be performed by 10–12 weeks of pregnancy. Seronegative patients should be retested at 20–22 weeks' gestation and near term. Seroconverters require specific therapy.

Treatment

Treatment does not reverse central nervous system (CNS) damage in neonates but does markedly decrease late sequelae. A year of treatment is recommended for all congenitally infected infants; symptomatic patients receive 6 months of pyrimethamine and sulfadiazine, followed by alternating spiramycin and pyrimethamine–sulfadiazine monthly for the next 6 months. Subclinical infection is treated with pyrimethamine and sulfadiazine for 6 weeks, followed by alternating spiramycin for 6 weeks with pyrimethamine–sulfadiazine for 4 weeks.

Oral pyrimethamine at 1 mg/kg/d (maximum 25 mg) causes gastrointestinal upset, leukopenia, thrombocytopenia, and, rarely, agranulocytosis. Frequent blood counts should be performed to guide therapy. Leucovorin calcium (folinic acid), 5 mg given intramuscularly every 3 days, decreases myelotoxicity. The dosage of sulfadiazine or trisulfapyrimidines is 40–45 mg/kg twice a day orally (maximum 8 g/d). Clindamycin can be substituted for sulfadiazine in patients who cannot tolerate sulfonamides. Spiramycin and trimethoprim–sulfamethoxazole are less active.

In acquired infection, usually self-limited, the potentially toxic therapy should be prescribed with discretion, only if the illness is complicated.

In chorioretinitis, antimicrobial therapy is used for 4 weeks. A course of corticosteroids (prednisone, 1.5 mg/kg up to 75 mg) is recommended when lesions involve the macula or the optic nerve. Lesions tend to improve after 10 days of therapy.

In primary infection during pregnancy, spiramycin is started immediately. Pyrimethamine plus sulfadiazine, alternating every 3 weeks with spiramycin, are used when fetal infection has been documented.

GASTROINTESTINAL INFECTIONS

1. Amebiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Acute dysentery: diarrhea with blood and mucus, abdominal pain, tenesmus.

or

- *Chronic nondysenteric diarrhea.*

or

- *Hepatic abscess.*
- *Amebas or cysts in stool or abscesses; amebic antigen in stool.*
- *Serologic evidence of amebic infection.*

General Considerations

Amebiasis, caused by *Entamoeba histolytica*, is a common problem in areas with poor hygiene. An estimated 10% of the world's population is infected with *E histolytica* or *Entamoeba dispar*, and an estimated 100,000 people die of amebic infection each year. Amebiasis should be suspected in patients with a history of travel to, or contact with individuals who may be asymptomatic carriers from, endemic areas. In the United States, amebiasis may occur in homes for the handicapped, where poor hygiene fosters the spread of enteric pathogens. *E histolytica* has been found in the stools of as many as 30% of homosexual men. Individuals of any age may be infected. Transmission is usually fecal-oral, often from asymptomatic carriers who pass cysts. Trophozoites are killed by stomach acid and are not infectious. Infection with *E dispar*, which is morphologically identical to *E histolytica* but results only in asymptomatic carriage, is ten times more

common than infection with *E histolytica*. Furthermore, only 10% of *E histolytica* infections result in gastrointestinal or other symptoms.

Clinical Findings

Patients with intestinal amebiasis can present with asymptomatic cyst passage, acute amebic proctocolitis, chronic nondysenteric colitis, or ameboma. Because all *E dispar* infections and up to 90% of *E histolytica* infections are asymptomatic, carriage is the most common manifestation of amebiasis. Patients with acute amebic colitis typically have a 1- to 2-week history of watery stools containing blood and mucus, abdominal pain, and tenesmus. A minority of patients are febrile or dehydrated. Abdominal examination may reveal pain over the lower abdominal quadrants. Fulminant colitis is an unusual complication of amebic dysentery and is associated with a grave prognosis (more than 50% mortality). Patients with fulminant colitis present with severe bloody diarrhea, fever, and diffuse abdominal pain. Children younger than age 2 years appear to be at increased risk for this condition. Chronic amebic colitis is clinically indistinguishable from idiopathic inflammatory bowel disease; patients present with recurrent episodes of bloody diarrhea over a period of years. Ameboma is a localized amebic infection, usually in the cecum or ascending colon, which presents as a painful abdominal mass.

The most common complication of intestinal amebiasis is intestinal perforation and peritonitis. Perianal ulcers, a less common complication, are painful, punched-out lesions that usually respond to medical therapy. Infrequently, colonic strictures may develop following colitis.

Extraintestinal amebiasis can result in liver, lung, and cerebral abscesses and, rarely, genitourinary disease. Patients with amebic liver abscess, the most common form of extraintestinal amebiasis, present with recent-onset fever and right upper quadrant tenderness. The pain may be dull or pleuritic or referred to the right shoulder. Physical examination reveals liver enlargement in less than 50% of affected patients. Some patients have a subacute presentation lasting 2 weeks to 6 months. In these patients, hepatomegaly, anemia and weight loss are common findings, and fever is less common. Jaundice and diarrhea are rarely associated with an amebic liver abscess.

The most common complication of amebic liver abscess is pleuropulmonary amebiasis due to rupture of a right liver lobe. Lung abscesses may occur from hematogenous spread. Cough, dyspnea, and pleuritic pain can also be caused by the serous pleural effusions and atelectasis that frequently accompany amebic liver abscesses. Rupture of hepatic abscesses can lead to peritonitis and more rarely to pericarditis. Cerebral amebia-

sis is an infrequent manifestation. Genitourinary amebiasis, which is also uncommon, results from rupture of a liver abscess, hematogenous dissemination, or lymphatic spread.

Diagnosis

Intestinal amebiasis is diagnosed by detecting the parasite on stool examination or mucosal biopsy. The differential diagnosis of acute amebic colitis includes bacillary diarrhea and perhaps infection with *Balantidium coli* and *Dientamoeba fragilis*, which have occasionally been associated with acute diarrhea but whose pathogenic role remains controversial. Chronic amebic colitis has to be distinguished from inflammatory bowel disease, *Cyclospora*, and perhaps *B coli*. Occult blood is present in virtually all cases of amebic colitis and can be used as an inexpensive screening test. Fecal leukocytes are uncommon. The presence of hematophagous trophozoites in feces indicates pathogenic *E histolytica* infection.

Ideally, a wet mount of the stool should be examined no longer than 20 minutes after collection to detect motile trophozoites. Otherwise, specimens should be fixed with polyvinyl alcohol or refrigerated to avoid disintegration of the trophozoites. The use of three separate stool examinations has 90% sensitivity for the diagnosis of amebic dysentery. However, infection of the ascending colon, amebomas, and extraintestinal infections frequently yield negative stool examinations. The antigen detection test for stool is very sensitive and more specific, because it detects *E histolytica*-specific antigens that do not cross-react with *E dispar*. Colonoscopy and biopsy are most helpful in diagnosing amebic colitis when stool samples lack ova or parasites. Barium studies are contraindicated for patients with suspected acute amebic colitis because of the risk of perforation.

The presence of antibodies against *E histolytica* can differentiate *E histolytica* from *E dispar* infections. The antibody response follows both intestinal and extraintestinal invasive amebiasis and can be used for diagnostic purposes. ELISA and indirect hemagglutination assays are positive in 85–95% of invasive *E histolytica* colitis or amebic abscess. However, these antibodies persist for years, and a positive result does not distinguish between acute and past infection. Noninvasive imaging studies have greatly improved the diagnosis of hepatic abscesses. Ultrasonographic examination and computed tomography (CT) are sensitive techniques that can guide fine-needle aspiration to obtain specimens for definitive diagnosis. Because an amebic abscess may take up to 2 years to completely resolve on CT scans, imaging techniques are not recommended for therapeutic evaluation.

Table 39–6. Treatment of amebiasis.

Type of Infection	Drug of Choice	Dosage
Asymptomatic	Iodoquinol	30–40 mg/kg/d up to 2 g/d in three doses for 20 d
	or Paromomycin	25–35 mg/kg/d in three doses for 7 d
	or Diloxanide furoate ^a	20 mg/kg/d up to 1.5 g/d in three doses for 10 d
Intestinal disease and hepatic abscess ^b	Metronidazole	35–50 mg/kg/d up to 2.25 g/d in three doses for 10 d
	or Tinidazole ^c	50 or 60 mg/kg up to 2 g/d for 3 d

^aDiloxanide furoate is available from the CDC Drug Service, 404-639-3670.

^bTreatment should be followed by iodoquinol or another intraluminal cysticidal agent.

^cNot marketed in the United States; higher dosage is for hepatic abscess.

Treatment & Prevention

Treatment of amebic infection is complex because different agents are required for eradicating the parasite from the bowel or tissue (Table 39–6). Whether treatment of asymptomatic cyst passers is indicated is a controversial issue. The prevalent opinion is that asymptomatic infection with *E histolytica*, as evidenced by amebic cysts in the stool and a positive serologic test, should be treated in nonendemic areas. If serology is negative, the cysts are more likely to represent infection with the nonpathogenic *E dispar*, which does not require treatment. Among the drugs active against intraluminal cysts, iodoquinol is the most readily available but also the most toxic (causing prominent gastrointestinal side effects, interfering with thyroid function, and causing dose-dependent optic neuritis). Paromomycin, a nonabsorbable aminoglycoside, can be used safely during pregnancy and has only mild intestinal side effects, including flatulence and increased number of stools. Diloxanide furoate is relatively nontoxic and used widely outside the United States. The treatment of invasive amebiasis requires metronidazole. Metronidazole has a disulfiram-like effect and should be avoided in patients receiving ethanol-containing medications. Tinidazole, a more potent nitroimidazole against amebic infection can be used for shorter treatment courses and is well tolerated in children.

In patients who cannot tolerate metronidazole or tinidazole, erythromycin and tetracycline are active against intestinal trophozoites but are inactive against trophozoites in liver abscesses. Conversely, chloroquine is active only against hepatic amebiasis. Treatment of invasive amebiasis should always be followed with an intraluminal cysticidal agent, even if the stool examination is negative. Patients with large, thin-walled hepatic abscesses may need therapeutic aspiration to avoid abscess rupture. Patients with amebiasis should be placed under enteric precautions. Travelers to endemic areas need to follow the precautions designed to prevent enteric infections—drink bottled or boiled water and eat cooked or peeled vegetables and fruits.

Thielman NM et al: Acute infectious diarrhea. *N Engl J Med* 2004;350:38 [PMID: 14702426].

2. Giardiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic relapsing diarrhea, flatulence, bloating, anorexia, poor weight gain.
- Absence of fever and hematochezia.
- Detection of trophozoites, cysts, or *Giardia* antigens in stool.

General Considerations

Giardiasis is the most common intestinal protozoal infection in children in the United States and in most of the world. It is caused by *Giardia lamblia*. Endemic worldwide, the infection is classically associated with drinking contaminated water, either in rural areas or in areas with faulty purification systems. But even ostensibly clean urban water supplies can be contaminated intermittently. Persons have acquired the infection in swimming pools. Fecal–oral contamination allows person-to-person spread. Day care centers have become a major source of infection, with an incidence of up to 50% reported in some centers. No symptoms occur in 25% of infected persons, facilitating spread to household contacts. Food-borne outbreaks also occur. Although infection is rare in neonates, giardiasis may occur at any age.

Clinical Findings

A. SYMPTOMS AND SIGNS

Giardia infection is followed by asymptomatic cyst passage, acute self-limited diarrhea, or a chronic syndrome

of diarrhea, malabsorption, and weight loss. Acute diarrhea occurs 1–2 weeks after infection and is characterized by abrupt onset of diarrhea with greasy, malodorous stools; malaise; flatulence; bloating; and nausea. Fever and vomiting occur in a minority of patients. Urticaria, reactive arthritis, biliary tract disease, gastric infection, and constipation have occasionally been reported. The disease has a protracted course (> 1 week) and frequently leads to weight loss. Patients who develop chronic diarrhea complain of profound malaise, lassitude, headache, and diffuse abdominal pain in association with bouts of diarrhea—most typically foul-smelling, greasy stools—intercalated with periods of constipation or normal bowel habits. This syndrome can persist for months until specific therapy is administered or until it subsides spontaneously. Chronic diarrhea frequently leads to malabsorption, steatorrhea, vitamin A and vitamin B₁₂ deficiencies, and disaccharidase depletion. Lactose intolerance, which develops in 20–40% of patients, can persist for several weeks after treatment and needs to be differentiated from relapsing giardiasis or reinfection.

B. LABORATORY FINDINGS

The diagnosis of giardiasis relies on finding the parasite in stool or duodenal aspirates or detecting *Giardia* antigen in feces. For ova and parasite examination, a fresh stool provides the best examination results. Liquid stools have the highest yield of trophozoites, which are more readily found on wet mounts. With semifformed stools, the examiner should look for cysts in fresh or fixed specimens, preferably using a concentration technique. When these techniques are applied carefully, one examination has a 50–70% sensitivity; three examinations increase the sensitivity to 90%. Antigen assays detect *Giardia* by means of immunofluorescence or ELISA. They are comparable in cost to a stool ova and parasite examination and are 85–90% sensitive and 95–100% specific. With a careful stool ova and parasite examination or with the use of a new antigen test, direct sampling of the duodenal contents should be restricted to particularly difficult cases. Three methods are currently available: the string test (Entero-Test), duodenal aspiration, and duodenal biopsy.

Treatment & Prevention

Metronidazole is the drug of choice for treatment of giardiasis. When given at 5 mg/kg (up to 250 mg) three times daily for 5 days, metronidazole has 80–95% efficacy. The drug is well tolerated in children. It has a disulfiram-like effect and should be avoided in patients receiving ethanol-containing medication. Metronidazole can be administered safely during pregnancy. Furazolidone is frequently used in children as an alternative

drug because it is available in suspension. Administered at 1.5 mg/kg (up to 100 mg) four times daily for 7–10 days, it has only 80% efficacy. Furazolidone may cause gastrointestinal side effects, turn urine red, and cause mild hemolysis in patients with G6PD deficiency. For patients who do not respond to metronidazole or furazolidone or who suffer relapse, a second course with the same drug or switching to the other drug is equally effective. In cases of repeated treatment failure, albendazole (400 mg/day for 5–10 days), although not specifically released in the United States for the treatment of giardiasis, is an effective option. Tinidazole, which is not available in the United States, and the recently FDA-approved broad-spectrum antiparasitic nitazoxanide have higher efficacy than any of the drugs already mentioned. Furthermore, nitazoxanide is available in liquid formulation and reduces the duration of treatment to 3 days. Recommended doses are 100 mg (5 mL) every 12 hours for children 12–4 months of age and 200 mg (10 mL) for 4- to 11-year-olds.

The prevention of giardiasis requires proper treatment of water supplies and interruption of person-to-person transmission. Travelers to developing countries or wilderness areas should halogenate or boil (for over 10 minutes) drinking water and avoid uncooked foods that might have been washed with contaminated water. Sexual transmission is prevented by avoiding oral–anal and oral–genital sex. Interrupting fecal–oral transmission requires strict hand washing. However, outbreaks of diarrhea in day care centers might be particularly difficult to eradicate, and reinforcing hand-washing and treating the disease in both symptomatic and asymptomatic carriers may be necessary.

Aboud P et al: Successful treatment of metronidazole- and albendazole-resistant giardiasis with nitazoxanide in a patient with acquired immunodeficiency syndrome. *Clin Infect Dis* 2001;32:1792 [PMID: 11360222].

Thielman NM et al: Acute infectious diarrhea. *N Engl J Med* 2004;350:38 [PMID: 14702426].

3. *Cryptosporidiosis*

Cryptosporidium parvum is an intracellular protozoan that has gained importance because it causes severe diarrhea in patients with acquired immunodeficiency syndrome (AIDS) and in other immunodeficient persons. The parasite is ubiquitous and infects and reproduces itself in the epithelial cell lining of the digestive and respiratory tracts of humans and most other vertebrate animals. Humans acquire the infection from contaminated water supplies or from close contact with infected humans or animals.

Clinical Findings

A. SYMPTOMS AND SIGNS

Immunocompetent persons infected with *Cryptosporidium* usually develop self-limited diarrhea (2–26 days) with or without abdominal cramps. Diarrhea is intermittent and scant or continuous, watery, and voluminous. Low-grade fever, nausea, vomiting, loss of appetite, and malaise may accompany the diarrhea. Young children (< age 2 years) appear more susceptible to infection than are older children. Immunocompromised patients (either cellular or humoral deficiency) tend to develop prolonged disease, which usually subsides only after the immunodeficiency is corrected. Other clinical manifestations associated with cryptosporidiosis in immunocompromised hosts include cholecystitis, pancreatitis, hepatitis, and respiratory symptoms.

B. LABORATORY FINDINGS

Cryptosporidiosis has no characteristic laboratory features other than identification of the microorganism in feces or on biopsy. ELISA and PCR tests are more sensitive than staining of stool specimens or concentrates.

Treatment & Prevention

Immunocompetent patients and those with temporary immunodeficiencies may benefit from treatment with nitazoxanide, antidiarrheal agents, and hydration. Immunocompromised patients usually require more intense supportive care with parenteral nutrition in addition to hydration and nonspecific antidiarrheal agents. Octreotide acetate, a synthetic analogue of somatostatin that inhibits secretory diarrhea, has been associated with symptomatic improvement but not with parasitologic cure. Among the antiparasitic agents, nitazoxanide, paromomycin/azithromycin, rifabutin, and hyperimmune bovine colostrum, in that order, have met with success. For patients with AIDS, institution of effective antiretroviral therapy eliminates symptomatic cryptosporidiosis. Prevention of *Cryptosporidium* infection is limited by oocyst resistance to some of the standard water purification procedures and to common disinfectants. Enteric precautions are recommended for infected persons. Boiled or bottled drinking water may be considered for those at high risk for developing chronic infection (eg, patients with AIDS).

Amadi B et al: Effect of nitazoxanide on morbidity and mortality in Zambian children with cryptosporidiosis: A randomized controlled trial. *Lancet* 2002;360:1375 [PMID: 12423984].

Chen X et al: Cryptosporidiosis. *N Engl J Med* 2002;346:1723 [PMID: 12037153].

4. Cyclosporiasis

Cyclospora is a coccidian with worldwide distribution that infects both humans and animals. It causes food-associated outbreaks, characterized by an incubation period of 2–11 days followed by watery diarrhea in relapsing patterns, sometimes alternating with constipation. Other symptoms include profound fatigue, vomiting, and myalgias. Although the illness is self-limited, it may last for several weeks. Diagnosis is based on finding oocysts 8–10 mm in diameter on examination of stool specimens stained with acid-fast stain. The treatment of choice is trimethoprim–sulfamethoxazole for 7 days.

Herwaldt BL: Cyclospora cayetanensis: A review, focusing on the outbreaks of cyclosporiasis in the 1990s. Clin Infect Dis 2000;31:1040 [PMID: 11049789].

5. Free-Living Amebas

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute meningoencephalitis: fever, headache, meningismus, acute mental deterioration.
- Swimming in warm, fresh water in endemic areas.
- Chronic granulomatous encephalitis: insidious onset of focal neurologic deficits.
- Keratitis: pain, photophobia, conjunctivitis, blurred vision.

General Considerations

Infections with free-living amebas are uncommon. *Naegleria* species, *Acanthamoeba* species, and *Balamuthia* (previously called leptomaxid) amebas have been associated with human disease.

Acute meningoencephalitis, caused by *N fowleri*, occurs mostly in children and young adults. Patients present with abrupt fever, headache, nausea and vomiting, meningismus, and decreased mental status a few days to 2 weeks after swimming in warm fresh-water lakes. Swimming history may be absent. CNS invasion occurs after nasal inoculation of *N fowleri*. The disease is rapidly progressive, and death ensues within 1 week of onset.

Chronic granulomatous encephalitis, caused by *Acanthamoeba* or *Balamuthia*, occurs most commonly in patients who are immunocompromised from corticosteroid use, chemotherapy, or AIDS. There is no association with fresh-water swimming. This disease has

an insidious onset of focal neurologic deficits, and approximately 50% of patients present with headache. Skin, sinus, or lung infections with *Acanthamoeba* precede many of the CNS infections and may still be present at the onset of neurologic disease. The granulomatous encephalitis progresses to fatal outcome over a period of weeks to months (average 6 weeks).

Acanthamoeba keratitis is a corneal infection associated with minor trauma or use of soft contact lenses in otherwise healthy persons. Frequently misdiagnosed as herpes simplex or bacterial keratitis, *Acanthamoeba* keratitis has a characteristic dendriform epithelial pattern that suggests the diagnosis.

Diagnosis

Amebic encephalitis should be included in the differential diagnosis of acute meningoencephalitis in children with a history of recent fresh-water swimming. The CSF is usually hemorrhagic, with leukocyte counts that may be normal early in the disease but later range from 400 to 2600/μL with neutrophil predominance, low to normal glucose, and elevated protein. The etiologic diagnosis relies on finding trophozoites on a wet mount of the CSF.

Granulomatous encephalitis is diagnosed by brain biopsy of CT-identified nonenhancing lucent areas. The CSF of these patients is usually nondiagnostic with intermediate white blood cell counts, elevated protein, and decreased glucose. *Acanthamoeba* or leptomaxid amebas have not been found in the CSF; however, they can be visualized in biopsies or grown from brain or other infected tissues.

Acanthamoeba keratitis is diagnosed by finding the trophozoites in corneal scrapings or by isolating the parasite from corneal specimens or contact lens cultures.

Treatment & Prevention

The few patients who have survived acute amebic meningoencephalitis received high-dose intravenous and intrathecal amphotericin B, accompanied by miconazole, rifampin, and sulfisoxazole in some cases. The first two cases of successful treatment of *Balamuthia* encephalitis were reported after combination therapy with flucytosine, pentamidine, fluconazole, sulfadiazine, and a macrolide.

Acanthamoeba keratitis responds well to surgical debridement followed by 3–4 weeks of topical 1% miconazole; 0.1% propamidine isethionate; and polymyxin B sulfate, neomycin, bacitracin (Neosporin).

Because primary amebic meningitis occurs infrequently, active surveillance of lakes for *N fowleri* is not warranted. However, in the presence of a documented case, it is advisable to close the implicated lake to swim-

ming. *Acanthamoeba* keratitis can be prevented by heat disinfection of contact lenses, by storage of lenses in sterile solutions, and by not wearing lenses when swimming in fresh water.

Deetz TR et al: Successful treatment of *Balamuthia* amoebic encephalitis: Presentation of two cases. *Clin Infect Dis* 2003; 37:1304 [PMID: 14583863].

Kumar R et al: Recent advances in the treatment of *Acanthamoeba* keratitis. *Clin Infect Dis* 2002;35:434 [PMID: 12145728].

McKee T et al: Primary amebic meningoencephalitis—Georgia, 2002. *MMWR* 2003;52:962 [PMID: 14534512].

TRICHOMONIASIS

Trichomonas vaginalis is discussed in Chapter 40.

METAZOAL INFECTIONS

NEMATODE INFECTIONS

1. Enterobiasis (Pinworms)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Anal pruritus.
- Worms in the stool or eggs on perianal skin.

General Considerations

This worldwide infection is caused by *Enterobius vermicularis*. The adult worms are about 5–10 mm long and live in the colon; females deposit eggs on the perianal area, primarily at night, causing intense pruritus. Scratching contaminates the fingers and allows transmission back to the host (autoinfection) or to contacts.

Clinical Findings

A. SYMPTOMS AND SIGNS

Although blamed for myriad symptoms, pinworms are definitely associated only with localized pruritus. Adult worms may migrate within the colon or up the urethra or vagina in girls. They can be found within the bowel wall, in the lumen of the appendix (usually an incidental finding by the pathologist), in the bladder, and even in the peritoneal cavity of girls. The granulomatous reaction that may be present around these ectopic worms is usually asymptomatic. Worm eradication may correspond with the cure of recurrent urinary tract infections in some young girls.

B. LABORATORY FINDINGS

The usual diagnostic test consists of pressing a piece of transparent tape on the child's anus in the morning prior to bathing, then placing it on a drop of xylene on a slide. Microscopic examination under low power usually demonstrates the ova. Occasionally eggs or adult worms are seen in fecal specimens. Parents may also notice adult worms.

Differential Diagnosis

Nonspecific irritation or vaginitis, streptococcal perianal cellulitis (usually painful; marked erythema), and vaginal or urinary bacterial infections may at times resemble pinworm infection, although the symptoms of pinworms are often so suggestive that a therapeutic trial is justified without a confirmed diagnosis.

Treatment

A. SPECIFIC MEASURES

Treat all household members at the same time to prevent reinfections. Because the drugs are not active against the eggs, therapy should be repeated after 2 weeks to kill the recently hatched adults.

Pyrantel pamoate is given as a single dose (11 mg/kg, maximum 1 g); it is safe and very effective. Mebendazole and albendazole are highly effective for this and other helminthic infections. A single oral dose of 100 mg mebendazole or 400 mg albendazole is used for all ages.

B. GENERAL MEASURES

Personal hygiene must be emphasized. Nails should be kept short and clean. Children should wear undergarments to bed to diminish contamination of fingers; bedclothes should be laundered frequently. Although eggs may be widely dispersed in the house and multiple family members infected, the disease is mild and treatable. Avoid creating in the parents an excessive concern with contamination.

St Georgiev V: Chemotherapy of enterobiasis (oxyuriasis). *Expert Opin Pharmacother* 2001;2:267 [PMID: 11336585].

2. Ascariasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal cramps and discomfort.
- Large, white or reddish, round worms, or ova in the feces.

General Considerations

Ascaris lumbricoides is a worldwide human parasite. Ova passed by carriers may remain viable for months under the proper soil conditions. The ova contaminate food or fingers and are subsequently ingested by a new host. The larvae hatch, penetrate the intestinal wall, enter the venous system, reach the alveoli, are coughed up, and return to the small intestine, where they mature. The female lays thousands of eggs daily.

Clinical Findings

A. SYMPTOMS AND SIGNS

Infections usually remain asymptomatic; severe cases, however, can be associated with pain, weight loss, anorexia, diarrhea, or vomiting. Adult worms may be seen in feces or vomitus. Rarely, they perforate or obstruct the small bowel, biliary system, or appendix. Large numbers of larvae migrating through the lungs may cause an acute, transient eosinophilic pneumonia (Löffler syndrome).

B. LABORATORY FINDINGS

The diagnosis is made by observing the large round worms in the stool or by microscopic detection of the ova.

Treatment

Because the adult worms live less than a year, asymptomatic infection need not be treated. Mebendazole (100 mg twice daily for 3 days), pyrantel pamoate (a single dose of 11 mg/kg, maximum 1 g), and albendazole (400 mg in a single dose) are highly and equally effective. In cases of intestinal or biliary obstruction, piperazine (150 mg/kg initially, followed by six doses of 65 mg/kg every 12 hours by nasogastric tube) is recommended because it narcotizes the worms and helps relieve obstruction. However, surgical removal is occasionally required.

3. Trichuriasis (Whipworm)

Trichuris trichiura is a widespread human and animal parasite common in children living in warm, humid areas conducive to survival of the ova. The adult worms live in the cecum and colon; the ova are passed and become infectious after several weeks in the soil. Ingested infective eggs hatch in the upper small intestine. Unlike *Ascaris*, *Trichuris* does not have a migratory tissue phase. Symptoms are not present unless the infection is severe, in which case pain, diarrhea, and mild abdominal distention are present. Massive infections may also cause rectal prolapse and dysentery. Detection of the

characteristic barrel-shaped ova in the feces confirms the diagnosis. Adult worms may be seen in the prolapsed rectum or at proctoscopy; their thin heads are buried in the mucosa, and the thicker posterior portions extrude. Mild to moderate eosinophilia may be present.

Mebendazole (100 mg orally twice daily for 3 days) or albendazole (400 mg in a single dose) improves gastrointestinal symptoms and terminates constitutional symptoms.

Crompton DW et al: Nutritional impact of intestinal helminthiasis. *Ann Rev Nutr* 2002;22:35 [PMID: 12055337].

4. Hookworm

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Iron deficiency anemia.
- Abdominal discomfort, weight loss.
- Ova in the feces.

General Considerations

The common human hookworms are *Ancylostoma duodenale* and *Necator americanus*. Both are widespread in the tropics and subtropics. The larger *A duodenale* is more pathogenic because it consumes more blood, up to 0.5 mL per worm per day.

The adults live in the jejunum. Eggs are passed in the feces and develop and hatch into infective larvae in warm, damp soil within 2 weeks. The larvae penetrate human skin on contact, enter the blood, reach the alveoli, are coughed up and swallowed, and develop into adults in the intestine. The adult worms attach with their mouth parts to the mucosa, from which they suck blood. Blood loss is the major sequela of infection. Infection rates reach 90% in areas without sanitation.

A separate species, *A braziliense* (dog or cat hookworm), causes creeping eruption (cutaneous larva migrans). This disease occurs mainly on the warm-water American coasts.

Clinical Findings

A. SYMPTOMS AND SIGNS

The larvae usually penetrate the skin of the feet and cause intense local itching (ground itch). This subsides as the larvae continue their migration. Löffler syndrome

may supervene during lung migration. In creeping eruption, the nonhuman *Ancylostoma* larvae migrate blindly in the skin before dying, creating serpiginous burrows.

Mild intestinal infections produce no symptoms. Severe infections cause iron deficiency anemia and malnutrition. Occasionally abdominal pain and diarrhea may be observed.

B. LABORATORY FINDINGS

The large ova of both species of hookworm are found in feces and are indistinguishable. Microcytic anemia, hypoalbuminemia, eosinophilia, and hematochezia occur in severe cases.

Prevention

Fecal contamination of soil and skin contact with potentially contaminated soil should be avoided.

Treatment

A. SPECIFIC MEASURES

Mebendazole (100 mg orally twice daily for 3 days) and pyrantel pamoate (11 mg/kg, maximum 1 g, daily for 3 days) are the drugs of choice. Topical thiabendazole or albendazole or oral thiabendazole are useful for creeping eruption.

B. GENERAL MEASURES

Iron therapy may be as important as worm eradication.

Prognosis

The outcome is usually excellent.

Caumes E: Treatment of cutaneous larva migrans. *Clin Infect Dis* 2000;30:811 [PMID: 10816151].

5. Strongyloidiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal pain, diarrhea.
- Eosinophilia.
- Larvae in stools and duodenal aspirates.
- Serum antibodies.

General Considerations

Strongyloides stercoralis is unique in having both parasitic and free-living forms; the latter can survive in the soil for several generations. The parasite is found in most tropical and subtropical regions of the world. The adults live in the submucosal tissue of the duodenum and occasionally elsewhere in the intestines. Eggs deposited in the mucosa hatch rapidly; the first-stage (rhabditiform) larvae, therefore, are the predominant form found in duodenal aspirates and feces. The larvae mature rapidly to the tissue-penetrating filariform stage and initiate internal autoinfection. The filariform larvae also inhabit the soil and can penetrate the skin of another host, subsequently migrating into veins and pulmonary alveoli, reaching the intestine when coughed up and swallowed.

Older children and adults are infected more often than are young children. Even low worm burden can result in significant clinical symptoms. Infestations due to poor sanitation and hygiene in homes for the retarded are noteworthy. Immunosuppressed patients may develop fatal disseminated strongyloidiasis, known as the hyperinfection syndrome.

Clinical Findings

A. SYMPTOMS AND SIGNS

At the site of the skin penetration, a pruritic rash may occur. Large numbers of migrating larvae can cause wheezing, cough, and hemoptysis. Although one third of intestinal infections are asymptomatic, the most prominent features of strongyloidiasis include abdominal pain, distention, diarrhea, vomiting, and occasionally malabsorption.

Patients with cellular immunodeficiencies and those on steroid therapy may develop disseminated infection involving the intestine, the lungs, and the meninges. Gram-negative sepsis may complicate disseminated strongyloidiasis.

B. LABORATORY FINDINGS

Finding larvae in the feces, in duodenal aspirates, on a string test (Entero-Test), or in sputum is diagnostic. IgG antibodies measured by ELISA or immunoblot are sensitive and specific for *Strongyloides*. These persist after successful therapy. Marked eosinophilia is common.

Differential Diagnosis

Strongyloidiasis should be differentiated from peptic disease, celiac disease, regional or tuberculous enteritis, hookworm infection, and other causes of intestinal symptoms or malabsorption. The pulmonary phase

may mimic asthma or bronchopneumonia. Patients with severe infection can present with an acute abdomen.

Treatment & Prevention

Thiabendazole (25 mg/kg orally twice daily for 2 days; maximum 3 g/d) and ivermectin (200 mg/kg/d for 1 or 2 days) are the drugs of choice. Relapses are common. In the hyperinfection syndrome, 2–3 weeks of therapy may be necessary. Patients from endemic areas should be tested for specific antibodies and receive treatment before undergoing immunosuppression.

Keiser PB et al: Strongyloides stercoralis in the immunocompromised population. *Clin Microbiol Rev* 2004;17:208 [PMID: 14726461].

6. Visceral Larva Migrans (Toxocariasis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Visceral involvement including hepatomegaly, marked eosinophilia, and anemia.
- Posterior or peripheral ocular inflammatory mass.
- Elevated antibody titers in serum or aqueous fluid; demonstration of *Toxocara* larvae on biopsy.

General Considerations

Visceral larva migrans is a worldwide disease. The agent is the cosmopolitan intestinal ascarid of dogs and cats, *Toxocara canis* or *Toxocara cati*. The eggs passed by infected animals contaminate parks and other areas that young children frequent. Children with pica are at increased risk. In the United States, seropositivity ranges from 2.8% in unselected populations to 23% in southern states to 54% in rural areas. Ingested eggs hatch and penetrate the intestinal wall, then migrate to the liver, lungs, eyes, and other organs, where they die and incite a granulomatous inflammatory reaction.

Clinical Findings & Diagnosis

A. VISCERAL LARVA MIGRANS

Toxocariasis is usually asymptomatic, but young children (age 1–5 years) sometimes present with anorexia, fever, fatigue, pallor, abdominal distention, abdominal pain, nausea, vomiting, and cough. Hepatomegaly is

common, splenomegaly is unusual, and adenopathy is absent. Lung involvement, usually asymptomatic, can be demonstrated readily by radiologic examination. Seizures are common, but more severe neurologic abnormalities are infrequent. Eosinophilia with leukocytosis, anemia, and elevated liver function tests are typical laboratory findings. ELISA is sensitive, specific, and useful in confirming the clinical diagnosis. Most patients recover spontaneously, but disease may last up to 6 months.

B. OCULAR LARVA MIGRANS

This condition occurs in older children and adults who present with a unilateral posterior or peripheral inflammatory mass. History of visceral larva migrans and eosinophilia are typically absent. Anti-*Toxocara* antibody titers are low in the serum and high in vitreous and aqueous fluids.

Diagnosis

Hypergammaglobulinemia and elevated isohemagglutinins sometimes result from cross-reactivity between *Toxocara* antigens and human group A and B blood antigens. The diagnosis is confirmed by finding larvae in granulomatous lesions. Positive serology in high titers (optical density ≥ 0.5) and the exclusion of other causes of hypereosinophilia allow a presumptive diagnosis to be made in typical cases.

Differential Diagnosis

Diseases associated with hypereosinophilia must be considered. These include trichinosis (enlarged liver not common; muscle tenderness common), eosinophilic leukemia (rare in children; eosinophils are abnormal in appearance), collagen-vascular disease (those associated with eosinophilia are rare in young children), strongyloidiasis (no organomegaly; enteric symptoms are common), early ascariasis, tropical eosinophilia (occurring mainly in India), allergies, and hypersensitivity syndromes.

Treatment & Prevention

A. SPECIFIC MEASURES

The clinical benefit of specific anthelmintic therapy is not defined. Treatment with thiabendazole (25 mg/kg—maximum 3 g/d orally twice a day for 5–7 days), diethylcarbamazine (2 mg/kg three times a day orally for 7–10 days), albendazole (400 mg twice a day for 3–5 days), or mebendazole (100–200 mg twice a day for 5 days) is indicated for severe complications of brain, lung, or heart.

B. GENERAL MEASURES

Treating any cause of pica, such as iron deficiency, is important. Corticosteroids are used to treat marked inflammation of lung, eye, or other organs. Pets should be dewormed routinely. Other children in the household may be infected. Mild eosinophilia and positive serologic tests may be the only clue to their infection. Therapy is not necessary for these individuals.

7. Trichinosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Vomiting, diarrhea, and pain within 1 week of eating infected meat.
- Fever, periorbital edema, myalgia, and marked eosinophilia.

General Considerations

Trichinella spiralis is a small roundworm that inhabits hogs and several other meat-eating animals. The human cycle begins with ingestion of viable larvae in undercooked meat. In the intestine, the larvae develop into adult worms which mate and produce hundreds of larvae. The larvae enter the bloodstream and migrate to the striated muscle where they continue to grow and eventually encyst. Symptoms are caused by the inflammatory response in the intestines or muscle.

Clinical Findings

A. SYMPTOMS AND SIGNS

Most infections are asymptomatic. The initial bowel penetration may cause nausea, vomiting, diarrhea, and cramps within 1 week after ingestion of contaminated meat. This may progress to the classic myopathic form, which consists of fever, periorbital edema, myalgia, and weakness. Many organs may be infected by the migrating larvae: diaphragm, heart, lungs, kidneys, spleen, skin, and brain. Severe cerebral involvement may be fatal. Myocarditis may also be severe or fatal. Symptoms usually peak after 2–3 weeks but may last months.

B. LABORATORY FINDINGS

Marked eosinophilia is the rule. Serology confirms the diagnosis. Muscle biopsy is rarely necessary.

Differential Diagnosis

The classic symptoms are pathognomonic if one is aware of this disease. It has to be distinguished from dermatomyositis, typhoid fever, sinusitis, influenza with myopathy, and angioneurotic edema.

Prevention

Because a microscopic examination must be performed, meat in the United States is not inspected for trichinosis. Although all states require the cooking of hog swill, hog-to-hog or hog-to-rat cycles may continue. All pork and sylvatic meat (eg, bear or walrus) should be heated to at least 65°C. Freezing meat to at least –15°C for 3 weeks may also prevent transmission. Animals used for food should not be fed or allowed access to raw meat.

Treatment

Mebendazole has activity against the intestinal, circulating, and tissue stages of infection. The adult dose is 200–400 mg three times daily for 3 days followed by 400–500 mg three times daily for 10 days. Pediatric dosing has not been standardized. Concurrent corticosteroids are used in an attempt to prevent the Herxheimer reaction associated with treatment.

Prognosis

Death may occur within the first weeks, but most infections are self-limited.

Bruschi F et al: New aspects of human trichinellosis: The impact of new *Trichinella* species. *Postgrad Med J* 2002;78:15 [PMID: 11796866].

CESTODE INFECTIONS (FLUKES)

1. Taeniasis & Cysticercosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Mild abdominal pain; passage of worm segments (*taeniasis*).
- Focal seizures, headaches (*neurocysticercosis*).
- *Cysticerci* present in biopsy specimens, on plain films (as calcified masses), or on CT scan or magnetic resonance imaging.
- Proglottids and eggs in feces; specific antibodies in serum or CSF.

General Considerations

Both the beef tapeworm (*Taenia saginata*) and the pork tapeworm (*Taenia solium*) cause taeniasis. The adults live in the intestines of humans; the egg-laden distal segments, or proglottids, break off and are passed in feces, disintegrating and releasing the ova in the soil. After ingestion in food or water by cattle or pigs, the eggs hatch and the larvae migrate to and encyst in skeletal muscle. Encysted larvae in meat ingested by humans mature into adults.

Humans can be an intermediate host for *T solium* (but not *T saginata*), and the larvae released from ingested eggs encyst in a variety of tissues, especially muscle and brain. Full larval maturation occurs in 2 months, but the cysts cause little inflammation until they die months to years later. Inflammatory edema ensues with calcification or disappearance of the cyst. A slowly expanding mass of sterile cysts at the base of the brain may cause obstructive hydrocephalus (racemose cysticercosis).

Both parasites are distributed worldwide. Contamination of foods by eggs in human feces allows infection without exposure to meat or travel to endemic areas. Asymptomatic cases are common, but neurocysticercosis is a leading cause of seizures in endemic areas.

Person-to-person spread may occur, resulting in infection of individuals with no exposure to infected meat.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Taeniasis—In most tapeworm infections, the only clinical manifestation is the passage of fecal proglottids, white, motile bodies 1–2 cm in size. They occasionally crawl out onto the skin and down the leg, especially the larger *T saginata*. Children may harbor the adult worm for years and complain of abdominal pain, anorexia, and diarrhea.

2. Cysticercosis—Most cases are asymptomatic. Subcutaneous nodules of 1–2 cm may be the only sign. After several years, the cysticerci calcify and appear as radiographic opacities. Brain cysts may remain silent or cause seizures, headache, hydrocephalus, and basilar meningitis. Rarely, the spinal cord is involved. Neurocysticercosis manifests an average of 5 years after exposure but may cause symptoms in the first year of life. In the eye, cysts cause bleeding, retinal detachment, and uveitis. Definitive diagnosis requires histologic demonstration of larvae or cyst membrane. Presumptive diagnosis is often made by the characteristics of the cysts seen on CT scan or magnetic resonance imaging; the differential diagnosis may include tuberculosis, brain abscess, arachnoid cyst, and tumor. The presence of *T*

solium eggs in feces is uncommon but supports the diagnosis.

B. LABORATORY FINDINGS

Eggs or proglottids may be found in feces or on the perianal skin (using the tape method employed for pinworms). Eggs of both *Taenia* species are identical. The species are identified by examination of proglottids.

Peripheral eosinophilia is minimal or absent. CSF eosinophilia is seen in 10–75% of cases of neurocysticercosis; its presence supports an otherwise presumptive diagnosis.

ELISA antibody titers are eventually positive in up to 98% of serum specimens and over 75% of CSF specimens from patients with neurocysticercosis. Solitary cysts are associated with seropositivity less often than are multiple cysts. High titers tend to correlate with more severe disease. CSF titers are higher if cysts are near the meninges.

Treatment

A. TAENIASIS

Praziquantel (5–10 mg/kg once) and albendazole are equally effective. Feces free of segments or ova for 3 months suggest cure.

B. CYSTICERCOSIS

Specific treatment is reserved for patients with meningitis or parenchymal cysts. In contrast, those with inactive disease require only symptomatic treatment (anti-convulsants). Praziquantel and albendazole cause disappearance of noninflamed cysts and possibly more rapid resolution of inflamed ring-enhancing cysts. Albendazole, 15 mg/kg divided into three doses daily for 8 days, is the treatment of choice. Larval death may result in clinical worsening because of inflammatory edema. A short course of dexamethasone may decrease these symptoms. Giant subarachnoid cysts may require more than one cycle of therapy or surgery (or both). Follow-up scans every several months help assess the response to therapy. Treatment of patients with calcified lesions and seizure disorder results in a decrease of generalized seizures.

Prevention

The incidence in the United States is low, because beef and pork are inspected for taeniasis. Prevention requires proper cooking of meat, careful washing of raw vegetables and fruits, treatment of intestinal carriers, avoiding the use of human excrement for fertilizer, and providing proper sanitary facilities.

Prognosis

The prognosis is good in intestinal taeniasis. Symptoms associated with a few cerebral cysts may disappear in a few months; heavy brain infections may cause death or chronic neurologic impairment.

Garcia HH et al: A trial of antiparasitic treatment to reduce the rate of seizures due to cerebral cysticercosis. *N Engl J Med* 2004;350:249 [PMID: 14724304].

Proano JV et al: Medical treatment for neurocysticercosis characterized by giant subarachnoid cysts. *N Engl J Med* 2001;345: 879 [PMID: 11565520].

2. Hymenolepiasis

Hymenolepis nana, the cosmopolitan human tapeworm, is a common parasite of children; *Hymenolepis diminuta*, the rat tapeworm, is rare. The former is capable of causing autoinfection. Larvae hatched from ingested eggs penetrate the intestinal wall and then reenter the lumen to mature into adults. Their eggs are immediately infectious for the same or a new host. The adult is only a few centimeters long. Finding the characteristic eggs in feces is diagnostic.

H diminuta has an intermediate stage in rat fleas and other insects; children are infected when they ingest these insects.

Light infections with either tapeworm are usually asymptomatic; heavy infection can cause diarrhea and abdominal pain. Therapy is with praziquantel (25 mg/kg once).

3. Echinococcosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cystic tumors of liver, lung, kidney, bone, brain, and other organs.
- Eosinophilia.
- Urticaria and pruritus if cysts rupture.
- Protoscolices or daughter cysts in the primary cyst.
- Positive serology.
- Epidemiologic evidence of exposure

General Considerations

Dogs, cats, and other carnivores are the hosts for *Echinococcus granulosus*. Endemic areas include Aus-

tralia, New Zealand, and the southwestern United States, including Native American reservations where shepherding is practiced. The adult tapeworm lives in sheep intestines, and eggs are passed in the feces. When ingested by humans, the eggs hatch, and the larvae penetrate the intestinal mucosa and disseminate in the bloodstream. The larvae produce cysts; the primary sites of involvement are the liver (60–70%) and the lungs (20–25%). A unilocular cyst is most common. Over years, the cyst may reach 25 cm in diameter, although most are much smaller. The cysts of *Echinococcus multilocularis* are multilocular and demonstrate more rapid growth.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical disease is due to pressure from the enlarging cysts, vessel erosion, and sensitization to cyst or worm antigens. Liver cysts present as slowly expanding tumors that may cause biliary obstruction. Most are in the right lobe and extend inferiorly; 25% are on the upper surface and may be asymptomatic for years. Omental torsion or hemorrhage from vessel erosion may occur.

Rupture of a pulmonary cyst causes coughing, dyspnea, wheezing, urticaria, chest pain, and hemoptysis; cyst and worm remnants are found in sputum. Brain cysts may cause focal neurologic signs and convulsions; renal cysts cause pain and hematuria; bone cysts cause pain.

B. LABORATORY FINDINGS

Presumptive diagnosis is made by a combination of radiographic or ultrasonographic and serologic findings. ELISA, which is the method most widely used for antibody testing, is highly sensitive but has only limited specificity. Confirmation may be obtained by ultrasonography-guided fine-needle aspiration coupled with parasitologic exam for protoscolices, rostellar hooks, antigens, or DNA. Eosinophilia is variable and may be absent. Serologic tests are useful for diagnosis and follow-up of therapy.

C. IMAGING

Pulmonary or bone cysts may be visible on plain films. Other imaging techniques are preferred for cysts in other organs. Visualization of daughter cysts is highly suggestive of echinococcosis.

Differential Diagnosis

Tumors, bacterial or amebic abscess, and tuberculosis (pulmonary) must be considered.

Complications

Sudden cyst rupture with anaphylaxis, and death is the worst complication. If the patient survives, secondary infections from seeding of daughter cysts may occur. Segmental lung collapse, secondary bacterial infections, effects of increased intracranial pressure, and severe renal damage due to renal cysts are other potential complications.

Treatment

Definitive therapy of *E multilocularis* requires meticulous surgical removal of the cysts, preceded by careful injection of the cyst with formalin, iodine, or 95% alcohol solution to sterilize infectious protoscolexes, freezing the cyst wall and injecting silver nitrate prior to its removal, or puncture-aspiration/injection-reaspiration technique, which is best suited for treatment of multiple cysts. A surgeon familiar with this disease should be consulted. Medical therapy may be of additional benefit, particularly in disseminated disease. Albendazole (15 mg/kg/d for 28 days with repeat courses as necessary following a 14-day rest period) is effective in many cases of *E granulosus* infection (hydatid disease). If the cyst leaks or ruptures, the allergic symptoms must be managed immediately.

Prognosis

Patients with large liver cysts may be asymptomatic for years. Surgery is often curative for lung and liver cysts but not always for cysts in other locations. Secondary disease has a much worse prognosis; about 15% of patients with this disease die.

TREMATODE INFECTIONS

Schistosomiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Transient pruritic rash after exposure to fresh water.
- Fever, urticaria, arthralgias, cough, lymphadenitis, and eosinophilia.
- Weight loss, anorexia, hepatosplenomegaly.
- Hematuria, dysuria.
- Eggs in stool, urine, or rectal biopsy specimens.

General Considerations

One of the most common serious parasitic diseases, schistosomiasis, is caused by several species of *Schistosoma* flukes. *Schistosoma japonicum*, *S mekongi*, and *S mansoni* involve the intestines and *S haematobium* the urinary tract. The first two are found in eastern and southeastern Asia; *S mansoni* in tropical Africa, the Caribbean, and parts of South America; and *S haematobium* in northern Africa.

Infection is caused by free-swimming larvae (cercariae), which emerge from the intermediate hosts, certain species of fresh-water snails. The cercariae penetrate human skin, migrate to the liver, and mature into adults, which then migrate through the portal vein to lodge in the bladder veins (*S haematobium*), superior mesenteric veins (*S mekongi*, *S japonicum*), or inferior mesenteric veins (*S mansoni*). Clinical disease results primarily from inflammation caused by the many eggs that are laid in the perivascular tissues or that embolize to the liver. Escape of ova into bowel or bladder lumen allows microscopic visualization and diagnosis from stool or urine specimens, as well as contamination of fresh water and infection of the snail hosts that ingest them.

Clinical Findings

Much of the population in endemic areas is infected but asymptomatic. Only heavy infections produce symptoms.

A. SYMPTOMS AND SIGNS

The cercarial penetration may cause a pruritic rash; larval migration may cause fever, urticaria, and cough; the maturation phase may cause tender hepatospleno-

megaly followed by days to weeks of fever and malaise as the worms migrate to their final destination. Bladder infection results in dysuria, hematuria, reflux, stones, and incontinence. Secondary pyelonephritis and ureteral obstruction may occur. Intestinal infection is usually asymptomatic. The final stages of disease are characterized by hepatic fibrosis, portal hypertension, splenomegaly, ascites, and bleeding from esophageal varices. The chronic inflammation in the urinary tract associated with *S haematobium* infections may result in obstructive uropathy, stones, infection, bladder cancer, fistulas, and anemia due to chronic hematuria. Spinal cord granulomas and paraplegia due to egg embolization into the Batson plexus have been reported.

B. LABORATORY FINDINGS

The diagnosis is made by finding the species-specific eggs in feces (*S japonicum*, *S mekongi*, *S mansoni*, and occasionally *S haematobium*) or urine (*S haematobium* and occasionally *S mansoni*). A rectal biopsy may reveal *S mansoni* and should be done if other specimens are negative. Peripheral eosinophilia is common, and eosinophils may be seen in urine.

Prevention

The best prevention is to avoid contact with contaminated fresh water in endemic areas. Efforts to destroy the snail hosts have been successful in areas of accelerated economic development.

Treatment

A. SPECIFIC MEASURES

Praziquantel is the treatment of choice for schistosomiasis. A dosage of 40 mg/kg/d in two divided doses (*S mansoni* or *S haematobium*) or 20 mg/kg three times in 1 day (*S japonicum* or *S mekongi*) is very effective and nontoxic. Oxamniquine (20 mg/kg/d in two doses once per day) is an alternative regimen for treatment of *S mansoni* infection. Arthameter, 6 mg/kg every 3 weeks, may prevent new infections or reinfection after curative treatment.

B. GENERAL MEASURES

Medical therapy of nutritional deficiency or secondary bacterial infections may be needed. The patient's urinary tract should be evaluated carefully in *S haematobium* infection; reconstructive surgery may be needed. Hepatic fibrosis requires careful evaluation of the portal venous system and surgical management of portal hypertension when appropriate.

Prognosis

Medical therapy decreases the worm infection and liver size, despite continued exposure in endemic areas. Early disease responds well to therapy, but once significant scarring or severe inflammation has occurred, eradication of the parasites is of little benefit.

II. INFECTIONS: MYCOTIC

Fungi can be classified as yeasts, which are unicellular and reproduce by budding; as molds, which are multicellular and consist of tubular structures (hyphae) and grow by elongation and branching; or as dimorphic fungi, which can exist either as yeasts or molds depending on environmental conditions. Fungal infections can be categorized as shown in Table 39–7.

In the United States, systemic disease in normal hosts is commonly caused by three organisms—*Coccidioides*, *Histoplasma*, and *Blastomyces*—which are restricted to certain geographic areas. Prior residence in or travel to these areas, even for a brief time, is a prerequisite for inclusion in a differential diagnosis. Of these three, *Histoplasma* most often relapses years later in patients who are immunosuppressed.

Immunosuppression, foreign bodies (eg, central catheters), ulceration of gastrointestinal and respiratory mucosae, broad-spectrum antimicrobial therapy, malnutrition, HIV infection, and neutrophil defects or depletion are major risk factors for opportunistic fungal disease.

Laboratory diagnosis may be difficult because of the small number of fungi present in some lesions, slow growth of some organisms, and difficulty in distinguishing normal colonization of mucosal surfaces from infection. A tissue biopsy with fungal stains and culture is the best method for diagnosing systemic disease. Repeat blood cultures may be negative even in the presence of intravascular infections. Serology is useful for diagnosing coccidioidomycosis and histoplasmosis, and antigen detection is useful for diagnosing histoplasmosis and cryptococcosis.

The risk of empiric treatment is greater for fungal than for bacterial infections because of the toxicity of some antifungals (especially amphotericin B), the frequent need for prolonged parenteral administration, and the limited data available for choosing the best dose

Table 39–7. Pediatric fungal infections.

Type	Agents	Incidence	Diagnosis	Diagnostic Tests	Therapy	Prognosis
Superficial	<i>Candida</i> Dermatophytes <i>Malassezia</i>	Very common	Simple	KOH prep	Topical	Good
Subcutaneous	<i>Sporothrix</i> ^b	Uncommon	Simple ^a	Culture	Oral	Good
Systemic: normal host	<i>Coccidioides</i> <i>Histoplasma</i> <i>Blastomyces</i>	Common: regional	Often presumptive	Chest radiograph Serology, antigen detection (histoplasmosis) Histology Culture of body fluids or tissue	None ^c or systemic	Good
Systemic: opportunistic infection	<i>Candida</i> ^b <i>Pneumocystis</i> ^d <i>Aspergillus</i> <i>Malassezia</i> <i>Pseudallescheria</i> <i>Cryptococcus</i>	Uncommon	Difficult ^e	Tissue biopsy, culture, antigen detection (cryptococcosis)	Systemic, prolonged	Poor if therapy delayed and in severely immunocompromised patients

^aSporotrichosis may require biopsy for diagnosis.

^b*Candida* and *Sporothrix* in immunocompromised patients may cause severe, rapidly progressive disease and require systemic therapy.

^cOften self-limited in normal host.

^dNow reclassified as a fungus. May infect many normal hosts.

^eExcept *Cryptococcus*, which is often diagnosed by antigen detection.

or regimen. Delay in treating systemic disease, however, may prove fatal.

Susceptibility testing of *Candida* species with some drugs is now available, but testing of other organisms, especially molds, and testing with additional antifungal agents, is not well standardized.

The common superficial fungal infections of the hair and skin are discussed in Chapter 14.

BLASTOMYCOSIS

General Considerations

The causative fungus, *Blastomyces dermatitidis*, is found in soil primarily in the Mississippi and Ohio River valleys, additional southeastern and south central states, and the states bordering the Great Lakes. Transmission is by inhalation of spores. Subclinical disease is common. Severe disease is much more common in adults and males. In children, infection rates are similar in both sexes.

Clinical Findings

A. SYMPTOMS AND SIGNS

Primary infection is unrecognized or produces pneumonia. Acute symptoms include cough, chest pain,

headache, weight loss, and fever occurring several weeks to months after inoculation. Infection is usually self-limited in immunocompetent patients (50%). In some patients an indolent progressive pulmonary disease occurs after an incubation period of 30–45 days. Cutaneous lesions usually represent disseminated disease; local primary inoculation is rare. Slowly progressive ulcerating lesions with a sharp, heaped-up border or verrucous lesions occur. Bone disease resembles other forms of chronic osteomyelitis. Lytic skull lesions in children are typical, but long bones, vertebrae, and the pelvis may be involved. Extrapulmonary disease occurs in 25–40% of patients. A total body radiographic examination is advisable when blastomycosis is diagnosed in the skin or another nonpulmonary site. The genitourinary tract involvement characteristic of dissemination in adults is rare in prepubertal children. Lymph nodes, brain, and kidneys may be involved.

B. LABORATORY FINDINGS

Diagnosis requires isolation or visualization of the fungus. Pulmonary specimens (sputum, tracheal aspirates, lung biopsy) may be positive with conventional stains or fungal cell wall stains. An initial suppurative response is followed by an increase in the number of mononuclear cells, and then formation of noncaseating

granulomas. On microscopic examination, the budding yeasts are thick-walled, have refractile walls, and are very large and distinctive. Sputum specimens are positive in 50–80% of cases; skin lesions are positive in 80–100%. The fungus can be grown readily in most laboratories, but 2–4 weeks are required. Serologic tests are generally not helpful for diagnosis.

C. IMAGING

Radiographic consolidation and fibronodular interstitial and alveolar infiltrates are typical; effusions, hilar nodes, and cavities are less common. The paucity of cavitation distinguishes acute blastomycosis from histoplasmosis and tuberculosis. Miliary patterns also occur with acute infection. Chronic disease can develop in the upper lobes, with cavities and fibronodular infiltrations similar to that seen in tuberculosis, but, unlike in tuberculosis or histoplasmosis, these lesions rarely caseate or calcify.

Differential Diagnosis

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections. Blastomycosis should be considered when a significant pulmonary infection in an endemic area fails to respond to antibiotic therapy. Subacute infection mimics tuberculosis, histoplasmosis, and coccidioidomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

Treatment

Mild pulmonary blastomycosis does not require treatment; indeed, it is rarely recognized. Recommended therapy for life-threatening (especially in the immunocompromised patient) or CNS infections is amphotericin B (0.7–1.0 mg/kg intravenously for a total of 1.5–2.0 g). Itraconazole (6–8 mg/kg/d for 6 months) is preferred for other forms of blastomycosis. Bone disease may require a full year of itraconazole therapy. Surgical debridement is required for devitalized bone, drainage of large abscesses, and pulmonary lesions not responding to medical therapy.

Bradsher RW et al: Blastomycosis. *Infect Dis Clin North Am* 2003;17:21 [PMID: 12751259].

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- In normal or immunosuppressed individuals: superficial infections (oral thrush or ulcerations; vulvovaginitis; erythematous intertriginous rash with satellite lesions); fungemia related to intravascular devices.
- In immunosuppressed individuals: systemic infections (renal, hepatic, splenic, pulmonary, or cerebral abscesses); cotton-wool retinal lesions; cutaneous nodules.
- In either patient population: budding yeast and pseudohyphae seen in biopsy specimens, body fluids, or scrapings of lesions; positive culture.

General Considerations

Disease due to *Candida* is caused by *Candida albicans* in 60–80% of cases; similar systemic infection may be due to *C tropicalis*, *C parapsilosis*, *C glabrata*, and a few other *Candida* species. Speciation is important because of differences in pathogenicity and response to azole therapy. In tissue, pseudohyphae or budding yeast (or both) are seen. *Candida* grows on routine media more slowly than bacteria; growth is usually evident on agar after 2–3 days and in blood culture media in 2–7 days.

C albicans is ubiquitous and often present in small numbers on skin, mucous membranes, or in the intestinal tract. Normal bacterial flora, intact epithelial barriers, neutrophils and macrophages in conjunction with antibody and complement, and normal lymphocyte function (manifested by skin test reactivity) are factors in preventing invasion. Disseminated infection is almost always preceded by prolonged broad-spectrum antibiotic therapy, instrumentation (including intravascular catheters), or immunosuppression. Patients with diabetes mellitus are especially prone to superficial *Candida* infection, for whom thrush and vaginitis are most common. *Candida* is the third most common blood isolate in hospitals in the United States and is a common cause of catheter-related urinary tract infection.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Oral candidiasis (thrush)—Adherent creamy white plaques on the buccal, gingival, or lingual mucosa

are seen. These may be painful. Lesions may be few and asymptomatic, or they may be extensive, extending into the esophagus. Thrush is very common in otherwise normal infants in the first weeks of life; it may last weeks despite topical therapy. Spontaneous thrush in older children is unusual unless they have recently received antimicrobials. Steroid inhalation for asthma predisposes patients to thrush. HIV infection should be considered if there is no other reason for oral thrush, or if it is persistent or recurrent. *Angular cheilitis* is the name given to painful erythematous fissures caused by *Candida* at the corners of the mouth, often in association with a vitamin or iron deficiency.

2. Vaginal infection—Vulvovaginitis occurs in sexually active girls, in diabetic patients, and in girls receiving antibiotics. Thick, odorless, cheesy discharge with intense pruritus is typical. The vagina and labia are usually erythematous and swollen. Outbreaks are more frequent before menses.

3. Skin infection—

a. Diaper dermatitis—Diaper dermatitis is often due entirely or partly to *Candida*. Pronounced erythema with a sharply defined margin and satellite lesions is typical. Pustules, vesicles, papules, or scales may be seen. Weeping, eroded lesions with a scalloped border are common. Any moist area, such as axillae or neck folds, may be involved.

b. Congenital skin lesions—These lesions may be seen in infants born to women with *Candida* amnionitis. A red maculopapular or pustular rash is seen. Dissemination may occur in premature babies or infants after prolonged rupture of membranes.

c. Scattered red papules or nodules—Such findings may represent cutaneous dissemination.

d. Paronychia and onychomycosis—These conditions occur in immunocompetent children but are often associated with immunosuppression, hypoparathyroidism, or adrenal insufficiency (*Candida* endocrinopathy syndrome). The selective absence of specific T-cell responses to *Candida* can lead to marked, chronic skin and nail infections called *chronic mucocutaneous candidiasis*.

e. Chronic draining otitis media—This problem may occur in patients who have received multiple courses of antibiotics and are superinfected with *Candida*.

4. Enteric infection—Esophageal involvement in immunosuppressed patients is the most common enteric manifestation. It is manifested by substernal pain, dysphagia, painful swallowing, and anorexia. Nausea and vomiting are common in young children. Most patients do not have thrush. Stomach or intestinal ulcers also

occur. A syndrome of mild diarrhea in normal individuals who have predominant *Candida* on stool culture has also been described, although *Candida* is not considered a true enteric pathogen. Its presence more often reflects recent antimicrobial therapy.

5. Pulmonary infection—Because the organism frequently colonizes the respiratory tract, it is commonly isolated from respiratory secretions. Thus demonstration of tissue invasion is needed to diagnose *Candida* pneumonia or tracheitis. It is rare, being seen in immunosuppressed patients and patients intubated for long periods, usually while taking antibiotics. The infection may cause fever, cough, abscesses, nodular infiltrates, and effusion.

6. Renal infection—Candiduria may be the only manifestation of disseminated disease. More often, candiduria is associated with instrumentation, an indwelling catheter, or anatomic abnormality of the urinary tract. Symptoms of cystitis may be present. Masses of *Candida* may obstruct ureters and cause obstructive nephropathy. *Candida* casts in the urine suggest renal tissue infection.

7. Other infections—Endocarditis, myocarditis, meningitis, and osteomyelitis usually occur only in immunocompromised patients or neonates.

8. Disseminated candidiasis—Skin and mucosal colonization precedes but does not predict dissemination. Too often, dissemination is confused with bacterial sepsis. This occurs in neonates—especially premature infants—in an intensive care unit setting, and is recognized when the infant fails to respond to antibiotics or when candidemia is documented. A careful search should be carried out for lesions suggestive of disseminated *Candida* (retinal cotton-wool spots or nodular dermal abscesses). If these findings are absent, diagnosis is often based presumptively on the presence of a compatible illness in an immunocompromised patient, a burn patient, or a patient with prolonged postsurgical or intensive care unit course who has no other cause for the symptoms; who fails to respond to antimicrobials; and who usually has *Candida* colonization of mucosal surfaces. Treatment for presumptive infection is often undertaken because candidemia is not identified antemortem in many such patients.

Hepatosplenic candidiasis occurs in immunosuppressed patients. The typical case consists of a severely neutropenic patient who develops chronic fever, variable abdominal pain, and abnormal liver function tests. No bacteria are isolated, and there is no response to antimicrobials. Symptoms persist even when neutrophils return. Ultrasound or CT scan of the liver and spleen demonstrates multiple round lesions. Biopsy is needed to confirm the diagnosis.

B. LABORATORY FINDINGS

Budding yeast cells are easily seen in scrapings or other samples. A wet mount of vaginal secretions is 40–50% sensitive; this is increased to 50–70% with the addition of 10% KOH. The use of a Gram-stain smear is 70–100% sensitive. The presence of pseudohyphae suggests tissue invasion. Culture is definitive. Ninety-five percent of positive blood cultures will be detected within 3 days, but cultures may remain negative (10–40%), even with disseminated disease or endocarditis. *Candida* should never be considered a contaminant in cultures from normally sterile sites. *Candida* in any number in appropriately collected urine suggests true infection. Antigen tests are not sensitive or specific enough for clinical use. Antibody tests are not useful. The ability of yeast to form germ tubes when incubated in human serum gives a presumptive speciation for *C. albicans*.

Differential Diagnosis

Thrush may resemble formula (which can be easily wiped away with a tongue blade or swab, revealing normal mucosa without underlying erythema or erosion), other types of ulcers (including herpes), or burns. Skin lesions may resemble contact, allergic, chemical, or bacterial dermatitis; miliaria; folliculitis; or eczema. Candidemia and systemic infection should be considered in any seriously ill patient with the risk factors previously mentioned.

Complications

Failure to recognize disseminated disease early is the greatest complication. Osteoarthritis and meningitis occur more often in neonates than in older children. Blindness from retinitis, massive emboli from large vegetations of endocarditis, and abscesses in any organ are other complications; the greater the length or degree of immunosuppression and the longer the delay before therapy, the more complications are seen.

Treatment

A. ORAL CANDIDIASIS

In infants, oral nystatin suspension (100,000 units four to six times a day in the buccal fold after feeding until resolution) usually suffices. Nystatin must come in contact with the lesions because it is not absorbed systemically. Older children may use it as a mouthwash (200,000–500,000 units four times a day), although it is poorly tolerated because of its taste. Clotrimazole troches (10 mg) four times a day are an alternative in older children. Prolonged therapy with either agent or more frequent dosing may be needed. Painting the lesions with a cotton swab dipped in gentian violet

(0.5–1%) is visually dramatic and messy but may help refractory cases. Eradication of *Candida* from pacifiers, bottle nipples, toys, or the mother's breasts (if the infant is breast-feeding and there is candidal infection of the nipples) may be helpful.

Oral azoles—ketoconazole (200 mg/m² in divided doses every 12 hours for 5–7 days) and fluconazole (6 mg/kg/d)—are effective in older children with candidal infection refractory to nystatin. Discontinuation of antibiotics or corticosteroids is advised when possible.

B. SKIN INFECTION

Cutaneous infection usually responds to a cream or lotion containing nystatin, amphotericin B, or an imidazole. Associated inflammation, such as severe diaper dermatitis, is also helped by concurrent use of a topical mild corticosteroid cream, such as 1% hydrocortisone. One approach is to keep the involved area dry; a heat lamp and nystatin powder may be used. Cornstarch is a yeast nutrient and should not be used as a drying agent.

Suppression of intestinal *Candida* with nystatin and eradicating thrush may speed recovery and prevent recurrence of the diaper dermatitis.

C. VAGINAL INFECTIONS

Vaginal infection (see Chapter 40) is treated with clotrimazole, miconazole, triazoles, or nystatin (cheapest if generic is used) suppositories or creams, usually applied once nightly for 3–7 days. In general, nystatin is less effective and longer therapy is required. A high-dose clotrimazole formulation need be given for only a single night. *Candida balanitis* in sexual partners should be treated. Oral azole therapy is equally effective. A single 150-mg oral dose of fluconazole is effective for vaginitis. It is more expensive but very convenient. No controlled study has shown that treating colonization of male sexual partners prevents recurrence in females. Frequent recurrent infections may require elimination of risk factors, the use of oral therapy, or some prophylactic antifungal therapy, such as a single dose of fluconazole weekly.

D. RENAL INFECTION

Candiduria limited to the bladder may be treated with amphotericin B bladder irrigation (if a catheter is already in place). A more effective approach is a 7- to 14-day course of fluconazole, which is concentrated in the urine. Renal abscesses or ureteral fungus balls require systemic antifungal therapy. Surgical debridement may be required. Removal of an indwelling catheter is imperative. Amphotericin B may improve poor renal function caused by renal candidiasis, even though the drug is nephrotoxic.

E. SYSTEMIC INFECTION

Systemic infection is dangerous and resistant to therapy. Surgical drainage of abscesses and removal of all infected tissue (eg, a heart valve) are required for cure. Hepatosplenic candidiasis should be treated until all lesions have disappeared or are calcified on imaging studies. Systemic infection is optimally treated with amphotericin B or a lipid formulation. Lipid forms of amphotericin B retain the antifungal potency of the free drug but are much better tolerated. Although they are much more expensive than amphotericin B, they are indicated for patients who are intolerant of conventional therapy, for those whose infection is refractory to treatment, or for those who have a high likelihood of developing renal toxicity from such therapy.

Correction of predisposing factors is important (eg, discontinuing antibiotics and immunosuppressives and improving control of diabetes). Addition of flucytosine (50–75 mg/kg/d orally in four doses; keep serum levels below 75 µg/mL) may help. This is frequently added to treat neonatal infections, but clinical outcome seems to be similar when amphotericin B is used alone. Unlike amphotericin B, flucytosine penetrates tissues well; it is also synergistic with amphotericin B against many organisms. It should not be used as a single agent in serious infections because resistance develops rapidly.

Fluconazole is an acceptable alternative for serious *C albicans* infections in nonneutropenic patients and is often effective as first-line therapy in immunocompromised patients. However, the decision to use fluconazole must include consideration of the local experience with fluconazole-resistant *Candida*. Susceptibility testing for *Candida* species is now available to guide this decision. *C glabrata* and *C krusei* are common isolates that may be resistant to azoles. Infected central venous lines must be removed immediately; this alone often is curative. Persistent fever and candidemia suggest infected thrombus, endocarditis, or tissue infection. If the infection is considered limited to the line and environs, a 14-day course (after the last positive culture) of an antifungal agent such as amphotericin B or fluconazole following line removal is recommended for immunocompromised patients. Fluconazole should also be considered for immunocompetent patients with candidemia, because of the late occurrence of focal *Candida* infection in some cases.

Fluconazole is well absorbed (oral and intravenous therapy are equivalent), reasonably nontoxic, and effective for a variety of *Candida* infections. It is the treatment of choice if amphotericin B is not tolerated. The dosage is 8–12 mg/kg/d in a single daily dose for initial therapy of severely ill children. Selected patients with prolonged immunosuppression (eg, after bone marrow transplantation) should receive fluconazole, itraconazole, or intermittent

amphotericin B prophylaxis. Treatment of azole-resistant *Candida* is now facilitated by the availability of voriconazole and by the first licensed echinocandin, caspofungin, which is active against these organisms. These drugs are less expensive than the lipid formulations of amphotericin and are becoming first-line alternatives.

Prognosis

Superficial disease in normal hosts has a good prognosis; in abnormal hosts, it may be refractory to therapy. Early therapy of systemic disease is often curative if the underlying immune response is adequate. The outcome is poor when therapy is delayed or when host response is inadequate.

COCCIDIOIDOMYCOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in or travel to an endemic area.
- Primary pulmonary form: fever, chest pain, cough, anorexia, weight loss, and often a macular rash or erythema nodosum or multiforme.
- Primary cutaneous form: trauma followed in 1–3 weeks by an ulcer and regional adenopathy.
- Spherules seen in pus, sputum, CSF, joint fluid; positive culture.
- Appearance of precipitating (early) and complement-fixing antibodies (late).

General Considerations

Coccidioidomycosis is caused by the dimorphic fungus *Coccidioides immitis*, which is endemic in the Sonoran Desert areas of western and southern parts of Texas, New Mexico, and Arizona, southern California, northern Mexico, and South America. Infection results from inhalation or inoculation of arthrospores (highly conta-

gious and readily airborne in the dry climate). Even brief travel in or through an endemic area, especially during windy seasons, may allow infection. Human-to-human transmission does not occur. More than half of all infections are asymptomatic, and fewer than 5–10% are associated with significant pulmonary disease. Chronic pulmonary disease or dissemination occurs in less than 1% of cases.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Primary disease—The incubation period is 10–16 days (range, 7–28 days). Symptoms vary from those of a mild fever and arthralgia to severe influenza-like illness with high fever, nonproductive cough, pleurisy, myalgias, arthralgias, headache, night sweats, and anorexia. Upper respiratory tract signs are not common. Severe pleuritic chest pain suggests this diagnosis. Signs vary from none to rash, rales, pleural rubs, and signs of pulmonary consolidation. Weight loss may occur.

2. Skin disease—Up to 10% of children develop erythema nodosum or multiforme. These manifestations imply a favorable host response to the organism. Less specific maculopapular eruptions occur in a larger number of children. Skin lesions can occur following fungemia. Primary skin inoculation sites develop indurated ulcers with local adenopathy. Contiguous involvement of skin from deep infection in nodes or bone also occurs. The presence of chronic skin lesions with this fungus should lead to a search for other areas of infection (eg, lung).

3. Chronic pulmonary disease—This is uncommon in children. Chronic disease is manifested by chronic cough (occasionally with hemoptysis), weight loss, pulmonary consolidation, effusion, cavitation, or pneumothorax.

4. Disseminated disease—This is less common in children than adults. It is more common in infants, neonates, pregnant women (especially during the third trimester), blacks, Filipinos, American Indians, and patients with HIV or any other type of immunosuppression. One or more organs may be involved. The most common sites involved are bone or joint (usually a single bone or joint; subacute or chronic swelling, pain, redness); nodes, meninges (slowly progressive meningeal signs, ataxia, vomiting, headache, cranial neuropathies); and kidney (dysuria, urinary frequency). As with most fungal diseases, the evolution of the illness is usually slow.

B. LABORATORY FINDINGS

Direct examination of respiratory secretions, pus, CSF, or tissue may reveal large spherules (30–60 mm) containing endospores. These are the product of coccidioidal spores germinating in tissue. Phase-contrast microscopy is useful for demonstrating these refractile bodies; Gram or methylene blue stains are not helpful, but periodic acid–Schiff reagent, methenamine silver, and calcofluor stains are. Fluffy, gray-white colonies grow within 2–5 days on routine fungal and many other media. They are highly infectious. CSF cultures are often negative.

Routine laboratory tests are nonspecific. The sedimentation rate is usually elevated. Eosinophilia may occur, particularly prior to dissemination and is more common in coccidioidomycosis than in many other conditions with similar symptoms. Meningitis causes a mononuclear pleocytosis (70% with eosinophils) with elevated protein and mild hypoglycorrhachia.

Within 2–21 days, most patients develop a delayed hypersensitivity reaction to coccidioidin skin test antigen (Spherulin 0.1 mL, intradermally, should produce 5-mm induration at 48 hours). Erythema nodosum predicts strong reactivity; when this reaction is present the antigen should be diluted 10–100 times before use. The skin test may be negative in immunocompromised patients or in those with disseminated disease. Positive reactions may remain for years and do not prove active infection.

Antibodies consist of precipitins (usually measurable by 2–3 weeks in 90% of cases and gone by 12 weeks) and complement-fixing antibodies (delayed for several weeks; appear as the precipitins are falling and disappear by 8 months, unless dissemination or chronic infection occurs). The extent of the complement-fixing antibody response reflects the severity of infection. Persistent high levels suggest dissemination. Serum precipitins usually indicate acute infection. Excellent ELISA assays are now available to detect IgM and IgG antibodies against the precipitin and complement-fixing antigens. The presence of antibody in CSF indicates CNS infection.

C. IMAGING

Approximately half of symptomatic infections are associated with abnormal chest radiographs—usually infiltrates with hilar adenopathy. Pulmonary consolidation, effusion, and thin-walled cavities may be seen. About 5% of infected patients have asymptomatic nodules or cysts after recovery. Unlike reactivation tuberculosis, apical disease is not prominent. Bone infection causes osteolysis that enhances with technetium. Cerebral imaging may show hydrocephalus and meningitis; in-

tracranial abscesses and calcifications are unusual. Radiographic evolution of all lesions is slow.

Differential Diagnosis

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections; subacute presentation mimics tuberculosis, histoplasmosis, and blastomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

Complications

Dissemination of primary pulmonary disease is associated with ethnic background, prolonged fever (> 1 month), a negative skin test, high complement-fixation antibody titer, and marked hilar adenopathy. Local pulmonary complications include effusion, empyema, and pneumothorax. Cerebral infection can cause noncommunicating hydrocephalus due to basilar meningitis.

Treatment

A. SPECIFIC MEASURES

Mild pulmonary infections in most normal hosts require no therapy. These patients should be assessed for 1–2 years to document resolution and to identify any complications early. Antifungal therapy is used for prolonged fever, weight loss, prolonged duration of night sweats, severe pneumonitis (especially if persisting for 4–6 weeks), or any form of disseminated disease. Neonates, those with genetic risk factors, pregnant women, and those with high antibody titer also receive treatment.

Amphotericin B is used to treat severe disease (1 mg/kg/d until better; then reduce dose; total duration, 2–3 months). For less severe disease and for meningeal disease, fluconazole is preferred (duration of therapy is more than 6 months). Chronic fibrocavitary pneumonia is treated for at least 12 months. Lifelong suppressive therapy is recommended after treating coccidioidal meningitis. Itraconazole may be superior to fluconazole. Refractory meningitis may require prolonged intrathecal or intraventricular amphotericin B therapy. Pregnant patients should not receive azoles.

B. GENERAL MEASURES

Most pulmonary infections require only symptomatic therapy, self-limited activity, and good nutrition. They are not contagious.

C. SURGICAL MEASURES

Excision of chronic pulmonary cavities or abscesses may be needed. Infected nodes, sinus tracts, and bone are other operable lesions. Azole therapy should be given prior to surgery to prevent dissemination; it is contin-

ued for 4 weeks arbitrarily or until other criteria for cure are met.

Prognosis

Most patients recover. Even with amphotericin B, however, disseminated disease may be fatal, especially in those racially predisposed to severe disease. Reversion of the skin test to negative or a rising complement-fixing antibody titer is an ominous sign. Individuals who later in life undergo immunosuppressive therapy may experience reactivation of dormant disease.

CRYPTOCOCCOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute pneumonitis in immunocompetent individuals.
- Immunosuppressed patients especially vulnerable to CNS infection (headache, vomiting, cranial nerve palsies, meningeal signs; mononuclear cell pleocytosis).
- Cryptococcal antigen detected in CSF; also in serum and urine in some patients.
- Readily isolated on routine media.

General Considerations

Cryptococcus neoformans is a ubiquitous soil yeast. It appears to survive better in soil contaminated with bird excrement, especially that of pigeons. However, most infections in humans are not associated with a history of significant contact with birds. Inhalation is the presumed route of inoculation. Infections in children are rare, even in heavily immunocompromised patients such as those with HIV infection. Immunocompetent individuals can also be infected. Asymptomatic carriage does not occur.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Pulmonary disease—Pulmonary infection precedes dissemination to other organs. It is frequently asymp-

matic (most older children and adults have serologic evidence of prior infection) and less often clinically apparent than cryptococcal meningitis. Pneumonia is the primary manifestation in one third of patients and CNS disease in 50%; cryptococcal pneumonia may coexist with cerebral involvement. Symptoms are nonspecific and subacute—cough, weight loss, and fatigue. The fungus can persist in a latent form in subpleural granulomas.

2. Meningitis—The most common clinical disease is meningitis, which follows hematogenous spread from a pulmonary focus. Symptoms of headache, vomiting, and fever occur over days to months. Meningeal signs and papilledema are common. Cranial nerve dysfunction and seizures may occur.

3. Other forms—Cutaneous forms are usually secondary to dissemination. Papules, pustules, and ulcerating nodules are typical. Bones (rarely joints) may be infected; osteolytic areas are seen, and the process may resemble osteosarcoma. Many other organs, especially the eye, can be involved with dissemination.

B. LABORATORY FINDINGS

The CSF usually has a lymphocytic pleocytosis; it may be completely normal in immunosuppressed patients who have cryptococcal meningitis. Direct microscopy may reveal organisms in sputum, CSF, or other specimens. The capsular antigen can be detected by latex agglutination or ELISA, which are both sensitive (> 90%) and specific. Serum, CSF, and urine may be tested. The serum may be negative if the only organ infected is the lung. False-negative CSF tests have been reported. The organism grows well after several days on many routine media; for optimal culture, collecting and concentrating a large amount of CSF (≤ 10 mL) is recommended, because the number of organisms may be low.

C. IMAGING

Radiographic findings are usually lower lobe infiltrates or nodular densities; less often effusions; and rarely cavitation, hilar adenopathy, or calcification. Single or multiple focal mass lesions (cryptococcoma) may be detected in the CNS on CT or magnetic resonance imaging scan.

Differential Diagnosis

Cryptococcal meningitis may mimic tuberculosis, viral meningoencephalitis, meningitis due to other fungi, or a space-occupying CNS lesion. Lung infection is difficult to differentiate from many causes of pneumonia.

Complications

Hydrocephalus may be caused by chronic basilar meningitis. Symptomatic intracranial hypertension is common. Significant pulmonary or osseous disease may accompany the primary infection or dissemination.

Treatment

Patients with symptomatic pulmonary disease should receive fluconazole for 3–6 months. All such immunocompromised patients should have a lumbar puncture to rule out CNS infection; this should also be done for immunocompetent patients with cryptococcal antigen in the serum. Severely ill patients should instead receive amphotericin B (0.7 mg/kg/d). Meningitis is treated with amphotericin B and flucytosine (100 mg/kg/d). The combination is synergistic and allows lower doses of amphotericin B to be used. Therapy is usually 6 weeks for cerebral infections (or for 1 month after sterilization) and 8 weeks for osteomyelitis. An alternative is to substitute fluconazole after 2 weeks of the combination therapy and continue fluconazole alone for 8–10 weeks. Fluconazole is the preferred maintenance therapy to prevent relapses in high-risk (HIV) patients. CSF antigen levels should be checked after 2 weeks of therapy. Intracranial hypertension is treated by frequent spinal taps or a lumbar drain.

Prognosis

Treatment failure, including death, is common in immunosuppressed patients, especially those with AIDS. Lifelong maintenance therapy is required in these patients. Poor prognostic signs are the presence of extrameningeal disease; fewer than 20 cells/ μ L of initial CSF; and initial CSF antigen titer greater than 1:32.

Perfect TF, Casadevall A: Cryptococcosis. *Infect Dis Clin North Am* 2002;16:837 [PMID:12512184].

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in or travel to endemic areas.
- Pneumonia with flu-like illness.
- Hepatosplenomegaly, anemia, leukopenia if disseminated.
- Histoplasmal antigen in urine, blood, or CSF.
- Detection of the organism in smears or tissue or by culture.

General Considerations

The dimorphic fungus *Histoplasma capsulatum* is found in the central and eastern United States (Ohio and Mississippi River valleys), Mexico, and most of South America. Soil contamination is enhanced by the presence of bat or bird feces. The small yeast form (2–4 μm) is seen in tissue, especially within macrophages. Infection is acquired by inhaling spores that transform into the pathogenic yeast phase. Infections in endemic areas are very common at all ages and are usually asymptomatic. Over two thirds of children are infected in these areas. Reactivation is very rare in children; it may occur years later, usually owing to significant immunosuppression. Reinfection also occurs. The extent of symptoms with primary or reinfection is influenced by the size of the infecting inoculum.

Clinical Findings

Because human-to-human transmission does not occur, infection requires exposure in the endemic area—usually within prior weeks or months. Congenital infection does not occur.

A. SYMPTOMS AND SIGNS

1. Asymptomatic infection (50% of infections)—

Asymptomatic histoplasmosis is usually diagnosed by the presence of scattered calcifications in lungs or spleen and a positive skin test. The calcification may resemble that caused by tuberculosis but may be more extensive than the usual Ghon complex.

2. Pneumonia—Approximately 45% of patients have mild to moderate disease. Most of these patients are not recognized as having a histoplasmal infection. Acute pulmonary disease may resemble influenza, with fever, myalgia, arthralgia, and cough occurring 1–3 weeks after exposure; the subacute form resembles infections such as tuberculosis, with cough, weight loss, night sweats, and pleurisy. Chronic disease is unusual in children. Physical examination may be normal, or rales may be heard. A small number of patients may have immune-mediated signs such as arthritis, pericarditis, and erythema nodosum. The usual duration of the disease is less than 2 weeks, followed by complete resolution. Symptoms may last several months and still resolve without antifungal therapy.

3. Disseminated infection (5% of infections)—

Fungemia during primary infection probably occurs in the first 2 weeks of all infections, including those with minimal symptoms. Transient hepatosplenomegaly may occur, but resolution is the rule in immunocompetent individuals. Heavy exposure, severe underlying pulmonary disease, and immunosuppression are risk factors for progressive reticuloendothelial cell infection,

with anemia, fever, weight loss, organomegaly, bone marrow involvement, and death. Dissemination may occur in otherwise immunocompetent children; usually they are younger than age 2 years.

4. Other forms—Ocular involvement consists of multifocal choroiditis. This usually occurs in immunocompetent adults who exhibit other evidence of disseminated disease. Brain, heart valve, pericardium, intestine, and skin (oral ulcers, nodules) are other involved sites. Adrenal gland involvement is common with systemic disease.

B. LABORATORY FINDINGS

Routine tests are normal or nonspecific in the benign forms. Pancytopenia is present in many patients with disseminated disease. The diagnosis can be made by demonstrating the organism by histology or culture. Tissue yeast forms are small and may be mistaken for artifact. They are usually found in macrophages, occasionally in peripheral blood leukocytes in severe disease, but rarely in sputum, urine, or CSF. Cultures of infected fluids or tissues may yield the organism after 1–6 weeks of incubation on fungal media, but even cultures of bronchoalveolar lavage or transbronchial biopsy specimens in immunocompromised patients are often negative (15%). Thus bone marrow and tissue specimens are needed. Detection of histoplasmal antigen in blood, urine, CSF, and bronchoalveolar lavage is probably the most sensitive diagnostic test (90% positive in the urine with disseminated disease; 75% positive with acute pneumonia). The level of antigen correlates with the extent of the infection, and antigen levels can be used to follow the response to therapy and to indicate low-grade infection persisting after completion of therapy (eg, in a child with HIV infection).

Antibodies may be detected by immunodiffusion, complement fixation, and precipitation; the latter two measures rise in the first 2–6 weeks of illness and fall unless dissemination occurs. Cross-reactions occur with some other endemic fungi. A single high titer or rising titer indicates a high likelihood of disease. Antigen detection has replaced serology as a rapid diagnostic test.

C. IMAGING

Scattered pulmonary calcifications in a well child are typical of past infection. Bronchopneumonia (focal midlung infiltrates) occurs with acute disease, often with hilar and mediastinal adenopathy, occasionally with nodules, but seldom with effusion. Apical cavitation occurs with chronic infection, often on the background of preexisting pulmonary infection.

Differential Diagnosis

Pulmonary disease resembles viral infection, tuberculosis, coccidioidomycosis, and blastomycosis. Systemic disease resembles disseminated fungal or mycobacterial infection, leukemia, histiocytosis, or cancer.

Treatment

Mild infections do not require therapy. Treatment is indicated for severe pulmonary disease (diffuse radiographic involvement), disseminated disease, when endovascular, CNS, or chronic pulmonary disease is present, and for children younger than age 1 year. Treatment should also be considered for patients who show no clinical improvement after 1 month. Disseminated disease in infants may respond to as little as 10 days of amphotericin B, although 4–6 weeks (or 30 mg/kg total dosage) is usually recommended. Amphotericin B is the preferred therapy for moderately severe forms of the disease. Patients with severe disease may benefit from a short course of steroid therapy (see also section on *Pneumocystis jiroveci*, formerly *Pneumocystis carinii*). Surgical excision of chronic pulmonary lesions is rarely required. Itraconazole (3–5 mg/kg/d for 6–12 weeks; achieve peak serum level of > 1.0 µg/mL) appears to be equivalent to amphotericin B therapy for mild disease and can be substituted for amphotericin B in severe disease after a favorable initial response has occurred. With chronic pulmonary, CNS, or disseminated disease, therapy may be required for prolonged periods.

Quantification of fungal antigen is useful for directing therapy. Histoplasmosis can reactivate in previously infected individuals who subsequently become immunosuppressed. Chronically immunosuppressed patients (eg, those with HIV) may require lifelong maintenance therapy with an azole.

Prognosis

Mild and moderately severe infections have a good prognosis. With early diagnosis and treatment, infants with disseminated disease usually recover; the prognosis worsens if the immune response is poor.

Wheat LJ, Kauffman CA: *Infect Dis Clin North Am* 2003;17:1 [PMID: 1271258].

SPOROTRICHOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Subacute cutaneous ulcers.*
- *New lesions appearing proximal to existing lesions along a draining lymphatic.*
- *Absence of systemic symptoms.*
- *Isolation of Sporothrix schenckii from wound drainage or biopsy.*

General Considerations

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungus present as a mold in soil, plants, and plant products from most areas of North and South America. Spores of the fungus can cause infection when they breach the skin at areas of minor trauma. Sporotrichosis has been transmitted from cutaneous lesions of pets.

Clinical Findings

Cutaneous disease is by far the most common manifestation. Typically at the site of inapparent skin injury an initial papular lesion will slowly become nodular and ulcerate. Subsequent new lesions develop in a similar fashion proximally along lymphatics draining the primary lesion. This sequence of developing painless, chronic ulcers in a linear pattern is strongly suggestive of the diagnosis. Solitary lesions may exist and some lesions may develop a verrucous character. Systemic symptoms are absent and laboratory evaluations are normal, except for acute phase reactants. The fungus rarely disseminates in immunocompetent hosts, but bone and joint infections have been described. Cavitory pneumonia is an uncommon manifestation when patients inhale the spores. Immunocompromised patients, especially those with HIV infection, may develop multiorgan disease and extensive pneumonia.

Diagnosis

The differential diagnosis of nodular lymphangitis (sporotrichoid infection) includes other endemic fungi and some bacteria, especially atypical mycobacteria. Diagnosis is made by culture. Biopsy of skin lesions will demonstrate a suppurative response with granulomas and provides the best source for laboratory isolation. Occasionally the characteristic yeast will be seen in the biopsy.

Treatment & Prognosis

Treatment is with itraconazole (100 mg/d or 5 mg/kg/d) for 3–6 months. Prognosis is excellent with lymphocutaneous disease in immunocompetent children. Pulmonary or osteoarticular disease, especially in immunocompromised individuals, requires longer therapy, and surgical debridement may be required.

Queiroz-Telles F et al: Subcutaneous mycoses. *Infect Dis Clin North Am* 2003;17:59 [PMID: 12751261].

OPPORTUNISTIC FUNGAL INFECTIONS

These infections occur most commonly when therapy with steroids, antineoplastic drugs, or radiation is used for treatment, thereby reducing the number or function of neutrophils and competent T lymphocytes. Inborn errors in immune function (combined immune deficiency; chronic granulomatous disease) may also be complicated by these fungal infections. Infection is also facilitated by altering the normal flora with antibiotics and by disruption of mucus membranes or skin with antineoplastic therapy and with indwelling lines and tubes.

Table 39–8 indicates that filamentous fungi are prominent causes of severe systemic fungal disease in immunocompromised patients. *Aspergillus* species (usually *fumigatus*) and *Zygomycetes* (usually *mucorales*) cause subacute pneumonia and sinusitis and should be considered when these conditions do not respond to antibiotics in immunocompromised patients. Mucormycosis is especially likely to produce severe sinusitis in patients with chronic acidosis, usually because of poorly controlled diabetes. This fungus may invade the orbit and cause brain infection. Mucormycosis also occurs in patients receiving iron chelation therapy. These fungal infections may disseminate widely. They are best diagnosed by aspiration or biopsy of infected tissues. *Cryptococcus*, which can cause disease in the immunocompetent host, is more likely to be clinically apparent and severe in immunocompromised patients. This yeast causes pneumonia and is a prominent cause of fungal meningitis. *Candida* species in these patients cause fungemia and multiorgan disease, with lung, esophagus, liver and spleen frequently affected.

Malassezia furfur is a yeast that normally causes the superficial skin infection known as tinea versicolor (see Chapter 14). This organism is considered an opportunist when it is associated with prolonged intravenous therapy, especially central lines used for hyperalimentation. The yeast, which requires skin lipids for its growth, can infect lines when lipids are present in the infusate. Some species will grow in the absence of

lipids. Unexplained fever and thrombocytopenia are common. Pulmonary infiltrates may be present. The diagnosis is facilitated by alerting the bacteriology laboratory to add olive oil to culture media. The infection will respond to removal of the line or the lipid supplement. Amphotericin B may hasten resolution.

Opportunistic fungal infections are always in the differential diagnosis for immunocompromised patients with unexplained fever or pulmonary infiltrates. These pathogens should be aggressively pursued with imaging studies and with tissue sampling when clues are available. These infections are difficult to treat. Amphotericin B and appropriate triazole drugs are usually indicated. Caspofungin is a member of a new class of drugs now available to treat *Candida* and *Aspergillus* infections. Voriconazole is a new triazole available for first-line treatment of resistant *Candida* infections and infections caused by *Aspergillus* species. Combinations of these antifungal drugs are being tested in order to improve the outcome. Many children who will have depressed phagocytic and T-cell-mediated immune function for long periods should receive antifungal prophylaxis, most often itraconazole.

Marr KA et al: *Aspergillus* pathogenesis, clinical manifestations, and therapy. *Infect Dis Clin North Am* 2002;16:875 [PMID: 12512185].

PNEUMOCYSTIS JIROVECI INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Significant immunosuppression.
- Fever, tachypnea, cough, dyspnea.
- Hypoxemia; diffuse interstitial infiltrates.

General Considerations

Although classified as a fungus on the basis of structural and nucleic acid characteristics, *Pneumocystis* responds readily to antiprotozoal drugs and antifolates. It is a ubiquitous pathogen. Infection is presumed to occur via inhalation, usually in early childhood. With normal immune function, clinical disease rarely occurs. A syndrome of afebrile pneumonia similar to that caused by *Chlamydia trachomatis* in normal infants has been described but is rarely diagnosed. Organisms dormant in the lung may be reactivated in heavily immunosup-

Table 39–8. Unusual fungal infections in children.

Organism	Predisposing Factors	Route of Infection	Clinical Disease	Diagnostic Tests	Therapy and Comments
<i>Aspergillus</i> species	None	Inhalation of spores	Allergic bronchopulmonary aspergillosis; wheezing, cough, migratory infiltrates, eosinophilia.	Organisms in sputum; positive skin test; specific IgE antibody; elevated IgE levels.	Hypersensitivity to fungal antigens. Use steroids. Antifungals may not be needed.
	Immuno-suppression	Inhalation of spores	Progressive pulmonary disease: consolidation, nodules, abscesses. Sinusitis. Disseminated disease: usually lung, brain; occasionally intestine, kidney, heart, bone. Invades blood vessels.	Demonstrate fungus in tissues by stain or culture; septate hyphae branching at 45-degree angle.	Amphotericin B and voriconazole are effective therapies. Caspofungin may be equally effective and can be used in combination with either of the other drugs.
<i>Malassezia furfur</i> , <i>M pachydermatis</i>	Central venous catheter, usually lipid infusion (can occur in the absence of lipid)	Line infection from skin colonization	Sepsis; pneumonitis, thrombocytopenia.	Culture of catheter or blood on lipid-enriched media (for <i>M furfur</i> ; <i>M pachydermatis</i> does not need lipid). Fungus may be seen in buffy coat.	Discontinuation of lipid may be sufficient. Remove catheter. Short-term amphotericin B may be added. Organism ubiquitous on normal skin; requires long-chain fatty acids for growth.
<i>Mucorales</i> (<i>Mucor</i> , <i>Rhizopus</i> , <i>Absidia</i>)	Immunosuppression, diabetic acidosis, iron chelation therapy	Inhalation, mucosal colonization	Rhinocerebral: sinus, nose, necrotizing vasculitis; central nervous system spread. Pulmonary. Disseminated: any organ.	Broad aseptate hyphae branching at 90-degree angles seen on tissue stains. Culture: rapidly growing, fluffy fungus.	Amphotericin B, surgical debridement; itraconazole may be a second agent for combined therapy. Poor prognosis.
<i>Pseudallescheria boydii</i>	Immuno-suppression	Inhalation	Disseminated abscesses (lung, brain, liver, spleen, other).	Culture of pus or tissue.	Surgical drainage; Voriconazole or caspofungin
	Minor trauma	Cutaneous	Mycetoma (most common).	Yellow-white granules in pus. Culture.	Aggressive surgery. Amputation may be needed.
<i>Sporothrix schenckii</i>	Minor trauma (thorns, splinters)	Cutaneous	Chronic skin ulcers, subcutaneous nodules along lymphatics. Rarely pneumonia, osteomyelitis, arthritis. Disseminated disease in immunocompromised host.	Gram or fungal stain of pus or tissue may show "hockey stick" organisms. Culture of pus, tissue.	Itraconazole, drainage, debridement.

pressed children, chiefly those with abnormal T-cell function such as occurs with HIV infection, hematologic malignancies, and organ transplantation. Environmental exposure is also presumed to cause infection in immunocompromised children. Prolonged, high-dose corticosteroid therapy is a risk factor; onset of illness as

steroids are tapered is a typical presentation. Severely malnourished infants with no underlying illness may also develop this infection, as can those with congenital humoral or cellular immune deficiency. The incubation period is usually at least 1 month after onset of immunosuppression.

Pneumocystis pneumonia is a common complication of advanced HIV infection and is one of the diseases that defines AIDS. Prophylaxis usually prevents this infection (see Chapter 37).

Infection is generally limited to the lower respiratory tract. In advanced disease, spread to other organs occurs.

Clinical Findings

A. SYMPTOMS AND SIGNS

In most patients, a gradual onset of fever, tachypnea, dyspnea, and mild cough occurs over 1–4 weeks. Initially the chest is clear, although retractions and nasal flaring are present. At this stage, the illness is nonspecific. Hypoxemia out of proportion to the clinical and radiographic signs is an early finding, however, and even minimally decreased arterial PaO₂ values should suggest this diagnosis in immunosuppressed children. Tachypnea, nonproductive cough, and dyspnea progress. Respiratory failure and death occur without treatment. In some children with AIDS or severe immunosuppression from chemotherapy or organ transplantation, the onset may be abrupt and progression more rapid.

The general examination is unremarkable. There are no upper respiratory signs, conjunctivitis, organomegaly, enanthem, or rash.

B. LABORATORY FINDINGS

Laboratory findings reflect the individual child's underlying illness and are not specific. Serum lactate dehydrogenase levels may be elevated markedly as a result of pulmonary damage. In moderately severe cases, the PaO₂ is less than 70 mm Hg or the A-a gradient is less than 35 mm Hg.

C. IMAGING

Early chest radiographs are normal. The classic pattern in later films is that of bilateral, interstitial, lower lobe alveolar disease starting in the perihilar regions, without effusion, consolidation, or hilar adenopathy. Older HIV-infected patients present with other patterns, including nodular infiltrates, lobar pneumonia, cavities, and upper lobe infiltrates.

Diagnosis

Diagnosis requires finding characteristic round (6–8 mm) cysts in a lung biopsy specimen, bronchial brushings or alveolar washings, induced sputum, or tracheal aspirates. The latter specimens are less sensitive but are more rapidly and easily obtained. They are more often negative in children with leukemia compared with those with HIV infection; presumably, greater immunosuppression results in larger numbers of

organisms. Because pneumonia in immunosuppressed patients may have many causes, negative results from tracheal secretions should prompt more aggressive diagnostic attempts. Bronchial washing using fiberoptic bronchoscopy is usually well tolerated and rapidly performed.

Several rapid stains—as well as the standard methenamine silver stain—are useful. The indirect fluorescent antibody method is most sensitive. These methods require competent laboratory evaluation, because few organisms may be present and many artifacts may be found.

Differential Diagnosis

In immunocompetent infants, *C trachomatis* pneumonia is the most common cause of the afebrile pneumonia syndrome described for *Pneumocystis*. In older immunocompromised children, the differential diagnosis includes influenza, respiratory syncytial virus, cytomegalovirus, adenovirus, and other viral infections; bacterial and fungal pneumonia; pulmonary emboli or hemorrhage; congestive heart failure; and *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* infections. Lymphoid interstitial pneumonitis, which occurs in older infants with HIV infection, is more indolent and the patient's lactate dehydrogenase level is normal (see Chapter 37). *Pneumocystis* pneumonia is uncommon in children who are complying with prophylactic regimens.

Prevention

Children at high risk for developing *Pneumocystis* infection should receive prophylactic therapy. Children at risk include those with hematologic malignancies or other reasons for receiving intensive chemotherapy or high-dose corticosteroids and children with organ transplants or advanced HIV infection. All children born to HIV-infected mothers should receive prophylaxis against *Pneumocystis* starting at age 6 weeks. Prophylaxis should be maintained until HIV infection has been ruled out or, if the infant is infected, until the patient's immunologic status has been clarified (see Chapter 37). The prophylaxis of choice is trimethoprim–sulfamethoxazole (150 mg/m²/d of trimethoprim and 750 mg/m²/d of sulfamethoxazole) for 3 consecutive days of each week. Alternatives to this prophylaxis regimen are described in Chapter 37.

Treatment

A. GENERAL MEASURES

Supplemental oxygen and nutritional support may be needed. Bronchodilators may be tried but are usually

not helpful. The patient should be in respiratory isolation.

B. SPECIFIC MEASURES

Trimethoprim–sulfamethoxazole (20 mg/kg/d of trimethoprim and 100 mg/kg/d of sulfamethoxazole in four divided doses intravenously or orally if well tolerated) is the treatment of choice. Improvement may not be seen for 3–5 days. Duration of treatment is 3 weeks in HIV-infected children. Methylprednisolone (2–4 mg/kg/d in four divided doses intravenously) should also be given to HIV-infected patients with moderate to severe infection for the first 5 days of treatment. The dosage is reduced 50% for the next 5 days, and further reduced by 50% until antibiotic treatment is completed. If trimethoprim–sulfamethoxazole is not tolerated or there is no clinical response in 5 days, pentamidine isethionate (4 mg/kg once daily by slow intravenous infusion) should be given. Clinical efficacy is similar with pentamidine, but adverse reactions are more common. These reactions include dysglycemia, pancreatitis, nephrotoxicity, and leukopenia. Other effective alternatives in adults include atovaquone, trimethoprim–dapsone, and primaquine plus clindamycin.

Prognosis

The mortality rate is high in immunosuppressed patients who receive treatment late in the illness.

Sexually Transmitted Infections

40

Ann-Christine Nyquist, MD, MSPH, Myron J. Levin, MD, & Eric J. Sigel, MD

The rate of sexually transmitted infections (STIs) acquired during adolescence remains high despite widespread educational programs and increased access to health care. The highest age-specific rates for gonorrhea, chlamydia, and human papillomavirus infection occur in adolescents. By age 18 years, half of youth will have had sexual intercourse. One quarter of those having intercourse will develop an STI—an estimated 3 million teenagers per year. Adolescents contract STIs at a higher rate than adults because of sexual risk-taking, age-related biologic factors, and barriers to health care access. Providers need to comply with state-sanctioned confidentiality laws covering STI-related services, while recognizing the importance of confidentiality to adolescents. Except in a few states, adolescents can provide consent for the diagnosis and confidential treatment of STIs without parental consent or knowledge. In many states, adolescents can also provide consent for HIV counseling and testing.

Providers should screen sexually experienced adolescents for STIs and use this opportunity to discuss risk reduction. Health education counseling should be non-judgmental and appropriate for the developmental level, yet sufficiently thorough to identify risk behaviors because many adolescents may not readily acknowledge engaging in these behaviors.

ADOLESCENT SEXUALITY

The spectrum of sexual behavior includes romance—holding hands and kissing; touching, including mutual masturbation; oral–genital contact; and vaginal and anal intercourse. Each has its associated risks. A small but statistically significant trend has occurred in the epidemiology of sexual risk taking toward less sexual involvement and later onset of vaginal intercourse. The most recent Youth Risk Behavior Survey reports that 46% of high school students have had vaginal intercourse during their lifetime; down from 50% in 1999. Seven percent of teenagers have initiated sex by age 13. Significant racial differences exist, with 16% of black students, 7% of Hispanics, and 5% of whites having initiated sex by age 13. Thirty-three percent of students have had sex in the last 3 months—48% of twelfth-graders and 23% of ninth-graders. Condom use has increased, with 58% of youth reporting that either they

or their partner had used a condom during their last sexual intercourse, compared with 42% in 1999. Paradoxically, condom use decreases with age—67% of ninth-graders report condom use at last intercourse compared with 49% of twelfth-graders.

Oral sex has not been as well studied. A recent study reports that 38% of boys, and 42% of girls in the tenth grade engaged in oral sex, with only 17% using any protection.

A significant number of teenagers exhibit higher risk sexual behavior: 22% of high school seniors have had four or more sexual partners. One million teenagers become pregnant annually. Eight percent of students have had sex forced on them—10% of females and 5% of males. Anal intercourse occurs in both heterosexual and homosexual populations.

Adolescents may not yet identify themselves as gay, lesbian, or bisexual but continue to be questioning and engage in high-risk behaviors with multiple partners. Anywhere from 10% to 30% of males experiment with same-sex partners in some fashion, with 4–10% practicing anal sex. Frequently teenage males have their first same-sex experience with partners who are significantly older, which puts them at higher risk for STIs. Lesbians often experiment with male partners during their teen years as they sort out their sexual orientation, placing them at increased risk for pregnancy and STIs.

Impaired judgment related to alcohol or drug use creates an environment for unsafe sexual experimentation. Eighty-two percent of high school students have experimented with alcohol; 50% of high school senior boys have been drunk in the last 30 days. Nationwide, among students who were currently having sexual intercourse, one fourth (25%) used alcohol or drugs the last time they had sex. This additional barrier to decision-making ability results in decreased condom use and an increased incidence of forced sex.

RISK FACTORS

Certain behaviors and experiences put the adolescent at higher risk for developing STIs. These include early age at sexual debut, lack of condom use, multiple partners, prior STI, history of STI in a partner, and sex with a partner who is 3 or more years older. The type of sex affects risk as well, with intercourse being riskier than

oral sex. Other risk-taking behaviors associated with STIs in adolescents are smoking, alcohol use, drug use, dropping out of school, pregnancy, and watching X-rated movies.

Biologically the adolescent female is predisposed to chlamydia, gonorrhea, and human papillomavirus (HPV) infection because the cervix during adolescence has an exposed squamocolumnar junction. The rapidly dividing cells in this area are especially susceptible to microorganism attachment and infection. During early to midpuberty this junction slowly invaginates as the uterus and cervix matures, and by the late teens to early 20s the squamocolumnar junction is inside the cervix.

PREVENTION OF SEXUALLY TRANSMITTED INFECTIONS

Efforts to reduce STI risk behavior should begin before the onset of sexual experimentation, first by helping youth personalize their risk for STIs and encouraging positive behaviors that minimize these risks, and then by helping them develop communication skills with sexual partners about STI prevention, abstinence, and condom use.

Primary prevention focuses largely on education and risk-reduction techniques. Health care providers should routinely discuss these as part of well adolescent check-ups. Nationwide, greater than 90% of students have been taught about acquired immunodeficiency syndrome (AIDS) or human immunodeficiency virus (HIV) infection in school. Although adolescents may be aware of HIV/AIDS or other STIs, they still have a difficult time personalizing risk. Discussing prevalence, symptoms, and sequelae of STIs can raise awareness and help teenagers make informed decisions about whether to initiate sexual activity and what safer sex techniques they should use. Making condoms available reiterates the message that safer sex is vital to health. Discussing condoms, dental dams, and the proper use of lubrication also facilitates safer sex practices. Condoms prevent infections with HIV, gonorrhea, *Chlamydia*, and herpes simplex. They are probably effective in preventing other STIs, as well.

Secondary prevention requires identifying and treating STIs (see Screening section) before infected individuals transmit infection to others. Access to medical care is critical to this objective. Identifying and treating STIs in partners are essential in limiting the spread of these infections. Cooperation with the state or county health department is valuable, because these agencies assume the responsibility for locating the contacts of infected persons and ensuring appropriate treatment.

Tertiary prevention is directed toward complications of a specific illness. Examples of tertiary prevention would be treating pelvic inflammatory disease (PID) before infertility develops; following the serologic response to syphilis to prevent late-stage syphilis; treating cervicitis to prevent PID; or treating a chlamydial infection before epididymitis ensues.

Finally, preexposure vaccination against hepatitis B or hepatitis A reduces the risk for these preventable STIs. All adolescents should have prior or current immunization against hepatitis B. However, because hepatitis B infection is frequently sexually transmitted, this vaccine is especially critical for all unvaccinated patients being evaluated for an STI. Hepatitis A vaccination is recommended for men who have sex with men and for injection drug users.

SCREENING FOR SEXUALLY TRANSMITTED INFECTIONS

An essential part of screening is by history. Teenagers should be asked open-ended questions about their sexual experiences to assess their risk for STIs. The ability of the health care provider to obtain an accurate sexual history is crucial in prevention and control efforts. Questions must be explicit and understandable to the teen. If the adolescent has ever engaged in sexual activity, the provider needs to determine what kind of sexual activity (mutual masturbation, oral, anal, or vaginal sex); whether it has been heterosexual, homosexual, or both; whether birth control and condoms were used; and whether it has been consensual or forced. During the interview, to assess degree of risk, the clinician should take the opportunity to discuss risk-reduction techniques. Importantly, female health care providers are twice as likely as male providers to screen female teenagers for STIs, so male health care providers need to better use screening opportunities.

A routine laboratory screening process is warranted if the patient has engaged in intercourse, presents with STI symptoms, or reports a partner with an STI. The availability of nucleic acid amplification tests (NAAT), primarily for *Chlamydia* and *Neisseria gonorrhoeae*, has changed the nature of STI screening and intervention. These amplification tests are more than 95% sensitive

and more than 99% specific, using either urine or cervical/urethral swabs.

Initial screening for urethritis in males begins with a physical exam. If there are no signs (urethral discharge/lesions) or symptoms, then a first-catch urine sample (the first 10–40 mL of voided urine collected after not voiding for 2 hours) should be sent for *Chlamydia* testing. If signs or symptoms are present, then either the urine or a urethral swab should be sent to test for both *Neisseria gonorrhoeae* and *Chlamydia*. A wet prep should then be done on a spun urine sample or from urethral discharge, evaluating for the presence of *Trichomonas vaginalis*.

For females, screening asymptomatic patients has become more complicated because a variety of approaches are available. Generally, either a first-void urine specimen or a cervical swab is used to screen for *Chlamydia* and *N gonorrhoeae* by NAAT. When screening for *N gonorrhoeae*, it is important to recognize that certain NAATs are less sensitive when using urine compared with a cervical swab, and the specific test available should guide the screening procedure. A wet mount of the vaginal secretions should be performed annually to check for bacterial vaginosis and trichomoniasis, and a potassium hydroxide (KOH) preparation to screen for yeast infections. The Papanicolaou (Pap) smear serves to evaluate the cervix for the presence of HPV or other cervical cytopathology. Recent availability of Thin Prep, which accomplishes HPV typing, along with an increased understanding of the progression of abnormal cervical changes, has led to a change in the recommendations for performing Pap smears. Though there is not an absolute consensus it appears that the initial Pap smear does not need to be done until 3 years after initiation of sexual intercourse, or by age 21.

For both sexes if high-risk behavior is present (three or more partners in the last 6 months or more than two partners per year for several years), then screening for hepatitis B surface antigen is warranted. In communities with a high prevalence of hepatitis B, practitioners should test for hepatitis B infection once in patients who have previously received the hepatitis B vaccine to detect anyone who was infected before receiving the vaccine. The presence of hepatitis B surface antigen indicates either the carrier state or active infection. Presence of only hepatitis B surface antibody identifies vaccinated individuals, whereas hepatitis B core antibody identifies individuals with past infection (see Chapter 21).

In urban areas with a relatively high rate of syphilis, an RPR/VDRL (rapid plasma reagin/Venereal Disease Research Laboratory) test should be drawn yearly. RPR should be done in all cases in which a concomitant STI is present. HIV antibody determination should be con-

sidered for any sexually active adolescent and is strongly recommended for patients engaging in high-risk behaviors.

Serlin M et al. What sexually transmitted disease screening method does the adolescent prefer? Adolescents' attitudes toward first-void urine, self-collected vaginal swab, and pelvic examination. *Arch Pediatr Adolesc Med* 2002;156:588 [PMID: 22035040].

SIGNS & SYMPTOMS

For males, the most common symptoms are dysuria and penile discharge resulting from urethral inflammation. Less common symptoms are scrotal pain, hematuria, proctitis, and pruritus in the pubic region. Signs include epididymitis, orchitis, and urethral discharge. Rarely do males develop systemic symptoms. For females, the most common symptoms are vaginal discharge and dysuria. Vaginal itching and irregular menses or spotting are also common. Abdominal pain, fever, and vomiting, though less common, are signs of PID. Pain in the genital region and dyspareunia may be present.

Signs that can be found in both males and females with an STI include genital ulcerations, adenopathy, and genital warts.

THE MOST COMMON ANTIBIOTIC-RESPONSIVE SEXUALLY TRANSMITTED INFECTIONS

Chlamydia trachomatis and *Neisseria gonorrhoeae* are sexually transmitted infections that are epidemic in the United States and are readily treated when appropriate antibiotics are administered in a timely fashion.

CHLAMYDIA TRACHOMATIS INFECTION

General Considerations

Chlamydia is the most common bacterial cause of STIs in the United States. Three million cases are estimated to occur annually in adolescents and young adults. *Chlamydia trachomatis* is an obligate intracellular bacterium that replicates within the cytoplasm of host cells. Destruction of *Chlamydia*-infected cells is mediated by host immune responses.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical infection in females manifests as dysuria, urethritis, vaginal discharge, cervicitis, or PID. The presence of mucopus at the cervical os (mucopurulent cervicitis) is a sign of *Chlamydia* infection or gonorrhea. *Chlamydia* infection is asymptomatic in 75% of females.

Chlamydial infection may be asymptomatic in 70% of males or manifest as dysuria, urethritis, or epididymitis. Some patients complain of urethral discharge. On clinical exam a clear white discharge may be found after milking the penis. Proctitis or proctocolitis from *Chlamydia* may occur in adolescents practicing receptive anal intercourse.

B. LABORATORY FINDINGS

NAAT (polymerase or ligase chain reaction) is the most sensitive (93–97%) way to detect *Chlamydia*. ELISA or direct fluorescent antibody tests are less sensitive but may be the only testing option in some centers. Culture is mandated for sexual abuse cases.

A cervical swab, using the manufacturer's swab provided with the specific test, or first-void urine specimen should be obtained. Often a single swab can be used to collect both the *Chlamydia* and *N gonorrhoeae* specimen. To optimize detection of *Chlamydia* from the cervix, columnar cells need to be collected by inserting the swab in the os and rotating it 360 degrees. If rectal symptoms are present, a rectal specimen should be obtained.

The first-void urine test for leukocyte esterase was previously used for screening asymptomatic, sexually active males. Due to the high false-positive rate, this screening technique is now less commonly used. In symptomatic males, examination of the urine sediment for white blood cells (WBCs) can provide evidence of urethritis, though it is often impractical to perform in a clinical setting. In general, a first-void urine sample, or urethral swab for NAAT should be done at least annually. Some studies suggest that more frequent screenings—every 6 months—in higher prevalence populations can decrease the rate of chlamydial infection. Evaluation of the symptomatic male patient or an asymptomatic contact for *Chlamydia* is the same.

For both males and females, testing urine allows for more frequent screening and simplifies screening in schools, the military, or other groups.

Complications

Epididymitis is a complication in males. Reiter syndrome occurs in association with chlamydial urethritis (see Chapter 26). This should be suspected in male pa-

tients who are sexually active and present with low back pain (sacroiliitis), arthritis (polyarticular), characteristic mucocutaneous lesions, and conjunctivitis. PID is an important complication in females.

Treatment

Infected patients and their contacts, regardless of the extent of signs or symptoms, need to receive treatment (Table 40–1). Because adolescents have a high risk of acquiring a repeat *Chlamydia* infection within several months of the first infection, all infected females should be rescreened 3–4 months after treatment.

Guaschino S, DeSeta F: Update on *Chlamydia trachomatis*. *Ann N Y Acad Sci* 2000;900:293 [PMID: 20278358].

Watson EJ et al: The accuracy and efficacy of screening tests for *Chlamydia trachomatis*: A systematic review. *J Med Microbiol* 2002;51:1021 [PMID: 22354463].

NEISSERIA GONORRHOEAE INFECTION

General Considerations

Gonorrhea is the second most prevalent bacterial STI. Sites of infection include the cervix, urethra, rectum, and pharynx. In addition, gonorrhea is a cause of PID. Humans are the natural reservoir. Gonococci are present in the exudate and secretions of infected mucus membranes.

Clinical Findings

A. SYMPTOMS AND SIGNS

In uncomplicated gonococcal cervicitis, females are symptomatic 57% of the time, presenting with vaginal discharge and dysuria. Urethritis and pyuria may be present. Mucopurulent cervicitis with a yellowish discharge may be found, and the cervix may be edematous and friable. Other symptoms include abnormal menstrual periods and dyspareunia. Approximately 15% of women with endocervical gonorrhea will have signs of involvement of the upper genital tract. Compared with *Chlamydia* infection, pelvic inflammation with gonorrhea often has a shorter duration but an increased intensity of symptoms and is more often associated with fever. Ninety-five percent of males with gonorrhea are symptomatic, with a yellowish green urethral discharge and burning on urination. Both males and females can develop gonococcal proctitis and pharyngitis after exposure.

B. LABORATORY FINDINGS

A cervical swab from females should be sent for NAAT or cultured on Thayer–Martin agar. Obtaining specimens from the rectum or pharynx when clinically indi-

Table 40–1. Treatment regimens

Disease	Recommended Regimens	Pregnancy ^a
Pelvic inflammatory disease (PID) Inpatient therapy regimen A Note: Therapy should be continued for 24–48 h after the patient has improved; therapy can then be switched to either oral regimen to complete a 14-d course. Inpatient therapy regimen B Note: Once clinically improved for 48 h, patients can be discharged and continue doxycycline 100 mg PO bid for 14 days total. ^b	Cefotetan, 2 g IV q6 h	Safe [B]
	or	
	Cefoxitin, 2 g IV q12 h	Safe [B]
	plus	
	Doxycycline, 100 mg IV or PO bid	Contraindicated [D]
	Clindamycin, 900 mg IV q8 h	Safe [B]
plus		
Gentamicin, 2 mg/kg IV loading dose, then 1.5 mg/kg IV q8 h	Safe [B]	
Alternative parenteral regimens	Ofloxacin, 400 mg IV q12 h ^c	Contraindicated [C]
	or	
	Levofloxacin, 500 mg IV once daily ^c with or without Metronidazole, 500 mg IV q8h	Contraindicated [C] Safe ^d [B]
	or	
Ampicillin/sulbactam, 3 g IV q6 h	Safe [B]	
plus		
Doxycycline, 100 mg IV or PO q12 h	Contraindicated [D]	
Outpatient therapy regimen A	Ofloxacin, 400 mg PO bid for 14 d ^c	Contraindicated [C]
	or	
Levofloxacin, 500 mg PO, once a day for 14 d ^c with or without	Contraindicated [C]	
Out patient therapy regimen B Note: Pregnant patients with PID should be hospitalized and given parenteral antibiotics. ^b	Ceftriaxone, 250 mg IM once	Safe [B]
	or	
	Cefoxitin, 2 g IM once plus probenidicid, 1 g PO	Safe [B]
	or	
	Third generation cephalosporin	Safe [B]
	plus	
Doxycycline, 100 mg, PO bid for 14 d with or without	Contraindicated [D]	
Metronidazole, 500 mg PO bid for 14 d	Safe ^d [B]	
Gonorrhea, uncomplicated Cervicitis, urethritis Note: Empiric treatment for <i>Chlamydia trachomatis</i> with azithromycin or doxycycline is recommended due to coexisting infection in 20–40% of patients with gonorrhea infection.	Cefixime, 400 mg PO as single dose	Safe [B]
	or	
	Ceftriaxone, 125 mg IM as single dose	Safe [B]
	or	
	Ciprofloxacin, 500 mg PO in a single dose	Contraindicated [C]
	or	
Ofloxacin, 400 mg PO as single dose ^c	Contraindicated [C]	
or		
Levofloxacin, 250 mg PO as single dose ^c	Contraindicated [C]	
Pharyngitis	Ceftriaxone, 125 mg IM once	Safe [B]
	or	
Ciprofloxacin, 500 mg PO once ^c	Contraindicated [C]	
Gonorrhea disseminated Note: Treat IV until clinically improved (usually 48h; then switch to PO)	Ceftriaxone, 1 g IV or IM every 24 h	Safe [B]
	or	
	Ceftizoxime, 1 g IV every 8 h	Safe [B]
	or	
Ciprofloxacin, 400 mg IV every 12 h	Contraindicated [C]	
or		

(continued)

Table 40–1. Treatment regimens (continued)

Disease	Recommended Regimens	Pregnancy ¹
Gonorrhea disseminated Note: Treat IV until clinically improved (usually 48h; then switch to PO)	Complete at least a 7 d course with cefixime, 400 mg PO bid or Ciprofloxacin, 500 mg PO bid or Ofloxacin, 400 mg PO bid or Levofloxacin, 500 mg PO once daily	
Nongonococcal, nonchlamydial urethritis	Azithromycin, 1 g PO as single dose or Doxycycline, 100 mg PO bid for 7 d	
Alternative regimens	Erythromycin base, 500 mg PO qid for 7 d or Erythromycin ethylsuccinate, 800 mg PO qid for 7 d or Ofloxacin, 300 mg PO bid for 7 d ^c or Levofloxacin, 500 mg PO once daily for 7 d ^c	
Recurrent or persistent urethritis	Metronidazole, 2 g PO as single dose plus Erythromycin base, 500 mg PO quid for 7 d or Erythromycin ethylsuccinate, 800 mg PO qid for 7 d	
Proctitis, proctocolitis, and enteritis	Ceftriaxone 125 mg IM plus Doxycycline, 100 mg PO bid for 7 d	Safe [B] Contraindicated [D]
<i>Trichomonas vaginalis</i> vaginitis or urethritis	Metronidazole, 2 g PO as single dose or Metronidazole, 500 mg PO bid for 7d	Safe ^d [B] Safe ^d [B]
Bacterial vaginosis	Metronidazole, 500 mg PO bid for 7 d or Metronidazole, 0.75% gel, 5 g intravaginally bid for 5 d or Clindamycin cream, 2%, one applicator intravaginally at bedtime for 5 d or Clindamycin ovules 100 mg intravaginal for 3 d	Safe ^d [B] Safe ^d [B] Safe [B] Safe ^d [B]
Alternative regimen	Metronidazole, 2 g PO as single dose or Clindamycin, 300 mg PO bid for 7 d or Clindamycin 100 mg intravaginally once at bedtime for 3d	Safe [B] Safe [B]
Vulvovaginal candidiasis	Butoconazole, clotrimazole, miconazole, terconazole or tioconazole, intravaginal for 1, 3, or 7 d Butoconazole sustained release, 5 g once intravaginally or Fluconazole, 150 mg oral tablet, in single dose	Safe [B] Safe [B] Contraindicated [C]

(continued)

Table 40–1. Treatment regimens (continued)

Disease	Recommended Regimens	Pregnancy ^a
Syphilis Early (primary, secondary, or latent < 1 y)	Benzathine penicillin G, 2.4 million units IM (for patients > 40 kg)	Safe [B]
	Benzathine penicillin G, 50,000 units/kg IM (for patients < 40 kg); up to 2.4 million units in one dose	Safe [B]
	or Doxycycline, 100 mg PO bid for 14 d	Contraindicated [D]
Epididymitis Most likely caused by gonococcal or chlamydial infection Most likely caused by enteric organisms, Patient older than 35 y old or allergies to cephalosporins and/or tetracyclines	Ceftriaxone, 250 mg IM as single dose	
	plus Doxycycline, 100 mg PO bid for 14 d	
	or Ofloxacin, 300 mg PO bid for 14 d or Levofloxacin, 500 mg PO once daily for 14 d	
Chlamydia trachomatis Cervicitis or urethritis	Azithromycin, 1 g PO as single dose	Safe [B]
	or Erythromycin, 500 mg PO qid for 7 d	Safe [B]
	Alternative regimen ^b Doxycycline, 100 mg PO bid for 7 d	Contraindicated [D]
	or Ofloxacin, 300 mg PO bid for 7 d or levofloxacin 500 mg PO once daily for 7 d	Contraindicated [C] Contraindicated [C]
Late (more than 1 y duration)	Benzathine penicillin G, 2.4 million units IM (for patients > 40 kg) once a week for 3 consecutive weeks	Safe [B]
	or Benzathine penicillin G, 50,000 units/kg IM (for patients < 40 kg) once a week for 3 consecutive weeks; up to 2.4 million units in one dose	
	or Doxycycline, 100 mg PO bid for 4 wk	Contraindicated [D]
Granuloma inguinale	Doxycycline, 100 mg PO bid for 3 wk or longer	Contraindicated [D]
	or Trimethoprim–sulfamethoxazole, one double-strength tablet PO bid for 3 weeks or longer	Safe [B]
	Alternative regimen Ciprofloxacin, 750 mg PO bid for at least 3 wk	Contraindicated [C]
	or Erythromycin base, 500 mg PO four times daily for at least 3 wk	Safe [B]
	or Azithromycin, 1 g PO once per week for at least 3 wk	Safe [B]
Lymphogranuloma venereum	Doxycycline, 100 mg PO bid for 3 wk	Contraindicated [D]
	or Erythromycin, 500 mg PO qid for 3 wk	Safe [B]
Herpes simplex First episode, genital	Acyclovir, 400 mg PO tid for 7–10 d	Safe [B]
	or Famciclovir, 250 mg PO tid for 7–10 d	
	or Valacyclovir, 1 g PO bid for 7–10 d	

(continued)

Table 40–1. Treatment regimens (continued)

Disease	Recommended Regimens	Pregnancy ¹
Recurrent	Acyclovir, 400 mg PO tid for 5 d or Acyclovir, 800 mg PO bid for 5 d or Famciclovir, 125 mg PO bid for 5 d or Valacyclovir, 500 mg PO bid for 5 d or Valacyclovir, 1 g PO once a day for 5 d	
Suppression	Acyclovir, 400 mg PO bid or Famciclovir, 250 mg PO bid or Valacyclovir, 500 mg PO daily (if < 10 recurrences per year; if ≥ 10 recurrences use 1 g daily)	Safe [B]
Chancroid	Azithromycin, 1 g PO as single dose or Ceftriaxone 250 mg IM once or Ciprofloxacin, 500 mg PO bid for 3 d or Erythromycin, 500 mg PO tid for 7 d	Safe [B] Safe [B] Contraindicated [D] Safe [B]
Human papillomavirus External lesions Note: Topical therapies usually require weekly treatments for 4 consecutive weeks	Podophyllin, 25% in benzoin tincture applied directly to warts; wash off in 1–4 h [contraindicated for urethral or intravaginal lesions] or Trichloroacetic acid (85%); apply directly to warts; wash off in 6–8 h or Podofilox, 0.5% solution; apply bid for 3 d; used by the patient at home; practitioner needs to demonstrate how compound is applied (to be used only on external lesions) or Imiquimod 5% cream, applied three times per week overnight (maximum of 16 weeks) Cryotherapy: liquid nitrogen, cryoprobe Electrocautery	Contraindicated [X] Safe Contraindicated [C] Contraindicated [B] Safe
Ectoparasitic infections Pediculosis pubis^e	Permethrin 1% cream rinse: wash off after 10 min or Lindane 1% shampoo: apply for 4 min, then wash off or Pyrethins with piperonyl butoxide: apply, wash off after 10 min	Safe [B] Contraindicated [B] Safe [B]

Table 40–1. Treatment regimens (continued)

Disease	Recommended Regimens	Pregnancy ^a
Scabies	Permethrin cream 5%: apply to entire body from the neck down	Safe [B]
	or Ivermectin 200 mg/kg orally, repeat in 2 weeks	Contraindicated [C]

^aFDA use in pregnancy ratings: [A] *Controlled studies show no risk.* Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy. [B] *No evidence of risk in humans.* Adequate, well-controlled studies in pregnant women have not shown increased risk of fetal abnormalities despite adverse findings in animals, or, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote but remains a possibility. [C] *Risk cannot be ruled out.* Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy; but the potential benefits outweigh the potential risk. [D] *Positive evidence of risk.* Studies in humans, or investigational or post-marketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective. [X] *Contraindicated in pregnancy.* Studies in animals or humans, or despite adverse findings in animals, or investigational or post-marketing reports have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient.

^bDoxycycline is contraindicated in pregnancy. Alternative therapies during pregnancy which include erythromycin, azithromycin, and amoxicillin are not as effective, but are clinically useful if the recommended regimens cannot be used due to allergy or pregnancy.

^cQuinolones should not be used in areas with increased prevalence of quinolone resistance (ie, Asia, the Pacific, Hawaii, California).

^dPreviously metronidazole was contraindicated in the first trimester.

^eBedding and clothing need to be decontaminated by washing in hot water or by dry cleaning. Regimen may be repeated in 1 week if complete response is not achieved.

^fThese are oil-based and should not be used with latex benion imfrocep.

cated will increase the likelihood of positive results. Pharyngeal infection requires more intensive therapy. Nongonococcal *Neisseria* species reside in the vagina, thereby negating the value of the Gram stain in a female.

Culture or NAAT for *N gonorrhoeae* in males can be achieved with a swab of the urethra or first-void urine. Gram stain of urethral discharge showing gram-negative intracellular diplococci indicates gonorrhoeae in a male.

If proctitis is present appropriate cultures should be obtained and treatment for both gonorrhoeae and *Chlamydia* infection given. If oral exposure to gonorrhoeae is suspected cultures should be taken and the patient given empiric treatment.

Differential Diagnosis

Gonococcal pharyngitis needs to be differentiated from streptococcal infection, herpes simplex pharyngitis, and infectious mononucleosis. *Chlamydia* infection needs to be differentiated from gonococcal infection.

Complications

Disseminated gonococcal infection occurs in a minority (0.5–3%) of patients with untreated gonorrhoeae. Hematogenous spread most commonly causes arthritis

and dermatitis. The joints most frequently involved are the wrist, metacarpophalangeal joints, knee, and ankle. Skin lesions are typically tender, hemorrhagic or necrotic pustules or bullae on an erythematous base occurring on the distal extremities. Disseminated disease occurs more frequently in women than in men. Risk factors include pregnancy and gonococcal pharyngitis. Gonorrhoeae is complicated occasionally by perihepatitis and very rarely by endocarditis or meningitis.

Treatment

Because chlamydial and gonorrhoeal infections coexist 20–40% of the time, both infections should be treated when one infection is diagnosed.

Centers for Disease Control and Prevention (CDC) guidelines state that *N gonorrhoeae* and *C trachomatis* do not require tests of cure when they are treated with first-line medications, unless the patient remains symptomatic. If rescreening is indicated it should be delayed for 1 month after completion of therapy if NAATs are used to document a test of cure. Rescreening might also be considered for sexually active adolescents likely to be reinfected. Patients should be advised to abstain from sexual intercourse until both they and their partners have completed a course of treatment. Treatment for disseminated disease may require hospitalization (see Table 40–1).

THE SPECTRUM OF SEXUALLY TRANSMITTED INFECTIONS

The patient presenting with an STI usually has one or more of the signs or symptoms presented in this section. Management considerations for STIs include assessing the patient's adherence to therapy and ensuring follow-up, treating STIs in partners, and determining pregnancy risk. Treatment of each STI is detailed in Table 40-1.

MUCOPURULENT CERVICITIS

General Considerations

Mucopurulent cervicitis (MPC) is caused by *C trachomatis* or *N gonorrhoeae* approximately 30% of the time. Herpes simplex virus and *Mycoplasma genitalium* are less common causes. MPC can also be present without an STI.

Clinical Findings

A. SYMPTOMS AND SIGNS

MPC is often asymptomatic, but many women have an abnormal vaginal discharge or postcoital bleeding. MPC is characterized by a purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen. The cervix is often friable with easily induced bleeding.

B. LABORATORY FINDINGS

Although endocervical Gram stain may show an increased number of polymorphonuclear leukocytes, it has a low positive predictive value and is not recommended for diagnosis. Patients who have MPC should be tested for *C trachomatis* and *N gonorrhoeae* by using the most sensitive and specific tests available at the site.

Complications

Persistent MPC is difficult to manage and requires reassessment of the initial diagnosis. MPC can persist despite repeated courses of antimicrobial therapy. Presence of a large ectropion can contribute to persistent MPC.

Treatment

Empiric treatment for both gonorrhea and *Chlamydia* infection is recommended when the prospect of follow-up is questionable or the patient is part of a high-risk population. If the patient is asymptomatic aside

from MPC, then treatment may wait until diagnostic tests are back (see Table 40-1). Follow-up is recommended if symptoms persist. Patients should be instructed to abstain from sexual intercourse until they and their sex partners are cured and treatment is completed.

PELVIC INFLAMMATORY DISEASE

General Considerations

PID is defined as inflammation of the upper female genital tract and may include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is the most common gynecologic disorder necessitating hospitalization for women of reproductive age in the United States. Over 1 million women develop PID annually, and 275,000 are hospitalized. The incidence is highest in the teen population. Teenage girls who are sexually active have a high risk (1 in 8) of developing PID, whereas women in their 20s have one tenth the risk. Predisposing risk factors include number of partners, younger age of initiating sexual intercourse, and lack of condom use. Lack of protective antibody from previous exposure to sexually transmitted organisms and cervical ectopy contribute to the development of PID. Many adolescents with subacute or asymptomatic disease are never identified.

PID is often polymicrobial. Causative agents include *N gonorrhoeae*, *Chlamydia*, anaerobic bacteria that reside in the vagina, and genital mycoplasmas. Vaginal douching and other mechanical factors such as an intrauterine device or prior gynecologic surgery increase the risk of PID by providing access of lower genital tract organisms to pelvic organs. Recent menses and bacterial vaginosis have been associated with the development of PID.

Clinical Findings

A. SYMPTOMS AND SIGNS

Acute PID is difficult to diagnose because of the wide variation in the symptoms and signs. No single historical, clinical, or laboratory finding has both high sensitivity and specificity for the diagnosis of PID. Diagnosis of PID is usually made clinically (Table 40-2). Typical patients have lower abdominal pain, nausea, vomiting, and fever. However, the patient may be afebrile. Vaginal discharge is variable. Cervical motion tenderness, uterine or adnexal tenderness, or signs of peritonitis are present. Mucopurulent cervicitis is present in 50% of patients. Tubo-ovarian abscesses can be detected by careful physical examination (feeling a mass or fullness in the adnexa).

Table 40–2. Diagnostic criteria for pelvic inflammatory disease (PID).**Minimum criteria**

Empiric treatment of PID should be initiated in sexually active young women and others at risk for sexually transmitted infections if all the following minimum criteria are present and no other cause(s) for the illness can be identified:

- Lower abdominal tenderness
- Uterine adnexal tenderness
- Cervical motion tenderness

Additional supportive criteria

- Oral temperature >38.3°C (101°F)
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of WBCs on saline microscopy of vaginal secretions
- Elevated erythrocyte sedimentation rate or elevated C-reactive protein
- Laboratory documentation of infection with *N gonorrhoeae* or *C trachomatis*

Definitive criteria [selected cases]

- Histopathologic evidence of endometritis on endometrial biopsy
- Tubo-ovarian abscess on sonography or other radiologic tests
- Laparoscopic abnormalities consistent with PID

Adapted, with permission, from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2002. MMWR 2002;51(No. RR-6):48–51.

Laparoscopy is the gold standard for detecting salpingitis; it can be used if the diagnosis is in question or to help differentiate PID from an ectopic pregnancy, ovarian cysts, or adnexal torsion. The clinical diagnosis of PID has a positive predictive value for salpingitis of 65–90% in comparison with laparoscopy. Pelvic ultrasonography also is helpful in detecting tubo-ovarian abscesses, which are found in almost 20% of teens with PID. Transvaginal ultrasound is more sensitive than abdominal ultrasound.

B. LABORATORY FINDINGS

Laboratory findings include elevated WBCs with a left shift and elevated acute-phase reactants (erythrocyte sedimentation rate or C-reactive protein). A positive test for *N gonorrhoeae* or *C trachomatis* is supportive, although 25% of the time neither of these bacteria is detected. Pregnancy needs to be ruled out, because patients with an ectopic pregnancy can present with abdominal pain.

Differential Diagnosis

Differential diagnosis includes other gynecologic illnesses (ectopic pregnancy, threatened or septic abortion, adnexal torsion, ruptured and hemorrhagic ovarian

cysts, dysmenorrhea, endometriosis, mittelschmerz); gastrointestinal illnesses (appendicitis, cholecystitis, hepatitis, gastroenteritis, inflammatory bowel disease); and genitourinary illnesses (cystitis, pyelonephritis, urinary calculi).

Complications

Scarring of the fallopian tubes is one of the major sequelae of PID. With one episode of PID, 17% of patients become infertile, 17% develop chronic pelvic pain, and 10% will have an ectopic pregnancy. Infertility rates increase with each episode of PID; three episodes of PID result in a 73% infertility rate. Fitz-Hugh–Curtis syndrome is inflammation of the liver capsule (perihepatitis) from either hematogenous or lymphatic spread of organisms from the fallopian tubes. This results in right upper quadrant pain and elevation of liver function tests.

Treatment

The objective of treatment is to achieve a clinical cure and prevent long-term sequelae. The ability of various therapeutic regimens in preventing sequelae has not been compared. PID is frequently managed at the outpatient level, although some clinicians argue that all adolescents with PID should be hospitalized because of the rate of complications. Severe systemic symptoms and toxicity, signs of peritonitis, inability to take fluids, pregnancy, and elevated WBCs and erythrocyte sedimentation rate support hospitalization. In addition, if the practitioner believes that the patient will not comply with medication, hospitalization is warranted. Surgical drainage may be required to ensure adequate treatment of tubo-ovarian abscesses.

The treatment regimens described in Table 40–1 are broad spectrum to cover the numerous microorganisms associated with PID. Outpatient treatment should be reserved for compliant patients who have classic signs of PID without systemic symptoms. Patients with PID who receive treatment as an outpatient should be reexamined within 24–48 hours, with phone contact in the interim, to detect persistent disease or treatment failure. Patients should have substantial improvement within 48–72 hours. An adolescent should be reexamined 7–10 days after the completion of therapy to ensure the resolution of symptoms.

Clinical Health (PEACH) Randomized Trial. *Am J Obstet Gynecol* 2002;186:929 [PMID: 22009815].

URETHRITIS

General Considerations

Common bacterial causes of urethritis in men are *N gonorrhoeae* and *C trachomatis*. Additionally, *Trichomonas vaginalis*, herpes simplex virus (HSV), *Ureaplasma urealyticum*, and *Mycoplasma genitalium* cause urethritis. Coliforms may cause urethritis in men practicing insertive anal intercourse. Mechanical manipulation or contact with irritants can also cause transient urethritis.

Women often present with symptoms of a urinary tract infection from which no enteric bacterial pathogens are isolated. These women often have urethritis caused by the organisms just mentioned.

Clinical Findings

A. SYMPTOMS AND SIGNS

Most commonly in men, a clear or purulent discharge from the urethra is present with dysuria. Hematuria and associated inguinal adenopathy can occur. Fifty percent of infections caused by *C trachomatis* and *T vaginalis* are asymptomatic, whereas 95% of gonococcal urethritis is symptomatic.

B. LABORATORY FINDINGS

In a symptomatic male a positive leukocyte esterase test on first-void urine, or microscopic examination of first-void urine demonstrating more than 10 WBCs per high-power field, is suggestive of urethritis. Gram stain of urethral secretions demonstrating more than 5 WBCs per high-power field is also suggestive. Gonococcal urethritis is established by documenting the presence of WBCs containing intracellular gram-negative diplococci. Urethral swab or first-void urine for culture or NAAT should be sent to the laboratory to detect *N gonorrhoeae* and *Chlamydia*. Evaluation for *T vaginalis* by a wet preparation of either urethral discharge or spun urine should be considered when the other test results are negative.

Complications

Complications include recurrent or persistent urethritis or epididymitis.

Treatment

Patients with evidence of urethritis should receive empiric treatment for gonorrhea and *Chlamydia* infection. If the infection is unresponsive and culture negative,

the syndrome of nongonococcal, nonchlamydial urethritis is often associated with *Mycoplasma genitalium* or *Ureaplasma urealyticum*. Approximately half of males with this syndrome have no identified pathogen. Trichomoniasis should be excluded. Patients should be instructed to return for evaluation if symptoms persist or recur after completion of initial empiric therapy. Symptoms alone, without documentation of signs or laboratory evidence of urethral inflammation, are not a sufficient basis for retreatment (see Table 40–1). Azithromycin is the initial recommended therapy for persistence of symptoms and urethritis.

Totten PA et al: Association of *Mycoplasma genitalium* with nongonococcal urethritis in heterosexual men. *J Infect Dis* 2001;183(2):269 [PMID: 21063472].

EPIDIDYMUS

General Considerations

Epididymitis is most often caused by *C trachomatis* or *N gonorrhoeae*. Epididymitis caused by *Escherichia coli* occurs among homosexual men who are the insertive partners during anal intercourse and in men who have urinary tract abnormalities.

Clinical Findings

A. SYMPTOMS AND SIGNS

Epididymitis is associated with unilateral testicular pain and tenderness. Palpable, tender swelling of the epididymis is usually present. Often these symptoms are accompanied by asymptomatic urethritis.

B. LABORATORY FINDINGS

Diagnosis is made clinically. Additional evaluation is similar to that described for suspected urethritis (see Urethritis section).

Differential Diagnosis

Acute epididymitis associated with sexual activity must be distinguished from orchitis due to infarct, testicular torsion, or viral infection.

Complications

Infertility is rare, and chronic local pain is uncommon.

Treatment

Empiric therapy is indicated before culture results are available. As an adjunct to therapy, bed rest, scrotal ele-

vation, and analgesics are recommended until fever and local inflammation subside. Lack of improvement of swelling and tenderness within 3 days requires reevaluation of both the diagnosis and therapy (see Table 40–1).

PROCTITIS, PROCTOCOLITIS, AND ENTERITIS

General Considerations

Proctitis occurs predominantly among persons who participate in anal intercourse. Enteritis occurs among those whose sexual practices include oral–fecal contact. Proctocolitis can be acquired by either route depending on the pathogen. Common sexually transmitted pathogens causing proctitis or proctocolitis include *C trachomatis*, *Treponema pallidum*, HSV, *N gonorrhoeae*, *Giardia lamblia*, and enteric organisms.

Clinical Findings

A. SYMPTOMS AND SIGNS

Proctitis, defined as inflammation limited to the distal 10–12 cm of the rectum, is associated with anorectal pain, tenesmus, and rectal discharge. Acute proctitis among persons who have recently practiced receptive anal intercourse is most often sexually transmitted. The symptoms of proctocolitis combine those of proctitis, plus diarrhea or abdominal cramps (or both), because of inflamed colonic mucosa more than 12 cm from the anus. Enteritis usually results in diarrhea and abdominal cramping without signs of proctitis or proctocolitis.

B. LABORATORY FINDINGS

Evaluation may include anoscopy or sigmoidoscopy, stool exam, and culture for appropriate organisms and serology for syphilis.

Treatment

Management will be determined by the etiologic agent (See Table 40–1 and Chapters 20 and 38). Reinfection may be difficult to distinguish from treatment failure.

Rompalo AM: Diagnosis and treatment of sexually acquired proctitis and proctocolitis: An update. *Clin Infect Dis* 1999; 28(Suppl 1):S84 [PMID: 99152439].

VAGINAL DISCHARGE

Adolescent girls may have a normal physiologic leukorrhea, secondary to turnover of vaginal epithelium. Infectious causes of discharge include *T vaginalis*, *C trachomatis*, *N gonorrhoeae*, and bacterial pathogens for vaginosis. Candidiasis is a yeast infection that produces

vaginal discharge but is not usually sexually transmitted.

Vaginitis is characterized by vaginal discharge, vulvar itching and irritation; the discharge may be foul-smelling. Discharge may be white, gray, or yellow. Physiologic leukorrhea is usually white, homogeneous, and not associated with itching, irritation, or foul odor.

Mechanical, chemical, allergic, or other noninfectious irritants of the vagina may cause vaginal discharge.

1. Bacterial Vaginosis

General Considerations

Bacterial vaginosis (BV) is a polymicrobial infection of the vagina caused by an imbalance of the normal bacterial vaginal flora. The altered flora has a paucity of hydrogen peroxide-producing lactobacilli and increased concentrations of *Mycoplasma hominis* and anaerobes, such as *Gardnerella vaginalis* and *Mobiluncus*. It is unclear whether BV is sexually transmitted, but it is associated with having multiple sex partners.

Clinical Findings

A. SYMPTOMS AND SIGNS

The most common symptom is a heavy, malodorous, homogeneous gray-white vaginal discharge. Patients may report vaginal itching or dysuria. The fishy odor may be more noticeable after intercourse or during menses, when the high pH of blood or semen volatilizes the amines.

B. LABORATORY FINDINGS

BV is most often diagnosed by the use of clinical criteria, which include (1) presence of gray-white discharge; (2) fishy odor before or after the addition of 10% KOH (whiff test); (3) pH of vaginal fluid greater than 4.5 determined with narrow range pH paper; and (4) presence of greater than 20% “clue cells.” Clue cells are squamous epithelial cells that have multiple bacteria adhering to them, making their borders irregular and giving them a speckled appearance. Diagnosis requires three out of four criteria, although many women who fulfill these criteria have no discharge or other symptoms.

Complications

BV during pregnancy is associated with adverse outcomes such as premature labor, preterm delivery, and postpartum endometritis. In the nonpregnant individual, it may be associated with PID and urinary tract infections.

Treatment

All women who have symptomatic disease should receive treatment to relieve vaginal symptoms and signs of infection (see Table 40–1). Additional goals for pregnant women include prevention of adverse outcomes of pregnancy. Treatment for patients who do not complain of vaginal discharge or itching, but who demonstrate BV on routine pelvic examination, is unclear. Because some studies associate BV and PID, the recommendation is to have a low threshold for treating asymptomatic BV. Follow-up visits are unnecessary if symptoms resolve. Recurrence of BV is not unusual. Follow-up examination 1-month after treatment for high-risk pregnant women is recommended.

Males do not develop infection equivalent to BV. Treatment of male partners has no effect on the course of infection in females.

Koumans EH et al: Indications for therapy and treatment recommendations for bacterial vaginosis in nonpregnant and pregnant women: A synthesis of data. *Clin Infect Dis* 2002;35:S152 [PMID: 12353202].

Schwabke JR: Bacterial vaginosis. *Curr Infect Dis Rep* 2000;2:14 [PMID: 11095832].

2. *Trichomonas Vaginalis* Infection

General Considerations

Trichomoniasis is caused by *T vaginalis*, a flagellated protozoan that infects 2.5–3 million people annually.

Clinical Findings

A. SYMPTOMS AND SIGNS

Fifty percent of females with trichomoniasis develop a symptomatic vaginitis with vaginal itching; a green-gray, malodorous frothy discharge; and dysuria. Occasionally postcoital bleeding and dyspareunia may be present. The vulva may be erythematous and the cervix friable. Half of men with trichomoniasis will have urethritis.

B. LABORATORY FINDINGS

Mixing the discharge with normal saline facilitates detection of the flagellated protozoan on microscopic examination (wet preparation). The infection may be detected by the pathologist when reviewing the Pap smear. The InPouch TV system is available for culture when the diagnosis is unclear. Culture and antigen detection are sensitive, but expensive and not readily available. Trichomonal urethritis frequently causes a positive urine leukocyte esterase test or WBCs on urethral smear.

Complications

Male partners of females diagnosed with trichomoniasis have a 22% chance of having trichomoniasis. *Trichomonas* infection in women has been associated with adverse pregnancy outcomes.

Treatment (See Table 40–1.)

Schwabke JR, Hook EW 3rd: High rates of *Trichomonas vaginalis* among men attending a sexually transmitted diseases clinic: Implications for screening and urethritis management. *J Infect Dis* 2003;188:465 [PMID: 22751764].

3. Vulvovaginal Candidiasis

General Considerations

Vulvovaginal candidiasis is caused by *Candida albicans* in 85–90% of cases. Most women will have at least one episode of vulvovaginal candidiasis, and almost half will have two or more episodes. The highest incidence is between ages 16 and 30 years. Predisposing factors include recent use of antibiotics, diabetes, pregnancy, and HIV. Risk factors include vaginal intercourse, use of oral contraceptives, and use of spermicide. This is rarely a sexually transmitted infection. Recurrences generally reflect reactivation of colonization.

Clinical Findings

A. SYMPTOMS AND SIGNS

Typical symptoms include pruritus and a white, “cottage cheese”-like vaginal discharge without odor. The itching is more common midcycle and shortly after menses. Other symptoms include vaginal soreness, vulvar burning, vulvar edema and redness, dyspareunia, and dysuria (especially after intercourse).

B. LABORATORY FINDINGS

The diagnosis is usually made by visualizing yeast or pseudohyphae with 10% KOH (90% sensitive) or Gram stain (77% sensitive) in the vaginal discharge. Fungal culture can be used if symptoms and microscopy are not definitive, although colonization is common in asymptomatic women. Vaginal pH is normal with yeast infections.

Complications

The only complication of vulvovaginal candidiasis is recurrent infections (ie, four or more episodes annually).

Treatment

Topical formulations effectively treat vaginal yeast infections. The topically applied azole drugs are more effective than nystatin. Treatment with azoles results in relief of symptoms and negative cultures in 80–90% of patients who complete therapy. Oral fluconazole as a one-time dose is an effective oral medication. Patients should be instructed to return for follow-up visits only if symptoms persist or recur. Six-month prophylaxis regimens have been effective in many women with persistent or recurrent yeast infection. Recurrent disease is usually due to *C albicans* that remains susceptible to azoles, and should be treated for 14 days with oral azoles. Some non-albicans *Candida* will respond to itraconazole. Boric acid capsules (600 mg daily for 14 days) intravaginally are effective. Treatment of sex partners is not recommended but may be considered for women who have recurrent infection (see Table 40–1).

GENITAL ULCERATIONS

In the United States, young, sexually active patients who have genital ulcers have genital herpes, syphilis, or chancroid. The relative frequency of each disease differs by geographic area and patient population; however, in most areas of the United States, genital herpes is the most prevalent of these diseases. More than one of these diseases could be present in a patient with genital ulcers. All ulcerative diseases are associated with an increased risk for HIV infection. The acute retroviral syndrome of HIV infection may be accompanied with oral and genital ulcers.

Ulcers are vaginal, vulvar, or cervical in females, and on any part of the penis in males. Oral lesions may occur concomitant with genital ulcerations in HSV and syphilis. Each etiologic agent has specific characteristics that are described in the following sections. Lesion pain, inguinal lymphadenopathy, and urethritis may be found in association with the ulcers.

1. Herpes Simplex Virus

General Considerations

HSV is the most common cause of visible genital ulcers. At least 50 million people are infected with HSV-2 in the United States. Approximately 0.5–1.5 million new cases occur each year. As with oral HSV infections, many primary genital infections are asymptomatic (60–80%) or not recognizable as herpetic in origin.

Clinical Findings

A. SYMPTOMS AND SIGNS

Symptomatic initial HSV infection causes vesicles of the external genitalia, quickly followed by shallow, painful ulcerations. These may occur in the vulva, vagina, cervix, penis, rectum, or urethra. Atypical presentation of HSV infection includes vulvar erythema and fissures. Urethritis may occur. Initial infection can be severe, lasting up to 3 weeks, and be associated with fever and malaise, as well as localized tender adenopathy. The pain and dysuria can be extremely uncomfortable, requiring sitz baths, topical anesthetics, and occasionally catheterization for urinary retention.

HSV-2 is the most common cause of genital herpes (80%). Symptoms tend to be more severe in females. Recurrence in the genital area with HSV-2 is likely (65–80%). Recurrent genital herpes is of shorter duration (7–10 days), with fewer lesions and usually no systemic symptoms. Prodromal pain in the genital, buttock, or pelvic region is common prior to recurrences. HSV-1, which accounts for 20% of first-episode genital herpes infections, is usually the consequence of oral–genital sex. Primary HSV-1 infection is as severe as HSV-2 infection, and treatment is the same. HSV-1 is associated with recurrent genital disease much less often (< 10%) than is HSV-2.

B. LABORATORY FINDINGS

Diagnosis of genital HSV is often made presumptively, but in one large series this diagnosis was incorrect for 20% of cases. Culture or antigen testing of the vesicles confirms the diagnosis; recurrent genital ulceration is suggestive of HSV infection.

Differential Diagnosis

Any genital ulcer should be cultured for HSV and differentiated from syphilis and chancroid ulcers. The character of the ulcers and inguinal nodes differ in these diseases. (See Chancroid and Syphilis sections).

Complications

Complications, usually with the first episode of genital HSV, include viral meningitis, urinary retention, transmission to newborns at birth, and pharyngitis.

Prevention

All patients with active lesions should be counseled to abstain from sexual contact. Most patients have periodic asymptomatic shedding of HSV, and many cases of genital HSV are transmitted by persons who are unaware that they have the infection or are asymptomatic when transmission occurs. Reactivation can occur in

dividuals who never had symptomatic disease. Individuals with prior HSV infection should be encouraged to always use condoms to protect susceptible partners. Antiviral prophylaxis of infected individuals reduces shedding and significantly reduces the chance of transmission to their sexual partners.

Treatment

Antivirals administered within the first 5 days of primary infection decrease the duration and severity of HSV infection (see Table 40–1). The effect of antivirals on the severity or duration of recurrent disease is limited. For best results, therapy should be started with the prodrome or during the first day of the attack. Although the current recommendations are for 5 days of therapy for recurrences, new information suggests that 3 days of therapy may be sufficient. If recurrences are frequent and cause significant physical or emotional discomfort, patients may elect to take antiviral prophylaxis on a daily basis to reduce the frequency (75% decrease) and duration of recurrences. Treatment of first or subsequent attacks will not prevent future attacks, but recurrence frequency decreases in many individuals over time.

Whitley RJ: Herpes simplex virus infection. *Semin Pediatric Infect Dis* 2002;13: 6–11 [PMID: 22409051].

2. Syphilis

General Considerations

Syphilis is an acute and chronic STI caused by infection with *T pallidum*. The overall rate of syphilis has increased since 1999 to 2.4/100,000 with rates of 3.8/100,000 in men, predominantly those who have sex with men. The South and certain urban areas continue to have high rates of syphilis.

Clinical Findings

A. SYMPTOMS AND SIGNS

Skin and mucous membrane lesions characterize the acute phase of primary and secondary syphilis. Lesions of the bone, viscera, aorta, and central nervous system predominate in the chronic phase (tertiary syphilis) (see Chapter 38). Prevention of syphilis is also important because syphilitic mucosal lesions facilitate transmission of HIV.

Primary syphilis usually presents as a solitary chancre—a painless ulcer with an indurated base and associated nontender, firm adenopathy. The chancre appears 10–90 days after exposure and resolves spontaneously

4–8 weeks later. Because it is painless, it may go undetected, especially if the lesion is within the vagina. Chancres may occur on the genitalia, lips, or anus. Secondary syphilis occurs 4–10 weeks after the chancre appears, with generalized malaise, adenopathy, and a non-pruritic maculopapular rash that often includes the palms and soles. Secondary syphilis resolves in 1–3 months but can recur. Verrucous lesions known as condyloma lata may develop on the genitalia. These must be distinguished from genital warts.

B. LABORATORY FINDINGS

If the patient has a suspect primary lesion, is at high risk, is a contact, or may have secondary syphilis, a nontreponemal serum screen—either RPR or VDRL—should be performed. If the nontreponemal test is positive, then a specific treponemal test, a fluorescent treponemal antibody-absorbed (FTA-ABS) or microhemagglutination–*Treponema pallidum* (MHA-TP) test, is done to confirm the diagnosis. An additional diagnostic tool is darkfield microscopy, which can be used to detect spirochetes in scrapings of the chancre base. Darkfield examinations and direct fluorescent antibody tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis.

If a patient is engaging in high-risk sexual behavior or is living in an urban area in which syphilis is endemic, RPRs should be drawn yearly to screen for asymptomatic infection. Syphilis is reportable to state health departments, and all contacts need to be evaluated. Patients also need to be evaluated for other STIs, including HIV.

Complications

Untreated syphilis can lead to tertiary complications with serious multiorgan involvement, including aortitis and neurosyphilis. Transmission to the fetus can occur from an untreated pregnant woman (see Chapters 1 and 38).

Treatment

See Table 40–1. Patients should be reexamined clinically and serologically with nontreponemal tests at 6 months and 12 months after treatment. If signs or symptoms persist or recur, or patients do not have a fourfold decrease in their nontreponemal test titer, they should be considered to have failed treatment, or be reinfected, and need retreatment.

Golden MR et al: Update on syphilis: Resurgence of an old problem. *JAMA* 2003;290:1510 [PMID: 13129993].

Primary and secondary syphilis—United States, 2002. *MMWR Morb Mortal Wkly Rep* 2003;52:1117 [PMID: 14627949].

3. Chancroid

General Considerations

Chancroid is caused by *Haemophilus ducreyi*. It is relatively rare but endemic in some urban areas and has been associated with HIV infection, drug use, and prostitution. Ten percent of patients with chancroid are coinfecting with HSV or syphilis.

Clinical Findings

A. SYMPTOMS AND SIGNS

The typical lesion begins as a papule that erodes after 24–48 hours into an ulcer. The ulcer has ragged, sharply demarcated edges and a purulent base, is painful (unlike syphilis), solitary, and somewhat deeper than HSV infection. Tender, fluctuant (unlike syphilis and HSV) inguinal adenopathy is present in one third of patients. A painful ulcer in combination with suppurative inguinal adenopathy is very often chancroid.

B. LABORATORY FINDINGS

Gram stain shows gram-positive cocci arranged in a boxcar formation. Culture can be performed on special culture media that is available in academic centers. Other causes of genital ulceration should be excluded.

Differential Diagnosis

Chancroid is distinguished from syphilis by the painful nature of the ulcer and the associated tender suppurative adenopathy. HSV vesicles often produce painful ulcers, but these are multiple, smaller, and shallower than chancroid ulcers. Adenopathy associated with initial HSV infection does not suppurate. A presumptive diagnosis of chancroid should be considered in a patient with typical painful genital ulcers and regional adenopathy, if the test results for syphilis and HSV are negative.

Treatment

Symptoms improve within 3 days after therapy (see Table 40–1). Most ulcers resolve in 7 days, although large ulcers may take 2 weeks to heal. All sexual contacts need to be examined and given treatment, even if asymptomatic.

Lewis DA: Chancroid: Clinical manifestations, diagnosis, and management. *Sex Trans Infect* 2003;79:68 [PMID: 22465222].

4. Other Ulcerations

Lymphogranuloma venereum (LGV), caused by *C trachomatis* serovars L1, L2, or L3, is rare in the United

States. Patients with LGV present with a painless vesicle or ulcer that heals spontaneously, followed by development of tender adenopathy, either unilateral or bilateral. A classic finding is the groove sign—an inguinal crease created by concomitant involvement of inguinal and femoral nodes. These become matted and fluctuant and may rupture. LGV can cause proctocolitis, fistulas, and strictures in patients with anal involvement. Diagnosis can be made by culturing a node aspirate for *Chlamydia* or by serology. Differential diagnosis during the adenopathy phase includes bacterial adenitis, lymphoma, and cat-scratch disease. Differential diagnosis during the ulcerative phase encompasses all causes of genital ulcers. Treatment is with doxycycline, 100 mg twice daily for 21 days.

Granuloma inguinale, or donovanosis, is caused by *Calymatobacterium granulomatis*, a gram-negative bacillus that is rare in the United States. An indurated subcutaneous nodule erodes to form a painless, friable ulcer with granulation tissue. Diagnosis is based on clinical suspicion and supported by a Wright or Giemsa stain of the granulation tissue that reveals intracytoplasmic rods (Donovan bodies) in mononuclear cells. See Table 40–1 for treatment recommendations.

Mabey D, Peeling RW: Lymphogranuloma venereum. *Sex Transm Dis* 2002;78:90 [PMID: 22075989].

Resnick SD: Skin signs of sexually transmitted diseases in adolescents. *Adolesc Med* 2001;12:285 [PMID: 21296765].

GENITAL WARTS (HUMAN PAPILOMAVIRUS)

General Considerations

Condylomata acuminata, or genital warts, are caused by HPV, which can also cause cervical dysplasia. Estimates suggest that up to one third of adolescent females having sexual intercourse in the United States have HPV infections. HPV is transmitted sexually: 30–60% of males whose partners have HPV have evidence of condylomata on examination.

HPV has multiple serotypes. Types 6 and 11 are detected most frequently in genital warts, whereas 16 and 18 cause more than 70% of cervical dysplasia. The infection is more common in persons with multiple partners and in women who have previously had an abnormal Pap smear or genital warts. Cervical HPV is relatively more common in the adolescent population because of increased susceptibility of the cervical transition zone.

The American Cancer Society indicates that there is little risk of missing an important cervical lesion until 3–5 years after initiation of intercourse. Pap smears should be obtained after this time or by age 21. There-

after, annual cervical screening should be performed using conventional Pap smears or every 2 years if using liquid-based cytology (Thin Prep), which can type HPV.

Clinical Findings

A. SYMPTOMS AND SIGNS

For males, verrucous lesions are found on the shaft or corona of the penis. Lesions also may develop in the urethra or rectum. Lesions do not produce discomfort. They may be single or found in clusters. Females develop verrucous lesions on any genital mucosal surface, either internally or externally. In women, cervical HPV infection may only be detected by cytology.

B. LABORATORY FINDINGS

External, visible lesions have unique characteristics that make the diagnosis straightforward. Condylomata acuminata can be distinguished from condylomata lata (syphilis), skin tags, and molluscum contagiosum by application of 5% acetic acid solution. Aceto-whitening is used to indicate the extent of cervical infection.

Pap smears detect cervical abnormalities. HPV infection is the most frequent cause of an abnormal smear. Pap smear findings are graded by the atypical nature of the cervical cells. These changes range from atypical squamous cells of undetermined significance (ASCUS) to low-grade squamous interepithelial lesions (LSIL) and high-grade squamous interepithelial lesions (HSIL). LSIL encompasses cellular changes associated with HPV and mild dysplasia. HSIL includes moderate dysplasia, severe dysplasia, and carcinoma in situ.

Follow-up for ASCUS is controversial, as only 25% progress to dysplasia, and the remainder either demonstrate no progression or regress. If ASCUS is present, the laboratory should be instructed to do HPV typing on Thin Prep Pap smears. If HSIL are found, colposcopy should be performed. If LSIL are detected, colposcopy is not needed and a repeat Pap smear should be done in 1 year. If LSIL or HSIL are subsequently detected, the patient is also referred for colposcopy for direct visualization or biopsy of the cervix (or both). If a Pap smear shows signs of inflammation only, and concomitant infection such as vaginitis or cervicitis is present, the smear should be repeated after the infection has cleared.

Differential Diagnosis

The differential diagnosis includes normal anatomic structures (pearly penile papules, vestibular papillae, sebaceous glands), molluscum contagiosum, seborrheic keratosis, and syphilis.

Complications

Because genital warts can proliferate and become friable during pregnancy, many experts advocate their removal during pregnancy. HPV types 6 and 11 can cause laryngeal papillomatosis in infants and children. Complications of appropriate treatment include scarring with changes in skin pigmentation or chronic pain at the treatment site. Cervical cancer is the most common and important sequel of HPV.

Prevention

The use of condoms may reduce, but does not eliminate, the risk for transmission to uninfected partners.

Treatment

All penile and external vaginal or vulvar lesions can be treated topically. Treatment should be for 4–6 weeks to clear the infection. An experienced practitioner should treat internal and cervical lesions (See Table 40–1).

Warts may resolve or remain unchanged if left untreated or they may increase in size or number. Treatment can induce wart-free periods in most patients. Most recurrences occur within the 3 months following completion of a treatment regimen. Appropriate follow-up of abnormal Pap smears is essential to detect any progression to malignancy.

OTHER VIRAL INFECTIONS

1. Hepatitis (See Chapters 21 and 36)

General Considerations

Hepatitis B and hepatitis C are often STIs. Hepatitis B is at least 10 times more common than HIV in the adolescent population. Since 1998, sexual transmission has accounted for approximately 50% of the estimated 181,000 new hepatitis B infections that occur annually in the United States. Heterosexuals who have unpro-

tected sex with multiple partners and men who have sex with men are the groups at highest risk for sexual transmission.

Hepatitis C generally is transmitted through blood products and shared intravenous needles, although about 10% of hepatitis C infections have been linked to sexual transmission. Hepatitis C needs to be considered in teenagers who are symptomatic and engage in high-risk sexual behavior or intravenous drug use. Outbreaks of sexually transmitted hepatitis A infection have occurred among men who have sex with men, although the efficiency of sexual transmission is low.

Clinical Findings

A. SYMPTOMS AND SIGNS

Symptoms, diagnosis, and treatment are described in Chapter 36.

B. LABORATORY FINDINGS

Adolescents with high-risk behaviors need to be screened for hepatitis B virus (see Screening section). If hepatitis B surface antigen test is present, the patient should be followed to distinguish acute from chronic infection and to provide appropriate management of chronic infection.

Complications

Hepatocellular carcinoma and chronic liver disease are complications of hepatitis B and C infections.

Prevention

Hepatitis B vaccination is the most effective means of preventing infection. All unvaccinated youth should be immunized. A simpler two-dose regimen is available for this age group. Vaccination against hepatitis A virus is recommended for travelers to high-prevalence areas, intravenous drug users, men who have sex with men, and individuals with chronic liver disease of other etiologies.

Treatment

See Chapters 21 and 36.

2. Human Immunodeficiency Virus (See Chapter 37.)

General Considerations

One in four new HIV infections in the United States is acquired by a person age 22 years or younger. Each hour two new young people in the United States become infected with HIV. Because of the long latency period between infection with HIV and progression to

AIDS, it is felt that many HIV-positive young adults contracted HIV during adolescence. The number of females who become HIV-positive has increased dramatically, representing almost half of teenagers with HIV infection.

Risk factors for contracting HIV include a prior STI, infrequent condom use, practicing insertive or receptive anal sex (both males and females), practicing survival sex (ie, trading sex for money or drugs), intravenous drug or crack cocaine use, homelessness, and being the victim of sexual abuse (males). HIV infection should be considered in any sexual risk-taking youths, whether they are practicing heterosexual or homosexual sex.

Clinical Findings

A. SYMPTOMS AND SIGNS

Adolescents may be asymptomatic with recent HIV infection or may present with the acute retroviral syndrome, which is evident 2–6 weeks after exposure. Fever, malaise, lymphadenopathy, rash, upper respiratory symptoms, oral and genital ulcerations, aseptic meningitis, and thrush may occur. If HIV infection is suspected, diagnosis is made in the acute period by p24 antigen detection or HIV polymerase chain reaction.

B. LABORATORY FINDINGS

Screening for HIV by serology should include risk-taking youths and those with any STI. Adolescents may also present to the office requesting an HIV test. In either case, a careful history of sexual behavior should be obtained to assess risk and intervene with risk-reduction counseling. It is also necessary to determine how teens may respond to being told they are HIV-positive and what support systems they have in place. If an adolescent is homeless; does not have emotional support from family, friends, or a counselor; or threatens suicide or homicide in response to the idea of being HIV-positive, then testing should be deferred until the practitioner is confident that the youth will be safe if the test is positive.

Treatment

Many experts recommend aggressive antiretroviral treatment of patients diagnosed with acute retroviral syndrome.

Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents:

<http://www.aidsinfo.nih.gov>

Futterman D et al: HIV and AIDS in adolescents. *Pediatr Clin North Am* 2000;47:171 [PMID: 20162755].

3. HIV Postsexual Exposure Prophylaxis

The risk of acquiring HIV infection through sexual assault or abuse is low but present. The risk for HIV transmission per episode of receptive penile–anal sexual exposure is estimated at 0.1–0.3%; the risk per episode of receptive vaginal exposure is estimated at less than 0.1–0.15%. For males practicing vaginal intercourse, the risk is somewhat less (0.03–0.1%). HIV transmission also occurs from receptive oral exposure, but the risk is unknown.

Health care providers who consider offering postexposure therapy should take into account the likelihood that exposure to HIV occurred, the potential benefits and risks of such therapy, and the interval between the exposure and initiation of therapy. It will be helpful to know the HIV status of the sexual contact. In general, postexposure therapy is not recommended for exposures to noninfectious fluids or exposures to intact skin and when more than 72 hours has passed since exposure. If the patient decides to take postexposure therapy, clinical management should be implemented according to CDC guidelines for occupational mucous membrane exposure.

CDC: Updated US Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. *MMWR Recomm Rep* 2001;50 (RR-11):1 [PMID: 11442229].

Havens PL et al: Postexposure prophylaxis in children and adolescents for nonoccupational exposure to human immunodeficiency virus. *Pediatrics* 2003;111:1475 [PMID: 22662832].

ECTOPARASITIC INFECTIONS

1. Pubic Lice

Phthirus pubis, or pubic lice, live in the pubic hair. The louse or the nits can be transmitted by close contact from person to person. Patients complain of itching, and they may report having seen the insect. Examination of the pubic hair may reveal the louse crawling around or attached to the hair. Closer inspection may reveal the nit or sack of eggs, which is a gelatinous material (1–2 mm) stuck to the hair shaft.

2. Scabies

Sarcoptes scabiei, or scabies, is an organism smaller than the louse. It can be identified by the classic burrow, created by the organism laying eggs and traveling just below the skin surface. Scabies can be sexually transmitted by close contact and can be found in the pubic region, groin, lower abdomen, or upper thighs. The rash is intensely pruritic, erythematous, and scaly.

See Table 40–1 for treatment options. The entire area needs to be covered with the lotion or shampoo for the time specified by the manufacturer. One treatment usually clears the infestation, although a second treatment may be necessary. Bed sheets and clothes must be washed in hot water. Both sexual and close personal or household contacts within the preceding month should be examined and treated.

Wendel K, Rompalo A: Scabies and pediculosis pubis: An update of treatment regimens and general review. *Clin Infect Dis* 2002;35:S146 [PMID: 12353201].

EVALUATION OF SEXUALLY TRANSMITTED INFECTIONS IN SEXUAL ABUSE AND ASSAULT

Sexual abuse is common: 25% of females and 12% of males will have suffered some form of sexual violence by age 18 years. Half of rape victims are younger than age 18 years. Rape is both a medical and a psychological emergency. Evaluation and treatment after sexual abuse or assault depends on the patient's age, his or her ability to communicate what occurred, and the timing of the abuse.

Teenagers usually can describe the kind of abuse (eg, oral, anal, vaginal; receptive or insertive), and evaluation needs to be directed accordingly. If the abuse has occurred in the preceding 72 hours, most states require, for legal purposes, that a rape kit be used. All practitioners should have access to a rape kit, which guides the practitioner through a stepwise collection of evidence and cultures. A thorough physical examination is indicated to evaluate for other signs of trauma.

Beyond 72 hours, evaluation is tailored to the history provided. The involved orifices should be cultured for *N gonorrhoeae* and *Chlamydia* (NAAT is not admissible in court), and vaginal secretions evaluated for *Trichomonas*. RPR, hepatitis B, and HIV serology should be drawn at baseline and repeated in 2–3 months. Pregnancy testing should be done as indicated.

Trichomoniasis, BV, chlamydia, and gonorrhea are the most frequently diagnosed infections among women who have been sexually assaulted. Because the prevalence of these STIs is substantial among sexually experienced women, their presence after an assault does not necessarily signify acquisition during the assault.

Prophylactic therapy should be offered when patients present within the incubation time of any of the disease processes: oral ceftriaxone for gonorrhea and azithromycin or doxycycline for *Chlamydia* infection. If a person is exposed and does not have anti-HBs anti-

body, give hepatitis B immune globulin (HBIG) and vaccine. The efficacy of HBIG for sexual exposure is diminished if delay is greater than 7 days after exposure, and the value after 14 days is uncertain. No effective prophylaxis is available for hepatitis C. Evaluating the perpetrator for STI, if possible, can help determine risk exposure and guide prophylaxis. HIV prophylaxis should be considered in certain circumstances (discussed earlier). Emergency contraception should be given if the abuse occurred within 72 hours. Psychological assessment at the time of presentation, as well as over the next several months, is a top priority. Any suspected abuse must be reported to the local authorities.

All younger children should be referred to child abuse multidisciplinary teams that help with the psychological aspect of the abuse and are well versed in helping children communicate what may have occurred. Colposcopic examination is critical in determining the extent of damage and provide documentation for the legal system.

Although it is often difficult for persons to comply with follow-up examinations weeks after an assault, such examinations are essential in detecting new infections, complete immunization with hepatitis B vaccination if needed, and continued psychological support.

Choosing a safe and effective treatment regimen for pediatric patients can be challenging. New medications and new approaches to drug dosing often originate from adult patient care and are then adapted to the care of pediatric patients. However, it is apparent that simply scaling down drug dosages to allow for differences in weight is not an optimal method of providing effective drug therapy to children. The process of physiologic growth and development is dynamic and extremely complex, resulting in equally dynamic changes in the disposition of drugs and subsequent response to therapies. Multiple patient-specific variables, such as developmental physiology, past medical history, pharmacokinetic and pharmacodynamic properties, desired therapeutic outcomes, and psychosocial issues, need to be considered when designing appropriate drug therapy regimens for children. Unfortunately, there is still a relative deficiency of information regarding exactly how these factors should best be considered when developing regimens that provide adequate therapeutic responses while minimizing potential adverse effects. This chapter provides a brief overview of those issues and how they apply in developing pediatric drug regimens and offers suggestions on how to avoid common medication-related errors.

DEVELOPING A PEDIATRIC DRUG REGIMEN

The various components of a drug therapy regimen—dose, route, frequency, and treatment duration—are dictated by the pharmacokinetic and pharmacodynamic properties of the drug.

Pharmacokinetic Considerations

Pharmacokinetic properties include absorption, distribution, metabolism, and elimination. These properties have not always been well described in terms of changes occurring during specific periods in the life of the child and the physiologic reasons for those changes.

A. ABSORPTION

Oral drug absorption in neonates, infants, and children can be unpredictable owing to variations in gastric pH, gastric emptying time, and intestinal transit time. At birth, gastric pH approaches neutral, but becomes more

acidic as acid secretory mechanisms become more functional, usually within hours of birth. An infant's gastric pH is closer to an adult's by 3 months of age. Gastric emptying in neonates and infants is often considerably prolonged (up to 8 hours or more) but approaches adult values by 6 to 8 months of age. Intestinal transit time is similarly prolonged, and peristaltic mechanisms may be quite erratic.

Elevated gastric pH, together with decreased gastric emptying time and intestinal transit time, may significantly affect a drug's absorption, depending on its physiochemical properties. Weak acids such as phenytoin, phenobarbital, and acetaminophen may be more slowly and incompletely absorbed due to decreased gastric acidity, whereas weak bases such as penicillin G and ampicillin may demonstrate increased bioavailability and more rapid absorption. Sustained release products (eg, theophylline) should be used with care due to the unpredictable and inconsistent absorption that may occur.

B. DISTRIBUTION

Drugs given intravenously (IV), intramuscularly (IM), subcutaneously (SC), topically (TP), or transdermally (TD) may have erratic and unpredictable distribution, especially in neonates. This may be due to poor perfusion (IV, IM, SC, TP, TD), decreased muscle mass (IM, SC), or differences in percentage of total body water (IM, SC, TP, TD). Premature and full-term infants may have body water percentages of 75–85% compared with the more normal adults values of 55–60%. These changes in body water result in significantly increased volumes of distribution and may cause concentrations of water-soluble drugs such as aminoglycoside antibiotics and theophylline to be unusually low with customary doses, whereas the lower volumes of distribution associated with fat-soluble agents such as antiepileptic agents may cause drug concentrations to reach toxic ranges. The reduction in total body water is rapid during the first year of life and reaches adult values by approximately 10–12 years of age.

Another physiologic factor that may affect a drug's distributive properties is the plasma protein (ie, albumin) concentration. Because this concentration in the neonate is lower, drugs such as phenytoin, which is highly protein bound, will have more unbound or ac-

tive drug circulating. This can result in more adverse effects even with an apparent therapeutic blood level. Unbound drugs also have greater membrane permeability, and changes in protein binding may also be at least partially responsible for increased toxicities observed with some centrally acting agents such as analgesics or antiepileptic drugs. Plasma proteins approach normal adult values by 10–12 months of life.

C. METABOLISM

Although a normal, healthy neonate is born with the same hepatic enzymes important for drug metabolism that an adult has, a reduced ability to metabolize drugs is present in the postnatal period. Hepatic enzyme activity is generally reduced in the neonate. As the infant ages, his or her ability to metabolize medications increases. It is interesting to note that, although total metabolic capacity is reduced in neonates and infants, certain metabolic pathways may actually be much more active than in adults and some medications may be metabolized through alternative pathways. Nevertheless, care should be taken during the postnatal period when using medications, such as phenytoin, phenobarbital, and diazepam, that are primarily hepatically metabolized.

D. ELIMINATION

The kidney is responsible for elimination of the majority of drugs and their metabolites from the body. At birth, glomerular filtration rate (GFR) is less than 50% of what it will be eventually. Renal tubular secretory pathways are also relatively immature and decreased in function. Consequently, elimination is prolonged and the dose or dosing intervals (or both) for renally eliminated drugs, such as vancomycin, ranitidine, gentamicin, and ampicillin, need to be adjusted accordingly (see Chapter 35). By age 6 months, the infant's GFR has matured to about 90% of the adult level.

Pharmacodynamic Considerations

Pharmacodynamics describes the relationship between concentrations of drug at the site of drug action and the magnitude of the resulting pharmacologic effect. In contrast to pharmacokinetics, which only considers the disposition of drug within the body, pharmacodynamics relates to how the pharmacokinetics of the drug interact with the target organ or microorganism to cause a drug effect. The purpose of characterizing the pharmacodynamics of drugs is to maximize drug effect and minimize drug toxicities by being able to anticipate the intensity as well as the time course of pharmacologic effects.

For example, the bactericidal effects of aminoglycoside antibiotics are maximized when high plasma con-

centrations of the drug are achieved rapidly; this pharmacodynamic property is referred to as **concentration-dependent** killing. Rapid bacterial killing and extended drug effects occur when peak plasma concentrations of 10–12 times the minimum inhibitory concentration (MIC) of the microbe are achieved. Thus, providing relatively large doses of a drug to achieve high concentrations optimizes the effectiveness of aminoglycosides. In contrast, the pharmacodynamic properties of β -lactam antibiotics (ie, penicillins, cephalosporins) are characterized as **time-dependent**. These drugs kill most effectively when blood levels above the MIC are achieved throughout the interval between drug doses. Thus, relatively smaller doses administered more frequently (every 8 hours or every 6 hours) provide an optimal pharmacodynamic setting.

Antimicrobial treatment is one of the best characterized and most commonly applied examples of pharmacodynamics in the clinical setting. An understanding of the relationship between drug concentration and drug effect is useful for many other drug classes. Theophylline requires approximately 1 hour after a dose for initial effects on pulmonary function to be seen and 12–24 hours after a dose to achieve maximum effects; these effects are not directly correlated with the pharmacokinetic properties of the drug. Maximum anti-inflammatory effects of prednisone or prednisolone occur 6–8 hours after the dose and return to baseline by 24–36 hours, long after blood concentrations of the drug become undetectable. Knowledge of the pharmacodynamics of commonly used agents may assist clinicians in anticipating when desired therapeutic responses will occur or in explaining unusual responses to drug therapy that may be inconsistent with the drug's systemic concentrations.

The pharmacodynamics of most drugs have not been well studied in children. Characterization of the pharmacodynamic properties of drugs in adults is usually based on the assumption that drug-binding receptors present at the site of drug action are stable in number and function. However, it has been demonstrated that certain receptors such as β -adrenergic receptors are quite variable in number and binding affinity, and that this variability is age-related. Further research pertaining to the pharmacodynamics of drugs in children will yield important information that will allow medications to be used more effectively and safely.

1. Therapeutic Drug Monitoring

Many factors can affect a patient's response to a medication, and individualized dosage adjustments may be necessary to achieve the desired response or outcome. Drugs that require routine blood concentration monitoring may require a patient-specific dose adjustment in

Figure 41-1. Differences between linear and nonlinear concentration–dose profiles. Drugs with nonlinear pharmacokinetics can produce unexpected toxic concentrations with only small incremental changes in dose.

order to achieve therapeutic and nontoxic concentrations (Figure 41-1). Three important pharmacokinetic principles govern appropriate individualization of drug doses based on blood concentration determinations.

Steady state is the time it takes for the drug concentration to reach physiologic equilibrium in the body and is directly related to the drug's elimination half-life. In general, a drug is considered to be at steady state after it has been administered continuously at the same dosage and interval (eg, gentamicin, 25 mg every 8 hours) for at least three to five half-lives. For some drugs, the half-life may be short (eg, gentamicin's half-life is 2–4 hours), and steady state is achieved in 1 day. Some drugs have a long half-life (eg, the half-life of phenobarbital is 24–36 hours) and require days or weeks to achieve steady state. Interpreting drug levels and making dosage adjustments on the basis of blood concentrations that are not at steady state can lead to overdosing and subsequent toxicity. Likewise, after a dosage adjustment has been made, sufficient time must be allowed (an additional three to five half-lives) and a new steady state must be achieved before rechecking the blood concentration and making additional clinical decisions based on the result.

A second principle is the **linear relationship** between the blood concentration of most drugs at steady state and the dose administered (eg, vancomycin, theophylline, phenobarbital). Therefore, if a steady-state blood concentration is 50% of that eventually desired, doubling the dosage will achieve the desired concentration after the drug achieves its new pharmacokinetic steady state.

A third concept is the **nonlinear relationship** among clearance, dosing rate, and blood concentration that exists for a select group of drugs (salicylates, ethanol, phenytoin). These drugs do not have a predictable correlation between dosing rate and steady-state blood concentration. Doubling the daily dosage of one of these drugs may result in a three- to fourfold increase in concentrations, overshooting the desired concentrations and resulting in exaggerated response or undesirable toxicities. Drugs with nonlinear pharmacokinetics thus require close drug monitoring by clinicians experienced with these drugs (Table 41-1).

It should be noted that the therapeutic blood levels shown in Table 41-1 are not absolute numbers that will produce desired responses in all patients. Recommended blood concentrations are based on the *probability* of a drug producing the desired response at those levels. Most patients will have good drug responses and therapeutic outcomes when blood concentrations are in the desired ranges. However, some patients may achieve adequate responses at less-than-recommended blood concentrations, while other patients may require concentrations far in excess of those normally required. Likewise, unacceptable drug toxicities may occur in some patients at concentrations less than those normally recommended, whereas others will tolerate high concentrations of drugs relatively well. The tremendous variability among patients requires that blood concentrations be interpreted in the overall context of a patient's clinical response rather than solely on the basis of recommended blood concentrations.

2. Drug Selection

Patient-Specific Factors

The patient's age is one of the most important parameters to consider when developing a drug therapy regimen. Additionally, physiologic and psychological age should influence the choice of drug, the route of administration, the dosing regimen, and the monitoring parameters. Physiologic factors such as the inability of newborns and infants to reliably absorb oral medications limit this route of administration. Psychological issues are more important when considering treatment for older children and adolescents or when the parents of a young child have limited cognitive functioning. The ability of the patient or parent to accurately administer a drug therapy can affect its efficacy and safety. Factors to keep in mind when selecting drug therapy are given in Table 41-2.

Because nearly all drugs are primarily eliminated from the body by the liver and kidneys, the function of these organs should be assessed before selecting drug therapy and throughout the treatment course. Renal

Table 41–1. Therapeutic blood levels.^a

Drug	Therapeutic Range
Acetaminophen	10–20 µg/mL
Amikacin	15–30 µg/mL (peak) < 5 µg/mL (trough)
Aspirin	150–300 µg/mL
Carbamazepine	4–12 µg/mL
Cyclosporine	50–250 mg/mL ^b
Digoxin	0.9–2.4 ng/mL
Ethanol	1000 µg/mL
Ethosuximide	40–100 µg/mL
Flucytosine	< 100 µg/mL < 80 µg/mL in newborns and infants
Gentamicin	6–10 µg/mL (peak) < 2 µg/mL (trough)
Lidocaine	< 100 ng/mL (newborn) 1.5–2.5 µg/mL (adult)
Methsuximide as the metabolite of <i>N</i> -desmethsuximide	10–40 µg/mL
Phenobarbital	15–40 µg/mL
Phenytoin	10–20 µg/mL
Primidone	4–12 µg/mL
Procainamide	4–6 µg/mL
Quinidine	3–5 µg/mL
Theophylline	5–20 µg/mL
Tobramycin	6–10 µg/mL (peak) < 2 µg/mL (trough)
Valproic acid	50–120 µg/mL
Vancomycin	20–40 µg/mL (peak) 4–12 µg/mL (trough)

^aTherapeutic level or range for drugs that can be routinely analyzed.

^bTherapeutic ranges will differ depending on type of cyclosporine assay used (eg, monoclonal versus polyclonal whole blood TDx assays) and the type of transplant (ie, heart, kidney, bone marrow).

function can be assessed easily by using serum creatinine concentrations to estimate GFR.

Since most of the renal dosing adjustment guidelines are derived from adult experience, it is necessary to calculate an infant's adjusted GFR by using his or her body surface area (BSA). This subsequently will better simulate adult values and allow for more accurate ad-

justments of pediatric doses to account for renal dysfunction. Close monitoring for drug toxicity is necessary when decreased hepatic metabolism is suspected in patients receiving hepatically metabolized drugs. Table 41–3 lists some commonly used drugs and their primary route of elimination.

The acuteness of the patient's condition should always be considered. Drug therapy may not be appropriate when the child has mild symptoms because drug side effects may be worse than the disease (eg, decongestant use in infants with a cold).

Drug-Specific Factors

Individualization of drug therapy requires specific knowledge about the patient and the potential drug treatment alternatives. The therapeutic index (Figure 41–2) is the ratio of the maximum tolerated dose to the minimum curative dose. It is a measure of the relative benefits and risks of a selected drug regimen. A drug with a wide therapeutic index has a greater margin of safety than one with a narrow index (Table 41–4). As with the relationship between drug blood concentrations and patient response, the therapeutic index for any specific drug is characterized by significant variation among individuals. However, this variability is usually more problematic in the clinical use of a drug with a narrow therapeutic index. Drugs with wide therapeutic indices are therefore usually selected for initial treatment if possible. Close patient monitoring is required to ensure an acceptable clinical response to drug therapy.

3. Routes Of Administration

Oral Route

Oral administration is the easiest, least expensive, and most convenient route of drug administration in children. Oral therapy is sometimes not the most appropriate in very young infants (younger than age 1–2 months) or in children with short bowel syndrome because of unpredictable absorption. Oral therapy is also not initially indicated for a severely ill child. When oral therapy is chosen, the desired dosage form for the child's age should be selected. Oral suspensions and liquids are available for many medications and are preferred for infants and young children. A number of drugs are not available in liquid formulations but can be compounded by pharmacies (Table 41–5). Several “sprinkle” formulations are available that can be added to foods. Chewable tablets can be used beginning at about age 12–18 months.

Absorption of orally administered medications can be affected by dietary factors. Recommendations for administration with or without food are specific for each drug and should be followed.

Table 41–2. Factors that can affect drug therapy selection and decision making.

Factors	Concerns
PHYSIOLOGIC	
Hyperbilirubinemia	Drugs such as ceftriaxone and sulfisoxazole can displace bilirubin and induce kernicterus in newborns.
Newborn immaturity	
GI malabsorption	Oral antibiotics are unreliably absorbed during the first month of life
Renal insufficiency	Renal-eliminated drugs such as the penicillins and aminoglycosides in newborns require extended dosing intervals
Hepatic insufficiency	Hepatic-eliminated drugs such as phenobarbital, morphine, and diazepam in newborns require lower doses and extended intervals.
Malnutrition (decreased albumin)	Drugs such as phenytoin, warfarin, and ibuprofen can have enhanced pharmacologic action due to decreased protein binding and increased free drug concentrations.
Short bowel syndrome	Oral medications of all types can have erratic absorption when the amount of bowel (especially duodenum) available to absorb drug is reduced.
Coordination of swallow	Solid oral medications (capsules, tablets) can be swallowed by children as young as 3 years
PSYCHOLOGICAL	
Cognitive ability	Decreased understanding of directions, indications, or monitoring of drug therapy can lead to noncompliance or delayed recognition of side effects.
PSYCHOSOCIAL	
	Patients with a chaotic home situation, those with multiple caregivers, and those in daycare or school can have difficulty with dosing regimens. Low-income families may have problems paying for expensive drug therapies.
COMPLIANCE	
Palatability	Liquid oral medications with an unpleasant taste, texture, or aftertaste.
Schedule	Dosing regimens with complicated schedules (tapering doses) or high-frequency intervals (four times daily).
Timing with respect to eating	Requirement to dose on empty stomach or with food.
Volume	Liquid oral medications with large volume doses (> 10 ml).
Side effects	Medications with undesirable side effects (eg, diarrhea).
MISCELLANEOUS	
Availability	The dosage form needs to be available either commercially or by extemporaneous preparation or by splitting a commercially available tablet.

Rectal Route

Rectal administration of medications should be reserved for children who cannot take oral medications. Incomplete dose administration can occur if the suppository does not remain in the rectum for sufficient time. Drug distribution within a suppository may not be uniform; therefore, administering half of a suppository may not provide half the dose, leading to either a subtherapeutic or a toxic response in the child.

Parenteral Route

Intravenous administration of drugs is the most reliable method of delivery and is preferred in severely ill children. Many physical incompatibilities have been identi-

fied with the coadministration of intravenous medications and maintenance fluids. If an incompatibility is suspected, a pharmacist should be contacted for documentation and management of the incompatibility. Although IV administration is the most direct way to deliver a medication, it is not without risks. Complications such as thrombophlebitis and extravasation, in addition to IV access itself, can be painful and detrimental to the child.

4. Drug Dosing

Methods Based on Weight

Nearly every drug that has been safely used in pediatric patients has an established milligram-per-kilogram dos-

Table 41–3. Primary route of elimination for drugs commonly used in pediatrics.

Renal Elimination	Hepatic Elimination
Acyclovir	Acetaminophen
Aminoglycosides	Anticonvulsants (phenytoin, carbamazepine)
Cephalosporins	Antidepressants (imipramine, fluoxetine)
Digoxin	Benzodiazepines (diazepam, lorazepam)
Fluconazole	Clindamycin
Furosemide	Erythromycin
Penicillins	Opiates (morphine, codeine)
Ranitidine and cimetidine	Steroids (anti-inflammatory and hormonal)
	Theophylline

Ibuprofen	Catecholamines (dopamine, epinephrine)
Penicillins	Digoxin
Ranitidine and cimetidine	Heparin and warfarin
Sucralfate	Lidocaine
	Opiate narcotics (morphine, codeine)
	Theophylline
	Vancomycin and immunosuppressants (cyclosporine)

^aRelatively safe; can round doses.

^bIncreased toxicity; requires specific dosing.

ing range. Drug dosing based on a child’s weight in kilograms is simple, convenient, and widely accepted. In general, drugs with a wide therapeutic index have wider dosing ranges, and rounding of doses to a standard dose (eg, amoxicillin 250 mg rather than 236 mg) is recommended.

Drugs with a narrow therapeutic index should be dosed based on the specific mg/kg dosing guidelines and adjusted during therapy with serum drug level monitoring, if available. Frequent recalculation of dosages should be incorporated into the care of children receiving long-term drug therapy because their growth will eventually necessitate increased dosages.

Methods Based on Body Surface Area

Drug dosing based on BSA may be more accurate. Many drugs with a narrow therapeutic index have dosing guidelines based on patient BSA. Antineoplastic (chemotherapy) drugs used to treat cancer in pediatric patients, antiretroviral drugs used to treat HIV infection, and some other antiviral agents are a few of the commonly prescribed pediatric drugs that are dosed according to BSA measurements. With some drugs (eg, acyclovir), dosing recommendations are based both on mg/kg and BSA, and the calculated dosages by the two methods can be discrepant. Limited data are available

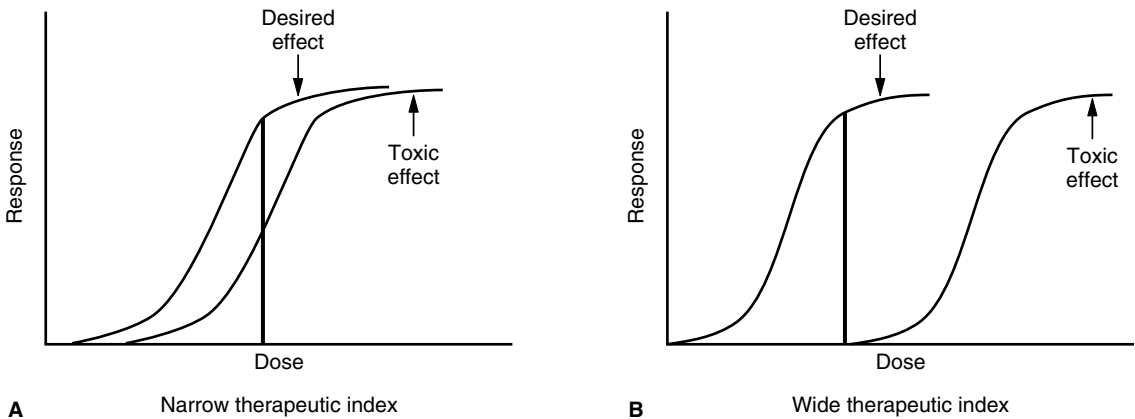

Figure 41–2. Graphs of therapeutic index defined as the difference between desired (therapeutic) effect and toxic effect of a drug at a given dose. **A:** Narrow therapeutic index. **B:** Wide therapeutic index.

Table 41–5. Common drugs that can be compounded into suspensions or liquids for oral administration.

Amlodipine	Metolazone
Azathioprine	Metronidazole

Caffeine	Phenazopyridine
Captopril	Rifampin
Clonidine	Sotolol
Dipyridamole	Spirolactone
Enalapril	Ursodiol
Ganciclovir	Verapamil

evaluating the differences in efficacy and safety of drugs dosed by each method; however, many clinicians believe that dosing based on BSA is a more accurate method.

Methods Based on Age

Drug dosing based on age is the least accurate method for determining the appropriate dose for a pediatric patient. This method can result in a child receiving a dose that is too high if the child is small for his or her age. This type of dosing method is appropriate only for children who are of average weight and height (ie, 50th percentile) or for medications with a wide therapeutic range. Over-the-counter medications are a class of drugs most commonly dosed based on the age method.

DRUG INTERACTIONS

Drug interactions can occur between several drugs or between drugs and food. Table 41–6 lists pediatric drugs that have known drug–drug interactions (see Table 41–7 for other sources for this information).

Table 41–6. Pediatric drugs commonly associated with drug interactions.

Inducers ^a	Inhibitors ^b
Carbamazepine	Cimetidine
Phenobarbital	Cisapride
Phenytoin	Erythromycin/clarithromycin
Rifampin	Fluconazole/itraconazole
	Valproate
	Ritonavir

^aInducers increase the metabolism of other medications, thus decreasing plasma levels.

^bInhibitors decrease the metabolism of other medications, thus increasing plasma levels.

Drug interactions are usually a direct result of the “overlapping” of the metabolism of two drugs. Most drugs undergo biotransformation to active metabolites in the liver. The liver can transform drugs in many ways. The cytochrome P-450 monooxygenase system contributes to the mechanism of many drug interactions. When evaluating drug combinations for safety, the physician must determine conflicting routes of metabolism. This is paramount when more than one hepatically metabolized drug is prescribed.

Drug interactions are not necessarily a contraindication to use of the drugs. With appropriate identification, proper dosage adjustment, and close therapeutic monitoring, some potentially interacting drug regimens can safely be used concurrently.

PREVENTING MEDICATION ERRORS

Primum non nocere—the first rule of medicine most certainly applies to the application of pharmacotherapy. Avoiding medication error is critical, especially in pediatric patients, in whom the margin of error is typically less. Prescribing errors can be reduced by a number of simple steps.

Decimal Point Placement

For doses less than one, always put a leading zero before the decimal point (ie, write 0.1 mg not .1 mg). Likewise, if the dose is a fractional whole number, never place a decimal point and a zero after the number (ie, write 1 mg not 1.0 mg). Decimal points can easily be overlooked or misinterpreted. This can result in a tenfold dosing error, either underdose or overdose.

Abbreviations

Abbreviations should be avoided. This includes the common use of Latin abbreviations and the use of abbreviations in reference to drug names (eg, qid, qd, MSO₄, MgSO₄). Abbreviations can have multiple meanings or be mistaken for numbers. For example, using the letter “u” to indicate units can be misinterpreted as a zero when closely following a number (ie, write 10 units not 10 u). The handwritten symbol “μg” commonly used as an abbreviation for microgram can be confused with another commonly used symbol “mg” for milligram (note 1000-fold difference). Prescribers are encouraged to use the abbreviation “mcg” for micrograms to avoid confusion and resulting dosing errors.

Legibility

Writing neat, legible orders will minimize the need for interpretation or clarification of orders. Additionally,

the use of institutionally approved preprinted order forms can increase legibility and decrease the chance of medication errors occurring. Unfortunately, many look-alike, sound-alike drug names exist (eg, Celexa, Cerebyx, Celebrix), and poor legibility can lead to mix-ups with these products.

Maximum Dosing

In older children weighing more than 40–50 kg, in whom pediatric doses based on body weight might exceed the normal adult dose, the normal adult dosage should be used as the upper limit to prevent toxicity and achieve desired efficacy.

SOURCES OF PEDIATRIC DRUG INFORMATION

The Pharmacist

Pharmacists—particularly those who practice in a pediatric care environment—are extremely useful sources of pediatric drug information. They often know drug doses, side effects, and practical issues regarding the appropriate therapeutic uses of pharmaceuticals in children. Their services are usually available at any hour, 7 days a week, at no cost to the patient.

References at Work

Table 41–7 summarizes useful pediatric-based drug references. Clinicians who care for pediatric patients should be familiar with these resources.

The Federal Drug Administration (FDA)

In 1997, the Food and Drug Modernization Act of 1997 was signed into law. The purpose behind this law was to remedy the lack of pediatric information avail-

able for many medications being prescribed for children. A list of drugs was created and, after consultation with pediatric experts, was posted on the FDA website, www.fda.gov. These medications have been targeted so that research surrounding their use in pediatric patients will be performed, thus providing clinicians with timely pediatric drug information. The hope is that enforcement of this act will lead to new and helpful prescribing guidelines that are more accessible to pediatric clinicians.

Fluid, Electrolyte, & Acid–Base Disorders & Therapy

42

Douglas M. Ford, MD

REGULATION OF BODY FLUIDS, ELECTROLYTES, & TONICITY

Total body water (TBW) constitutes 50–75% of the total body mass depending on age, sex, and fat content. After an initial postnatal diuresis, the TBW slowly decreases to the adult range near puberty (Figure 42–1). TBW is divided into the intracellular and extracellular spaces. Intracellular fluid (ICF) accounts for two thirds of the TBW, or roughly 50% of total body mass. Extracellular fluid (ECF) constitutes one third of the TBW and 25% of total body mass. The ECF is further compartmentalized into plasma (intravascular) volume and interstitial fluid (ISF).

The principal constituents of plasma are sodium, chloride, bicarbonate, and protein (primarily albumin). The ISF is similar to plasma but lacks significant amounts of protein (Figure 42–2). Conversely, the ICF is rich in potassium, magnesium, phosphates, sulfates, and protein.

An understanding of osmotic shifts between the ECF and ICF is fundamental to understanding disorders of fluid balance. Iso-osmolality is generally maintained between fluid compartments. Because the cell membrane is water-permeable, abnormal fluid shifts occur if the concentration of solutes that cannot permeate the cell membrane in the ECF does not equal the concentration of such solutes in the ICF. Thus, NaCl, mannitol, and glucose (in the setting of hyperglycemia) remain restricted to the ECF space and contribute effective osmoles by obligating water to remain in the ECF compartment. In contrast, a freely permeable solute, such as urea, does not contribute effective osmoles because it is not restricted to the ECF and readily crosses cell membranes. Tonicity, or effective osmolality, differs from measured osmolality in that it accounts only for osmotically active impermeable solutes rather than all osmotically active solutes, including those that are permeable to cell membranes. Osmolality may be estimated by the following formula:

$$\text{mOsm/kg} = 2(\text{Na}^+, \text{mEq/L}) + \frac{\text{Glucose, mg/dL}}{18} + \frac{\text{BUN, mg/dL}}{2.8}$$

Although osmolality and osmolarity differ, the former being an expression of osmotic activity per weight (kg) and the latter per volume (L) of solution, for clinical purposes they are similar and occasionally used interchangeably. Oncotic pressure represents the osmotic activity of macromolecular constituents such as albumin in the plasma and body fluids.

The principal mechanisms that regulate ECF volume and tonicity are antidiuretic hormone (ADH), thirst, aldosterone, and atrial natriuretic factor (ANF).

Antidiuretic Hormone

In the kidney, ADH increases water reabsorption in the cortical and medullary collecting ducts, leading to formation of a concentrated urine. In the absence of ADH, a dilute urine is produced. Under normal conditions, ADH secretion is regulated by the tonicity of body fluids rather than the fluid volume and becomes detectable at a plasma osmolality of 280 mOsm/kg or greater. However, tonicity may be sacrificed to preserve ECF volume, as in the case of hyponatremic dehydration, wherein ADH secretion and renal water retention are maximal.

Thirst

Water intake is commonly determined by cultural factors rather than by thirst. Thirst is not physiologically stimulated until plasma osmolality reaches 290 mOsm/kg, a level at which ADH levels are sufficient to induce maximal antidiuresis. Thirst provides control over a wide range of fluid volumes and can even be a response to absence of ADH with attendant production of copious and dilute urine. One who cannot perceive thirst develops profound problems with fluid balance.

Aldosterone

Aldosterone—released from the adrenal cortex in response to decreased effective circulating volume and stimulation of the renin–angiotensin–aldosterone axis or in response to increasing plasma K^+ —enhances renal tubular reabsorption of Na^+ in exchange for K^+ and, to

Figure 42-1. Body water compartments related to age. (Modified, with permission, from Friis-Hansen B: Body water compartments in children: Changes during growth and related changes in body composition. *Pediatrics* 1961;28:169.)

a lesser degree, H^+ . At a constant osmolality, retention of Na^+ leads to expansion of ECF volume and suppression of aldosterone release.

Atrial Natriuretic Factor

ANF, a polypeptide hormone secreted principally by the cardiac atria in response to atrial dilatation, plays an

important role in regulation of blood volume and blood pressure. ANF inhibits renin secretion and aldosterone synthesis and causes an increase in glomerular filtration rate and renal sodium excretion. ANF also guards against excessive plasma volume expansion in the face of increased ECF volume by shifting fluid from the vascular to the interstitial compartment. ANF inhibits angiotensin II- and norepinephrine-induced vasoconstrictic-

Figure 42-2. Composition of body fluids. ICF = intracellular fluid; ISF = interstitial fluid.

tion and acts in the brain to decrease the desire for salt and inhibit the release of ADH. Thus the net effect of ANF is a decrease in blood volume and blood pressure associated with natriuresis and diuresis.

ACID-BASE BALANCE

The pH of arterial blood is maintained between 7.38 and 7.42 to ensure that pH-sensitive enzyme systems function normally. Acid-base balance is maintained by interaction of the lungs, kidneys, and systemic buffering systems. Over 50% of the blood's buffering capacity is provided by the carbonic acid/bicarbonate system, roughly 30% by hemoglobin, and the remainder by phosphates and ammonium. The carbonic acid/bicarbonate system, depicted chemically as:

interacts with the lungs, kidneys, and nonbicarbonate systems to stabilize systemic pH. The concentration of dissolved CO_2 in blood is established by the respiratory system and that of HCO_3^- by the kidneys. Disturbances in acid-base balance are initially stabilized by chemical buffering, compensated for by pulmonary or renal regulation of CO_2 or HCO_3^- , and ultimately corrected when the primary cause of the acid-base disturbance is eliminated.

Renal regulation of acid-base balance is accomplished by the reabsorption of filtered HCO_3^- and the excretion of H^+ or HCO_3^- to match the net input of acid or base. When urine is alkalinized, HCO_3^- enters the kidney and is ultimately lost in the urine. Alkalinization of the urine may occur when an absolute or relative excess of bicarbonate exists. However, urinary alkalinization will not occur if there is a deficiency of Na^+ or K^+ , because HCO_3^- must also be retained to maintain electroneutrality. In contrast, the urine may be acidified if an absolute or relative decrease occurs in systemic HCO_3^- . In this setting, proximal tubular HCO_3^- reabsorption and distal tubular H^+ excretion are maximal. Some of the processes involved in acid-base regulation are shown in Figure 42-3.

FLUID & ELECTROLYTE MANAGEMENT

Therapy of fluid and electrolyte disorders is directed toward providing maintenance fluid and electrolyte requirements, replenishing prior losses, and replacing persistent abnormal losses. Therapy should be phased

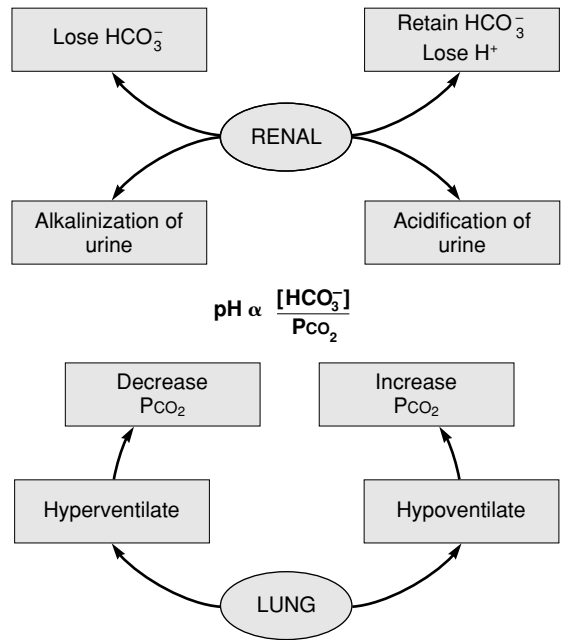

Figure 42-3. Maintaining metabolic stability via compensatory mechanisms.

to (1) rapidly expand the ECF volume and restore tissue perfusion, (2) replenish fluid and electrolyte deficits while correcting attendant acid-base abnormalities, (3) meet the patient's nutritional needs, and (4) replace ongoing losses.

The cornerstone of therapy involves an understanding of maintenance fluid and electrolyte requirements. Maintenance requirements call for provision of enough water, glucose, and electrolytes to prevent deterioration of body stores. During short-term parenteral therapy, sufficient glucose is provided to prevent ketosis and limit protein catabolism, although this is usually little more than 20% of the patient's true caloric needs. Prior to the administration of maintenance fluids, it is important to consider the patient's volume status and to determine whether intravenous fluids are needed at all.

Various models have been devised to facilitate calculation of maintenance requirements based on body surface area, weight, and caloric expenditure. A system based on caloric expenditure is most helpful, because 1 mL of water is needed for each kilocalorie expended. The system presented in Table 42-1 is based on caloric needs and is applicable to children weighing more than 3 kg.

As depicted in Table 42-1, a child weighing 30 kg would need 1700 kcal and 1700 mL of water daily. If

Table 42-1. Caloric and water needs per unit of body weight.

Body Weight (kg)	kcal/kg	mL of Water/kg
3–10 kg	100	100
11–20 kg	1000 kcal + 50 kcal/kg for each kg > 10 kg	1000 mL + 50 mL/kg for each kg > 10 kg
>20 kg	1500 kcal + 20 kcal/kg for each kg > 20 kg	1500 mL + 20 mL/kg for each kg > 20 kg

Adapted, with permission, from Holliday MA, Segar WE: The maintenance need for water in parenteral fluid therapy. *Pediatrics* 1957;19:823.

the child received parenteral fluids for 2 days, the fluid would usually contain 5% glucose, which would provide 340 kcal/d, or 20% of the maintenance caloric needs. Maintenance fluid requirements take into account normal insensible water losses and water lost in sweat, urine, and stool and assume the patient to be afebrile and relatively inactive. Maintenance requirements are greater for low-birth-weight and preterm infants. Table 42-2 lists other factors that commonly alter fluid and caloric needs.

Electrolyte losses occur primarily through the urinary tract and to a lesser degree via the skin and stool. Although maintenance electrolyte estimates vary, reasonable approximations for maintenance needs are 3 mEq Na⁺/100 kcal and 2 mEq K⁺/100 kcal or 30 mEq Na⁺/L and 20 mEq K⁺/L, respectively, of intravenous fluid.

It is helpful to monitor the patient's daily weight, urinary output, fluid input, and urine specific gravity. If fluid or electrolyte balance is abnormal, serial determination of electrolyte concentrations, blood urea ni-

trogen (BUN), and creatinine may be necessary. In patients with significant burns, anuria, oliguria, or persistent abnormal losses (eg, from a stoma, or polyuria secondary to a renal concentrating defect), it is important to measure output and, if needed, its components so that appropriate replacement can be provided.

DEHYDRATION

Depletion of body fluids is one of the most commonly encountered problems in clinical pediatrics. Children have a high incidence of gastrointestinal diseases, including gastroenteritis, and may demonstrate gastrointestinal symptoms in nongastrointestinal conditions. Infants and young children often decrease their oral intake when ill, and their high ratio of surface area to weight promotes significant evaporative losses. Renal concentrating mechanisms do not maximally conserve water in early life, and fever may significantly increase fluid needs. Dehydration decreases ECF volume, leading to decreased tissue perfusion, impaired renal function, compensatory tachycardia, and lactic acidosis. The clinical effects of dehydration relate to the degree of dehydration and to the relative amounts of salt and water lost. Caregivers must be particularly aware of dehydration occurring in breast-fed newborn infants who go home soon after birth and whose mothers fail to produce enough milk. This problem is more common in the hot summer months and has been associated with severe dehydration, brain damage, and death.

The clinical evaluation of a child with dehydration should focus on the composition and volume of fluid intake; the frequency and amount of vomiting, diarrhea, and urine output; the degree and duration of fever; the nature of any administered medications; and the existence of underlying medical conditions. A recently recorded weight, if known, can be very helpful in calculating the magnitude of dehydration. Important clinical features in estimating the degree of dehydration include the capillary refill time, postural blood pressure, and heart rate changes; dryness of the lips and mucous membranes; lack of tears; lack of external jugular venous filling when supine; a sunken fontanelle in an infant; oliguria; and altered mental status (Table 42-3). Children generally respond to a decrease in circulating volume with a compensatory increase in pulse rate and may maintain their blood pressure in the face of severe dehydration. A low or falling blood pressure is, therefore, a late sign of shock in children, and when present should prompt emergent treatment. Salient laboratory parameters include a high urine specific gravity (in the absence of an underlying renal concentrating defect), a relatively greater elevation in BUN than in creatinine, a low urinary [Na⁺] excretion (< 15 mEq/L), and an ele-

Table 42-2. Alterations of maintenance fluid requirements.

Factor	Altered Requirement
Fever	12% per °C ^a
Hyperventilation	10–60 mL/100 kcal

Hemodynamic signs			
Pulse	Normal	Slight increase	Tachycardia
Capillary refill	2–3 sec	3–4 sec	> 4 sec
Blood pressure	Normal	→	Low
Perfusion	Normal	→	Circulatory collapse
Fluid loss			
Urinary output	Mild oliguria	Oliguria	Anuria
Tears	Decreased	→	Absent
Urinary indices			
Specific gravity	> 1.020	→	Anuria
Urine [Na ⁺]	< 20 mEq/L	→	Anuria

vated hematocrit or serum albumin level secondary to hemoconcentration.

Emergent intravenous therapy is indicated when there is evidence of compromised perfusion (inadequate capillary refill, tachycardia, poor color, oliguria, or hypotension). The initial goal is to rapidly expand the plasma volume and to prevent circulatory collapse. A 20 mL/kg bolus of isotonic fluid should be given intravenously as rapidly as possible. Either colloid (5% albumin) or crystalloid (normal saline or Ringer lactate) may be used. Colloid is particularly useful in hypernatremic patients in shock, in malnourished infants, and in neonates. If no intravenous site is available, fluid may be administered intraosseously through the marrow space of the tibia. If there is no response to the first fluid bolus, a second bolus may be given. When adequate tissue perfusion is demonstrated by improved capillary refill, decreased pulse rate and urine output, and improved mental status, deficit replacement may be instituted. If adequate perfusion is not restored after 40 mL/kg of isotonic fluids, other pathologic processes must be considered such as sepsis, occult hemorrhage, or cardiogenic shock. Isotonic dehydration may be treated by providing half of the remaining fluid deficit over 8 hours and the second half over the ensuing 16 hours in the form of 5% dextrose with 0.2–0.45%

saline containing 20 mEq/L KCl. In the presence of metabolic acidosis, K⁺ acetate may be considered. Maintenance fluids and replacement of ongoing losses should also be provided. Typical electrolyte compositions of various body fluids are depicted in Table 42-4, although it may be necessary to measure the specific constituents of a patient's fluid losses to guide therapy. If the patient is unable to eat for a prolonged period, nutritional needs must be met through hyperalimentation or enteral tube feedings.

Oral rehydration may be provided to children with mild to moderate dehydration. Clear liquid beverages found in the home, such as broth, soda, juice, and tea, are inappropriate for the treatment of dehydration. Commercially available solutions provide 45–75 mEq/L of Na⁺, 20–25 mEq/L of K⁺, 30–34 mEq/L of citrate or bicarbonate, and 2–2.5% glucose. Frequent small aliquots (5–15 mL) should be given to provide approximately 50 mL/kg over 4 hours for mild dehydration and up to 100 mL/kg over 6 hours for moderate dehydration. Oral rehydration is contraindicated in children with altered levels of consciousness or respiratory distress who cannot drink freely; in children suspected of having an acute surgical abdomen; in infants with greater than 10% volume depletion; in children with hemodynamic instability; and in the setting of se-

Table 42-4. Typical electrolyte compositions of various body fluids.

	Na ⁺ (mEq/L)	K ⁺ (mEq/L)	HCO ₃ ⁻ (mEq/L)

vere hyponatremia ($[Na^+] < 120$ mEq/L) or hypernatremia ($[Na^+] > 160$ mEq/L). Failure of oral rehydration due to persistent vomiting or inability to keep up with losses mandates intravenous therapy. Successful oral rehydration requires explicit instructions to caregivers.

The type of dehydration is characterized by the serum $[Na^+]$. If relatively more solute is lost than water, the $[Na^+]$ falls, and hyponatremic dehydration ($[Na^+] < 130$ mEq/L) ensues. This is important clinically because hypotonicity of the plasma contributes to further volume loss from the ECF into the intracellular space. Thus tissue perfusion is more significantly impaired for a given degree of hyponatremic dehydration than for a comparable degree of isotonic or hypertonic dehydration. It is important to note, however, that significant solute losses also occur in hypernatremic dehydration. Furthermore, because plasma volume is somewhat protected in hypernatremic dehydration, it poses the risk of underestimating the severity of dehydration. Typical fluid and electrolyte losses associated with each form of dehydration are shown in Table 42-5.

Table 42-5. Estimated water and electrolyte deficits in dehydration (moderate to severe).

Type of Dehydration	H ₂ O (mL/kg)	Na ⁺ (mEq/kg)	K ⁺ (mEq/kg)	Cl ⁻ and HCO ₃ ⁻ (mEq/kg)
Isotonic	100-150	8-10	8-10	16-20

HYPONATREMIA

Hyponatremia may be factitious in the presence of high plasma lipids or proteins, which decrease the percentage of plasma volume that is water. Hyponatremia in the absence of hypotonicity also occurs when an osmotically active solute, such as glucose or mannitol, is added to the ECF. Water drawn from the ICF dilutes the serum $[Na^+]$ despite isotonicity or hypertonicity.

Patients with hyponatremic dehydration generally demonstrate typical signs and symptoms of dehydration (see Table 41-3), because the vascular space is compromised as water leaves the ECF to maintain osmotic neutrality. The treatment of hyponatremic dehydration is fairly straightforward. The magnitude of the sodium deficit may be calculated by the following formula:

$$\begin{aligned} \text{Na}^+ \text{ deficit} &= (\text{Na}^+ \text{ desired} - \text{Na}^+ \text{ observed}) \\ &\times \text{Body weight (kg)} \times 0.6 \end{aligned}$$

One half of the deficit is replenished in the first 8 hours of therapy, and the remainder is given over the following 16 hours. Maintenance and replacement fluids should also be provided. The deficit plus maintenance calculations generally approximate 5% dextrose with 0.45% saline. The rise in serum $[Na^+]$ should not exceed 2 mEq/L/h. The dangers of too rapid correction of hyponatremia include cerebral dehydration and injury due to fluid shifts from the ICF compartment.

Hypovolemic hyponatremia also occurs in cerebral salt wasting associated with central nervous system (CNS) insults, a condition characterized by high urine output and elevated urinary $[Na^+] (> 80$ mEq/L) due to an increase in ANF. This must be distinguished from the syndrome of inappropriate ADH (SIADH), which may also become manifest in CNS conditions and certain pulmonary disorders. In contrast to cerebral salt wasting, SIADH is characterized by euolemia or mild volume expansion and relatively low urine output due to ADH-induced water retention. Urinary $[Na^+]$ is high in both conditions, though generally not as high in SIADH. It is important to distinguish between these two conditions, because the treatment of the former involves replacement of urinary salt and water losses, whereas the treatment of SIADH involves water restriction.

In cases of severe hyponatremia (serum $[Na^+] < 120$ mEq/L) with CNS symptoms, intravenous 3% NaCl may be given over 1 hour to raise the $[Na^+]$ to 120 mEq/L, to alleviate CNS manifestations and sequelae. In general, 6 mL/kg of 3% NaCl will raise the serum $[Na^+]$ by 5 mEq/L. If 3% NaCl is administered, estimated Na^+ and fluid deficits should be adjusted ac-

cordingly. Further correction should proceed slowly, as outlined earlier.

Hypervolemic hyponatremia may occur in edematous disorders such as nephrotic syndrome, congestive heart failure, and cirrhosis, wherein water is retained in excess of salt. Treatment involves restriction of Na^+ and water and correction of the underlying disorder. Hypervolemic hyponatremia due to water intoxication is characterized by a maximally dilute urine (specific gravity < 1.003) and is also treated with water restriction.

HYPERNATREMIA

Although diarrhea is commonly associated with hyponatremic or isonatremic dehydration, hypernatremia may develop in the presence of persistent fever or decreased fluid intake or in response to improperly mixed rehydration solutions. Extreme care is required to treat hypernatremic dehydration appropriately. If the serum $[\text{Na}^+]$ falls precipitously, the osmolality of the ECF drops more rapidly than that of the CNS. Water shifts from the ECF compartment into the CNS to maintain osmotic neutrality. If hypertonicity is corrected too rapidly (a drop in $[\text{Na}^+]$ of greater than 0.5–1 mEq/L/h), cerebral edema, seizures, and CNS injury may occur. Thus, following the initial restoration of adequate tissue perfusion using isotonic fluids, a gradual decrease in serum $[\text{Na}^+]$ is desired (10–15 mEq/L/d). This is commonly achieved using 5% dextrose with 0.2% saline to replace the calculated fluid deficit over 48 hours. Maintenance and replacement fluids should also be provided. If the serum $[\text{Na}^+]$ is not correcting appropriately, the free water deficit may be estimated as 4 mL/kg of free water for each milliequivalent of serum $[\text{Na}^+]$ above 145 and provided as 5% dextrose over 48 hours. If metabolic acidosis is also present, it must be corrected slowly to avoid CNS irritability. Potassium is provided as indicated—as the acetate salt if necessary. Electrolyte concentrations should be assessed every 2 hours in order to control the decline in serum $[\text{Na}^+]$. Elevations of blood glucose and BUN may worsen the hyperosmolar state in hypernatremic dehydration and should also be monitored closely. Hyperglycemia is often associated with hypernatremic dehydration and may necessitate lower intravenous glucose concentrations (eg, 2.5%).

Patients with diabetes insipidus, whether nephrogenic or central in origin, are prone to develop profound hypernatremic dehydration as a result of unremitting urinary free water losses (urine specific gravity < 1.010), particularly during superimposed gastrointestinal illnesses associated with vomiting or diarrhea. Treatment involves restoration of fluid and electrolyte deficits as described earlier as well as replacement of excessive water losses, with subsequent water deprivation

testing during daylight hours to distinguish responsiveness to ADH. The evaluation and treatment of nephrogenic and central diabetes insipidus are discussed in detail in Chapters 22 and 30, respectively.

Hypervolemic hypernatremia (salt poisoning), associated with excess total body salt and water, may occur as a consequence of providing improperly mixed formula, excessive NaCl or NaHCO_3 administration, or as a feature of primary hyperaldosteronism. Treatment includes the use of diuretics and, potentially, concomitant water replacement or even dialysis.

POTASSIUM DISORDERS

The predominantly intracellular distribution of potassium is maintained by the actions of Na^+/K^+ ATPase in the cell membranes. Potassium is shifted into the ECF and plasma by acidemia and into the ICF in the setting of alkalosis, hypochloremia, or in conjunction with insulin-induced tissue glucose uptake. The ratio of intracellular to extracellular K^+ is the major determinant of the cellular resting membrane potential and contributes to the action potential in neural and muscular tissue. Abnormalities of K^+ balance are potentially life-threatening. In the kidney, K^+ is filtered at the glomerulus, reabsorbed in the proximal tubule, and excreted in the distal tubule. Distal tubular K^+ excretion is regulated primarily by aldosterone. Renal K^+ excretion continues for significant periods even after the intake of K^+ is decreased. Thus, by the time urinary $[\text{K}^+]$ decreases, the systemic K^+ pool has been depleted significantly.

The causes of net K^+ loss are primarily renal in origin. Gastrointestinal losses through nasogastric suction or vomiting reduce total body K^+ to some degree. However, the attendant volume depletion results in an increase in plasma aldosterone, promoting renal excretion of K^+ in exchange for Na^+ . Diuretics (especially thiazides), mineralocorticoids, and intrinsic renal tubular diseases (eg, Bartter syndrome) enhance the renal excretion of K^+ . Clinically, hypokalemia is associated with neuromuscular excitability, decreased peristalsis or ileus, hyporeflexia, paralysis, rhabdomyolysis, and arrhythmias. Electrocardiographic changes include flattened T waves, a shortened PR interval, and the appearance of U waves. Arrhythmias associated with hypokalemia include premature ventricular contractions; atrial, nodal, or ventricular tachycardia; and ventricular fibrillation. Hypokalemia increases responsiveness to digitalis and may precipitate overt digitalis toxicity. In the presence of arrhythmias, extreme muscle weakness, or respiratory compromise, intravenous K^+ should be given. If the patient is hypophosphatemic ($[\text{PO}_4^{3-}] < 2 \text{ mg/dL}$), a phosphate salt may be used. The first priority in the treatment of hypokalemia is the restoration of an adequate serum $[\text{K}^+]$. Providing main-

tenance amounts of K^+ is usually sufficient; however, when the serum $[K^+]$ is dangerously low and K^+ must be administered intravenously, it is imperative that the patient have a cardiac monitor. Intravenous K^+ should generally not be given faster than at a rate of 0.5 mEq/kg/h. Oral K^+ supplements may be needed for weeks to replenish depleted body stores.

Hyperkalemia—due to decreased renal K^+ excretion, mineralocorticoid deficiency or unresponsiveness, or K^+ release from the ICF compartment—is characterized by muscle weakness, paresthesias, and tetany; ascending paralysis; and arrhythmias. Electrocardiographic changes associated with hyperkalemia include peaked T waves, widening of the QRS complex, and arrhythmias such as sinus bradycardia or sinus arrest, atrioventricular block, nodal or idioventricular rhythms, and ventricular tachycardia or fibrillation. The severity of hyperkalemia depends on the electrocardiographic changes, the status of the other electrolytes, and the stability of the underlying disorder. A rhythm strip should be obtained when significant hyperkalemia is suspected. If the serum $[K^+]$ is less than 6.5 mEq/L, discontinuing K^+ supplementation is usually sufficient. If the serum $[K^+]$ is greater than 7 mEq/L or if potentiating factors such as hyponatremia, digitalis toxicity, and renal failure are present, more aggressive therapy is needed. If electrocardiographic changes or arrhythmias are present, treatment must be initiated promptly. Intravenous 10% calcium gluconate (0.2–0.5 mL/kg over 2–10 minutes) will rapidly ameliorate depolarization and may be repeated after 5 minutes if electrocardiographic changes persist. Calcium should be given only with a cardiac monitor in place and should be discontinued if bradycardia develops. The intravenous administration of a diuretic that acts in the loop of Henle, such as furosemide (1–2 mg/kg), will augment renal K^+ excretion and can be very helpful in lowering serum and total body $[K^+]$. Administering Na^+ and increasing systemic pH with bicarbonate therapy (1–2 mEq/kg) will shift K^+ from the ECF to the ICF compartment, as will therapy with a β -agonist such as albuterol. In nondiabetic patients, 0.5 g/kg of glucose over 1–2 hours will enhance endogenous insulin secretion, lowering serum $[K^+]$ 1–2 mEq/L. Administration of intravenous glucose and insulin may be needed as a simultaneous drip (0.5–1 g/kg glucose and 0.3 units of regular insulin per gram of glucose) given over 2 hours with monitoring of the serum glucose level every 15 minutes.

The therapies outlined provide transient benefits. Ultimately, K^+ must be reduced to normal levels by reestablishing adequate renal excretion using diuretics or optimizing urinary flow, using ion exchange resins such as sodium polystyrene sulfonate orally or as a retention enema (0.2–0.5 g/kg orally or 1 g/kg as an enema), or by dialysis.

ACID-BASE DISTURBANCES

When evaluating a disturbance in acid–base balance, the systemic pH, PCO_2 , serum $[HCO_3^-]$, and anion gap must be considered. The anion gap, $Na^+ - (Cl^- + HCO_3^-)$, is an expression of the unmeasured anions in the plasma and is normally 12 ± 4 mEq/L. An increase above normal suggests the presence of an unmeasured anion, such as occurs in diabetic ketoacidosis, lactic acidosis, salicylate intoxication, and so on. Although the base excess (or deficit) is also used clinically, it is important to recall that this expression of acid–base balance is influenced by the renal response to respiratory disorders and cannot be interpreted independently (as in a compensated respiratory acidosis, wherein the base excess may be quite large).

METABOLIC ACIDOSIS

Metabolic acidosis is characterized by a primary decrease in serum $[HCO_3^-]$ and systemic pH due to the loss of HCO_3^- from the kidneys or gastrointestinal tract, the addition of an acid (from external sources or via altered metabolic processes), or the rapid dilution of the ECF with nonbicarbonate containing solution (usually normal saline). When HCO_3^- is lost through the kidneys or gastrointestinal tract, Cl^- must be reabsorbed with Na^+ disproportionately, resulting in a hyperchloremic acidosis with a normal anion gap. Thus a normal anion gap acidosis in the absence of diarrhea or other bicarbonate-rich gastrointestinal losses suggests the possibility of renal tubular acidosis and should be evaluated appropriately (see Chapter 21). In contrast, acidosis that results from addition of an unmeasured acid is associated with a widened anion gap. Examples are diabetic ketoacidosis, lactic acidosis, starvation, uremia, toxin ingestion (salicylates, ethylene glycol, methanol), and certain inborn errors of organic or amino acid metabolism. Dehydration may also result in a widened anion gap acidosis as a result of inadequate tissue perfusion, decreased O_2 delivery, and subsequent lactic and keto acid production. Respiratory compensation is accomplished through an increase in minute ventilation and a decrease in PCO_2 . The patient's history, physical findings, and laboratory features should lead to the appropriate diagnosis.

The ingestion of unknown toxins or the possibility of an inborn error of metabolism (see Chapter 32) must be considered in children without an obvious cause for a widened anion gap acidosis. Unfortunately, some hospital laboratories fail to include ethylene glycol or methanol in their standard toxicology screens, so that these toxins must be requested specifically. This is of

grave importance when therapy with ethanol must be considered for either ingestion—and instituted quickly to head off profound toxicity. Ethylene glycol (eg, antifreeze) is particularly worrisome because of its sweet taste and accounts for a significant number of toxin ingestions. Screening by fluorescence of urine under a Wood lamp is relatively simple but does not replace specific laboratory assessment. Salicylate intoxication has a stimulatory effect on the respiratory center of the CNS; thus, patients may initially present with respiratory alkalosis or mixed respiratory alkalosis and widened anion gap acidosis.

Most types of metabolic acidosis will resolve with correction of the underlying disorder, improved renal perfusion, and acid excretion. Intravenous NaHCO_3 administration may be considered in the setting of metabolic acidosis when the pH is less than 7.0 or the $[\text{HCO}_3^-]$ is less than 5 mEq/L, but only if adequate ventilation is ensured. The dose (in mEq) of NaHCO_3 may be calculated as:

$$\text{Weight (kg)} \times \text{Base deficit} \times 0.3$$

and given as a continuous infusion over 1 hour. The effect of NaHCO_3 in lowering serum potassium and ionized calcium concentrations must also be considered and monitored.

METABOLIC ALKALOSIS

Metabolic alkalosis is characterized by a primary increase in $[\text{HCO}_3^-]$ and pH resulting from a loss of strong acid or gain of buffer base. The most common cause for a metabolic alkalosis is the loss of gastric juice via nasogastric suction or vomiting. This results in a Cl^- -responsive alkalosis, characterized by a low urinary $[\text{Cl}^-]$ (< 20 mEq/L) indicative of a volume-contracted state that will be responsive to the provision of adequate Cl^- salt (usually in the form of normal saline). Cystic fibrosis is also commonly associated with a Cl^- -responsive alkalosis due to the high losses of NaCl through the sweat, whereas congenital Cl^- -losing diarrhea is a rare cause of Cl^- -responsive alkalosis. Chloride-resistant alkaloses are characterized by a urinary $[\text{Cl}^-]$ greater than 20 mEq/L and include Bartter syndrome, Cushing syndrome, and primary hyperaldosteronism, conditions associated with primary increases in urinary $[\text{Cl}^-]$, or volume-expanded states lacking stimuli for Cl^- reabsorption. Thus the urinary $[\text{Cl}^-]$ is helpful in distinguishing the nature of a metabolic alkalosis but must be specifically requested in many laboratories because it is not routinely included in urine electrolyte screens. The serum $[\text{K}^+]$ is also low in these settings (hypokalemic metabolic alkalosis) owing to a

combination of increased mineralocorticoid activity associated with volume contraction, the shift of K^+ to the ICF compartment, preferential reabsorption of Na^+ rather than K^+ to preserve intravascular volume, or primary mineralocorticoid excess.

RESPIRATORY ACIDOSIS

Respiratory acidosis develops when alveolar ventilation is decreased, increasing PCO_2 and lowering systemic pH. The kidneys compensate for a respiratory acidosis by increasing HCO_3^- reabsorption, a process that takes several days to manifest. Patients with acute respiratory acidosis frequently demonstrate air-hunger with retractions and the use of accessory respiratory muscles. Respiratory acidosis occurs in upper or lower airway obstruction, ventilation-perfusion disturbances, CNS depression, and neuromuscular defects. Hypercapnia is not as detrimental as the hypoxia that usually accompanies these disorders. The goal of therapy is to correct or compensate for the underlying pathologic process, to improve alveolar ventilation. Bicarbonate therapy is not indicated in a pure respiratory acidosis, because it will worsen the acidosis by shifting the equilibrium of the carbonic acid-bicarbonate buffer system to increase PCO_2 .

RESPIRATORY ALKALOSIS

Respiratory alkalosis occurs when hyperventilation results in a decrease in PCO_2 and an increase in pH. Patients may experience tingling, paresthesias, dizziness, palpitations, syncope, or even tetany and seizures due to the associated decrease in ionized calcium. Causes of respiratory alkalosis include psychobehavioral disturbances, CNS irritation from meningitis or encephalitis, and salicylate intoxication. Therapy is directed toward the causal process. Rebreathing into a paper bag will decrease the severity of symptoms in acute hyperventilation.

Information Technology in Pediatrics

43

Carol S. Kamin, MS, EdD, & David W. Kaplan, MD, MPH

Increasing numbers of physicians and patients are taking advantage of technologic resources, especially those available on the Internet. Nearly 100% of physicians report access to the Internet through office, hospital, or home connections. In a survey of British physicians conducted in June 2000, 88% of pediatricians reported using the Internet, with 50% using it both at work and at home (www.rsm.ac.uk/new/websurvey.htm). A global study done in 1998 found in phase-one telephone interviews that 80% of physicians in 11 North American, European, and Asian countries own a computer and 44% of them access the Internet. In phase two, 2,500 Internet-connected physicians from 105 countries were surveyed. Ninety-five percent of these physicians said they use the Internet to access disease information, 88% read medical journals online, and 86% said they use the Internet to obtain drug information. Sixty-three percent have visited a pharmaceutical company's Website, 62% have referred their patients to medical information on the web, and 33% report that patients have brought medical or health related information from the Internet to their office (www.xpresspress.com/news/physiciansurvey.html). Because the Internet has such an abundance of information, navigating its terrain is problematic. Increasingly, sites are being created as indexes of multiple Websites of interest to a particular population (eg, www.generalpediatrics.com). Keeping these indexes current is a relentless task since new sites are added daily and old sites may be removed or changed. However, this changing Internet landscape can provide opportunities to improve health by supporting and educating both providers and patients.

Note: When typing the address of a Website into your browser, always use the site's exact designation, which may or may not start with *www*. Websites listed in this chapter that omit *www* should be typed exactly that way, as in pediatrics.about.com. Your browser will automatically add the familiar tag, *http://*.

CONTINUING MEDICAL EDUCATION

The numbers of continuing medical education (CME) Websites and continuing education online providers

are increasing (Table 43–1). In 2000, 96 CME sites were available; in 2001, this number increased to 200 (www.netcantina.com). By 2004, one Website linked to 270 online CME sites with more than 12,000 courses (www.cmelist.com/list.htm). An example of an award-winning free Website is the one on breastfeeding at www.breastfeedingbasics.org. Accreditation Council for Continuing Medical Education (ACCME) requirements are still grounded in conferences and have been slow to adopt regulations regarding CME credit for computer-based educational materials. In addition, limited educational strategies have been applied to those that are available. For the most part, existing programs and lectures have been transferred to the Internet without much thought about how the medium could best be used to improve the instruction, evidenced by the fact that most CME Websites are text-based with only 20% containing interactive components. Cases and tutorials on CD-ROMs can provide more interactivity and video images than the Internet bandwidth can currently manage, but this could change quickly.

In a 2002 survey of 2200 US office-based physicians, the most common reason physicians look for Internet-based CME is to solve a specific patient problem. They expect these programs to be easy to use, relevant, and credible. An example of the potential for case-based CME is an award-winning CME program on genetic counseling produced by the Dartmouth Interactive Media Laboratory. This highly interactive program incorporates multiple learning strategies with rich video cases (Available at no cost from iml.dartmouth.edu/education/cme/index.html).

Conferences

Today's busy clinical practice makes it difficult to attend local and national conferences. The Internet offers opportunities to make conference materials available to those unable to attend. These may include PowerPoint

slides with audio tracks, streaming video, or papers. You can see an example of streaming video at the University of Nebraska site that has a Grand Round lecture series (www.unmc.edu/Pediatrics/GrandRounds/home.htm).

Many Websites include directories of medical meetings. One example is the Physician's Guide to the Internet, at www.physiciansguide.com. In addition to announcements of CME events and national conferences, this site contains sections on professional opportunities, clinical practice guidelines, and practical advice (eg, repaying medical loans).

Consultation

With electronic access to experts and colleagues readily available, it is not surprising that clinicians and patients seek advice over the Internet. This may be done directly by e-mail or as part of an asynchronous discussion group or listserv. To have e-mail service, you must have an account with an Internet service provider who has an address (a server) or mailbox where you receive incoming mail. Listservs use e-mail technology to allow users to subscribe to discussion groups (Table 43-2). If you subscribe to a listserv, you receive a copy of every message sent to the group. Some of these services offer the option of receiving messages in a digest form that compiles several messages into one. Some of them also keep an archive of old messages that can be searched by key words. A listserv may be moderated to ensure that messages are appropriate for its audience. Discussion groups are slightly different from listservs. The messages are posted on restricted (password-protected)

Websites. Users log into the site to read or add messages. Younger age, urban setting, private practice, and infrequent consultation with colleagues were found to be the most common characteristics of the users of the discussion groups on Physicians' Online, an Internet-based information and communication network with more than 200,000 members.

Angelo SJ, Citkowitz E: An electronic survey of physicians using online clinical discussion groups. *Conn Med* 2001;65(3):135 [PMID: 11291565].

Self-Study

Scientific information is growing exponentially, and most physicians have difficulty managing and evaluating this abundance of information. The Internet provides access to tools to help the practitioner manage the information overload. In addition to exclusively online journals, many print journals now have subscription online versions that can be searched by keywords (Table 43-3). Electronic newsletters inform subscribers of the latest research findings. Abstracts can be sent to an e-mail account on topics the subscriber selects. You can find the latest pediatric practice guidelines online (Table 43-4). Do you have questions about a new drug? Information on specific drugs is available online. In fact, some Websites have e-detailing, which provides multimedia presentations of new drugs. If you still have questions about the drug, you can create an online request for a call from a drug representative.

A new service being subscribed to by individual practitioners and institutions is UpToDate (www.uptodate.com). Over 3000 authors contribute to this growing database of expert clinical information. Some studies report that this resource is used more frequently than any other electronic clinical reference. It can also be accessed on wireless PDAs. CME credit is available.

The pressure to practice evidence-based medicine (EBM) is growing, by integrating individual clinical expertise with the best available external clinical evidence from systematic research. Clinical databases, like PubMed (www.ncbi.nlm.nih.gov/PubMed), a Web-based resource of Medline, is a service of the National

Library of Medicine and can offer access to over 11 million citations. Before conducting your search, identify key concepts you are interested in and consider alternative phrasing of those concepts. Next, limit your search by refining the dates, gender and age if possible, and the type of publication (clinical trials, editorials, letters, meta-analysis, practice guidelines, randomized control trials, or reviews). Boolean logic represents the relationship between more than one keyword. Use AND (in all caps) to retrieve citations which contain all of the search terms. Use OR to retrieve citations that contain at least one of the search terms. Use NOT to exclude the retrieval of terms from your search (eg, lead poison-

ing NOT adults). Under clinical queries, you can use filters to limit your search to therapy, etiology, diagnosis, or prognosis. An example of results using these strategies for a search on Otitis Media is found in Table 43-5. What you hope to find is a manageable number of articles that match your clinical question as closely as possible. You still must evaluate the studies and determine whether they offer any new information for your patients.

Systematic reviews and meta-analyses of the literature are available in evidence-based medicine databases

that have been contributed by EBM experts. Most of these services require a fee. However, as medical schools struggle to enhance clinical sites to provide experience to students and residents, one of the fringe benefits increasingly provided to preceptors is access to library resources that may include EBM databases. Critically appraised topics (CATS) Websites offer opportunities to read others' appraisals of the literature or tools to contribute your own. Additional EBM resources are listed in Table 43-6.

CLINICAL SUPPORT

E-Mail

Corresponding through e-mail is becoming commonplace in clinical practice communication. The utility of e-mail is its asynchronous nature. It provides a permanent form of documentation and helps prevent "telephone tag." The use of e-mail has dramatically increased, with over 100 million users in year 2000 in the United States. E-mail communication is being used for consultation, patient communication, and practice management. With the growing use of e-mail in clinical practice, the American Medical Informatics Association has published guidelines for the use of electronic mail with patients for clinical purposes:

- Establish turnaround time for messages. Do not use e-mail for urgent matters.
- Inform patients about privacy issues.

Table 43–6. EBM Resources.

Tools to improve search strategies—Note the second link, an excellent tutorial from the National Library of Medicine	www.urmc.rochester.edu/miner/Educ/Expertsearch.html www.nlm.nih.gov/bsd/pubmed_tutorial/m1001.html
Critically Appraised Topics (CATS) in Pediatrics	PedsCCM.wustl.edu/EBJ/EB_Resources.html www.med.umich.edu/pediatrics/ebm/CAT.htm
CAT Tools	www.cebm.net/cats.asp www.hsc.usf.edu/~bdjulbeg/Programs/evidencetable.htm

- Determine who besides the addressee on the receiving end processes messages.
- Include messages as part of the medical record.
- Establish acceptable types of transactions (prescription refill, appointment scheduling, etc), and discourage e-mail communications on sensitive matters (eg, HIV, mental health).
- Instruct patients to put the type of transaction in the subject line for triaging: “prescription,” “appointment,” “medical advice,” “billing question.”
- Request that patients put their name and medical record or patient identification number in the body of the message.
- Configure an automatic reply to acknowledge receipt of message.
- Print all messages with replies and confirmation of receipt and place the e-mail in the patient’s paper chart.
- Send a message to inform the patient of completion of the request.
- Request that the patients reply to the provider’s message, to acknowledge receipt.
- Configure e-mail messages so that, when broadcasting to a group of patients, individual recipients are not visible to others on the mailing list.
- Pay attention to the tone of your message. Avoid anger, sarcasm, harsh criticism.

In addition, the American Medical Informatics Association recommended the following medicolegal and administrative guidelines:

- Consider obtaining the patient’s informed consent for the use of e-mail. The consent form should include the communication guidelines, provide instructions for when and how to escalate to phone calls and office visits, describe security mechanisms in place, indemnify the health care institution for information lost due to technical failures, and waive encryption requirement, if any, at the patient’s insistence.

- Use password-protected workstations in the clinical setting.
- Never forward patient identifiable information to a third party without the patient’s express permission.
- Never use the patient’s e-mail address for marketing.
- Use encrypted secure e-mail that is user friendly and practical.
- Regularly back up e-mail onto long-term storage.

E-mail is used for patient education, including distribution of disease specific “handouts,” and for conveying medication information, gathering references for current medical research, and sharing Internet resources. It is used for monitoring such markers of chronic illness as peak flow measurements, weight, blood pressure, and glucose levels. Finally, e-mail is used for administrative information including requests for referrals, address changes, and other demographic updates along with requests for prescription refills, laboratory test results, and reminders about appointments and vaccinations.

As the volume of e-mail begins to increase, providers may resist the burden of this new form of communication. It is not known if physicians will begin to provide e-mail care when it is reimbursed.

Kohn L et al (eds): *To Err Is Human: Building a Safer Health System*. Committee on Quality of Health Care in America. Institute of Medicine. National Academy Press, 1999.

Electronic Medical Records

Electronic medical record (EMR) systems, also known as digital health records (DHR), are systems that provide quicker retrieval of patient data with the potential for greater accuracy. The Institute of Medicine (IOM) has produced two companion reports. The first, entitled “To Err is Human: Building a Safer Health Sys-

tem,” concluded that “reorganization and reform are urgently needed to fix what is now a disjointed and inefficient health care system.” Studies estimate that between 44,000 and 98,000 patients die each year as a result of medical errors, and preventable medication errors occur in 7.3% of hospital admissions. Even using the lower estimate for deaths, more people die in a given year as a result of medical errors than from motor vehicle accidents, breast cancer, or AIDS. The decentralized and fragmented nature of the health care delivery system contributes to unsafe conditions for patients, and serves as an impediment to efforts to improve safety.

The second IOM report, “Crossing the Quality Chasm: A New Health System for the Twenty-First Century,” calls for action to improve health care over the next decade and emphasizes the use of information technology as key to a comprehensive strategy. The IOM committee believes that “information technology must play a central role in the redesign of the health care system if substantial improvement in quality is to be achieved in the coming decade.” Health care delivery has been relatively untouched by the revolution in information technology that has been transforming nearly every other aspect of society. Health care organizations are only beginning to apply technologic advances. Patient information typically is dispersed in a collection of paper records, which often are poorly organized, illegible, and not easy to retrieve, making it nearly impossible to manage various chronic illnesses that require frequent monitoring and ongoing patient support.

Growth in clinical knowledge and technology has been profound, yet many health care settings lack basic computer systems to provide clinical information or support clinical decision making. The implementation of an electronic clinical information system offers the potential for improved patient safety, efficiency, and effectiveness. Standardized data collection can assist in implementing consistent care pathways and eliminating the need for data interpretation after the fact. The general attributes of a computer-based patient record should include the following:

- Problem list
 - Measurement and recording of health status and functional level
 - Statements about the logical basis for all diagnoses and conclusions
 - Linkage with all of the patient’s clinical records across settings and time periods
 - Assurance of confidentiality
 - Widespread accessibility
 - Selective retrieval and formatting
 - Linkage to local and remote knowledge sources
- Structured data collection using a defined vocabulary
 - Expandability to meet evolving needs
- Features specific for pediatrics include the following:
- Ability to calculate, display, and compare a child’s growth percentiles and body mass index with normal ranges
 - Special terminology and information to document developmental milestones and physical findings in infants and children
 - Age-based normal ranges for vital signs and other physiologic parameters
 - Prescribing medications based on age, weight, and body surface area of the child
- Tools such as clinical alerts, ordering guidelines, care paths, and structured clinical documentation can provide clinicians with assistance in ordering and delivering health care. Clinical data repositories designed to capture, store, and analyze extensive patient information can form the foundation for effective care decisions. When automated documentation becomes part of the workflow, effective data collection becomes a byproduct rather than an additional task.
- Although all-inclusive, computer-based patient records are still rare, especially outside the area of primary care, the benefits of an electronic patient record system are significant:
- Convenient access to patient data from a variety of locations, whenever it is needed. With the advent of the Internet, remote access to clinical data has been further simplified.
 - Electronic access to clinical data allows for rapid filtering, sorting, and searching for specific information. Numeric data such as height, weight, and blood pressure can be graphed.
 - Automated alerts, reminders, and suggestions can be built into clinical orders and decision points.
 - Population-based data are available for clinical research, epidemiologic studies, and the development of quality measures.
 - Clinical patient records offer the potential of coordinated information collected at all points of care, incorporating primary care, consultation, hospitalization, laboratory and radiology data, transcription, rehabilitation, and home care.

Telemedicine

Telemedicine uses telecommunications technology for medical diagnostic, monitoring, and therapeutic purposes when distance separates the users. There are three general categories of telemedicine: (1) store-and-forward, (2) self-monitoring and testing, and (3) clinical interactive services. Store-and-forward telemedicine services collect data, store them, and then forward them for interpretation later. The store-and-forward system eliminates the need for the patient and clinician to be available at the same time and place. It is generally used in clinical consultation. Self-monitoring and testing enable providers to monitor physiologic measurements, test results, images, and sounds, usually collected in another care facility or the patient's residence. This modality is used to monitor patients with chronic illnesses and those whose conditions limit their mobility. In the United States more than 450 telemedicine programs exist. The most common activities are consultation or second opinions, diagnostic test interpretation, chronic disease management, and posthospitalization or postoperative follow-up.

Telemedicine is being used in a wide variety of clinical settings, some examples of which are disasters and emergencies; home care and home nursing; new neurologic out-patient referrals; psychiatric and neuropsychological evaluation; hypertension and diabetes management; and surgical consultation. In addition to a growing number of programs in western countries, it is being used to assist in delivering health services in other parts of the globe, such as northwest Russia, Bangladesh, Thailand, Taiwan, and Africa.

In pediatrics, telemedicine is being used in a range of subspecialties for consultation. Among these is remote echocardiographic diagnosis of congenital heart defects. In one 2-year study in Halifax, the telemedicine network saved a necessary patient transfer in 31 cases and avoided over \$100,000 in additional costs. Use of the Internet and telemedicine has been studied as an adjunct in improving care for high-risk infants. The technology was used to enhance interactions among families, staff, and community providers. A video conferencing module allowed for virtual visits and distance learning from a family's home during an infant's hospitalization, as well as for virtual house calls and remote monitoring after discharge. In a randomized study of

very low birth weight infants, the study group (Baby CareLink) reported a higher overall quality of care and greater satisfaction. Although the length of hospitalization was similar between the study and control groups, all of the study infants were discharged directly to home, whereas 20% of the control infants were transferred to a community hospital before discharge.

A number of questions remain for clinical telemedicine consultation and monitoring. What are the geographic limits for reimbursement? Which practitioners are eligible to present patients? Which practitioners are eligible to act as consultants? What teleconsultative services will be covered? What technologies will be covered? One reason for the lack of coverage of telemedicine has been an uncertainty about its efficacy and cost. In a systematic review of clinical outcomes resulting from telemedicine interventions commissioned by the US Health Care Financing Agency and the Agency for Healthcare Research and Quality, evidence concerning the benefits of its use exists in only a small number of health care areas despite widespread use of telemedicine.

Reimbursement for telemedicine services varies among states and insurers. Presently in the United States, at least 18 states are allowing reimbursement through Medicaid for services provided via telemedicine, for reasons that include improved access to specialists for rural communities and reduced transportation costs.

With faster and less expensive computers and greater access to high bandwidth, telemedicine should continue to improve in quality and ease of use. As the use of telemedicine matures, essential elements to improve performance will include the following:

1. Licensing and credentialing. Telemedicine overcomes geographic boundaries but may be constrained by state laws.
2. Data security and privacy. Telemedicine consultation records need to be stored to document clinical decisions, especially for risk management.
3. Informed consent.
4. Peer-reviewed quality assessment.

Personal Digital Assistants

PDAs, also known as Palm-tops or handheld computers, have grown in popularity, and as they have so have their software applications. Harris Interactive Polls conducted interviews with 834 practicing US physicians and found that the use of PDAs increased from 15% in 1999 to 26% in 2001. The number using PDAs as an integral part of their practice almost doubled from 10%

to 18%. This use is higher among doctors younger than 45 (33%) than among older doctors (21%). It is also higher among wholly or partly hospital-based physicians (33% and 29%) than among those who are mostly office-based (23%).

Sittig and colleagues conducted a study to determine what physicians wanted from a PDA. Important tasks cited included checking drug information and treatment regimens, viewing patient data, and looking up diagnostic codes and laboratory values. New PDA software is being created specifically for pediatricians, with database-driven tools for basic vital signs, lab values for all ages, growth and development tools, vaccine recommendations, electrocardiographic findings, resuscitation dosage codes, and more (see www.kidometer.com). PediSuite, a suite of seven modules providing calculations and other information, recently won the RNpalm NFP award (see www.rnpalm.com/pedisuite_review.htm). Downloadable database programs using JFile or HanDBase can be found at www.keepkidshealthy.com/pediatricpilotpage/jfile.html. To find out more about pediatric-specific PDA software, see the comprehensive Website at www.pediatricsonhand.com where software is organized by subspecialty and other specific areas of interest.

As wireless PDAs increase in popularity, we could see applications proliferate. Currently users can subscribe to channels of information. For information about software for physicians in any specialty, check out PdaMD.com. Many software developers creating PDA applications for physicians are developing companion products for patients. One example includes award-winning PediSuite by Medical Wizards, who have also created PediParents. Instead of keeping paper diaries, physicians can monitor electronic diaries kept by their patients with asthma on PDAs and specialized software (eg, asthma application at www.HealthEngage.com/healthengageasthma.html).

Johns Hopkins Department of Pediatrics describes their progress in the use of PDAs as well as some of the clinical applications they have developed at www.welch.jhu.edu/about/mac2002_pdas.pdf.

Sittig DF et al: Techniques for identifying the applicability of new information management technologies in the clinical setting: An example focusing on handheld computers (Proceedings). AMIA Symposium 2000;20 (Suppl):804 [PMID: 11079995].

Security

Although the principles of protecting the confidentiality and privacy of medical records apply to all forms of personally identifiable information, whether communicated on paper, orally, or electronically, the electronic

dissemination of patient data is of special concern. Computerization makes it much easier to acquire, manipulate, and disseminate vast amounts of personal health information rapidly. Highly sensitive health data flow through employer-sponsored health plans, managed care organizations, hospitals, pharmacies, laboratories, and physicians' offices. These data are used for numerous health-related purposes, including clinical care, quality assurance, utilization review, reimbursement, research, and public health. In 1996, the Health Insurance Portability and Accountability Act (HIPAA) authorized the federal government to establish a national standard for medical record privacy either by legislative or regulatory action. In 1999, the Department of Health and Human Services published regulations to guarantee patients new rights and protections against the misuse or disclosure of their health records. The regulations apply to what are called "covered entities": healthcare providers, health plans, and healthcare clearinghouses that transmit health information in electronic form. The regulations are made up of three distinct parts: transaction standards, privacy, and security. The transactions standards call for use of common electronic claims standards, common code sets, and unique identifiers for all healthcare payers and providers. The privacy rules govern the release of individually identifiable health information, specifying how health providers must provide notice of privacy policies and procedures to patients, obtain consent and authorization for use of information; tell how information is generally shared; and how patients can access, inspect, copy and amend their own medical record. The security regulations dictate the kind of administrative procedures and physical safeguards covered entities must have in place to ensure the confidentiality and integrity of protected health information. All medical records and other individually identifiable health information used or disclosed by a covered entity in any form, whether electronically, on paper, or orally, are covered by the new rule. Providers and health plans will be required to give patients a clear written explanation of how their health data may be used and their health information disclosed. In general, the disclosure of health information will be limited to the minimum amount necessary for purposes of the disclosure. In very limited circumstances, health information may be disclosed in emergencies, for public health concerns, and for research when a waiver of authorization is independently approved by a privacy board or institutional review board.

PATIENT EDUCATION

Patients are accessing many kinds of Websites that offer information about their conditions. Home usage of the

Internet is more common among highly educated and wealthier individuals, with no difference based on gender or community size. Sixty-three percent of women and 46% of male Internet users use the Internet to get medical information on a regular basis (www.pewinternet.org/reports/toc.asp?Report=26). How might this change the patient–physician relationship? A study of patients with breast cancer who participated in online education and support groups reported that patients increased their confidence in their physicians and their competence to participate in their own care. A Harris online poll found that patients who used the Internet to look for health information were more likely to ask informed questions of their physicians and were more likely to comply with prescribed treatment plans. Similar results have been reported in studies of patients with cystic fibrosis and amyotrophic lateral sclerosis (ALS).

In addition to changing the relationship between physician and patient, patient outcomes can improve as a result of online patient education. In a study of patients participating in an online diabetes education and support group, patients lowered their blood glucose level more than the control group.

Physicians can help their patients evaluate the accuracy of information found on the Web and provide links to reliable patient education resources. General sites, like Medline Plus (www.nlm.nih.gov/medlineplus), provide a great deal of reliable information indexed at one site by the National Library of Medicine. Specialty listservs or discussion groups for parents are also available.

A recent review of online pediatric patient education materials suggests that the majority of materials are not written at an appropriate reading level for the average adult (eighth to ninth grade). If your practice is interested in hosting a patient education Website, consider the following guidelines:

- Write patient guidelines clearly, make them highly visible, and ensure that all parties read and understand them before they use the resource.
- Present a statement about the intent and limitations of the resource, and provide contact information should the user have questions.
- Address concerns about privacy; identify possible security breaches and the steps users must take to protect their information.
- Define and clarify which areas of the resource are for posting private messages to providers containing health information, and which areas are public.
- Define the patient's rights and responsibilities, and provide examples of queries that should be posted and those situations that require more immediate medical attention.
- Define the provider's responsibilities.

Because a mixture of high-quality and low-quality resources are available for patients on the Web, it is important that physicians are aware of Web-based resources and have reliable sites to recommend to an increasingly sophisticated population.

Technology and the Internet are changing our culture as well as medical education and healthcare delivery. Properly implemented and adopted, these new applications offer physicians the opportunity to harness the technology for better and more efficient patient care.

Chemistry & Hematology Reference Ranges

44

Iris M. Osberg, MT

Pediatricians and other health professionals caring for children have the responsibility to insist on accurate, rapid, and comprehensive laboratory testing. Collecting large blood samples for biochemical assay is not suitable for the proper care of children, especially for premature infants or older children in intensive care units, where repetitive sampling may be essential.

In infants and young children, blood samples taken by heel-prick are better collected by laboratory personnel than by physicians or nurses.

INTERPRETATION OF LABORATORY VALUES

Accreditation by the College of American Pathologists and by state or federal agencies has done much to ensure standardized laboratory performance. Methods used in various laboratories differ, as do reference (normal) values for the methods. Reference (normal) range is, of course, a combination of biologic variation and intrinsic laboratory variation; thus, an acceptable range of reference (normal) values should ideally be composed of data developed within the laboratory for the population it serves. Any laboratory should be able to provide information on the coefficient of variation and standard deviation applicable to each test performed in that laboratory. Each laboratory should maintain a rigorous procedure of checks with daily standards and quality control specimens. Errors may still occur but can usually be detected by retesting before a questionable result is reported. Fortunately, errors occur much less commonly today than in the past.

The clinical value of a test is related to its sensitivity and specificity. Sensitivity is an expression of the incidence of positive test results in those who have the disease. Specificity is an expression of the incidence of negative test results in those free of the disease. Sensitivity and specificity are calculated as follows:

$$\text{Sensitivity (\%)} = \frac{\text{TP}}{\text{TP} + \text{FN}} \times 100$$

(ie, the percentage of TP detected by the test in those with the disease)

$$\text{Specificity (\%)} = \frac{\text{TN}}{\text{TN} + \text{FP}} \times 100$$

(ie, the percentage of TN detected by the test in those without the disease)

where TP = a true-positive result, FP = a false-positive result, TN = a true-negative result, and FN = a false-negative result.

Screening tests must be interpreted with appreciation of sensitivity and specificity. These expressions are illustrated in Figure 44–1 in terms of a screening test for phenylketonuria in newborns. The values are not strictly correct but serve the purpose of illustration. According to Figure 44–1, a blood phenylalanine level of 4 mg/dL is the discriminating point above which all infants are presumed to have the disease and below which they are presumed to be normal. However, no test is ever quite that exact. Some normal infants will have levels above 4 mg/dL; the test results in these will be false-positive. Some abnormal infants will have levels below 4 mg/dL; the test results in these infants will be false-negative. The discriminating point is a compromise between sensitivity and specificity. Moving the point to 2 mg/dL would effect 100% sensitivity, but there would be a large increase in the number of false-positive results. Moving it to 6 mg/dL would make it very specific, but this would increase the number of false-negative responses, which would result in failure to detect phenylketonuria in a much larger proportion of affected children.

These concepts can be viewed in yet another way. Suppose that this test were set at a specificity of

Figure 44-1. Screening test for phenylketonuria in newborns. Data have been simplified to illustrate the concepts of sensitivity and specificity (see text).

99.9%. This would mean that in a sample of 10,000 tests, there would be 10 false-positive results. In a rare condition such as phenylketonuria, however, the true incidence of the disease may be only 1:12,000. The ratio of true-positive to false-positive results is thus 1:12; this is a reflection of the low incidence of the disease and the relatively high incidence of false-positive results because of the nature of the assay. These consid-

erations, of course, apply to the interpretation of all laboratory tests.

LABORATORY VALUES

Blood chemistry and miscellaneous other laboratory reference ranges are shown in Tables 44-1 to 44-3.

Table 44-1. Normal blood chemistry values and miscellaneous other hematologic values. (Values may vary with the procedure used.)

Determinations for
 (S) = Serum (P) = Plasma
 (B) = Whole blood (RBC) = Red blood cells

Acid Phosphatase (S, P)

Values using *p*-nitrophenyl phosphate buffered with citrate (end-point determination)

Newborns: 7.4–19.4 IU/L at 37 °C

2–13 y: 6.4–15.2 IU/L at 37 °C

Adult males: 0.5–11 IU/L at 37 °C

Adult females: 0.2–9.5 IU/L at 37 °C

Alanine Aminotransferase (ALT, SGPT) (S)

Newborns (1–3 d): 1–25 IU/L at 37 °C

Adult males: 7–46 IU/L at 37 °C

Adult females: 4–35 IU/L at 37 °C

Alkaline Phosphatase (S)

Values in IU/L at 37 °C using *p*-nitrophenyl phosphate buffered with AMP (kinetic)

Group	Males	Females
Newborns (1–3 d)	95–368	95–368
2–24 mo	115–460	115–460
2–5 y	115–391	115–391
6–7 y	115–460	115–460
8–9 y	115–345	115–345
10–11 y	115–336	115–437
12–13 y	127–403	92–336
14–15 y	79–446	78–212
16–18 y	58–331	35–124
Adults	41–137	39–118

Ammonia (P)

Newborns: 90–150 µg/dL (53–88 µmol/L); higher in premature and jaundiced infants

Thereafter: 0–60 µg/dL (0–35 µmol/L) when blood is drawn with proper precautions

Amylase (S)

Values using maltotetrose substrate (kinetic)

Neonates: Undetectable

2–12 mo: Levels increase slowly to adult levels

Adults: 28–108 IU/L 37 °C

Anticoagulation Factors (P)

Values in U/mL. Shown are mean values and 2 SD or lower range (in parentheses)

Anticoagulation Factors (P)

Factor	Preterm (25–32 wk)	Term Infant	Infant (6 mos)	Adult
AT III	0.35 (0.20)	0.56 (0.32)	1.04 (0.84)	1.0 (0.8)
PC	0.29 (0.20)	0.50 (0.30)	0.59 (0.37)	1.0 (0.6)
PS, total	. . .	0.24 (0.10)	0.87 (0.55)	1.0 (0.6)
PS, free	0.48	0.42	. . .	1.0 (0.5)
HCF II	0.25 (0.10)	0.49 (0.36)	0.97 (0.59)	1.0 (0.7)

AT III = antithrombin III, PC = protein C, PS = protein S, HCF II = heparin cofactor II.

α₁-Antitrypsin (antiprotease) (S)

1–3 mo: 127–404 mg/dL

3–12 mo: 145–362 mg/dL

1–2 y: 160–382 mg/dL

2–15 y: 148–394 mg/dL

Ascorbic Acid: See Vitamin C.

Aspartate Aminotransferase (AST, SGOT) (S)

Newborns (1–3 d): 16–74 IU/L at 37 °C

Adult males: 8–46 IU/L at 37 °C

Adult females: 7–34 IU/L at 37 °C

Bicarbonate, Actual (P)

Calculated from pH and P_{aCO_2}

Newborns: 17.2–23.6 mmol/L

2 mos–2 y: 19–24 mmol/L

Children: 18–25 mmol/L

Adult males: 20.1–28.9 mmol/L

Adult females: 18.4–28.8 mmol/L

Bile Acids, Total^a (S)

Values in µmol/L

1 mo 11–69

3 mos 1–41

6–12 mos 1–37

Bilirubin (S)

Values in mg/dL (µmol/L)

Levels after 1 mo are as follows:

Conjugated: 0–0.3 mg/dL (0–5 µmol/L)

Unconjugated: 0.1–0.7 mg/dL (2–12 µmol/L)

Blood Volume

Premature infants: 98 mL/kg

At 1 y: 86 mL/kg (range, 69–112 mL/kg)

Older children: 70 mL/kg (range, 51–86 mL/kg)

(continued)

Table 44-1. Normal blood chemistry values and miscellaneous other hematologic values. (Values may vary with the procedure used.) (continued)

BUN: See Urea Nitrogen.

C Peptide (S)

5-15 y (8:00 am fasting): 1-4 ng/mL
 Adults (8:00 am fasting): < 4 ng/mL
 Adults (nonfasting): < 8 ng/mL

C-Reactive Protein (S)

3-16 y: 0.1-1.5 mg/dL

Calcium, Ionized (P)

0-2 d: 1.1-1.4 mmol/L
 3-4 d: 1.1-1.5 mmol/L
 5-8 d: 1.2-1.5 mmol/L
 9-14 d: 1.3-1.6 mmol/L
 2 mo-18 y: 1.2-1.4 mmol/L

Calcium, Total (S)

Premature infants (first week): 3.5-4.5 mEq/L (1.7-2.3 mmol/L)
 Full-term infants (first week): 4-5 mEq/L (2-2.5 mmol/L)
 Thereafter: 4.4-5.3 mEq/L (2.2-2.7 mmol/L)

Carbon Dioxide, Total (S, P)

Cord blood: 15-20.2 mmol/L
 Children: 18-27 mmol/L
 Adults: 24-35 mmol/L

Carnitine (P)

Values in mmol/L, measured by an enzymatic radioisotopic method:

Age	Total Carnitine	Free Carnitine	Acyl-carnitine	AC/FC Ratio
1 day	23.3-67.9	11.5-36.0	7.0-36.6	0.37-1.68
2-7 d	17.4-40.6	10.1-21.0	2.9-23.8	0.15-1.44
8-28 d	18.5-58.7	12.3-46.2	4.1-14.5	0.11-0.65
1 mo-1 y	38.1-68.0	26.9-49.0	7.4-19.0	0.23-0.50
1-6 y	34.6-83.6	24.3-62.5	4.0-28.3	0.11-0.83
6-10 y	27.8-82.9	21.7-66.4	3.1-32.1	0.08-0.87
10-17 y	33.7-77.0	21.6-64.5	3.7-29.2	0.09-0.88
22-60 y	33.8-77.5	25.4-54.1	5.4-30.1	0.11-0.78

Cation-Anion Gap (S, P)

5-15 mmol/L

Ceruloplasmin (Copper Oxidase) (S, P)

21-43 mg/dL (1.3-2.7 μmol/L)

Chloride (S, P)

Premature infants: 95-110 mmol/L
 Full-term infants: 96-116 mmol/L
 Children: 98-105 mmol/L
 Adults: 98-108 mmol/L

Cholesterol, Total (S, P)

Values in mg/dL (mmol/L)

Group	Males	Females
6-7 y	115-197 (2.97-5.09)	126-199 (3.25-5.14)
8-9 y	112-199 (2.89-5.14)	124-208 (3.20-5.37)
10-11 y	108-220 (2.79-5.68)	115-208 (2.97-5.37)
12-13 y	117-202 (3.02-5.21)	114-207 (2.94-5.34)
14-15 y	103-207 (2.66-5.34)	102-208 (2.63-5.37)
16-17 y	107-198 (2.76-5.11)	106-213 (2.73-5.50)

Coagulation Factors (P)

Values in U/mL. Shown are mean values and -2 SD or lower range (in parentheses).

Factor	Preterm (25-32 wk)	Term Infant	Infant (6 mos)	Adult
II	0.32 (0.18)	0.52 (0.25)	0.88 (0.60)	1.0 (0.7)
V	0.80 (0.43)	1.00 (0.54)	0.91 (0.55)	1.0 (0.6)
VII	0.37 (0.24)	0.57 (0.35)	0.87 (0.50)	1.0 (0.6)

vWF = von Willebrand factor, PreK = prekallikrein.

Complement (S)

C3: 96-195 mg/dL
 C4: 15-20 mg/dL

Copper (S)

Cord blood: 26-32 μg/dL (4.1-5.2 μmol/L)
 Newborns: 26-32 μg/dL (4.1-5.2 μmol/L)
 1 mo: 73-93 μg/dL (11.5-14.6 μmol/L)
 2 mo: 59-69 μg/dL (9.3-10.9 μmol/L)
 6 mo-5 y: 27-153 μg/dL (4.2-24.1 μmol/L)
 5-17 y: 94-234 μg/dL (14.8-36.8 μmol/L)
 Adults: 70-118 μg/dL (11-18.6 μmol/L)

Copper Oxidase: See Ceruloplasmin.

Cortisol (S, P)

Morning (8:00 am): 5-25 μg/dL (0.14-0.68 μmol/L)
 Evening: 5-15 μg/dL (0.14-0.41 μmol/L)

Creatine (S, P)

0.2-0.8 mg/dL (15.2-61 mmol/L)

(continued)

Table 44-1. Normal blood chemistry values and miscellaneous other hematologic values. (Values may vary with the procedure used.) (continued)

Creatine Kinase (S, P)

Newborns (1-3 d): 40-474 IU/L at 37 °C
 Adult males: 30-210 IU/L at 37 °C
 Adult females: 20-128 IU/L at 37 °C

Creatinine (S,P)

Values in mg/dL (μmol/L)

Group	Males	Females
Newborns (1-3 d)*	0.2-1.0 (17.7-88.4)	0.2-1.0 (17.7-88.4)
1 y	0.2-0.6 (17.7-53.0)	0.2-0.5 (17.7-44.2)
2-3 y	0.2-0.7 (17.7-61.9)	0.3-0.6 (26.5-53.0)
4-7 y	0.2-0.8 (17.7-70.7)	0.2-0.7 (17.7-61.9)
8-10 y	0.3-0.9 (26.5-79.6)	0.3-0.8 (26.5-70.7)
11-12 y	0.3-1.0 (26.5-88.4)	0.3-0.9 (26.5-79.6)
13-17 y	0.3-1.2 (26.5-106.1)	0.3-1.1 (26.5-97.2)
18-20 y	0.5-1.3 (44.2-115.0)	0.3-1.1 (26.5-97.2)

*Values may be higher in premature newborns.

Creatinine Clearance

Values show great variability and depend on the specificity of the analytical methods used.

Newborns (1 d): 5-50 mL/min/1.73 m (mean, 18 mL/min/1.73 m)

Newborns (6 d): 15-90 mL/min/1.73 m² (mean, 36 mL/min/1.73 m²)

Adult males: 85-125 mL/min/1.73 m²

Adult females: 75-115 mL/min/1.73 m²

2,3-Diphosphoglycerate (B)

Values vary with the method used and with altitude.
 4.5-6 mmol/L

Factor: See Anticoagulation Factors and Coagulation Factors.

Fatty Acids, "Free" (P)

Newborns: 435-1375 μEq/L

4 mo-10 y (14-h fast): 500-900 μEq/L

4 mo-10 y (19-h fast): 730-1200 μEq/L

Adults (14-h fast): 310-590 μEq/L

Adults (19-h fast): 405-720 μEq/L

Ferritin (S)

Newborns: 20-200 ng/mL (mean, 117 ng/mL)

1 mo: 60-550 ng/mL (mean, 350 ng/mL)

1-15 y: 7-140 ng/mL (mean, 31 ng/mL)

Adult males: 50-225 ng/mL (mean, 140 ng/mL)

Adult females: 10-150 ng/mL (mean, 40 ng/mL)

Fibrinogen (P)

200-500 mg/dL (5.9-14.7 μmol/L)

Galactose (S, P)

1.1-2.1 mg/dL (0.06-0.12 mmol/L)

Galactose 1-Phosphate (RBC)

Normal: 1 mg/dL of packed erythrocyte lysate; slightly higher in cord blood

Infants with congenital galactosemia on a milk-free diet: < 2 mg/dL

Infants with congenital galactosemia taking milk: 9-20 mg/dL

Galactose-1-Phosphate Uridyl Transferase (RBC)

Normal: 308-475 mIU/g of hemoglobin

Heterozygous for Duarte variant: 225-308 mIU/g of hemoglobin

Homozygous for Duarte variant: 142-225 mIU/g of hemoglobin

Heterozygous for congenital galactosemia: 142-225 mIU/g of hemoglobin

Homozygous for congenital galactosemia: < 8 mIU/g of hemoglobin

Glomerular Filtration Rate

Newborns: About 50% of values for older children and adults

Older children and adults: 75-165 mL/min/1.73 m² (levels reached by about 6 mo)

Glucose (S, P)

Premature infants: 20-80 mg/dL (1.11-4.44 mmol/L)

Full-term infants: 30-100 mg/dL (1.67-5.56 mmol/L)

Children and adults (fasting): 60-105 mg/dL (3.33-5.88 mmol/L)

Glucose-6-Phosphate Dehydrogenase (RBC)

150-215 U/dL

(continued)

Table 44-1. Normal blood chemistry values and miscellaneous other hematologic values. (Values may vary with the procedure used.) (continued)

Glucose Tolerance Test (S):

Glucose tolerance test results in serum.

Normal levels based on results in 13 normal children given glucose.
1.75 g/kg orally in one dose, after 2 wk on a high-carbohydrate diet.

Time	Glucose		Insulin		Phosphorus	
	mg/dL	mmol/L	μU/mL	pmol/L	mg/dL	mmol/L
Fasting	59-96	3.11-5.33	5-40	36-287	3.2-4.9	1.03-1.58
30 min	91-185	5.05-10.27	36-110	258-789	2.0-4.4	0.64-1.42
60 min	66-164	3.66-9.10	22-124	158-890	1.8-3.6	0.58-1.16
90 min	68-148	3.77-8.22	17-105	122-753	1.8-3.6	0.58-1.16
2 h	66-122	3.66-6.77	6-84	43-603	1.8-4.2	0.58-1.36
3 h	47-99	2.61-5.49	2-46	14-330	2.0-4.6	0.64-1.48
4 h	61-93	3.39-5.16	3-32	21-230	2.7-4.3	0.87-1.39
5 h	63-86	3.50-4.77	5-37	36-265	2.9-4.4	0.94-1.42

γ-Glutamyl Transpeptidase (S)

- 0-1 mo: 12-271 IU/L at 37 °C (kinetic)
- 1-2 mo: 9-159 IU/L at 37 °C (kinetic)
- 2-4 mo: 7-98 IU/L at 37 °C (kinetic)
- 4-7 mo: 5-45 IU/L at 37 °C (kinetic)
- 7-12 mo: 4-27 IU/L at 37 °C (kinetic)
- 1-15 y: 3-30 IU/L at 37 °C (kinetic)
- Adult males: 9-69 IU/L at 37 °C (kinetic)
- Adult females: 3-33 IU/L at 37 °C (kinetic)

Glycohemoglobin (Hemoglobin A_{1c}) (B)

Normal: 6.3-8.2% of total hemoglobin
 Diabetic patients in good control of their condition ordinarily have levels < 10%
 Values tend to be lower during pregnancy; they also vary with technique

Growth Hormone (GH) (S)

After infancy (fasting specimen): 0-5 ng/mL
 In response to natural and artificial provocation (eg, sleep, arginine, insulin, hypoglycemia): > 8 ng/mL
 During the newborn period (fasting specimen), GH levels are high (15-40 ng/mL) and responses to provocation are variable

Haptoglobin (S)

50-150 mg/dL has hemoglobin-binding capacity.

Hematocrit (B)

- At birth: 44-64%
- 14-90 d: 35-49%
- 6 mo-1 y: 30-40%
- 4-10 y: 31-43%

Hemoglobin A_{1c}: See Glycohemoglobin

Hemoglobin Electrophoresis (B)

A₁ hemoglobin: 96-98.5% of total hemoglobin
 A₂ hemoglobin: 1.5-4% of total hemoglobin

Hemoglobin, Fetal (B)

At birth: 50-85% of total hemoglobin
 At 1 y: < 15% of total hemoglobin
 Up to 2 y: Up to 5% of total hemoglobin
 Thereafter: < 2% of total hemoglobin

Immunoglobulins (S)

Values in mg/dL

Group	IgG	IgA	IgM
Cord blood	766-1693	0.04-9	4-26
2 wk-3 mo	299-852	3-66	15-149
3-6 mo	142-988	4-90	18-118
6-12 mo	418-1142	14-95	43-223
1-2 y	356-1204	13-118	37-239
2-3 y	492-1269	23-137	49-204
3-6 y	564-1381	35-209	51-214
6-9 y	658-1535	29-384	50-228
9-12 y	625-1598	60-294	64-278
12-16 y	660-1548	81-252	45-256

Immunoreactive Trypsinogen^{de} (IRT) (P)(S)

Normal controls 10-57 ng/ml
 Chronic pancreatitis < 1.5-47 ng/ml
 Acute pancreatitis 92-850 ng/ml
 Total pancreatectomy < 1.5 ng/ml

(continued)

Table 44-1. Normal blood chemistry values and miscellaneous other hematologic values. (Values may vary with the procedure used.) (continued)

Insulin

Levels > 20 µg/dL (> 0.97 µmol/L) indicate the need for medical and environmental evaluation and possible pharmacologic intervention.

Insulin Clearance

< 1 mo: 29–88 mL/min/1.73 m²
 1–6 mos: 40–112 mL/min/1.73 m²
 6–12 mos: 62–121 mL/min/1.73 m²
 < 1 y: 78–164 mL/min/1.73 m²

Levels > 70 µg/dL (> 3.38 µmol/L) indicate the immediate need for medical and environmental management.

Iron (S, P)

Newborns: 20–157 µg/dL (3.6–28.1 µmol/L)
 6 wk–3 y: 20–115 µg/dL (3.6–20.6 µmol/L)
 3–9 y: 20–141 µg/dL (3.6–25.2 µmol/L)
 9–14 y: 21–151 µg/dL (3.8–27 µmol/L)
 14–16 y: 20–181 µg/dL (3.6–32.4 µmol/L)
 Adults: 44–196 µg/dL (7.2–31.3 µmol/L)

Lipase (S, P)

20–136 IU/L based on 4-h incubation

Lipoprotein Cholesterol, High-Density (HDL) (S)

Values in mg/dL (mmol/L)

Group	Males	Females
6–7 y	35–77 (0.90–1.98)	24–76 (0.62–1.96)
8–9 y	31–80 (0.80–2.06)	34–77 (0.87–1.98)
10–11 y	34–81 (0.87–1.09)	30–74 (0.77–1.91)
12–13 y	30–82 (0.77–2.11)	33–73 (0.85–1.88)
14–15 y	26–72 (0.67–1.86)	29–73 (0.74–1.88)
16–17 y	25–66 (0.72–1.70)	27–78 (0.69–2.01)

Iron-Binding Capacity (S, P)

Newborns: 59–175 µg/dL (10.6–31.3 µmol/L)
 Children and adults: 275–458 µg/dL (45–72 µmol/L)

Lipoprotein Cholesterol, Low-Density (LDL) (S)

Values in mg/dL (mmol/L)

Group	Males	Females
6–7 y	56–134 (1.44–3.46)	52–149 (1.34–3.85)
8–9 y	52–129 (1.34–3.33)	57–143 (1.47–3.69)
10–11 y	45–149 (1.16–3.85)	56–140 (1.44–3.61)
12–13 y	55–135 (1.42–3.48)	58–138 (1.49–3.56)
14–15 y	48–143 (1.24–3.69)	47–140 (1.21–3.61)
16–17 y	53–134 (1.36–3.36)	44–147 (1.13–3.79)

Lactate (B)

Venous blood: 5–18 mg/dL (0.5–2 mmol/L)
 Arterial blood: 3–7 mg/dL (0.3–0.8 mmol/L)

Lactate Dehydrogenase (LDH) (S, P)

Values using lactate substrate (kinetic)
 Newborns (1–3 d): 40–348 IU/L at 37 °C
 1 mo–5 y: 150–360 IU/L at 37 °C
 5–8 y: 150–300 IU/L at 37 °C
 8–12 y: 130–300 IU/L at 37 °C
 12–14 y: 130–280 IU/L at 37 °C
 14–16 y: 130–230 IU/L at 37 °C
 Adult males: 70–178 IU/L at 37 °C
 Adult females: 42–166 IU/L at 37 °C

Magnesium (S, P)

Newborns: 1.5–2.3 mEq/L (0.75–1.15 mmol/L)
 Adults: 1.4–2 mEq/L (0.7–1 mmol/L)

LDH: See Lactate Dehydrogenase.

Lead (B)

< 10 µg/dL (< 0.48 mmol/L)
 When a large proportion of a population of children have blood lead levels in the range of 10–19 µg/dL (0.48–0.92 µmol/L), communitywide childhood lead poisoning activities are warranted.

Methemoglobin (B)

0–0.3 g/dL (0–186 µmol/L)

Osmolality (S, P)

270–290 mOsm/kg

Proteins in serum.

Values are for cellulose acetate electrophoresis and are in g/dL. SI conversion factor: g/dL × 10 = g/L.

Group	Total Protein	Albumin	α ₁ -Globulin	α ₂ -Globulin	β-Globulin	γ-Globulin
At birth	4.6–7.0	3.2–4.8	0.1–0.3	0.2–0.3	0.3–0.6	0.6–1.2
3 mos	4.5–6.5	3.2–4.8	0.1–0.3	0.3–0.7	0.3–0.7	0.2–0.7
1 y	5.4–7.5	3.7–5.7	0.1–0.3	0.5–1.1	0.4–1.0	0.2–0.9
> 4 y	5.9–8.0	3.8–5.4	0.1–0.3	0.4–0.8	0.5–1.0	0.4–1.3

(continued)

Table 44–1. Normal blood chemistry values and miscellaneous other hematologic values. (Values may vary with the procedure used.) (continued)

<p>Oxygen Capacity (B) 1.34 mL/g of hemoglobin</p> <p>Oxygen Saturation (B) Newborns: 30–80% (0.3–0.8 mol/mol of venous blood) Thereafter: 65–85% (0.65–0.85 mol/mol of venous blood)</p> <p>Partial Thromboplastin Time (P) Children: 42–54 s</p> <p>Phenylalanine (S, P) 0.7–3.5 mg/dL (0.04–0.21 mmol/L)</p> <p>Phosphatase: See Acid Phosphatase and Alkaline Phosphatase.</p> <p>Phosphorus, Inorganic (S, P) Premature infants: At birth: 5.6–8 mg/dL (1.81–2.58 mmol/L) 6–10 d: 6.1–11.7 mg/dL (1.97–3.78 mmol/L) 20–25 d: 6.6–9.4 mg/dL (2.13–3.04 mmol/L) Full-term infants: At birth: 5–7.8 mg/dL (1.61–2.52 mmol/L) 3 d: 5.8–9 mg/dL (1.87–2.91 mmol/L) 6–12 d: 4.9–8.9 mg/dL (1.58–2.87 mmol/L) Children: 1 y: 3.8–6.2 mg/dL (1.23–2 mmol/L) 10 y: 3.6–5.6 mg/dL (1.16–1.81 mmol/L) Adults: 3.1–5.1 mg/dL (1–1.65 mmol/L) (See also Glucose Tolerance Test.)</p> <p>Potassium (S, P) Premature infants: 4.5–7.2 mmol/L Full-term infants: 3.7–5.2 mmol/L Children: 3.5–5.8 mmol/L Adults: 3.5–5.5 mmol/L</p> <p>Prealbumin: See Transthyretin.</p> <p>Proteins (S): See table on page 1345.</p> <p>Prothrombin Time (P) Children: 11–15 s</p> <p>Protoporphyrin, “Free” (FEP, ZPP) (B) Values for free erythrocyte protoporphyrin (FEP) and zinc protoporphyrin (ZPP) are 1.2–2.7 µg/g of hemoglobin.</p> <p>Pyruvate (B) Resting adult males (arterial blood): 50.5–60.1 µmol/L Adults (venous blood): 34–102 µmol/L</p>	<p>Retinol-Binding Protein (S)</p> <table border="1"> <tbody> <tr> <td>3–5 y</td> <td>1.0–5.0 mg/dL</td> </tr> <tr> <td>6–8 y</td> <td>1.5–5.9 mg/dL</td> </tr> <tr> <td>9–11 y</td> <td>1.5–6.5 mg/dL</td> </tr> <tr> <td>12–16 y</td> <td>1.5–7.0 mg/dL</td> </tr> </tbody> </table> <p>Sedimentation Rate (Micro) (B) < 2 y: 1–5 mm/h > 2 y: 1–8 mm/h</p> <p>SGOT: See Aspartate Aminotransferase.</p> <p>SGPT: See Alanine Aminotransferase.</p> <p>Sodium (S, P) Children and adults: 135–148 mmol/L</p> <p>Sugar: See Glucose.</p> <p>T₃: See Triiodothyronine.</p> <p>T₄: See Thyroxine.</p> <p>TBG: See Thyroxine-Binding Globulin.</p> <p>Thrombin Time (P) Children: 12–16 s</p> <p>Thyroid-Stimulating Hormone (TSH) (S) Values in µIU/mL</p> <table border="1"> <thead> <tr> <th></th> <th>Males</th> <th>Females</th> </tr> </thead> <tbody> <tr> <td>1–30 d</td> <td>0.52–16.0</td> <td>0.72–13.1</td> </tr> <tr> <td>1 mo–5 y</td> <td>0.55–7.1</td> <td>0.46–8.1</td> </tr> <tr> <td>6–18 y</td> <td>0.37–6.0</td> <td>0.36–5.8</td> </tr> </tbody> </table> <p>Thyroxine (T₄) (S) 1–2 d: 11.4–25.5 µg/dL (147–328 nmol/L) 3–4 d: 9.8–25.2 µg/dL (126–324 nmol/L) 1–6 y: 5–15.2 µg/dL (64–196 nmol/L) 11–13 y: 4–13 µg/dL (51–167 nmol/L) > 18 y: 4.7–11 µg/dL (60–142 nmol/L)</p> <p>Thyroxine, “Free” (Free T₄) (S) 1–2.3 ng/dL</p> <p>Thyroxine-Binding Globulin (TBG) (S) 1–7 mos: 2.9–6 mg/dL 7–12 mos: 2.1–5.9 mg/dL Prepubertal children: 2–5.3 mg/dL Pubertal children and adults: 1.8–4.2 mg/dL</p>	3–5 y	1.0–5.0 mg/dL	6–8 y	1.5–5.9 mg/dL	9–11 y	1.5–6.5 mg/dL	12–16 y	1.5–7.0 mg/dL		Males	Females	1–30 d	0.52–16.0	0.72–13.1	1 mo–5 y	0.55–7.1	0.46–8.1	6–18 y	0.37–6.0	0.36–5.8

Table 44-1. Normal blood chemistry values and miscellaneous other hematologic values. (Values may vary with the procedure used.) (continued)

α-Tocopherol: See Vitamin E.

Transaminase: See Alanine Aminotransferase and Aspartate Aminotransferase.

Transthyretin (prealbumin) (S, P)

- 2-5 mos: 14-33 mg/dL
- 6-11 mos: 12-27 mg/dL
- 12-17 mos: 11-26 mg/dL
- 18-23 mos: 14-24 mg/dL
- 24-36 mos: 11-26 mg/dL
- 3-5 y: 9.1-33.0 mg/dL
- 6-8 y: 15.3-45.5 mg/dL
- 9-11 y: 16.0-47.6 mg/dL
- 12-16 y: 19.0-50.0 mg/dL

Triglyceride (S, P)

Fasting (> 12 h) values in mg/mL (mmol/L)

Group	Males	Females
6-7 y	32-79 (0.36-0.89)	24-128 (0.27-1.44)
8-9 y	28-105 (0.31-1.18)	34-115 (0.38-1.29)
10-11 y	30-115 (0.33-1.29)	39-131 (0.44-1.48)
12-13 y	33-112 (0.37-1.26)	36-125 (0.40-1.41)
14-15 y	35-136 (0.39-1.53)	36-122 (0.40-1.37)
16-17 y	38-167 (0.42-1.88)	34-136 (0.38-1.53)

Note: Lower values represent the 5th percentile, whereas upper values are calculated from the mean + 2 SD.

Triiodothyronine (T₃) (S)

- 1-3 d: 89-405 ng/dL
- 1 wk: 91-300 ng/dL
- 1-12 mos: 85-250 ng/dL
- Prepubertal children: 119-218 ng/dL
- Pubertal children and adults: 55-170 ng/dL

Tyrosine (S, P)

- Premature infants: 3-30.2 mg/dL (0.17-1.67 mmol/L)
- Full-term infants: 1.7-4.7 mg/dL (0.09-0.26 mmol/L)
- 1-12 y: 1.4-3.4 mg/dL (0.08-0.19 mmol/L)
- Adults: 0.6-1.6 mg/dL (0.03-0.09 mmol/L)

Ubiquinone, Total^b (Coenzyme Q10) (S)

- Values in μg/mL
- 1 mo-< 8 years 0.40-1.19 (0.46-1.38 μmol/L)
 - 8-18 y 0.29-0.89 (0.34-1.03 μmol/L)

Urea Clearance

- Premature infants: 3.5-17.3 mL/min/1.73 m²
- Newborns: 8.7-33 mL/min/1.73 m²
- 2-12 mos: 40-95 mL/min/1.73 m²
- ≥ 2 y: > 52 mL/min/1.73 m²

Urea Nitrogen (S, P)

- 1-2 y: 5-15 mg/dL (1.8-5.4 mmol/L)
- Thereafter: 10-20 mg/dL (3.5-7.1 mmol/L)

Uric Acid (S, P)

- Males:
- 0-14 y: 2-7 mg/dL (119-416 μmol/L)
 - > 14 y: 3-8 mg/dL (178-476 μmol/L)
- Females:
- 0-14 y: 2-7 mg/dL (119-416 μmol/L)
 - > 14 y: 2-7 mg/dL (119-416 μmol/L)

Vitamin A (Retinol) (S, P)

- Total vitamin A: 19-81 μg/dL (0.66-2.82 μmol/L)
- Retinol: 19-77 μg/dL (0.66-2.68 μmol/L)
- Retinyl esters: 0.1-4.7 μg/dL (0.01-0.16 μmol/L)

Vitamin C (Ascorbic Acid) (S, P)

- 0.2-2 mg/dL (11-114 μmol/L)

Vitamin D (S)

- 1,25-Dihydroxycholecalciferol:
 - Normal: 37 ± 12 pg/mL
 - X-linked vitamin D-resistant disease: 16 ± 8 pg/mL
 - Vitamin D dependency: 9.5 ± 3 pg/mL in type I. Normal in type II.
 - Hypophosphatemic bone disease: 30 ± 6 pg/mL
 - Lead poisoning: 20 ± 1 pg/mL
- 25-Hydroxycholecalciferol:
 - Normal: 26-31 ng/mL

Vitamin E (Tocopherol) (S, P)

- α-Tocopherol:
- < 12 y: 3.8-15.5 μg/mL (9.1-37.2 μmol/L)
 - > 12 y: 4.7-203 μg/mL (11.3-48.7 μmol/L)
- γ-Tocopherol:
- The γ isomer contributes 10-20% of the total tocopherols in plasma but is only 10% as active as the α form in vivo.
- Vitamin E status is best assessed by performing chromatographic separation of the isomers and determining both α- and γ-tocopherol levels. Levels should be expressed in terms of vitamin E/total lipid ratio:
- < 12 y: > 0.6 mg/g (> 1.4 μmol/g)
 - > 12 y: > 0.8 mg/g (> 1.9 μmol/g)

Volume (B)

- Premature infants: 98 mL/kg (mean)
- Full-term infants: 75-100 mL/kg
- 1 y: 69-112 mL/kg (mean, 86 mL/kg)
- Older children: 51-86 mL/kg (mean, 70 mL/kg)

(continued)

Table 44–1. Normal blood chemistry values and miscellaneous other hematologic values.¹ (Values may vary with the procedure used.) (continued)**Volume (P)**

Full-term neonates: 39–77 mL/kg
 Infants: 40–50 mL/kg
 Older children: 30–54 mL/kg

Water (B, S, RBC)

Whole blood: 79–81 g/dL
 Serum: 91–92 g/dL
 Red blood cells: 64–65 g/dL

Xylose Absorption Test (B)

Following a 5-g loading dose, the laboratory will report the D-xylose concentration of the baseline and 60-min samples in mg/dL. The difference between these two values should be corrected to a constant surface area of 1.73 m² according to the formula shown below.

The actual surface area can be derived from a number of available nomograms using the patient's weight and height.

Normal corrected blood values^c: 9.8–20 mg/dL

Effect of age and sex: No significant differences between males and females. No significant differences in ages 14–92 y.

Zinc (S)

Males: 83–88 µg/dL (12.7–13.5 µmol/L)

Females: 85–91 µg/dL (13–13.9 µmol/L)

Females taking oral contraceptives: 86–93 µg/dL
 (13.2–14.2 µmol/L)

At 16 wk of gestation: 66–70 µg/dL (10.1–10.7 µmol/L)

At 38 wk of gestation: 54–58 µg/dL (8.3–8.9 µmol/L)

(continued)

Table 44–2. Normal values: urine, duodenal fluid, feces, sweat, and miscellaneous. (continued)**Porphyrins**

δ-Aminolevulinic acid: 0–7 mg/24 h (0–53.4 μmol/24 h)
 Porphobilinogen: 0–2 mg/24 h (0–8.8 μmol/24 h)
 Coproporphyrin: 0–160 μg/24 h (0–244 nmol/24 h)
 Uroporphyrin: 0–26 μg/24 h (0–31 nmol/24 h)

Potassium

26–123 mmol/L

Sodium

Infants: 0.3–3.5 mmol/24 h (6–10 mmol/m²)
 Children and adults: 5.6–17 mmol/24 h

Urobilinogen

< 3 mg/24 h (< 5.1 μmol/24 h)

Uroporphyrin: See Porphyrins.

Vanillylmandelic Acid (VMA)

Because of the difficulty in obtaining an accurately timed 24-h collection, values based on micrograms per milligram of creatinine are the most reliable indications of VMA excretion in young children.

1–12 mos: 1–35 μg/mg of creatinine
 (31–135 μg/kg/24 h)

1–2 y: 1–30 μg/mg of creatinine

2–5 y: 1–15 μg/mg of creatinine

5–10 y: 1–14 μg/mg of creatinine

10–15 y: 1–10 μg/mg of creatinine (1–7 mg/24 h;
 5–35 μmol/24 h)

Adults: 1–7 μg/mg of creatinine (1–7 mg/24 h;
 5–35 μmol/24 h)

VMA: See Vanillylmandelic Acid.

Xylose Absorption Test

Mean 5-h excretion expressed as a percentage of the ingested load

< 6 mos: 11–30%

6–12 mos: 20–32%

1–3 y: 20–42%

3–10 y: 25–45%

> 10 y: 25–50%

Or: % excretion > (0.2 × age [mo]) + 12

DUODENAL FLUID**Enzymes**

Amylase: (Anderson)

0–2 mos: 0–10 U/mL

2–6 mos: 10–20 U/mL

6–12 mos: 40–150 U/mL

1–2 y: 100–225 U/mL

2–5 y: 125–275 U/mL

Carboxypeptidase:

0.4–1 U (Ravin)

Chymotrypsin:

11–65 U (Ravin)

Protease:

18–70 U (Free-Meyers)

Trypsin: (Anderson or as noted)

0–2 mos: 110–160 U/mL

2–6 mos: 115–160 U/mL

6–12 mos: 120–290 U/mL; 3–10 U

(Nothman et al)

1–2 y: 200–300 U/mL

2–5 y: 200–275 U/mL

pH

6–8.4

FECES**Fat, Total**

2–6 mos: 0.3–1.3 g/d

6 mos–1 y: < 4 g/d

Children: < 3 g/d

Adolescents: < 5 g/d

Adults: < 7 g/d

Lipids, Split Fat

Adults: > 40% of total lipids

Lipids, Total

Adults: Up to 7 g/d on normal diet, 10–27% of dry weight

Nitrogen

Infants: < 1 g/d

Children: < 1.2 g/d

Adults: < 3 g/d

Pancreatic Elastase-1^{ab} (E1)

Normal 200 to >500 μg E1/g stool

Moderate to mild exocrine pancreatic insufficiency 100–200 μg E1/g stool

Severe exocrine pancreatic insufficiency <100 μg E1/g stool

insufficiency

SWEAT**Electrolytes**

Values for chloride. Elevated values in the presence of a family history or clinical findings of cystic fibrosis are diagnostic of cystic fibrosis.

Normal: < 40 mmol/L

Borderline: 40–60 mmol/L

Elevated: > 60 mmol/L

^aThese data have been compiled from several sources. Emphasis is given to recent studies using electronic counters and to the selection of populations that are likely to exclude individuals with iron deficiency. The mean ± 2 SD can be expected to include 95% of the observations in a normal population.

(Based on Cairo MS: In: Rudolph AM [ed]: *Pediatrics*, 20th ed. Appleton & Lange, 1996:1222. As modified in Lubin BH: Reference values in infancy and childhood. In: Nathan DG, Oski FA [eds]: *Hematology of Infancy and Childhood*, 4th ed. WB Saunders, 1993:Appendix iii.)

^bNumbers of leukocytes are in thousands per cubic millimeter, ranges are estimates of 95% confidence limits, and percentages refer to differential counts. Neutrophils include band cells at all ages and a small number of metamyelocytes and myelocytes in the first few days of life.

From Cairo MS: In: Rudolph AM [ed]: *Pediatrics*, 20th ed. Appleton & Lange, 1996. As modified in Lubin BH: Reference values in infancy and childhood. In: Nathan DG, Oski FA [eds]: *Hematology of Infancy and Childhood*, 4th ed. WB Saunders, 1993: Appendix xi.)

MCV = mean corpuscular volume; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration.

- Vaginal discharge, sexually transmitted, **1302–1304**
- Vaginal pouch, 139–140
- Vaginal ring, for adolescents, 143
- Vaginal speculum, in pelvic examination, 129–130
- Vaginitis, 1302
allergic or contact, 146
foreign body, 146
treatment of, 1295t
- Vaginosis, bacterial, 1295t, **1302–1303**
in adolescents, 145–146
- Valacyclovir
for herpes simplex virus infection, 1296t–1297t
for herpes zoster infection, 1151
ophthalmic, 442
for infectious mononucleosis (Epstein-Barr virus), 1157
for varicella zoster infection, 1151
- Valproate
for bipolar affective disorder, 195
for seizure disorders, in newborns, 63
for status epilepticus, 757t
- Valproic acid, 215–216
for seizure disorders, 755t
therapeutic blood levels of, 1314t
- Valvular aortic stenosis, 583
- Valvular pulmonary stenosis with intact ventricular septum, 579–580
- Vancomycin, 1114t, 1123–1124
for bacterial pneumonia, 532
for bacterial sepsis in newborn, 50
guidelines for use of, 1116t
in newborns, 1118t
for meningococcal infections, 1203
for pneumococcal meningitis, 1197
for staphylococcal infections, 1199, 1200
endocarditis, 1200
methicillin-resistant *S. aureus*, 1123
pneumonia, 1200
toxic shock syndrome, 1200–1201
for streptococcal infections group B, 1191, 1192t
non-A, non-B, 1194
therapeutic blood levels of, 1314t
- Vanillylmandelic acid (VMA), 1350t
- VAPP (vaccine-associated paralytic poliomyelitis), 1144
- Varicella, bullous, 420
- Varicella immune globulin, for premature infants, after exposure, 534
- Varicella vaccine, **272–274**
adverse effects of, 273–274
antibody preparations of, 274
contraindications & precautions with, 258t, 274
dosage & schedule of administration of, 252t–255t, 273
preparations of, 273
- Varicella-zoster immune globulin (VZIG), postexposure prevention with, 1151
- Varicella-zoster virus infection, **1149–1151**
acute retinal necrosis syndrome from, 449
antimicrobials for, 1113t
congenital, **54**
diagnostic tests for, 1133t
in newborn, **54**
of skin, 423

fat-soluble, **293–299**
toxicity from, 293, 294t
in nutritional support, 313–314
poisoning with, 371
water-soluble, 294t, **297–299**
biologic roles of, 297t
deficiencies of, causes of, 298t
dietary reference intake for, 295t
dietary sources of, 298t
- Vitamin A (retinol), **293–294**
dietary reference intake for, 295t
excess, toxicity of, 294t
normal blood values for, 1347t
poisoning with, 371
teratogenicity of, 1076–1077
- Vitamin B, **297–299**
deficiencies of
causes of, 298t
clinical features of, 299t
dietary reference intake for, 295t
dietary sources of, 298t
excess, toxicity of, 294t
water-soluble, 297t
- Vitamin B₂ (riboflavin), **297–298**
biologic roles of, 297t
deficiencies of
causes of, 298t
clinical features of, 299t
dietary reference intake for, 295t
dietary sources of, 298t
excess, toxicity of, 294t
for fatty acid oxidation disorders, 1031
for mitochondrial respiratory chain defects, 1021
water-soluble, 297t
- Vitamin B₆ (pyridoxine), **297–298**
biologic roles of, 297t
deficiencies of
causes of, 298t
clinical features of, 299t
dietary reference intake for, 295t
dietary sources of, 298t
excess, toxicity of, 294t
for homocystinuria, 1027
poisoning with, from vitamins, 371
for primary hyperoxaluria, 729
for seizure disorders, in newborns, 63

- Vitamin B₁₂ (cobalamin), **297–298**
 biologic roles of, 297t
 deficiencies of, 863
 causes of, 298t
 clinical features of, 299t
 dietary reference intake for, 295t
 dietary sources of, 298t
 excess, toxicity of, 294t
 for homocystinuria, 1027
 for ketotic hyperglycinemia, 1029
- Vitamin C (ascorbic acid), **297–299**
 biologic roles of, 297t
 for Chédiak-Higashi syndrome, 883
 deficiencies of
 causes of, 298t
 clinical features of, 299t
 dietary reference intake for, 295t
 dietary sources of, 298t
 excess, toxicity of, 294t
 normal blood values for, 1347t
 for tyrosinemia of newborn, 1025
- Vitamin D, **294–296**
 dietary reference intake for, 295t
 excess, toxicity of, 294t
 for hepatitis, viral neonatal, 661
 hormonal action of, 961
 for hypercalcemia, 986
 for hypocalcemia, 984
 in newborn, 64
 for Lowe syndrome, 727
 normal blood values for, 1347t
 poisoning with, 371
 for rickets, 727
- 1,25-(OH)₂ Vitamin D, in calcium homeostasis, 979–980
- Vitamin D analogues, for scleroderma, 852
- Vitamin D deficiency rickets, hypocalcemia with, 981t
- Vitamin D refractory rickets, hypocalcemia with, 981t
- Vitamin E (tocopherol), **296**
 dietary reference intake for, 295t
 excess, toxicity of, 294t
 for hepatitis, viral neonatal, 661
 normal blood values for, 1347t
- Vitamin K, **296–297**
 for bleeding disorders from liver disease, 896
 deficiency of, bleeding disorders from, 896–897
 dietary reference intake for, 295t
 excess, toxicity of, 294t
 for hepatitis, viral neonatal, 661
 for Reye syndrome, 686
 for vitamin K deficiency bleeding, 897
 of newborn, 59
- Vitamin K deficiency bleeding of newborn (VKDB), **58–59**, 59t
- Vitiligo, **431**
- VLCAD deficiency, 1030–1031
