Ectopic Eruption

Ectopic eruption occurs when the position of an erupting tooth is abnormal. In severe instances, the order in which teeth erupt is affected. If the dental arch provides

insufficient room, permanent teeth may erupt abnormally. In the mandible, lower incisors may be lingually placed to such an extent that the primary incisors do not exfoliate. The parents' concern about a "double row of teeth" may be the reason for the child's first dental visit. If the primary teeth are not loose, they may be removed by the dentist; if they are loose, they are generally allowed to exfoliate naturally. In the maxilla, inadequate room for eruption of the permanent first molar may cause abnormal resorption of the distal root structures of the second primary molar. If the problem is severe, the permanent molar may even become caught under the unresorbed enamel crown of the deciduous molar and thus require extraction of the primary tooth and orthodontic repositioning of the permanent first molar after it has erupted. If the first molar is not repositioned, the second premolar is likely to become impacted. If problems are detected early, the dentist may be able to redirect the permanent molar's eruption pathway so that it erupts correctly and the second primary molar is not lost.

Impaction

Impaction occurs when a tooth is prevented from erupting for any reason. The teeth most often affected are the third molars (wisdom teeth) and the maxillary canines. Patients with impacted third molars are at risk for developing odontogenic tumors or dentigerous cysts. The impacted third molar (along with its opposing third molar) may be removed after it has been determined that eruption cannot occur, but this decision may not be possible until the late teens. Impacted maxillary canines should not be extracted because of their aesthetic importance and key role in facial development and dental occlusion. They can often be brought into correct alignment through surgical exposure and orthodontic treatment.

Other Variations

Failure of teeth to develop—a condition sometimes called congenitally missing teeth—is rare in the primary dentition. However, it occurs in about 5% of permanent dentitions, with one or more of the third molars missing in about 25% of all individuals. The ones most frequently missing are maxillary lateral incisors and mandibular second premolars. The incidence of congenitally missing teeth varies among different genetic groups.

Occasionally, extra teeth are present, most typically an extra (fourth) molar or extra (third) bicuspid. Mesiodens, which are peg-shaped supernumerary teeth situated at the maxillary midline that occur in about 5% of individuals, may interfere with eruption of permanent incisors. Mesiodens should be considered for removal even if they do not erupt.

DENTAL CARIES & PERIODONTAL DISEASE

The process of tooth decay (caries) and periodontal disease are among the most common and easily preventable of all infectious diseases. Current research is changing the traditional view of dental caries as the manifestation of caries activity (eg, “holes in the teeth”). Practitioners are now pursuing the more practical objective of diagnosing and treating the caries process in the context of a life continuum, rather than only as cavitated teeth. The traditional “cavity” is irreversible and requires surgical correction. Filling cavities does nothing to address the underlying pathologic process that caused them. Prevention, early diagnosis, and prompt intervention offer greater efficiency and better health outcomes with lower costs.

The basic tenets of cariology are

1. Caries is the most common chronic disease of childhood.

2. Caries is an infectious disease that is transmissible and caused by colonization with *Streptococcus mutans*.
3. *S mutans* is transmitted from a mother to her child and detectable by 26 months on average, with a range of 12–36 months.
4. Caries is a process present in all individuals. The expression of cavities depends on its level of activity and the host’s resistance.
5. After establishment of *S mutans* in the oral cavity, caries is a dietary disease.
6. Control of caries before age 3 years is aimed at limiting the establishment of *S mutans* by reducing the number of episodes of direct transmission from highly infected mothers; reducing dietary support for *S mutans* (refined carbohydrates); and ensuring proper levels of fluoride exposure topically and systemically.
7. Control of caries after age 3 years is aimed at limiting the acidogenesis of oral flora by reducing the frequency of carbohydrate ingestion and maintaining a high frequency of fluoride exposures.
8. There is a threshold of caries activity below which clinical disease does not develop.
9. Caries is largely a disease of poverty; the 29 million children and adolescents in low-income families account for 80% of tooth decay.

Teeth can be attacked by acidogenic bacteria, especially *S mutans*. Dental plaque accumulates on the surface of the teeth as an adherent film. As plaque grows, bacteria accumulate within it in close proximity to the tooth. An equally important factor is a substrate for the bacteria. Carbohydrate—especially a refined carbohydrate such as sucrose—is the most effective substrate for caries, since bacteria readily metabolize sucrose to produce acid. The acidic environment causes the enamel of the teeth to dissolve, which is the beginning of caries. After the decay process has penetrated the enamel, there is very little to keep it from affecting the vital tissues (nerve) of the tooth. The tooth subsequently becomes necrotic, and an abscess occurs (Figure 16–6). This process is not always symptomatic, but it can lead to severe pain, fever, and swelling.

In the early stages of decay, the tooth may be sensitive to temperature changes or, especially, to sweets. At this point, the tooth can be repaired by removing the caries and filling the defect. As the decay progresses, more pain may be involved, and root canal therapy may be necessary for both primary or permanent teeth. Once an abscess has formed, with or without swelling, a choice must be made between root canal therapy and removal of the tooth. In the presence of cellulitis or fa-

Figure 16-6. Tooth anatomy and progression of caries.

cial space abscess, extraction is usually the treatment of choice.

Many people question the importance of the primary dentition. Baby teeth allow the child to eat properly, speak properly, have a good self-image, and preserve the space for the permanent dentition. Premature loss of primary teeth can cause major orthodontic and dental growth and development problems.

Preventing Dental Caries

To prevent dental caries, it is necessary to remove the bacteria on a regular basis. Oral hygiene for the infant should start at birth. The gums can be cleaned gently with a moist, soft cloth. Once the teeth begin to erupt, oral hygiene must be practiced in earnest. Again, a moist, soft cloth can be used after feeding to gently rub the teeth. A very small, very soft toothbrush can be used as well. Toothpaste at the start is not necessary but should be added by age 2 years. Prior to age 6 years parents may need to be involved in brushing and flossing. Brushing with a fluoride-containing toothpaste (at least twice daily) and flossing the teeth regularly will minimize the oral flora. A second step is to decrease the amount of substrate

available to the bacteria. Eliminating refined carbohydrates is very effective (low-sugar diets), but limiting exposure to them is also beneficial because each exposure produces an acidic environment for up to 30 minutes. The form of the substrate is important. Caramels, licorice, raisins, gummy bears, and so on are concentrated sugar with a sticky texture that will remain on the teeth much longer than the same sugar in liquid form. The primary care physician can play an invaluable role in disseminating this information and reinforcing these ideas.

Fluoride

Fluoride prevents dental caries predominantly after eruption of the tooth into the mouth. Its actions are primarily topical for both children and adults. The mechanisms of action include inhibition of demineralization, enhancement of remineralization, and inhibition of bacterial activity in dental plaque. Table 16-1 sets forth the current systemic fluoride dosages to be administered to children as recommended by the American Academy of Pediatrics and the AAPD. It is important not to exceed these recommendations because doing so may lead to fluorosis, which is unsightly

Table 16-1. Fluoride dosages administered to children based on tap water fluoride supply.

Age (years)	Dose of Fluoride Administered		
	If < 0.3 ppm F in Drinking Water	If 0.3–0.6 ppm F in Drinking Water	If > 0.6 ppm F in Drinking Water
6 months to 3 years	0.25 mg/d	0	0
3–6 years	0.5 mg/d	0.25 mg/d	0
6–16 years	1 mg/d	0.5 mg/d	0

staining of the permanent teeth. Children from low-income families residing in areas with fluoridated water incur treatment costs one half less than that for such children in nonfluoridated areas, and they require less hospitalization for treatment.

Daily topical fluoride therapy is used in addition to all other oral hygiene measures in certain high-risk children. Children allowed to take their bottle to bed and those who nurse at will and fall asleep nursing are at risk for nursing caries. This particular type of decay involves mostly the maxillary incisors. When a child is lying in bed sucking on a bottle, the contents of the bottle are “trapped” between the backs of the front teeth and the tongue. This allows for more concentrated damage to the teeth as the acid produced by bacteria fails to dissipate. In addition, as the child falls asleep, salivary function decreases dramatically. This further endangers the teeth by eliminating the buffering capacity of saliva and its remineralizing potential. Topical fluoride may slow the decay process and, combined with elimination of high-risk nursing practices and institution of good oral hygiene, can prevent serious dental problems in these infants.

Patients with chronically low oral pH may benefit from daily topical fluoride. This patient group includes those with gastroesophageal reflux, bulimia, or salivary dysfunction from radiation, graft-versus-host disease, or autoimmune disease. Saliva is a very effective oral cavity buffer. It also helps remineralize minor enamel dissolution. Xerostomia can lead to rampant caries. These children need dental care more frequently than healthy children. Multiply handicapped children who cannot maintain proper oral hygiene can also benefit from additional topical fluoride. Any child with a serious medical problem or disability should be referred to a pediatric dentist as early as possible, usually before age 1 year.

Periodontal Disease

Periodontal disease involves the supporting structures: bone, gums, and ligaments. It begins as inflammation of the gum tissue adjacent to the tooth. Bacterial accumulation in the space between the tooth and gum (gingival sulcus) causes irritation that leads to inflamed tissue. This beginning phase is called gingivitis. As the inflammation spreads through the sulcus, it involves more soft tissue. Eventually soft tissue destruction and loss of bone occur as disease spreads toward the apex of the tooth. This is called periodontitis and requires professional cleaning and often medication or surgery for correction. Figure 16–7 shows the different stages and progression of periodontal disease.

The prevention and initial management of periodontal disease in children involves removal of bacteria from the teeth with proper oral hygiene.

Figure 16–7. Periodontal disease.

OROFACIAL TRAUMA

Orofacial trauma often consists only of abrasions or lacerations of the lips, gingiva, tongue, or mucosa, including the frena, without damage to the teeth. Lacerations should be cleansed and inspected for foreign bodies and sutured if necessary. Occasionally, radiographs of the tongue, lips, or cheeks are used to detect tooth fragments or other foreign bodies.

Tooth-related trauma can result in displacement (luxation), fracture, or loss of teeth (avulsion). Figure 16–8 demonstrates the different luxation injuries, and Figure 16–9 shows the different degrees of tooth fracture.

The least problematic luxation injury is mobility without displacement (subluxation). Unless mobility is extensive, this condition can be followed without active intervention. An intrusive luxation in the primary dentition is usually observed for a period of time to discern whether the tooth or teeth will reerupt (see Figure 16–8). If this has not occurred after several months or if the area becomes infected, the teeth are usually removed. Permanent teeth may be damaged with any intrusive injury of primary teeth. Permanent teeth intrusions are corrected with surgical or orthodontic repositioning of teeth and placement of a splint for 10–14 days. Root canal treatment may be necessary later. Lateral and extrusive luxations of permanent teeth are generally repositioned and splinted. Severe luxations in any direction in primary teeth are treated with extraction.

Avulsed primary dentition is not replanted. The area is investigated for fractured roots or foreign bodies. Avulsed permanent teeth are gently cleansed and replanted with splinting. If replaced into the alveolar bone within 1 hour, the prognosis for these teeth is good. The prognosis worsens rapidly with increased time outside of the mouth. Hank solution is the best storage and transport medium for avulsed teeth that

Figure 16-8. Patterns of luxation injuries.

will be replanted. Milk or saline can be used if Hank solution is not accessible.

All luxated and replanted teeth need to be followed carefully and regularly by a dentist. These teeth can become abscessed or fused to the bone (ankylosed) at any time during the healing process.

A patient with fractured teeth should be seen promptly by a dentist. Fractured teeth need to be protected quickly to avoid sensitivity, pain, or infection of exposed pulp. Severe fracture may require immediate root canal surgery.

All facial trauma needs to be evaluated for jaw fracture. Blows to the chin are among the most common childhood orofacial traumas. They are also a leading

Figure 16-9. Patterns of crown fractures.

cause of condylar fracture in the pediatric population. Condylar fracture should be suspected when pain or deviation occurs when the jaw is opened.

DENTAL EMERGENCIES

Dental emergencies other than trauma are usually associated with pain or swelling due to advanced caries. Odontogenic pain usually responds to acetaminophen, ibuprofen, codeine, or, in severe cases, hydrocodone. As with teething, topical application of medicaments is of limited value.

Swelling confined to the gum tissue above or below the tooth is usually not an urgent situation. This “gumboil” or parulis represents infection that has spread outward from the root of the tooth through the bone and periosteum into the gum. Usually it will begin to drain and leave a fistulous tract. If the infection invades the facial spaces, cellulitis can occur. Swelling of the mid-face—especially the bridge of the nose and the lower eyelid—should be urgently evaluated as a potential dental infection. Extraction of teeth or root canal therapy combined with antibiotics is the usual treatment. With extensive facial cellulitis, many young children require hospitalization and intravenous antibiotics.

ANTIBIOTICS IN PEDIATRIC DENTISTRY

The antibiotics of choice for odontogenic infection are amoxicillin and clindamycin. Several patient groups require prophylactic antibiotic coverage prior to any invasive dental manipulation, including tooth cleaning. Children with heart diseases that place them at risk for subacute bacterial endocarditis head this list. Some immunosuppressed patients also receive coverage during dental procedures. Although there is some controversy regarding the need for antibiotics in children with indwelling central venous catheters (eg, Broviac, Quinton, Hickman, and other lines), some experts medicate them prior to invasive dental treatment.

Children with a ventriculoperitoneal shunt should not receive prophylaxis because there is no circulatory connection to such a shunt.

SPECIAL PATIENT POPULATIONS

Children with Cancer

Children with cancer should be evaluated by a dentist knowledgeable about pediatric oncology soon after diagnosis. The aim is to eliminate all existing and potential sources of infection before the child receives chemotherapy and becomes neutropenic. Areas of concern include abscessed teeth, teeth with extensive caries, teeth that will soon exfoliate, ragged or broken teeth or

fillings, and orthodontic appliances. Once chemotherapy begins, there is a brief interval before its myelosuppressive effects reach their nadir (7–14 days). Once the child becomes neutropenic, abscessed, infected, or severely carious teeth can no longer be considered innocent, even if asymptomatic. A loose tooth that will soon exfoliate can become a nidus for infection as well as a cause of bleeding for a thrombocytopenic patient. Sharp, ragged teeth can be an irritation that leads to infection. Chemotherapeutic drugs and local irradiation are cytotoxic to the oral mucosa, which becomes atrophic and ulcerates with ease (mucositis). This is painful and often leads to inadequate oral intake and nutrition. Once the mucosal barrier is breached by ulceration, the patient can become septic, especially with α -hemolytic streptococci and other mouth flora. Herpes simplex virus is another pathogen that can enhance drug-induced mucositis. Friction and damage to the mucosa is the main concern with braces. Therefore, all orthodontic hardware is removed prior to chemotherapy.

The pediatric oncology patient should be monitored throughout therapy to screen for infection, manage oral bleeding, and control oral pain. These children can experience spontaneous oral hemorrhaging, especially when the platelet count is below 20,000/mL. Poor oral hygiene or areas of irritation can increase the chances of bleeding.

Children receiving radiation therapy to the head and neck are prone to develop extensive salivary dysfunction (xerostomia) when salivary tissue is in the path of the primary beam of radiation. Xerostomia should be managed aggressively to avoid rapid extensive destruction of dentition. Customized fluoride applicators are used in this situation in combination with close follow-up.

Children undergoing bone marrow transplantation may have acute graft-versus-host reaction as another contributor to severe oral mucositis. Long-term follow-up includes managing salivary dysfunction from total body radiation and treatment of oral graft-versus-host disease.

The pediatric oncology patient also needs to be followed by a dentist who is familiar with young children and their growth and development. Oral and maxillofacial growth disturbances can occur after therapy. Late effects of therapy include morphologic changes in tooth development (microdontia or extensive hypocalcification) and disturbances in eruption (blunted roots or delayed eruption).

Children with Hematologic Problems

The child with hemophilia needs to have the appropriate clotting factor provided before and after any invasive dental procedures (including the administration of

local anesthesia, even for simple fillings) (see Chapter 27). Some patients with very mild factor VIII deficiency or von Willebrand disease may respond to desmopressin acetate. Antifibrinolytic medications such as aminocaproic acid and tranexamic acid are used successfully after dental treatment. Postoperative bleeding can also be treated with a wide variety of topical medicaments, such as Gelfoam and thrombin.

The pediatric patient receiving anticoagulant therapy must undergo dosage adjustment before invasive dental treatment. This is a relatively simple matter when dealing with heparin, with its short half-life of 4–6 hours. It is a much more difficult problem with warfarin, which has a half-life of 40–70 hours.

Children with Diabetes

Children who are insulin-dependent are prone to dental problems. They have an impaired capacity to heal, a higher incidence of periodontal disease, and a higher caries rate. These children need to be followed carefully on a routine basis. Care must be taken not to disturb the regular cycle of eating and insulin dosage. Anxiety associated with dental appointments can cause a major upset in the diabetic child's routine. Postoperative pain or pain from dental abscess can prevent them from eating. Warnings about eating until the numbness wears off or until the filling gets hard can also alter their normal schedule of food intake and insulin dosage. Insulin levels must be adjusted to conform to treatment needs and vice versa.

MATERNAL-FETAL RELATIONSHIP

In addition to the discovery that childhood caries is an infectious disease transmitted by bacteria from the mother to the child, a number of other maternal-fetal relationships related to the oral cavity have been identified. A recent large prospective study has shown a significant association between maternal periodontitis at 21–24 weeks' gestation and preterm birth. It is unknown whether treatment of periodontitis will reduce the risk of preterm birth.

The risk of preterm birth is elevated if a mother smokes and is of low socioeconomic status, both of which also increase the risk for periodontitis. Second-hand or passive smoke also increases the risk of caries in children who grow up around smokers. This association is independent of age, family income, geographic region, and frequency of dental visits.

Given the known association between maternal periodontitis and preterm birth, passive smoke and children's dental caries, and the knowledge of maternal transmission of caries-causing bacteria, it is important

to advise expectant teenage mothers about these risk factors.

Moreover, low-birth-weight, preterm children have a greater predisposition to many oral developmental anomalies than normal-birth-weight children. These include generalized enamel hypoplasia associated with increased predisposition to early childhood caries, localized enamel hypoplasia, crown dilaceration of the maxillary left incisors, and palatal deformations associated with laryngoscopy and endotracheal intubation. Dental development in preterm infants is retarded in the eruption of the primary dentition and in the development of the permanent teeth.

DENTAL REFERRAL

Referral to a dentist is appropriate whenever there is a question about a child's oral and maxillofacial health

and development. Most pediatric dentists will want to see a child for a first visit by age 12 months. The average child should be seen every 6 months for dental follow-up. Any child with additional risk factors should be seen earlier and more frequently.

I. THE EAR

INFECTIONS OF THE EAR

The spectrum of ear diseases includes the structures of the outer ear (otitis externa), the middle ear (acute otitis media), the mastoid bone (mastoiditis), and the inner ear (labyrinthitis).

1. Otitis Externa

Otitis externa is inflammation of the skin lining the ear canal and surrounding soft tissue. The most common cause is loss of the protective function of cerumen, leading to maceration of the underlying skin. Other causes are trauma to the ear canal from using cotton-tipped applicators for cleaning or from using poorly fitted ear plugs while swimming; contact dermatitis due to hair sprays, perfumes, or self-administered ear drops; secondary infection of the canal from otitis media with a patent tympanostomy tube; and chronic drainage from a perforated tympanic membrane (TM). Infections due to *Staphylococcus aureus* or *Pseudomonas aeruginosa* are the most common.

Symptoms include pain and itching in the ear, especially with chewing or pressure on the tragus. Movement of the pinna or tragus causes considerable pain. Drainage may be minimal unless the otitis externa is from a draining PE tube or TM perforation. The ear canal may be grossly swollen, and the patient may resist any attempt to insert an ear speculum. Debris is noticeable in the canal. It is often impossible to visualize the TM. Hearing is normal unless complete occlusion has occurred.

Treatment

Topical treatment usually suffices. The crucial initial step is removal of desquamated epithelium and moist cerumen. This debris can be irrigated out or suctioned out using warm Burow solution (one packet of Domeboro powder [aluminum acetate and acetic acid] to 250 mL tap water) or normal saline, as long as it is known that the TM is intact. If the TM cannot be seen, then a perforation may be presumed to exist. Children

with otitis externa secondary to draining tubes or perforations should be treated with topical therapy only in the absence of systemic symptoms. The topical therapy chosen must be safe for the inner ear because the perforation or the patent tube allows the drops access to the middle and inner ear. Safe drops, such as fluoroquinolone drops, have no aminoglycoside or toxic preservatives. Once the ear canal is open, instill antibiotic ear drops two or three times daily. A corticosteroid may reduce the inflammatory response, but this is debated. If the canal is too edematous to allow the ear drop to get in, an ear wick for the first few days may be helpful. Oral antibiotics are indicated if any signs of invasive infection, such as fever, cellulitis of the auricles, or tender postauricular lymph nodes, are present. Prescribe an antistaphylococcal antibiotic while awaiting the results of culture of the ear canal discharge. Systemic antibiotics alone without topical treatment will not clear up otitis externa. Analgesics may be required temporarily.

During the acute phase, the patient should avoid swimming. A cotton ear plug is not helpful and may prolong the infection. Schedule a follow-up visit in 1 week to document an intact tympanic membrane (Figure 17-1). Children who have intact TMs and are predisposed to this problem should receive 2 or 3 drops of a 1:1 solution of white vinegar and 70% ethyl alcohol into the ears before and after swimming.

2. Otitis Media

Classification & Clinical Findings

Otitis media is an infection associated with middle ear effusion (a collection of fluid in the middle ear space) or with otorrhea (a discharge from the ear through a perforation in the TM or a ventilating tube). Otitis media can be further classified by its associated clinical symptoms, otoscopic findings, duration, frequency, and complications. These more specific classifications are

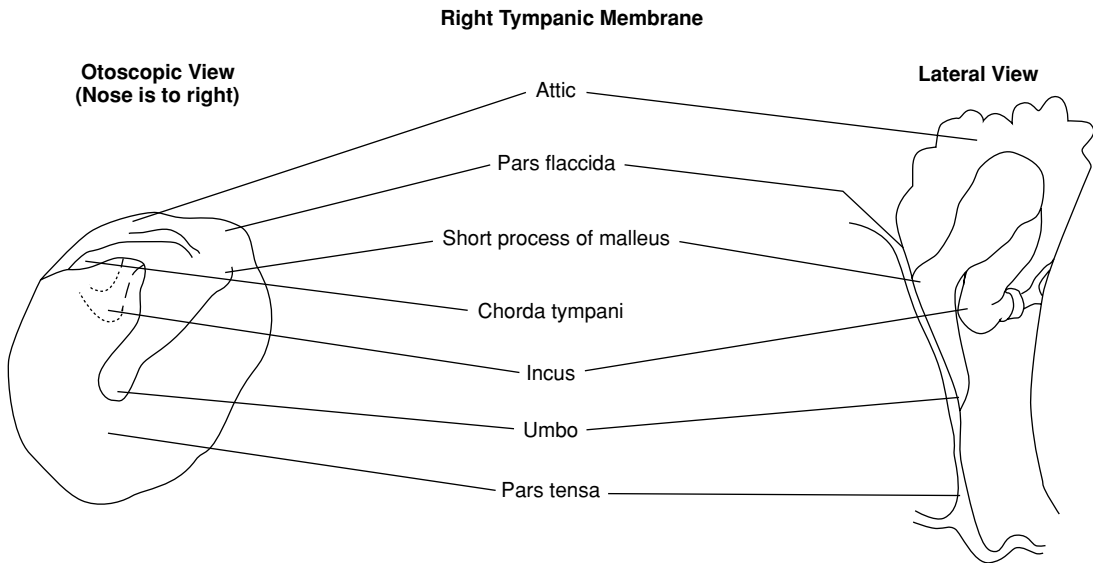

Figure 17-1. Tympanic membrane.

acute otitis media, otitis media with effusion, and chronic suppurative otitis media.

A. ACUTE OTITIS MEDIA

Acute otitis media (AOM) is commonly defined as inflammation of the middle ear resulting in an effusion and associated with rapid onset of symptoms such as otalgia, fever, irritability, anorexia, or vomiting. An ear effusion is best documented by pneumatic otoscopy or tympanometry. To distinguish AOM from otitis media with effusion (OME), signs of inflammation of the TM or symptoms of acute infection must be present. Otoscopic findings specific for AOM are a bulging TM; impaired visibility of the ossicular landmarks; a yellow, white, or bright red color; opacification of the eardrum; and squamous exudate or bullae on the eardrum. OME is associated with a nonbulging eardrum, which may be retracted or neutral, but always has decreased mobility, may have opacification, and may have white or amber discoloration. Children with OME may develop acute infection, but they will then exhibit inflammation of the eardrum as described for AOM.

B. OTITIS MEDIA WITH EFFUSION

Otitis media with effusion is defined as an asymptomatic middle ear effusion that often follows AOM, but may have no such antecedent history. Otoscopic findings that suggest OME include visualization of air–fluid levels or bubbles, and a clear or amber middle ear fluid. Effusion is usually associated with either a

mild or a moderate conductive hearing impairment of 15 dB or higher. OME can also be associated with negative middle ear pressure, which results in prominence of the malleus and a negative pressure peak on tympanometry.

C. CHRONIC SUPPURATIVE OTITIS MEDIA

This type of otitis media is defined as persistent otorrhea lasting longer than 6 weeks. Most often it occurs in children with tympanostomy tubes or TM perforations. Occasionally, it is an accompanying sign of cholesteatoma. Organisms commonly isolated are *Pseudomonas aeruginosa* and *Staphylococcus aureus*, but fungi and anaerobic bacteria may also play a role.

Pathogenesis of Acute Otitis Media

Factors that make otitis media more common in children than in adults include bacterial nasopharyngeal colonization in the absence of antibody, frequent upper respiratory infections (URI), exposure to parental cigarette smoke, unfavorable eustachian tube function, and allergies.

A. BACTERIAL COLONIZATION

Nasopharyngeal colonization with *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* increases the risk of otitis media. Colonization with normal flora such as viridans streptococci may prevent otitis episodes by inhibiting the growth of these

pathogens, and a nasal spray of viridans streptococci is under study. Colonization usually occurs sequentially with different serotypes of pathogen, and there is a risk of AOM with each new serotype acquired. Infants in daycare acquire these serotypes at a younger age than those in home care. Since younger children are at higher risk of AOM, the increased number of children in daycare over the last 3 decades has played a major role in the increase in AOM.

B. VIRAL UPPER RESPIRATORY INFECTIONS

These infections increase the colonization of the nasopharynx with otitis pathogens, perhaps because of increased adherence to the mucosa. Viral infection also impairs eustachian tube function by adenoidal swelling and edema. Therefore, factors that increase the frequency of viral respiratory infections, such as child care attendance, smoke exposure, later birth order, and absence of breast-feeding, promote colonization with otitis pathogens and predispose to otitis.

C. SMOKE EXPOSURE

Passive smoking increases the risk of persistent middle ear effusion by enhancing attachment of the pathogen, prolonging the inflammatory response, and impeding drainage through the eustachian tube. For infants age 12–18 months, exposure to each additional pack of cigarettes smoked at home is associated with an 11% increase in the duration of a middle ear effusion.

D. EUSTACHIAN TUBE DYSFUNCTION

Infants born with craniofacial disorders, such as Down syndrome or a cleft palate, are often affected by AOM and OME. The patency of the tube allows aeration of the middle ear. When the tube is obstructed, a vacuum develops, which can pull nasopharyngeal secretions into the middle ear.

E. HOST IMMUNE DEFENSES

Immunocompromised children usually experience recurrent AOM and sinusitis, as well as pneumonia. However, children who experience recurrent or persistent otitis may have selective impairments of immune defenses against specific otitis pathogens. For example, a recent study showed some such children have low-to-absent IgG2 or IgA pneumococcal polysaccharide antibody responses (or both) after vaccination, despite normal serum levels of total IgG2 and IgA.

F. BREAST-FEEDING

Breast-feeding reduces the incidence of acute respiratory infections, provides IgA antibodies that reduce colonization with otitis pathogens, and decreases the aspiration of contaminated secretions into the middle ear space.

G. GENETIC SUSCEPTIBILITY

Although we know AOM to be multifactorial, and no gene for susceptibility has yet been identified, recent studies of twins and triplets suggest that as much as 70% of the risk is genetically determined. This has implications for the subsequent offspring of parents with a child experiencing recurrent AOM. These families might wish to consider breast-feeding and home care for later children.

Microbiology of Acute Otitis Media

The role of respiratory viral infection in precipitating otitis media is unquestionable, yet fewer than 12% of ear effusions grow viruses. Recent studies with sensitive viral antigen or nucleic acid tests have detected virus in over 40% of infected ears. The viral infection may precede the bacterial otitis media by 3–14 days and presumably causes adenoid hypertrophy and eustachian tube dysfunction. The two viruses most clearly shown to precipitate otitis media are respiratory syncytial virus and influenza, accounting for the annual surge in otitis media cases in January to April in temperate climates.

About 50% of AOM in the Midwestern and northeastern United States is due to *S pneumoniae*, while the warmer, drier climates of southern Israel and Denver report a preponderance of nontypable *H influenzae*—the same two organisms most frequently associated with sinusitis. Another pathogen, *M catarrhalis*, may cause up to 25% of AOM in colder climates, but is much less common in Denver and southern Israel, possibly because of the drier, hotter climate (Table 17–1). The fourth organism found is *Streptococcus pyogenes*; this organism and *S pneumoniae* are the predominant causes of mastoiditis. The microbiologic causes of AOM in early infancy differ only slightly from those in later life. The risk of gram-negative enteric infection is increased in infants younger than age 4 weeks who are or have been hospitalized in a neonatal intensive care nursery.

Resistant *S pneumoniae* is a common pathogen in acute otitis, representing up to 40% of isolates, as well as in persistent effusions and chronic suppurative otitis. Children with resistant strains tend to be younger and to have had more unresponsive infections. Antibiotic treatment in the preceding 3 months also increases the risk of harboring resistant pathogens. Penicillin resistance develops through stepwise mutations in the structure of the penicillin-binding proteins. Strains for which minimum inhibitory concentrations (MICs) of penicillin range between 0.12 and 1.0 µg/mL are said to exhibit “intermediate” resistance. Strains for which MICs are equal to or higher than 2 µg/mL are said to have a “high-level resistance.” The prevalence of resis-

tant strains no longer varies significantly among geographic areas within the United States. These strains are also resistant to other drug classes. Approximate rates of resistance are 60% for trimethoprim–sulfamethoxazole, 15% for macrolides, and 2% for amoxicillin (dosed at 90 mg/kg/d). Between 90% and 100% of highly penicillin-resistant strains are susceptible to clindamycin and rifampin, and 97% are susceptible to fluoroquinolones. Second-generation fluoroquinolones such as ciprofloxacin and norfloxacin are much less active against *S pneumoniae* than are the third-generation agents such as gatifloxacin and levofloxacin. Unfortunately, fluoroquinolones are not approved for children younger than 16 years; however, studies are under way to assess their safety and efficacy in this age group.

Diagnosis

A. PNEUMATIC OTOSCOPY

Acute otitis media is overdiagnosed. Contributing to errors in diagnosis are the temptation to accept the diagnosis without removing enough cerumen to adequately visualize the eardrum, and the mistaken belief that a red eardrum establishes the diagnosis. In fact, redness of the eardrum can be caused by a viral URI, the child's crying, or even efforts to remove cerumen. Failure to achieve an adequate seal with the otoscope, poor visualization due to low light intensity, and mistaking the ear canal wall for the membrane can make it difficult to assess eardrum mobility.

A pneumatic otoscope with a rubber suction bulb and tube is used to assess mobility of the TM. The speculum inserted into the patient's ear canal must be large enough to provide an airtight seal. Placing a piece of rubber tubing 0.25–0.5 cm wide near the end of the

ear speculum helps to create an adequate pneumatic seal. The tubing should fit snugly on the speculum at a distance about 0.5 cm from its end. The largest possible speculum (usually 3 or 4 mm) should be used to maximize the field of view, avoiding disposable specula if possible. When the rubber bulb is squeezed, the TM will move freely to and fro if no fluid is present; if fluid is present in the middle ear space, the mobility of the TM will be absent or resemble a fluid wave. The ability to assess mobility is compromised by low light intensity; a halogen source is necessary. These bulbs dim, but rarely ever “burn out.”

Disposable ear specula have become popular but are not needed for infection control, because reusable specula can be easily disinfected. The disposable specula are sharp at the tip and often cause pain when pushed to get an airtight seal.

B. CERUMEN REMOVAL

Cerumen removal is an essential skill for anyone who cares for children. Impacted cerumen can cause itching, pain, hearing loss, or otitis externa. Parents should be advised that earwax protects the ear (cerumen contains lysozymes and immunoglobulins that inhibit infection) and will come out by itself; therefore, parents should never put anything solid into the ear canal to remove the earwax. Eardrops (discussed later) may be used.

The physician may remove cerumen under direct vision through the operating head of an otoscope, provided two adults are present to hold the child. Cerumen that obstructs the view of the TM can often be pushed aside, the pneumatic seal reestablished, and mobility assessed without removing the speculum. Alternatively, a plastic disposable ear curette of about size 0 (often green) may be used.

Irrigation can also be used to remove cerumen. Very hard cerumen may adhere to the wall of the ear canal and cause pain or bleeding if one attempts to remove it with a curette. This type of wax can be softened with carbamyl peroxide solutions, mineral oil, or a few drops of detergent before irrigation is attempted. After 20 minutes, irrigation with a soft bulb syringe can be started with water warmed to 35–38°C to prevent vertigo. A commercial jet tooth cleanser (eg, Water Pik) is also an excellent device for removing cerumen, but it is important to set it at low power (2 or less) to prevent damage to the TM. A perforated TM is a contraindication to any form of irrigation. In difficult cases, it may be necessary to consult an otolaryngologist.

C. TYMPANOMETRY

Tympanometry can identify an effusion, and it requires little training. It should supplement and not replace pneumatic otoscopy because it does not identify inflammation. Because of the compliance of the cartilaginous canal of the infants, tympanometry should be reserved for children older than age 6 months. Tympanometry uses an electroacoustic impedance bridge to measure TM compliance and display it in graphic form (along the y -axis, expressed in mm H₂O). Compliance is determined at air pressures from +200 to –400 mm H₂O that are created in the sealed external ear canal. The existing middle ear pressure can be measured by determining the ear canal pressure at which the TM is most compliant. Because total visualization of the TM is not necessary, tympanometry does not require removal of cerumen unless the canal is completely blocked.

Tympanograms can be classified into four major patterns, as shown in Figure 17–2. The pattern shown in Figure 17–2A, characterized by maximum compliance at normal atmospheric pressure, indicates a normal TM, good eustachian tube function, and absence of effusion. The pattern shown in Figure 17–2B identifies a nonmobile TM, which indicates middle ear effusion. The pattern shown in Figure 17–2C indicates an intact mobile TM with poor eustachian tube function and excessive negative pressure (> –300 mm H₂O air pressure) in the middle ear. Figure 17–2D shows a flat tracing, which would have a very large middle ear volume on the printout, due to a patent tube or large perforation.

D. ACOUSTIC REFLECTOMETRY

Acoustic reflectometry measures the spectral gradient of the TM using a handheld instrument, without requiring an airtight seal. However, recent data suggest that this method cannot reliably distinguish negative middle ear pressure from effusion. Much more study is re-

quired before this method can be recommended, and the instrument is presently not being sold.

Treatment of Acute Otitis Media

An algorithm for the management of AOM is presented in Figure 17–3. Drugs commonly used are listed in Table 17–2.

A. THE OBSERVATION OPTION

Nontreatment: Few issues in clinical medicine are as controversial as antibiotic treatment of otitis media, because of the increasing prevalence of resistant organisms since 1990 and questions about how to measure efficacy. The natural history of AOM is that it improves clinically through host defenses; however, bacteriologic cure rates (determined by a second tympanocentesis while on therapy) were only 32% at 2–7 days on placebo in Dr Howie's classic studies. In children receiving a placebo, the cure rate is 16% for *S pneumoniae*, 84% for *M catarrhalis*, and 50% for nontypable *H influenzae*. Therefore, the absence of overt symptoms does not necessarily mean that the bacterial infection has been cured. In a meta-analysis of 33 trials of antibiotic treatment of AOM, only 4 trials contained a placebo. Eighty-one percent of patients who received a placebo became asymptomatic by 7–14 days, and treatment with antibiotics increased the resolution rate by 14%. This study has led to the assertion that seven children must be treated with antibiotics to benefit one child. However, the age group younger than 2 years, who experience the highest rate of AOM, were barely included in this meta-analysis. Although most clinicians routinely treat acute otitis with antibiotics, it is also reasonable to individualize this decision and involve the family in the process. This calls for a trade-off between the risks of antibiotic treatment (allergic reactions, side effects, and colonization with an antibiotic-resistant pathogen) and the benefit of a more rapid clinical response. More rapid pain relief may be a reasonable justification for treatment. Patients not receiving treatment who fail to improve within 48 to 72 hours should be reassessed and given antibiotics if symptoms of AOM are still present. It is advisable to treat otitis media in all children younger than age 2 years with antibiotics because they respond less well to bacterial polysaccharide and are more likely to develop complications. Of three recent studies of placebo compared with antibiotics in children younger than 2 years, clinical cure rates were 28–42% with placebo and 41–74% with an antibiotic.

One can avoid the antibiotic treatment dilemma by not overdiagnosing AOM. To summarize, to accurately diagnose otitis media, cerumen must first be thor-

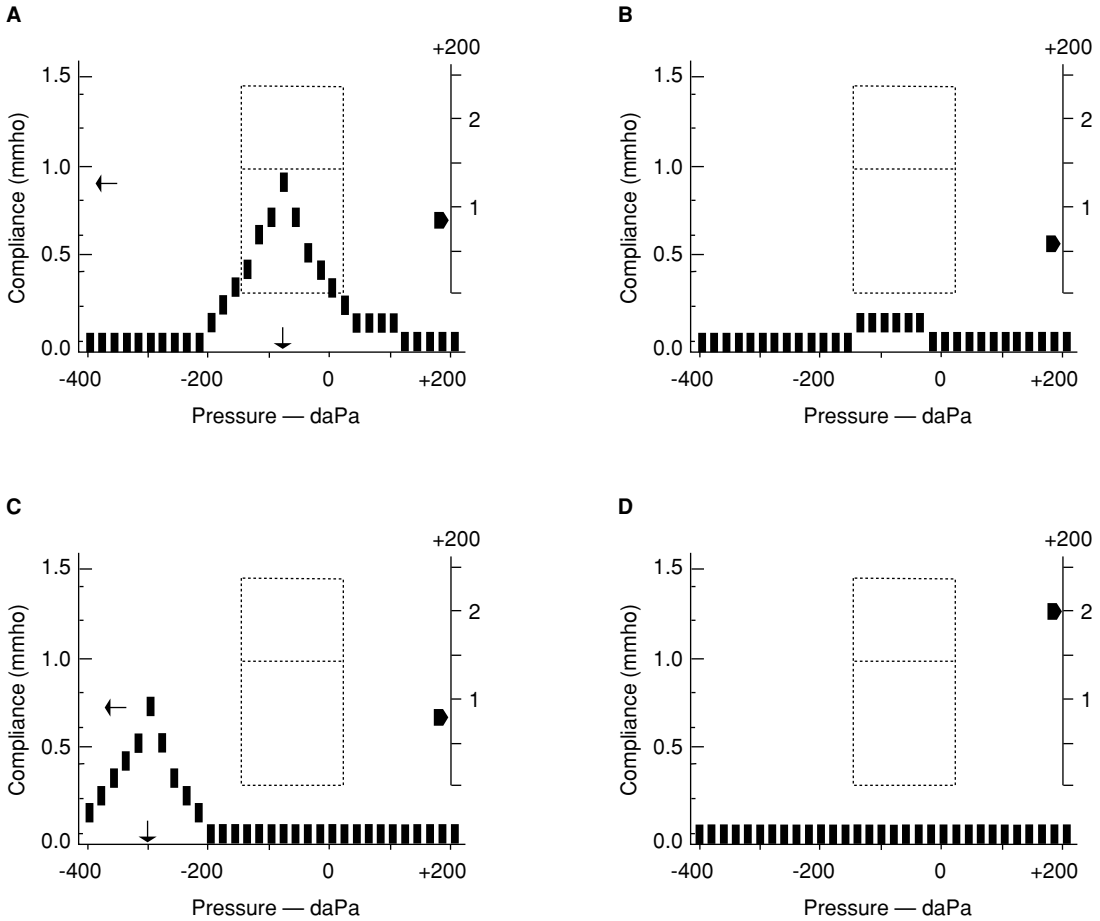

Figure 17-2. Four types of tympanograms obtained with Welch–Allyn MicroTym 2. **A:** Normal middle ear. **B:** Otitis media with effusion or acute otitis media. **C:** Negative middle ear pressure due to eustachian tube dysfunction. **D:** Patent tympanostomy tube or perforation in the tympanic membrane. Same as B except for a very large middle ear volume.

oughly removed. Pneumatic otoscopy is mandatory to avoid misinterpreting red ears.

B. ANTIBIOTIC THERAPY

Amoxicillin remains the first-line antibiotic for treating otitis media, even with a high prevalence of drug-resistant *S pneumoniae*, because resistance to β -lactam antibiotics, such as amoxicillin, develops as a stepwise process over many years. A bacterial strain resistant to low levels of amoxicillin will usually be eradicated by a higher dosage. Amoxicillin dosage may be raised considerably without toxicity; for example, a dosage of 200 mg/kg/d has been used to treat meningitis in children, and a maximum daily dose of 4 g has been used

in adults. Studies have shown that increasing the dosage from 40 mg/kg to 90 mg/kg yields a drug concentration in middle ear fluid that surpasses the minimal level needed to inhibit 98% of all pneumococcal otitis media. A second advantage is that dosing amoxicillin at these higher levels may help delay stepwise emergence of resistance. In recognition of this new pharmacodynamic data, the federal government in June 1999 doubled the MIC used to define resistance to amoxicillin to 8 μ g/mL or greater. Because otitis media is not a life-threatening disease, it is not necessary for a first-line antibiotic to achieve 100% cure. High-dose amoxicillin will usually eradicate the most invasive pathogen, *S pneumoniae*, and if no improvement occurs, a second-

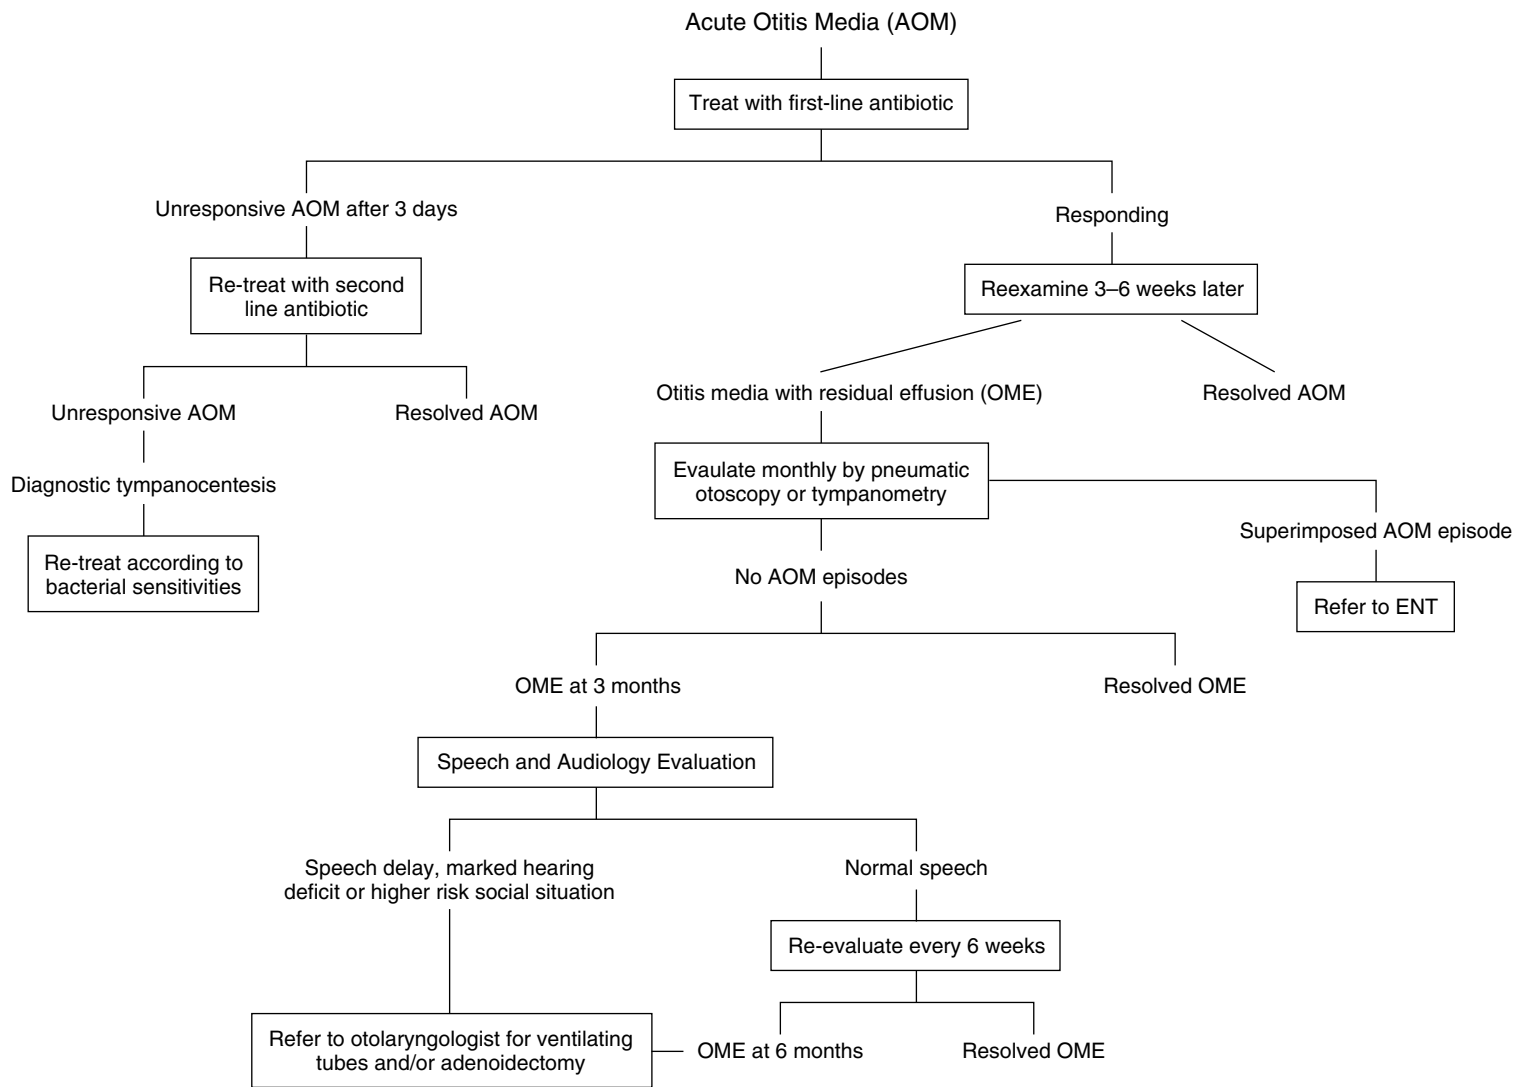

Figure 17-3. Algorithm for acute otitis media. AOM = acute otitis media; ENT = ear, nose, and throat consult; OME = otitis media with effusion.

Table 17–2. Treatment of acute otitis media in an era of drug resistance.

First-line therapy
1. Amoxicillin 90 mg/kg/d, up to 4 g d. For children over 2 years of age, give for 5 days; under 2 years of age, for 10 days.
2. If amoxicillin has caused a rash, give cefuroxime (Ceftin), cefdinir (Omnicef), or cefpodoxime (vantin).
3. If urticaria or other IgE-mediated events have occurred, give trimethoprim-sulfa or azithromycin (Zithromax).
4. If the child is unable to take oral medication, give single intramuscular dose of ceftriaxone (Rocephin).
Second-line therapy
This is for clinical failure after 48–72 hours of treatment, or for recurrences within 4 weeks.
1. Amoxicillin-clavulanate (Augmentin ES-600), given so that the patient receives amoxicillin at 90 mg/kg/d.
2. If amoxicillin has caused allergic symptoms, see recommendations above.
Third-line therapy
1. Tympanocentesis is recommended to determine the cause.
2. Ceftriaxone (Rocephin), two doses given intramuscularly, 48 hours apart, with the option of a third dose.
Recurrences > 4 weeks after the first episode
1. A new pathogen is likely, so restart first-line therapy.
2. Be sure the diagnosis is not OM with effusion (OME), which may be observed for 3–6 months without treatment.

line antibiotic may be chosen to cover *M catarrhalis* and β -lactamase-producing *H influenzae*.

Amoxicillin-clavulanate enhanced strength (ES), with 90 mg/kg/d of amoxicillin dosing and unchanged amounts of clavulanic acid, is an appropriate choice as a second-line antibiotic when a child is clinically failing after 48 to 72 hours on amoxicillin (see Table 17–2). If generic dosing is preferred to reduce costs, two prescriptions are required: low-dose amoxicillin-clavulanate and 45 mg/kg of amoxicillin. The generic amoxicillin-clavulanate should never be doubled in dosage, since the amount of clavulanate will be too high. In this situation, the most likely pathogen is *H influenzae*, and the addition of clavulanate to amoxicillin will broaden the coverage while retaining efficacy against *S pneumoniae*.

Three oral cephalosporins are more β -lactamase-stable (cefuroxime, cefpodoxime, and cefdinir), and these are alternative choices for second-line therapy for children who develop papular rashes with amoxicillin (see Table 17–2). Unfortunately, these do not cover highly

penicillin-resistant pneumococci, only the intermediately resistant class. Of these three drugs, only cefdinir is palatable in the liquid form; the other two drugs have a bitter aftertaste which is difficult, but not impossible, to conceal with milk or sweet food given after the drug. A second-line agent is also indicated when a child experiences symptomatic infection within 1 month of stopping amoxicillin; however, repeat use of high-dose amoxicillin is indicated if more than 4 weeks has passed without symptoms, because a new pathogen is usually present. Macrolides and sulfonamides are not recommended as second-line agents due to poor coverage of *H influenzae*. The major use of these drug classes is in children with urticaria or anaphylactic reactions to β -lactams.

If a child remains symptomatic longer than 3 days while taking a second-line agent, a tympanocentesis may be useful to identify the causative pathogen or to prove sterility. The parents may be noncompliant or the child may not have absorbed the antibiotic well, in which case an organism sensitive to many drugs may be found. If a highly resistant pneumococcus is found or if tympanocentesis is not feasible, intramuscular ceftriaxone at 50 mg/kg/day for 3 consecutive days is the best choice. Further studies are needed in children failing second-line therapy. Table 17–2 also lists alternative drugs for penicillin-allergic children. If the child has experienced anaphylaxis to amoxicillin, cephalosporins should not be substituted. However, the maculopapular rash frequently seen with amoxicillin is not IgE-mediated, and cephalosporins may be used.

Figure 17–3 shows the recommended follow-up of AOM that resolves with a residual effusion at 3–4 weeks. Children, particularly those young enough to still be developing language skills, should be seen every 8 weeks for otoscopic exams to determine if the effusion is persistent or occurs only with symptomatic infections. Prophylactic antibiotics and corticosteroids are no longer recommended for OME. A hearing test should be performed after approximately 3 months of continuous bilateral effusion in children younger than 3 years and those at risk of language delay due to poverty or craniofacial anomalies. Children with hearing loss or speech delay should be referred to an otolaryngologist for possible ventilation tubes.

C. DURATION OF THERAPY

The duration of antibiotic treatment is controversial. Only three recent trials have used stringent entry and outcome criteria. Success rates were higher at 12–14 days following 10 days of therapy in all three studies, particularly for children younger than 2 years of age, and for those in daycare. At this time, short-

course (5-day) therapy can only be recommended for children older than 2 years and not in daycare.

A recent study of preschoolers by Schrag and colleagues demonstrated that drug-resistant pneumococcal carriage at day 28 posttherapy was lower in a short-course high-dose amoxicillin group compared with a group given a standard course of therapy. This is an important finding, because we now know that the nasopharyngeal flora determines the pathogen of the next AOM. Efforts to reduce drug-resistant pneumococci include use of Prevnar vaccine and the 23-valent pneumococcal vaccine in children older than 2 years.

D. PAIN MANAGEMENT

Children with pain related to AOM may obtain relief from acetaminophen, ibuprofen, or a topical anesthetic drop. In a randomized controlled trial, Auralgan (benzocaine and antipyrine) ear drops were superior to olive oil in reducing pain. A recent study of 88 children, all older than 2 years of age, found that Auralgan eardrops provided enough pain relief that the majority did not need antibiotic therapy. When pain persists after antimicrobial treatment, tympanocentesis should be considered for pain relief and to diagnose the causative pathogen.

E. FOLLOW-UP VISITS

The optimal timing for follow-up visits depends on the response to therapy. Children should be reassessed when symptoms of AOM continue beyond 72 hours or recur during treatment. The follow-up visit for preschool children should be 3–6 weeks after start of therapy. The need for follow-up visits for asymptomatic school-age children without risk factors of recurrent disease should be based on the history of speech delay or the presence of OME in the past.

F. TYMPANOCENTESIS OR MYRINGOTOMY

Tympanocentesis is performed by placing a needle through the TM and aspirating the middle ear fluid. Myringotomy involves making an incision in the drum with a myringotomy knife to drain the fluid. Indications for tympanocentesis or myringotomy are (1) AOM in a patient with compromised host resistance, (2) painful bulging of the TM, particularly in a toddler younger than 48 months, (3) a complete work-up for presumed sepsis or meningitis, such as in a neonate, (4) unresponsive otitis media despite courses of two appropriate antibiotics, and (5) acute mastoiditis or other suppurative complications. The technique of tympanocentesis is as follows:

1. Premedication—In the conditions mentioned, the pain associated with tympanocentesis is only slightly greater than the pain of existing acute inflammation of the TM. Therefore, no premedication is generally indi-

cated. The patient who is extremely difficult to hold may be premedicated with meperidine, 1 mg/kg intramuscularly. Tetracaine has been used, but no studies are available on its efficacy in children with acute inflammation, which rapidly removes locally administered drugs. Unquestionably, the best pain minimization method is to perform the procedure rapidly and return the child immediately to the parent's arms.

2. Restraint—The patient must be completely immobile while the procedure is being performed. A papoose board or a sheet can be used to immobilize the patient's body, and an extra attendant is required to hold the child's head steady. It is helpful to have the parent remain in sight of the child for reassurance.

3. Site selection—With an open-headed operating otoscope (Figure 17–4), the operator carefully selects a target. This is best done in the anteroinferior quadrant, although the posteroinferior quadrant is a safe but shallower alternative. These sites avoid damage to the ossicles during the procedure.

Figure 17–4. Operating head and Alden-Senturia trap for tympanocentesis. 18 gauge spinal needle attached and bent.

4. Aspiration—An 8.8-cm spinal needle (No. 18 or No. 20) with a short bevel is attached to a 3-mL syringe. Alternatively, either an Alden-Senturia trap (Storz Instrument Co., St. Louis, Mo.) or the Tympan Tap aspirator (Xomed Surgical Products, Jackson, Florida) is attached to a suction pump. The operator then aspirates the middle ear effusion from the anterior inferior quadrant. Aspirate should be placed directly onto culture plates for maximum recovery, and chocolate agar suffices to grow all common pathogens.

G. NONVACCINE PROPHYLAXIS

Chemoprophylaxis has been used successfully since the 1960s, and it is supported by a recent randomized, controlled trial by Teele's group in Boston. Though conducted in the era of drug-resistant pneumococci, this study found that the AOM attack rate in infants younger than 1 year was cut in half by the dose of amoxicillin (20 mg/kg/d) used in older studies. Sulfisoxazole was not as effective, and the sample size was inadequate to determine if it was superior to placebo. Nonetheless, the widespread use of chemoprophylaxis is likely to lead to bacterial resistance in the community, and it can thus be recommended only for selected non-daycare-attending children. For example, children who have had three well-documented episodes within 6 months or four in 1 year may be candidates, as well as infants younger than 6 months who have had more than one episode. Prophylaxis for 3–4 months is still useful in the spring season, because the absence of URIs in summer may obviate the need for PE tube placement. It is also valuable for children with PE tubes who continue to experience AOM episodes.

A second method of prophylaxis is to educate parents about risk factors for recurrent disease. This is time-consuming, but valuable. Specific topics:

1. Smoking is a risk factor both for URI and for AOM, and primary care doctors can provide literature on smoking cessation programs and nicotine-containing gums or patches.
2. Breast-feeding protects children from AOM, but the mechanism is unknown. Some researchers believe that propping a bottle of milk in the crib increases AOM risk.
3. The pacifier has been implicated as a risk factor by a study done in Finland in 2000; after nurses had educated parents about the risk, children not given a pacifier continuously had a 29% lower rate of otitis media over the first 18 months of life.
4. Daycare is clearly a risk factor for AOM, but few working parents can hire a nanny. Alternatives to suggest include care by relatives or care of the

child in a homecare setting with fewer children to expose the child to URIs.

Another method of prophylaxis being studied in Finland is xylitol, also known as birch sugar, found in plums, strawberries, and raspberries. It was first studied in Europe as a chewing gum to reduce dental caries, and was effective. Recently a double-blind study of chewing gum use in children with a mean age of 5 years found a 42% reduction in episodes of AOM. For children too young to chew gum safely, the same investigators studied a xylitol syrup given five times daily after meals or snacks, and found a 33% reduction. The main problem here is the frequency of dosing, which needs to be addressed before this therapy could be practical.

Surgical prevention of AOM is an effective, albeit expensive, alternative to antibiotic prophylaxis. A meta-analysis has shown that PE tubes reduce rates of AOM, but that adenoidectomy has only limited efficacy. Unfortunately, the rate of posttube otorrhea is 16%, and a small number of children will develop perforations after tube extrusion that require surgical repair. Adenoidectomy reduces the need for PE tube reinsertion and therefore will continue to play a role with the second insertion of PE tubes. The costs of the procedures and the possibility of long-term complications after tube extrusion have limited this method of prevention to children with long-standing problems.

H. VACCINES FOR THE PREVENTION OF OTITIS MEDIA

With the increasing problems of antibiotic therapy and prophylaxis, the prevention of both viral and bacterial pathogens causing AOM has become an exciting area of research. Unfortunately, the currently available heptavalent vaccine (Prevnam) does not contain the majority of strains of pneumococci causing AOM and yielded only a 6% reduction in infections due to all causes. It did produce a 57% reduction in otitis media due to those serotypes found in the vaccine, and these stains include the serotypes most likely to be penicillin- and macrolide-resistant. The heptavalent vaccine also reduced PE tube placements by 20% compared with a control group in Kaiser of California and greatly reduced AOM incidence in children having six or more episodes per year. Furthermore, studies are showing a herd immunity effect on the older siblings of vaccinated children, which may further reduce drug-resistant serotype circulation. Now that the shortage has ended, the vaccine should be used as a single dose for children 2–5 years with a history of either recurrent AOM or OME with superimposed AOM episodes, with consideration of the 23-valent vaccine 8 weeks after the conjugate vaccine.

In recent studies, intranasal influenza vaccine reduced the number of influenza-associated cases of

AOM by 92%. For children older than 6 months with recurrent AOM, it seems prudent to recommend yearly influenza vaccine, although this is not yet an official recommendation.

Vaccines currently being studied in animals that hold promise for AOM prevention include a respiratory syncytial virus vaccine and a nontypeable *H influenzae* vaccine. Pregnant women in the third trimester may have their antibody levels raised by a heptavalent pneumococcal vaccine. This may raise antibody levels in the offspring. A recent study showed that low cord blood levels of two common pneumococcal serotypes is a risk factor for AOM and OME, so this passive route is a logical next step.

The site contains links to other otitis-media-related resources as well as parent educational material.

Management of Otitis Media with Residual and Persistent Effusions

OME has been treated primarily to avoid any prolonged conductive hearing loss. Available data show a causal relationship between severe sensorineural hearing loss and language delay, but not between conductive hearing loss due to OME and language delay. Studies looking at middle ear effusion (MEE) and its effects of language development do not show differences at age 3. But auditory processing disorders are not testable until age 5–7 years, so final results of these studies are still pending. Two thirds of children with AOM have an MEE or high negative middle ear pressure 2 weeks after diagnosis and one third at 1 month after diagnosis regardless of antibiotic therapy. The management options for otitis media with residual effusion at 6 weeks to 4 months include observation and corticosteroid therapy. Corticosteroid (prednisone, 1 mg/kg/d) can be administered for 7 days. Unvaccinated children with no clear history of varicella infection who have been exposed in the preceding month should not receive prednisone because of the potential risk of disseminated varicella-zoster viral disease. Short courses of prednisone increase appetite and cause fluid retention, occasional vomiting, and, rarely, marked behavioral changes.

If the patient clears the persistent MEE unilaterally or bilaterally, the physician should follow the patient monthly. Because of the increase in antibiotic resistance, the use of prophylaxis, even intermittently, must be restricted to carefully selected patients. The guideline recommendation developed by the Agency for Health Care Policy and Research for the management of OME is that ventilating tubes should be placed after the effusion has persisted for 4 months and is accompanied by a bilateral hearing impairment of 20 dB or greater. Earlier placement of ventilating tubes should depend on the child's developmental and behavioral

status as well as on parental preference. The value of ventilating tubes for treating unilateral effusions in otherwise healthy children is unclear.

Children with otitis media and persistent effusion have an increased incidence of cholesteatoma, adhesive otitis, retraction pockets, membrane atrophy, and persistent membrane perforation. As there is no way to identify the small proportion of candidate children for whom insertion of ventilating tubes will prevent the damage, close follow-up of abnormal ears may be best accomplished by an otolaryngologist.

3. Mastoiditis

Mastoiditis is a spectrum of disease that ranges from inflammation of the mastoid periosteum to bony destruction of the mastoid air system (coalescent mastoiditis) or abscess development. Infection of the periosteum of the mastoid bone is a rare complication of AOM in the postantibiotic era. Mastoiditis can occur in any age group, but more than 60% of the patients are younger than age 2 years. The most common pathogens are *Streptococcus pneumoniae* and *S pyogenes*, with *Staphylococcus aureus* and *H influenzae* occasionally seen. Rarely gram-negative bacilli and anaerobes are isolated. Antibiotics may affect the incidence and morbidity of acute mastoiditis. In the Netherlands, where only 31% of AOM patients receive antibiotics, the incidence of acute mastoiditis is 4.2 per 100,000 people-years. In the United States, where more than 96% of patients with AOM receive antibiotics, the incidence of acute mastoiditis is 2 per 100,000 people-years. The higher antibiotic usage in the United States correlates with a higher rate of resistant organisms and more adverse drug interactions. Moreover, despite the routine use of antibiotics, the incidence of acute mastoiditis has been rising in some cities. The pattern change may be secondary to the emergence of resistant *S pneumoniae*.

Clinical Findings

The principal complaints of patients with mastoiditis are usually postauricular pain, fever, and outwardly dis-

placed pinna. On examination, the mastoid area often appears swollen and reddened. In the late stage, it may be fluctuant. The earliest finding is severe tenderness on mastoid palpation.

AOM, by otoscopy, is almost always present. Late findings are a pinna that is pushed forward by postauricular swelling and an ear canal that is narrowed in the posterosuperior wall because of pressure from the mastoid abscess. In infants younger than age 1 year, the swelling occurs superior to the ear and pushes the pinna downward rather than outward. In the acute phase, diffuse inflammatory clouding of the mastoid cells occurs, as in every case of AOM. In more severe cases, bony destruction and resorption of the mastoid air cells may occur. The best way to determine the extent of disease is by computed tomography (CT) scan.

Meningitis is a complication of acute mastoiditis and should be suspected when a child has associated high fever, stiff neck, severe headache, or other meningeal signs. Lumbar puncture should be performed for diagnosis. Brain abscess occurs in 2% of patients and may be associated with persistent headaches, recurring fever, or changes in sensorium. Facial palsy, cavernous sinus thrombosis, and thrombophlebitis may be encountered.

Treatment for noncoalescent mastoiditis is typically myringotomy, with or without tube placement, in order to obtain material for culture. Hospitalization for intravenous therapy follows. Reasonable initial therapy is ceftriaxone plus nafcillin or clindamycin until culture results are returned. If clinical improvement does not occur after 24–48 hours of intravenous or intramuscular therapy, or if any signs or symptoms of intracranial complications exist, immediate surgery to drain the mastoid abscess is indicated. The primary management for coalescent mastoiditis is cortical mastoidectomy. A recent review from the University of Texas–Southwestern revealed that 39% of patients required a mastoidectomy. After significant clinical improvement is achieved with parenteral therapy, oral antibiotics are begun and should be continued for 3 weeks.

4. Otitis Media with Complications

Complications of otitis media may involve damage to the middle ear structures, such as tympanosclerosis, retraction pockets, adhesions, ossicular erosion, cholesteatoma, perforations, and intratemporal and intracranial injury.

A. TYMPANOSCLEROSIS

A white plaque-like appearance on the TM is caused by chronic inflammation or trauma that produces granulation tissue and hyalinization. The appearance of a small defect in the posterosuperior area of the pars tensa or in

the pars flaccida suggests a retraction pocket. Retraction pockets occur when chronic inflammation and negative pressure in the middle ear space produce atrophy and atelectasis of the TM.

Continued inflammation can cause adhesions between the retraction pocket and the ossicles. This condition, referred to as adhesive otitis, predisposes to formation of a cholesteatoma or fixation and erosion of the ossicles (Figure 17–5). Erosion of the ossicles results from osteitis and compromise of the blood supply. Ossicular discontinuity may produce a maximal hearing loss with a 50-dB threshold. A tympanogram with very high compliance suggests ossicular discontinuity.

B. CHOLESTEATOMA

A greasy-looking mass or pearly white debris seen in a retraction pocket or perforation suggests a cholesteatoma, whether or not there is discharge (see Figure 17–5). A perforation is usually painless. If infection is absent, the middle ear cavity generally contains normal mucosa. If infection is superimposed, serous or purulent drainage will be seen, and the middle ear cavity may contain granulation tissue or even polyps. Persistent or recurrent otorrhea following appropriate medical management should make one suspect a cholesteatoma.

C. TYMPANIC MEMBRANE PERFORATION

Occasionally, an episode of AOM is associated with otorrhea. An aural discharge indicates that the TM has perforated. Most likely the perforation will heal spontaneously. If the perforation has not healed within 3 months, surgical intervention will be necessary. A

conductive hearing loss is usually present, depending on the size and location of the perforation. The site of perforation is important. Central perforations surrounded by intact TM are usually relatively safe from cholesteatoma formation. With a peripheral perforation, especially in the pars flaccida, the perforation extends to the canal wall without any intervening TM. Peripheral perforations create a risk for cholesteatoma because the ear canal epithelium may invade the perforation.

Most perforations with AOM heal within 2 weeks. When perforations fail to heal after 3–6 months, surgical repair may be needed. Repair of the defect in the TM is generally delayed until the child is older and eustachian tube function has improved. Procedures include paper patch, fat myringoplasty, and tympanoplasty. Tympanoplasty is generally deferred until age 7–9 years. In otherwise healthy children without any craniofacial anomalies, some surgeons repair the perforated TM earlier if the contralateral nonperforated drum remains free of infection and effusion for 1 year. This policy does not guarantee success. The age of the child when repair is performed is the more probable indicator of success. Occasionally, a perforation is closed in a child of younger age if recurrent otorrhea is thought to be secondary to water contamination or nasopharyngeal reflux. Earlier closure of the perforation will seal the middle ear space and reestablish the air cushion provided by the mastoid air system. An older child is more likely to have a successful outcome from closure of the perforation. Water activities should be limited to surface swimming, preferably with the use of an ear mold. Diving, jumping into the water, and underwater swimming should be prohibited.

D. FACIAL NERVE PARALYSIS

The facial nerve crosses the middle ear as it courses through the temporal bone to its exit at the stylomastoid foramen. Occasionally, the nerve is incompletely encased in bone, which makes it susceptible to inflammation during an episode of AOM. The acute onset of a facial nerve paralysis is not idiopathic Bell palsy until all other causes have been excluded. If middle ear fluid is present, a prompt myringotomy is indicated. Placement of a ventilation tube will allow for prolonged ventilation. CT is indicated if a cholesteatoma is suspected or acute coalescent mastoiditis is present.

E. CHRONIC SUPPURATIVE OTITIS MEDIA

Chronic suppurative otitis media is present when persistent otorrhea occurs in a child with tympanostomy tubes or TM perforations. Occasionally, it is an accompanying sign of cholesteatoma. Visualization of the TM, meticulous cleaning with culture of the drainage, and appropriate antimicrobial therapy are keys to man-

Figure 17–5. Attic cholesteatoma, formed from an in-drawing of an attic retraction pocket.

agement of cases not related to cholesteatoma. The successful treatment of chronic suppurative otitis usually requires therapy with an antibiotic that covers *Pseudomonas* and anaerobes. Oral quinolone antibiotics effective against *Pseudomonas* infection are not yet approved for use in growing children. Recent studies suggest that topical quinolones for 14 days may be effective. It is very important to clean the ear canal by suction to allow penetration of drops, and it is often useful to culture the secretions. An ear wick should be inserted and drops placed on the wick several times daily. The child should be seen in 7 days, the wick removed, and suction repeated if necessary. When a cholesteatoma is associated with chronic suppurative otitis media, medical therapy is not effective (see Figure 17–5). If the discharge does not respond to 2 weeks of aggressive therapy, mastoiditis, cholesteatoma, tuberculosis, or fungal infection should be suspected. Serious central nervous system (CNS) complications such as extradural abscess, subdural abscess, brain abscess, meningitis, labyrinthitis, or lateral sinus thrombophlebitis can occur with extension of this process. Therefore, patients with facial palsy, vertigo, or other CNS signs should be immediately referred to an otolaryngologist.

ACUTE TRAUMA TO THE MIDDLE EAR

Head injuries, a blow to the ear canal, sudden impact with water, blast injuries, or the insertion of pointed instruments into the ear canal can lead to perforation of the TM or hematoma of the middle ear. One study reported that 50% of serious penetrating wounds of the TM were due to parental use of a cotton-tipped swab.

Treatment of middle ear hematomas consists mainly of watchful waiting. Antibiotics are not necessary unless signs of infection appear. The prognosis for unimpaired hearing depends on whether the ossicles are dislocated or fractured in the process. The patient needs to be followed with audiometry until hearing has returned to normal.

Traumatic perforations of the TM often do not heal spontaneously, in which case the patient should be referred to an otolaryngologist. Perforations caused by a foreign body must be attended to immediately, especially if accompanied by vertigo.

EAR CANAL FOREIGN BODY

Numerous objects can be inserted into the ear canal by a child. If the object is large, wedged into place, or difficult to remove with available instruments, the patient should be referred to an otolaryngologist early rather than risk traumatizing the ear canal and causing edema that will require removal under anesthesia. An emergency condition exists if the foreign body is a disk-type battery used in clocks, watches, and hearing aids. An electric current is generated in the moist canal, and a severe burn with resulting scarring can occur in less than 4 hours.

HEMATOMA OF THE PINNA

Trauma to the ear can result in a hematoma between the perichondrium and cartilage. The hematoma appears as a boggy purple swelling of the upper half of the ear. If this is not treated, it can cause pressure necrosis of the underlying cartilage and result in “cauliflower ear.” To prevent this cosmetic deformity, physicians should refer patients to an otolaryngologist for aspiration and application of a carefully molded pressure dressing. Recurrent or persistent hematoma of the ear may require surgical drainage.

CONGENITAL EAR MALFORMATIONS

Agenesis of the external ear canal results in conductive hearing loss that requires evaluation in the first month of life by hearing specialists and an otolaryngologist.

“Lop ears,” folded down or protruding ears (so-called Dumbo ears), are a source of much teasing and ridicule. In the past, surgical correction at age 5 or 6 years was the only answer. Taping the ears into a correct anatomic position is very effective if performed in the first 72–96 hours of life. Tape is applied over a molding of wax and continued for 2 weeks. Another alternative for the ear that can be molded solely by finger pressure into a normal configuration is an incisionless otoplasty, which can be performed at a much earlier age

and is associated with little postoperative morbidity. Because no cartilage destruction is associated with this technique, future growth is unaffected.

An ear is low-set if the upper pole is below eye level. This condition is often associated with renal malformations (eg, Potter syndrome), and renal ultrasound examination is suggested.

Preauricular tags, ectopic cartilage, fistulas, sinuses, and cysts require surgical correction, mainly for cosmetic reasons. Children exhibiting any of these findings should have their hearing tested. Most preauricular pits cause no symptoms. If one should become infected, the patient should receive antibiotic therapy and be referred to an otolaryngologist for eventual excision.

DETECTION & MANAGEMENT OF HEARING DEFICITS

Hearing deficits are classified as conductive, sensorineural, or mixed. Conductive hearing loss results from blockage of the transmission of sound waves from the external auditory canal to the inner ear and is characterized by normal bone conduction and reduced air conduction hearing. In children, conductive losses are most often caused by MEE. Sensorineural hearing loss occurs when the auditory nerve or cochlear hair cells are damaged. Mixed hearing loss is characterized by components of both conductive and sensorineural loss. The criteria for children are more stringent than for adults because children are in the process of learning language. In children, a hearing loss of 15–30 dB is considered mild, 31–50 dB moderate, 51–80 dB severe, and 81–100 dB profound.

Conductive Hearing Loss

By far the most important cause of conductive hearing loss during childhood is otitis media and its sequelae such as MEE. Other causes include atresia, stenosis, or collapse of the ear canal; furuncle, cerumen, or foreign body in the ear; aural discharge; bony growths; otitis externa; perichondritis; and middle ear anomalies (eg, stapes fixation, ossicular malformation).

The average hearing loss due to MEE (whether serous, purulent, or mucoid) is 27–31 dB, the equivalent of a mild hearing loss. This loss may be intermittent in nature and may occur in one or both ears.

The American Academy of Pediatrics recommends that hearing be assessed and language skills monitored in children who have frequently recurring AOM or MEE persisting longer than 3 months. The effects of hearing loss may be insidious and not discernible until the explosive phase of expressive language development occurs between ages 16 and 24 months; therefore, the optimal time for screening language in young children is between 18 and 24 months. An acceptable tool for language screening at this time is the Early Language Milestone Scale. Children age 3, 4, and 5 years with recurring OME should also be screened for language delays.

To diminish the likelihood of communication disorder, the physician should inform the parents of a child with middle ear disease that the child's hearing may not be normal and should instruct the parents to (1) turn off sources of background noise (eg, televisions, radios, dishwashers) when speaking to the child, (2) focus on the child's face and gain his or her direct attention before speaking, (3) speak slightly louder than usual, and (4) have the teacher place the child in the front of the classroom.

Sensorineural Hearing Loss

Sensorineural hearing loss arises from a lesion in the cochlear structures of the inner ear or in the neural fibers of the auditory nerve (cranial nerve VIII). Most sensorineural losses in children are congenital, with an estimated incidence of 2.0–3.0 per 1000 live births. Causes can be classified as either congenital or postnatal and, within each classification, as genetic or non-genetic. Approximately two thirds of genetic hearing loss is autosomal recessive and is not associated with a known syndrome. Mutations in the *Connexin 26 (Cx26)* gene have been found to account for approximately 20% of all childhood deafness. In older children, one should suspect congenital hearing loss if the hearing is normal in the low and high frequencies, but poor in the middle frequencies (“cookie bite” or U-shaped audiogram). Clues that a patient may have a syndrome associated with the hearing loss and should be referred to a geneticist include the following physical exam findings: asymmetrical face, skin tags, abnormal eye exam, widely spaced eyes, preauricular pits, abnormal ear appearance, café au lait spots, white forelock, sinus tracts in the neck, abnormal digits, and thyromegaly. One should consider screening of first-degree relatives if idiopathic sensorineural hearing loss is present. If a first-degree relative also has a sensorineural loss, the hearing loss is most likely genetic.

A common congenital genetic cause is inner ear dysplasia. Postnatal onset of sensorineural hearing loss often occurs with associated genetic abnormalities (eg,

Alport syndrome and Klippel–Feil syndrome). Nongenetic causes of congenital hearing loss include prenatal infections, teratogenic drugs, and perinatal injuries. Congenital syphilis is responsible for delayed-onset sensorineural hearing loss (usually after age 2 years). Common postnatal nongenetic causes are infections, trauma, ototoxic drugs, metabolic disorders, neoplastic diseases, and autoimmune diseases. A major factor in hearing loss in premature infants is hypoxia. A difficult delivery or an Apgar score of 6 or less is associated with an increased risk of hearing loss. Neonates with a history of persistent pulmonary hypertension or children who have been on ECMO are at an increased risk for late-onset hearing loss and should be followed closely. Before the introduction of *H influenzae* type B vaccine, meningitis was the most common cause of acquired hearing loss, with deafness occurring in about 10% of children who had bacterial meningitis. Pneumococcal and other bacterial meningitides still remain an indication to screen for hearing loss.

In the past, the effect of unilateral deafness on school performance was thought to be insignificant. Studies now show that more than one third of affected children fail one or more grades in school. Therefore, merely recommending preferential classroom seating for these children is no longer sufficient; they should be referred for full evaluation of their hearing needs.

Acquisition of language skills is affected more severely by bilateral than by unilateral sensorineural hearing loss. The earlier the hearing loss occurs, the graver the consequences for language development; thus, the earlier a sensorineural loss is detected and treated (by sound amplification and language habilitation), the better the chances of a good outcome. The mild, fluctuating hearing loss associated with OME is much less likely to cause language problems, presumably because it is intermittent and may often be unilateral. (See Otitis Media with Effusion section.)

Screening for Hearing Deficits

Screening procedures are established for early detection and diagnosis of hearing deficits. Infants at high risk for hearing loss are best tested by auditory brainstem response (ABR) screening or evoked otoacoustic emission (OAE) testing, preferably before discharge from the hospital. Many states now mandate universal newborn hearing screening by physiologic test procedures. All universal newborn hearing screening programs are using either ABR or OAE as the screening test. The procedures listed in the following sections are intended to serve as a guide, and confirmation of sensorineural hearing loss is dependent on audiologic testing.

A. SCREENING OF NEWBORNS (SEE CHAPTER 1.)

B. SCREENING OF INFANTS

Hearing screening for infants (29 days to 2 years) is recommended if one of the following risk criteria is identified: (1) concerns regarding hearing, speech, language, or developmental delay; (2) bacterial meningitis; (3) neonatal risk factors (see Chapter 1); (4) head trauma; (5) ototoxic drug use; (6) neurodegenerative disorders; and (7) childhood infectious diseases (eg, mumps, measles).

In the past, the parents' report of their infant's behavior was considered an adequate assessment of hearing. However, a deaf infant's behavior can appear normal and mislead the parents as well as the professional, especially if the infant has autosomal recessive deafness and is the firstborn child of carrier parents. The following office screening techniques should identify gross hearing losses but may not detect less severe losses due to otitis media:

1. Birth to 4 months—In response to a sudden loud sound (70 dB or more) produced by a horn, clacker, or special electronic device, the infant should show a startle reflex or blink the eyes.

2. 4 months to 2 years—While the infant is distracted with a toy or bright object, a noisemaker is sounded softly outside the field of vision at the child's waist level. Normal responses are as follows: at 4 months, there is widening of the eyes, interruption of other activity, and perhaps a slight turning of the head in the direction of the sound; at 6 months, the head turns toward the sound; at 9 months or older, the child is usually able to locate a sound originating from below as well as turn to the appropriate side; after 1 year, the child is able to locate sound whether it comes from below or above.

After responses to soft sounds are noted, a loud horn or clacker should be used to produce an eye blink or startle reflex. This latter maneuver is necessary because deaf children are often visually alert and able to scan the environment so actively that their scanning can be mistaken for an appropriate response to the softer noise test. A deaf child will not blink in response to the loud sound. Consonant sounds such as “mama,” “dada,” and “baba” should be present in speech by age 11 months. Children who fail to respond appropriately should be referred for audiologic assessment.

C. SCREENING OF OLDER CHILDREN

When children reach age 3 years, their hearing can be tested by earphones and pure tone audiometry. The test frequencies for screening are 1000 Hz, 2000 Hz, and 4000 Hz, with the same tone presented at each fre-

quency. Normally, the screening level is 20 dB. If a soundproof room is not available, the screening may be done at 25 dB. If the child does not respond at any one of the test frequencies in either ear, the test should be repeated within 1 week. Failure on rescreening requires referral for audiologic evaluation.

High-risk categories in older children include those with osteogenesis imperfecta and conditions associated with deafness, such as Waardenburg, Hurler, Alport, Treacher Collins, Klippel–Feil, and fetal alcohol syndromes. Children with these disorders should always receive audiologic evaluation. In addition, before any child is labeled as having mental retardation, autism, or severe behavior problems, the adequacy of the child's hearing must be determined. If a developmental speech delay is diagnosed, the child's hearing should be tested as the first step in evaluating the language problem.

Referral

In addition to the referrals for audiologic testing mentioned in the preceding section, a child with confirmed hearing loss should be referred to an otolaryngologist for evaluation and further treatment. Any child failing the language screen should be referred to a speech pathologist for language evaluation. Home language enrichment programs for children with mild language delays can be directed by the physician or by a speech pathologist. Programs for the deaf child vary from aural to total communication; the latter includes elements of aural programs plus signing. Each program should be scrutinized thoroughly for its relevance to the deaf child's age and hearing level.

Prevention

Appropriate care may treat or prevent conditions causing hearing deficits. Aminoglycosides and diuretics, especially in combination, are potentially ototoxic and should be used judiciously and monitored carefully, especially in premature infants and in patients with renal insufficiency. Reduction of repeated exposure to loud noise in the child's environment—loud music, firecrackers, or shots from guns or cap pistols—may help prevent high-frequency hearing losses.

II. THE NOSE & PARANASAL SINUSES

ACUTE VIRAL RHINITIS (Common Cold; see also Chapter 36.)

The common cold is the most common pediatric infectious disease, and the incidence is higher in early childhood than in any other period of life. Children younger than age 5 years have 6–12 colds per year, of which 30% are caused by rhinoviruses, 15% influenza or parainfluenza, 10% coronavirus, and 5% enterovirus.

Clinical Findings

The patient usually experiences a sudden onset of clear or mucoid rhinorrhea, nasal congestion, and fever. Mild sore throat and cough may develop. Although the fever is usually low grade in older children, in the first 5 or 6 years of life it can be as high as 40.6°C without superinfection. The nose, throat, and TM can appear red and inflamed. Figure 17–6 shows the duration of cough, sore throat, and rhinorrhea in adults with rhinovirus-proven infections. Note that one quarter are still symptomatic at 14 days, although they may be improving.

Treatment

An algorithm for the management of acute nasal congestion and sinusitis is presented in Figure 17–7. Treatment for the common cold should be purely symptomatic; however, a recent study showed that 44% of children younger than age 18 years seen by physicians were given an antibiotic prescription. Acetaminophen or ibuprofen is helpful for fever, sore throat, or muscle aches. A stuffy, congested nose can be treated with normal saline nose drops (mix ½ tsp table salt with 6 oz of water), 3 drops in each nostril. After several minutes, a suction bulb can be used to remove the secretions if the infant is unable to blow his or her nose. If this procedure fails after several attempts and the stuffy nose still interferes with feeding or sleep, consider long-acting xylometazoline or oxymetazoline 0.05% nose drops twice daily. Drops should be used only when the nose is congested and discontinued within 4 days to prevent rebound chemical rhinitis.

Antihistamines are not effective in relieving cold symptoms. In rhinoviral colds, increased levels of histamine are not observed. Antibiotics do not prevent superinfection and should not be used. Cough suppression at night is the number one goal of many parents; however, the effectiveness of dextromethorphan is un-

Figure 17-6. Duration of symptoms in the common cold in adults. (From Gwaltney JM: JAMA 1967;202:158.)

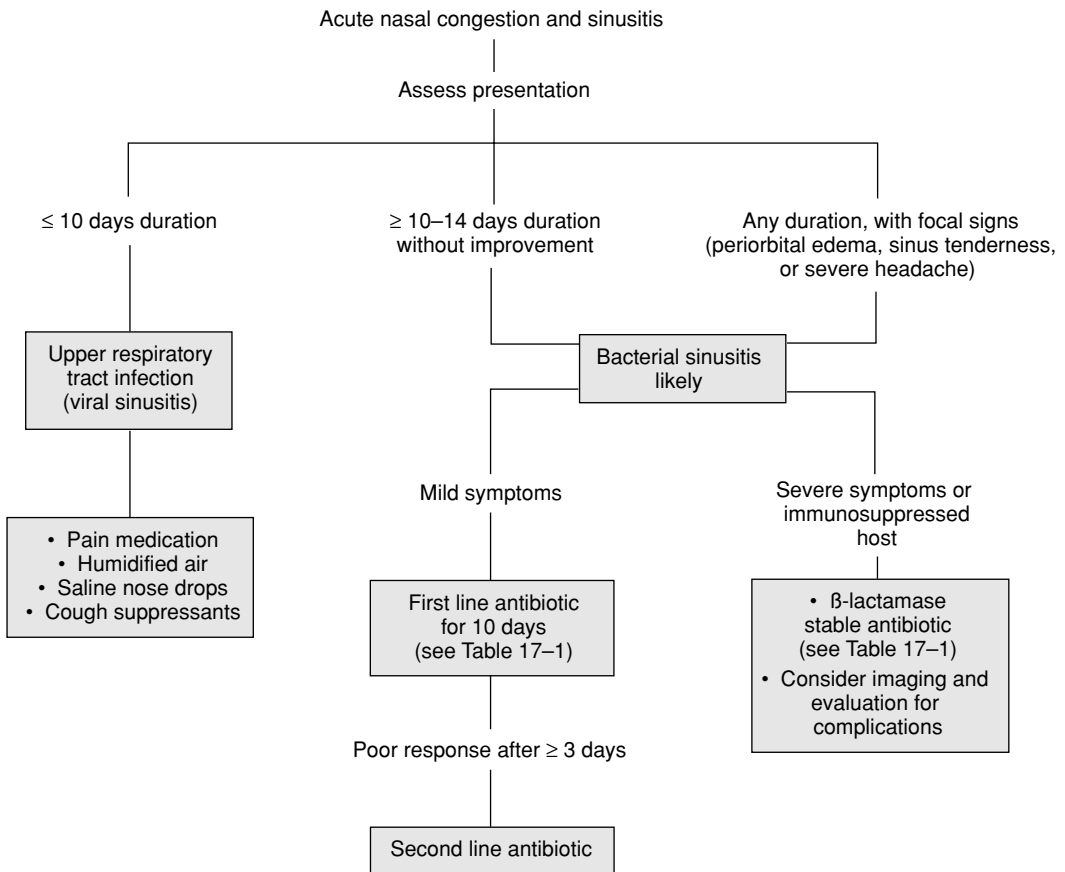

Figure 17-7. Algorithm for acute nasal congestion and sinusitis.

clear. It is believed by most experts to be effective in adults and adolescents, but it has not been studied adequately in children with colds. Use of codeine should be discouraged because it has caused fatal respiratory distress. A cool mist vaporizer or humidifier may help the cough, but the device should be washed every 3 days or less, to prevent mold growth. Parents should be instructed that fast breathing or difficult breathing with retraction is a sign of lower respiratory infection such as bronchiolitis or pneumonia. Prolonged fever may indicate otitis media or sinusitis. An antiviral agent called pleconaril is being studied for URIs due to rhinovirus or enterovirus.

RHINOSINUSITIS

The use of the term *sinusitis* versus *rhinosinusitis* has been debated. Rhinosinusitis implies that the nasal and sinus mucosa are involved in similar and concurrent inflammatory processes.

1. Acute Bacterial Rhinosinusitis

Acute bacterial infection of the paranasal sinuses lasting less than 30 days and in which the symptoms resolve completely is called acute bacterial sinusitis. The maxillary and ethmoidal sinuses are most commonly involved when mucociliary clearance and drainage are impaired by a URI or allergic rhinitis. Both the ethmoid and maxillary sinuses are present at birth, forming in the third to fourth gestational month. The sphenoid sinuses pneumatize as an extension of a posterior ethmoid cell by age 5 years, and the frontal sinuses form from an anterior ethmoid cell appearing about age 7–8 years. Frontal sinusitis is unusual before age 10 years.

A combination of anatomic, mucosal, microbial, and immune pathogenic processes is believed to underlie sinusitis in children. Both viral and bacterial infections have integral roles in the pathogenesis of sinusitis. Viral URIs commonly cause sinus mucosal injury and swelling, resulting in osteomeatal obstruction, loss of ciliary activity, and mucous hypersecretion. The bacterial pathogens that cause acute sinusitis are usually *S pneumoniae*, *H influenzae* (nontypable), *M catarrhalis*, and β -hemolytic streptococci. Rarely, anaerobic bacterial infections can cause fulminant frontal sinusitis.

Clinical Findings

The development of symptoms in acute sinusitis in children may be gradual or sudden. With gradual-onset disease, nasal discharge or postnasal drip and daytime cough persist longer than 10 days without improvement, but less than 30 days. Additional symptoms: a low-grade fever, malodorous breath, and painless periorbital swelling. Older patients may complain of headache, a sense of facial fullness, or facial pain overlying the involved sinus. With the more sudden onset, the patient has a fever of at least 102°F and concurrent purulent nasal discharge present for 3–4 consecutive days. The physical examination is rarely helpful in making a diagnosis of acute bacterial sinusitis, as the findings will be nearly the same as those in a child with viral rhinosinusitis. Occasionally percussion tenderness overlying the sinus is present, but this is a finding typical only of the older child and is unreliable when compared with antral irrigation results. Transillumination of the sinuses is difficult to perform and not very helpful unless the sinuses are grossly asymmetrical.

The physician should consider sinus aspiration by an otolaryngologist for diagnostic purposes in patients with complications and in immunocompromised patients. Gram stain or culture of nasal discharge does not correlate with cultures of sinus aspirates. If the patient is hospitalized because of complications, a blood culture should be obtained.

Imaging studies of the paranasal sinuses during acute illness are not indicated except for evaluation of complications. In the past, plain radiography was used to diagnose sinusitis when an air–fluid level or mucosal thickening greater than 4 mm was seen. Today, CT scans should be ordered only in children with complications or lack of resolution following adequate antibiotic therapy. Findings consistent with sinusitis may be found in asymptomatic patients with colds or nasal allergies. Because of the lack of specificity between abnormal CTs or plain films, the Sinus and Allergy Health Partnership (see references) does not recommend any imaging study to diagnose uncomplicated cases of acute bacterial sinusitis in any age group.

Complications

Complications are most apt to develop with ethmoiditis. These complications represent a continuum beginning with preseptal cellulitis, then postseptal cellulitis, subperiosteal abscess, orbital abscess, and cavernous sinus thrombosis. They are associated with decreased extraocular movement, proptosis, chemosis, and altered visual acuity (see Chapter 15). The most common complication of frontal sinusitis is osteitis of the frontal bone (Pott puffy tumor). Intracranial extension leads to

meningitis and to epidural, subdural, and brain abscesses. The most common maxillary complication is cellulitis of the cheek. Rarely, osteomyelitis of the maxilla can develop. In a series of children admitted for severe sinusitis, 17% had intracranial abscesses identified on CT scanning. In this and other studies, male adolescents predominated, for unknown reasons. Interestingly, only 1 of 13 children had a history of a previous sinus infection. No information is available on the rate of complications in ambulatory sinusitis patients, but the severity of the complications suggests that the patient should be carefully followed while receiving treatment.

Treatment

A meta-analysis of five randomized controlled trials suggested a modest benefit of antibiotics in reducing sinus symptoms; however, approximately six children required therapy to achieve one additional cure. Despite limited proof of efficacy, antibiotic treatment is recommended for most children with acute and subacute sinusitis because bacterial pathogens are recoverable from the majority of affected sinuses. Patients with evidence of invasive infection or any CNS complications should be hospitalized immediately. Intravenous therapy with nafcillin or clindamycin plus a third-generation cephalosporin such as cefotaxime should be initiated until culture results become available. For uncomplicated sinus infections, oral antibiotics for 10 days is appropriate. Antibiotic treatment should continue for another week if the patient has improved but is not totally asymptomatic. Amoxicillin at 90 mg/kg/d can be used if the patient is older than 2 years old, not in daycare, has not had recent antibiotic therapy, and has sinusitis that is mild to moderate in severity. The majority of children, therefore, will need to be treated with high-dose amoxicillin-clavulanate ES-600 (amoxicillin, 90 mg/kg/d, and clavulanate, 6.4 mg/kg/d). Alternative therapy (eg, cefdinir, cefuroxime, or cefpodoxime) is recommended for children intolerant of amoxicillin. Resistance to any bacteriostatic antibiotic such as trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole is great enough that these medications are no longer recommended unless the patient is allergic to both penicillin and cephalosporin. Clindamycin is another possible choice, particularly in older patients, but it is not effective against gram-negative organisms such as *H influenzae*. Failure to improve after 48 hours suggests a resistant organism or potential complication. [See the section on unresponsive AOM for antibiotic recommendations (Table 17-2), which are also appropriate for sinusitis.]

Topical decongestants and oral combinations are frequently used in acute sinusitis to promote drainage.

Their effectiveness has not been proved, and concern has been raised about potential adverse effects related to impaired ciliary function, decreased blood flow to the mucosa, and reduced diffusion of antibiotic into the sinuses. Patients with underlying allergic rhinitis may benefit from intranasal cromolyn or corticosteroid nasal spray. Vasoconstrictor nose drops and spray are associated with rebound edema if used for more than 4 days.

The patient may require acetaminophen, ibuprofen, or even codeine to permit sleep until drainage is achieved. The application of ice over the sinus may help to relieve pain.

2. Recurrent or Chronic Sinusitis

Recurrent acute bacterial sinusitis is now defined as successive episodes of bacterial infections of the sinuses, each lasting less than 30 days and separated by intervals of at least 10 days, during which the patient is asymptomatic. Chronic sinusitis is now defined as episodes of inflammation of the paranasal sinuses lasting more than 90 days. Although recent meta-analysis evaluations have resulted in recommendations for acute sinusitis, there is a paucity of data for the treatment of recurrent or chronic sinusitis. Important factors to consider include allergies, anatomic variations, and disorders in host immunity. Mucosal inflammation leading to obstruction is most commonly caused by allergic rhinitis and occasionally by nonallergic rhinitis. Gastroesophageal reflux has also been found to be associated with chronic sinusitis, and its treatment may result in dramatic improvements in sinus symptoms. Rarely, chronic sinusitis is caused by anatomic variations, such as septal deviation, polyp, or foreign body. Allergic

polyps are unusual in children younger than age 10 years and therefore indicate a work-up for cystic fibrosis. In cases of chronic or recurrent pyogenic pansinusitis, poor host resistance (eg, an immune defect, Kartagener syndrome, or cystic fibrosis)—though rare—must be ruled out by immunoglobulin studies, microscopic studies of respiratory cilia, and a sweat chloride test. Anaerobic and staphylococcal organisms are often responsible for chronic sinusitis. Evaluation by an allergist and an otolaryngologist may be useful in determining the underlying causes.

Medical Treatment

Antibiotic therapy is similar to that used for acute sinusitis, but the duration is longer. Antimicrobial choice should include drugs effective against staphylococcal organisms. Adjuvant therapies such as saline nasal irrigations, decongestants, antihistamines, and topical intranasal steroids may be helpful depending on the underlying cause.

Surgical Treatment

A. ANTRAL LAVAGE

Antral lavage, generally regarded as a diagnostic procedure, may have some therapeutic value. An aspirate or a sample irrigated from the maxillary sinus is retrieved either with a spinal needle or a curved-tip instrument under anesthesia. In the very young child, this may be the only procedure that should be performed.

B. ENDOSCOPIC SINUS SURGERY

No data are available comparing the outcome of this procedure with traditional surgical drainage procedures. There are large variations in the reported uses of this procedure by otolaryngologists, especially in younger patients.

C. EXTERNAL DRAINAGE

External drainage procedures are reserved for complications arising from ethmoid and frontal sinusitis.

CHOANAL ATRESIA

Choanal atresia occurs in approximately 1 in 7000 live births. The female-to-male ratio is 2:1, and unilateral to bilateral is also 2:1. Bilateral atresia results in severe respiratory distress at birth and requires immediate placement of an oral airway. Unilateral atresia usually appears later as a unilateral chronic nasal discharge that can be confused with chronic sinusitis. Diagnosis may be suspected if a 6 Fr catheter cannot be passed through the nose and is confirmed by axial CT scan. CHARGE (coloboma, heart disease, atresia chonae, retarded growth and retarded development and/or CNS anomalies, genital hypoplasia, and ear anomalies and/or deafness) association (see Chapter 33) or other congenital anomalies are present in 50% of patients. An oral airway should be used when a newborn has been diagnosed with bilateral choanal atresia until more definitive treatment by an otolaryngologist has been accomplished.

Keller JL, Kacker A: Choanal atresia, CHARGE association, and congenital nasal stenosis. *Otolaryngol Clin North Am* 2000;33:1343 [PMID: 11449791].

RECURRENT RHINITIS

Recurrent rhinitis is frequently seen in the office practice of pediatrics. The child is brought in with the chief complaint of having “one cold after another,” “constant colds,” or “always being sick.” Approximately two thirds of these children have recurrent colds, and the remainder have either allergic rhinitis or recurrent sinusitis.

Allergic Rhinitis

Allergic rhinitis has significant morbidity and may contribute to the development of sinusitis and asthma exacerbations. Symptoms of frequent sneezing, rubbing of the nose, and clear drainage interfere with concentration at school. Nighttime nasal congestion interferes with sleep and causes daytime somnolence and hyperactivity. On physical examination the nasal turbinates are swollen, but may be red or pale pink. Treatment with nasal steroids is effective in decreasing the airway obstruction and rhinorrhea. Sneezing and clear drainage are controlled with nonsedating antihistamines. Ipratropium can be used as an adjunctive therapy.

Pullerits T et al: Comparison of a nasal glucocorticoid, antileukotriene, and a combination of antileukotriene and anti-

histamine in the treatment of seasonal allergic rhinitis. *J Allergy Clin Immunol* 2002;109(6):949 [PMID: 12063523].

The allergy report: http://www.aaaai.org/ar/working_vol1/073.asp.

Vasomotor Rhinitis

Some children react to sudden changes in environmental temperature with prolonged congestion and rhinorrhea. Air pollution (especially tobacco smoke) may be a factor. Oral decongestants or nasal steroids can be used to give symptomatic relief.

EPISTAXIS

The nose is an extremely vascular structure. In most cases, epistaxis (nosebleed) is due to mild trauma to the anterior portion of the nasal septum (Kiesselbach area), usually due to vigorous nose rubbing, nose blowing, or nose picking. If a patient has been using a nasal steroid spray, check the patient's technique to make sure he or she is directing the nozzle at the lateral canthus of the eye and not the septum. If this does not reduce the nosebleeds, then the steroid spray should be discontinued. Examination of the Kiesselbach area usually reveals a red, raw surface with fresh clots or old crusts. Also look for telangiectasia, hemangiomas, or varicosities.

Less than 5% of epistaxis is caused by a bleeding disorder such as von Willebrand disease. Patients need a hematologic work-up if any of the following is present: a family history of a bleeding disorder; a medical history of easy bleeding, particularly with circumcision or dental extraction; spontaneous bleeding at any site; bleeding that lasts for over 30 minutes or blood that will not clot with direct pressure by the physician; onset before age 2 years; or a drop in hematocrit due to epistaxis. High blood pressure may rarely predispose to prolonged nosebleeds.

A nasopharyngeal angiofibroma may be manifested by recurrent epistaxis. Adolescent boys are affected almost exclusively. CT scan of the nasal cavity and nasopharynx is diagnostic.

Treatment

The following approach can be carried out in the office or offered as phone advice: The patient should sit up and lean forward so as not to swallow the blood. Swallowed blood may cause nausea, and hematemesis alarms the family. The nasal cavity should be cleared of clots by gentle blowing. The soft part of the nose is pinched firmly enough to prevent arterial blood flow, with pressure over the bleeding site being maintained for 5 minutes by the clock. If bleeding continues, the bleeding site needs to be visualized. A small piece of gelatin sponge (Gelfoam) or collagen sponge (Surgicel) can be

inserted over the bleeding site and held in place by the parent.

Friability of the nasal vessels can be decreased with daily application of water-based ointment by cotton-tipped applicator. The lubricant is applied daily until 5 days have passed without a nosebleed, then weekly for 1 month. Twice daily nasal saline irrigation and humidification of the patient's bedroom may also be helpful. Aspirin and ibuprofen should be avoided, as should vigorous blowing of the nose.

NASAL INFECTION

A nasal furuncle is an infection of a hair follicle in the anterior nares. Hair plucking or nose picking can provide a route of entry. The most common organism is *S aureus*. The diagnosis is made by finding an exquisitely tender, firm, red lump in the anterior nares. Treatment includes dicloxacillin or cephalexin orally for 5 days to prevent spread. The lesion should be gently incised and drained as soon as it points, usually with a needle. Topical bacitracin ointment may be of additional value. Because this lesion is in the drainage area of the cavernous sinus, the patient should be followed closely until healing is complete. Parents should be advised never to pick or squeeze a furuncle in this location—and neither should the physician. Associated cellulitis or spread requires hospitalization for administration of intravenous antibiotics.

A nasal septal abscess usually follows nasal trauma or a nasal furuncle. Examination reveals a fluctuant gray septal swelling, usually bilateral. The possible complications are the same as for nasal septum hematoma (see following discussion). In addition, spread of the infection to the CNS is possible. Treatment consists of immediate hospitalization and incision and drainage by an otolaryngologist.

NASAL TRAUMA

Newborn infants rarely present with subluxation of the quadrangular cartilage of the septum. In this disorder, the top of the nose deviates to one side, the inferior septal border deviates to the other side, the columella leans, and the nasal tip is unstable. This disorder must be distinguished from the more common transient flattening of the nose caused by the birth process. In the past, physicians were encouraged to reduce all subluxations in the nursery. Otolaryngologists are more likely to perform the reduction under anesthesia for more difficult cases.

Most blows to the nose result in swallowing of blood and hematoma formation without fracture. A persistent nosebleed after trauma, crepitus or instability of the bones in the nasal bridge, and marked deviation

of the nose to one side indicate fracture. However, septal injury can be ruled out only by careful intranasal examination, not radiologically. Patients with suspected nasal fractures should be referred to an otolaryngologist for definitive therapy. Resetting of the nasal fracture can be postponed up to 1 week without resulting in permanent deformity.

After nasal trauma, it is essential to examine the inside of the nose with a nasal speculum. Hematoma of the nasal septum imposes a considerable risk of pressure necrosis and resorption of the cartilage, leading to septal perforation or a saddle-back nose in adulthood. This diagnosis is confirmed by the abrupt onset of nasal obstruction following trauma and the presence of a boggy, widened nasal septum. The normal nasal septum is only 2–4 mm thick, and the back end of a cotton swab may be helpful for palpation.

Treatment consists of prompt referral to an otolaryngologist for evacuation of the hematoma and packing of the nose.

FOREIGN BODIES IN THE NOSE

The most common foreign bodies in the nose are seeds or beads. If the diagnosis is delayed, unilateral rhinorrhea, foul smell, halitosis, bleeding, or nasal obstruction may occur. The leading cause of halitosis in children is a nasal foreign body, and not dental disease as in adults.

There are many ways to remove nasal foreign bodies. The obvious first maneuver is vigorous nose blowing if the child is old enough. The next step in removal requires topical anesthesia, nasal decongestion, good lighting, correct instrumentation, and physical restraint. Topical tetracaine or lidocaine can be used in young children. Nasal decongestion can be achieved by topical pseudoephedrine or oxymetazoline. When the child is properly restrained, most nasal foreign bodies can be removed using a pair of alligator forceps through an operating head otoscope. If the object seems unlikely to be removed on the first attempt, is wedged in, or is quite large, the patient should be referred to an otolaryngologist rather than worsening the situation through futile attempts at removal.

Because the nose is a moist cavity, the electrical current generated by disk-type batteries—such as those used in clocks, watches, and hearing aids—can cause necrosis of mucosa and cartilage destruction in less than 4 hours. This constitutes a true foreign body emergency.

Kelley PE: Foreign bodies in the nose and pharynx. In Burg FD et al (eds): *Gellis and Kazan's Current Pediatric Therapy*, 16th ed. WB Saunders, 1999.

III. THE THROAT & ORAL CAVITY

ACUTE STOMATITIS

Recurrent Aphthous Stomatitis

Also referred to as canker sores, these small ulcers (3–10 mm) are found on the insides of the lips or in the anterior mouth; rarely they may appear on the tonsils or palate. There is usually no associated fever and no cervical adenopathy. The ulcers may be painful and last 1–2 weeks. They may recur numerous times throughout life. The cause is unknown, although an allergic or autoimmune basis is suspected.

Treatment consists of coating the lesions with betamethasone valerate ointment twice daily, because unlike other topical steroids, it adheres to the mucosa. Pain can also be reduced by eating a bland diet, avoiding salty or acidic foods and juices, and giving acetaminophen or ibuprofen at bedtime.

Other less common causes of recurrent aphthous ulcers include Behçet disease, familial Mediterranean fever, and the fever, aphthous stomatitis, pharyngitis, and cervical adenopathy syndrome (FAPA) syndrome. A diagnosis of Behçet disease requires two of the following: genital ulcers, uveitis, and erythema nodosum-like lesions. Patients with Mediterranean fever have a positive family history, serosal involvement, and fever. FAPA syndrome was first described in 1987, and its cause is unknown. It usually begins before a child is 5 years of age and continues through adolescence, then resolves. It recurs at 4- to 6-week intervals, and an episode may be dramatically improved with prednisone bursts, but recurrences continue. In one case report it resolved totally with a 6-month course of cimetidine, suggesting an immune etiology. FAPA may also resolve with tonsillectomy (see Tonsillectomy section), and an otolaryngology referral is appropriate. The ulcers in all of these syndromes respond to betamethasone valerate application.

Dahn KA, Glode MP, Chan KH: Periodic fever and pharyngitis in young children: A new disease for the otolaryngologist? *Arch Otolaryngol Head Neck Surg* 2000;126:1146 [PMID: 10979131].

Herpes Simplex Gingivostomatitis (see also Chapter 36)

Children having their first encounter with the herpes simplex virus develop 10 or more small ulcers (1–3 mm) of the buccal mucosa, anterior pillars, inner lips, tongue, and especially the gingiva. The lesions are often associated with fever lasting up to 7 days, tender

cervical nodes, and generalized inflammation of the mouth. Affected children are commonly younger than 3 years of age. Gingivostomatitis lasts 7–10 days. Treatment is symptomatic, as described earlier for recurrent aphthous stomatitis, with the exception that corticosteroids are contraindicated because they may cause spread of the infection. If seen early in the course, the physician should prescribe oral acyclovir suspension (200 mg/5 mL), 20 mg/kg/dose, 4 times daily for 5 days. The patient must be followed closely because dehydration occasionally develops, requiring hospitalization. Herpetic laryngotracheitis is a rare complication.

Thrush (see also Chapter 39)

Oral candidiasis mainly affects infants and occasionally older children in a debilitated state. *Candida albicans* is a saprophyte that normally is not invasive unless the mouth is abraded or the patient is immunocompromised. The use of broad-spectrum antibiotics and systemic or inhaled steroids may be contributing factors. The symptoms include soreness of the mouth and refusal of feedings. Lesions consist of white curd-like plaques predominantly on the buccal mucosa. These plaques cannot be washed away after a water feeding.

Specific treatment consists of nystatin oral suspension, 2 mL four times daily for 1 week, or miconazole gel. Treatment should be preceded by attempts to remove large plaques with a moistened cotton-tipped applicator or piece of gauze, or half the nystatin may be rubbed on the lesions with an applicator. Gentian violet is probably also effective, but stains clothing and skin.

Traumatic Oral Ulcers

Mechanical trauma most commonly occurs on the buccal mucosa secondary to accidentally biting with the molars. Thermal trauma, from very hot foods, can also cause ulcerative lesions. Chemical ulcers can be produced by mucosal contact with aspirin, caustics, and the like. Oral ulcers can also occur with leukemia or on a recurrent basis with cyclic neutropenia. These lesions usually need no treatment. The pain subsides in 2 or 3 days.

ACUTE VIRAL PHARYNGITIS & TONSILLITIS

Figure 17–8 is an algorithm for the management of a sore throat.

Over 90% of cases of sore throat and fever in children are due to viral infections. Most children develop associated rhinorrhea and mild cough. The findings seldom give any clue to the particular viral agent, but six

types of viral pharyngitis are sufficiently distinctive to support an educated guess about the specific cause (see Chapter 36).

Clinical Findings

A. INFECTIOUS MONONUCLEOSIS

The findings are exudative tonsillitis, generalized cervical adenitis, and fever, usually in a patient older than 5 years of age. A palpable spleen or axillary adenopathy increases the likelihood of the diagnosis. The presence of more than 10% atypical lymphocytes on a peripheral blood smear or a positive mononucleosis spot test supports the diagnosis, although these tests are often falsely negative in children younger than age 5 years. Epstein–Barr virus serology showing an elevated IgM-capsid antibody is definitive.

B. HERPANGINA

Herpangina ulcers, 2–3 mm in size and surrounded by a halo, are found on the anterior pillars, the soft palate, and the uvula. No ulcers are present in the anterior mouth as there are in herpes simplex. Herpangina is caused by several members of the coxsackie A group of viruses, and a patient may have several bouts of herpangina.

C. LYMPHONODULAR PHARYNGITIS

The classic finding is small, yellow-white nodules in the same distribution as the small ulcers in herpangina. In this condition, which is caused by coxsackievirus A10, the nodules do not ulcerate.

D. HAND, FOOT, AND MOUTH DISEASE

This entity is caused by coxsackieviruses A5, A9, A10, and A16. Ulcers occur on the tongue and oral mucosa. Vesicles, which usually do not ulcerate, are found on the palms, soles, interdigital areas, and buttocks.

E. PHARYNGOCONJUNCTIVAL FEVER

This disorder is caused by an adenovirus and often is epidemic. Exudative tonsillitis, conjunctivitis, lymphadenopathy, and fever are the main findings, and treatment is symptomatic.

ACUTE BACTERIAL PHARYNGITIS

Approximately 10% of children with sore throat and fever have a group A streptococcal infection. Less common causes of bacterial pharyngitis are *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, groups C and G streptococci, and *Arcanobacterium hemolyticum*. Of the five, *M pneumoniae* is by far the most common and may cause over one third of all pharyngitis cases in adolescents and adults.

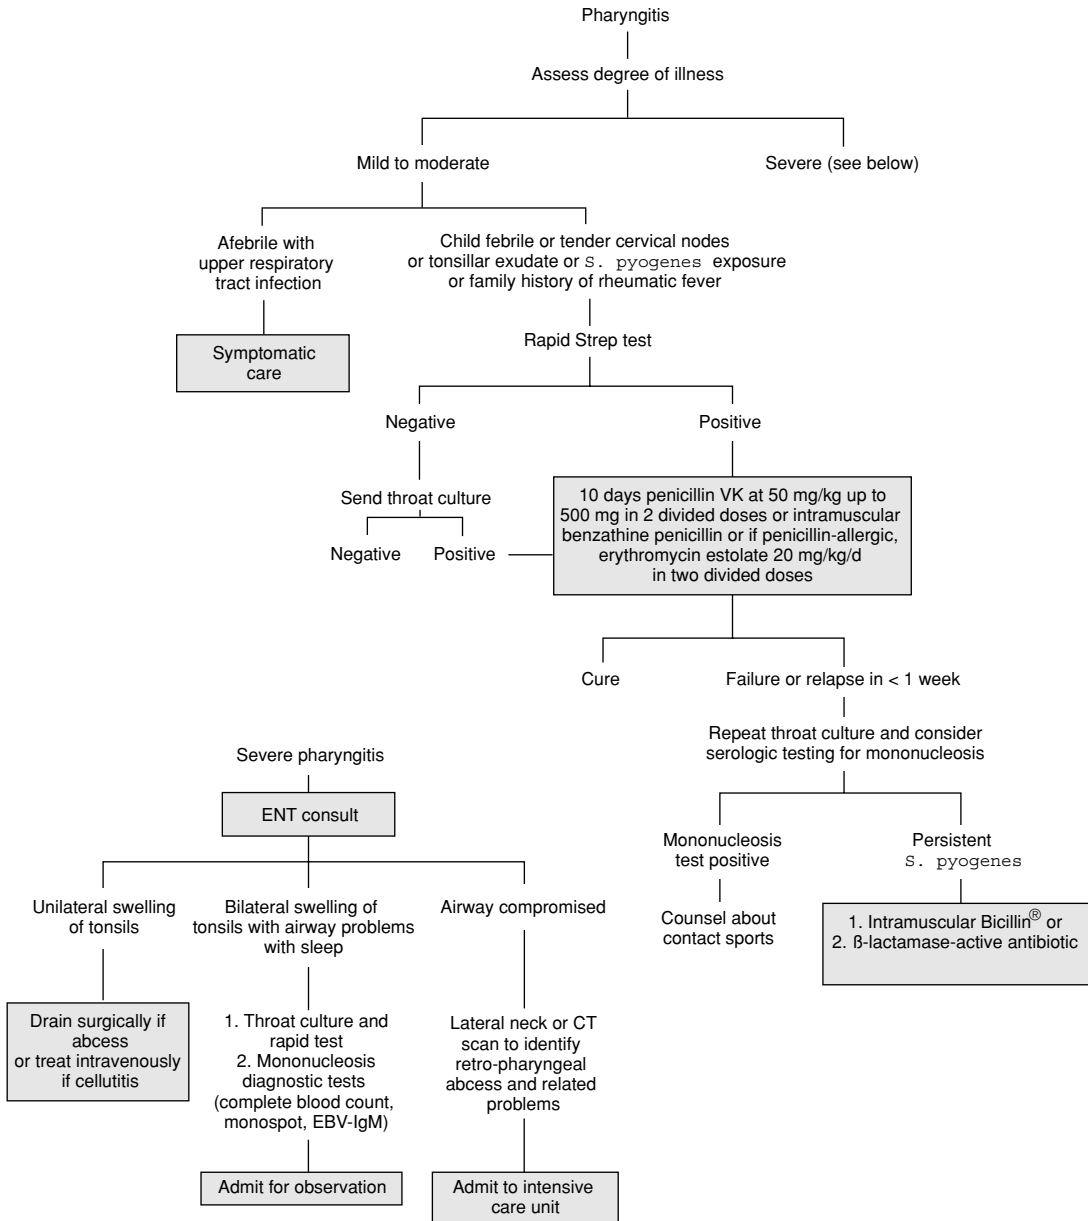

Figure 17-8. Algorithm for pharyngitis.

Untreated streptococcal pharyngitis can result in acute rheumatic fever, glomerulonephritis, and suppurative complications (eg, cervical adenitis, peritonsillar abscess, otitis media, cellulitis, and septicemia). Vesicles and ulcers are suggestive of viral infection, whereas tender anterior cervical nodes, petechiae, a beefy-red uvula, and a tonsillar exudate suggest streptococcal infection;

the only way to make a definitive diagnosis is by throat culture or rapid antigen test. Rapid antigen tests are very specific, but have a sensitivity of 85–95%. Therefore, a positive test indicates *S pyogenes* infection, but a negative result requires confirmation with culture.

The physician should treat cases of suspected or proven group A streptococcal infection with a 10-day

course of oral penicillin V potassium, a cephalosporin, or intramuscularly injected penicillin G benzathine (Table 17–3). Penicillin VK is equally effective if given in two or three divided doses, except in adolescents, for whom three doses are recommended, but is not effective once daily. Amoxicillin, azithromycin, and cefadroxil may be given once daily. Cephalexin given in four divided doses is inexpensive, but it has never been studied with fewer daily doses. Penicillin-allergic patients should be given erythromycin estolate in two or three divided doses, not the poorly absorbed ethylsuccinate preparation, which causes vomiting and abdominal cramping. The treatment failure rate after 10 days of penicillin VK administered three times daily varies from 6% to 23%. The small differences between the cure rates of penicillin and cephalosporins reported in the literature may represent eradication of the carrier state rather than treatment failure. Causes of treatment failure include unrecognized carriers, poor compliance, acquisition of a different strain, inactivation of penicillin by β -lactamase produced by throat flora, or the development of tolerance by *S pyogenes*. Approximately 5% of *S pyogenes* are resistant to erythromycin. Trimethoprim–sulfamethoxazole is not an effective antibiotic against *S pyogenes*. Children should receive 24 hours of therapy before returning to school.

If the child has a history of recurrent streptococcal infection, the physician should document the absence of *S pyogenes* in an asymptomatic patient following a course of therapy. If compliance or the adequacy of antibiotic dosage was questionable, the infection may be treated with intramuscular penicillin; otherwise, an antibiotic effective against β -lactamase-producing organisms (amoxicillin plus clavulanate, a cephalosporin, or a macrolide) may be used. If this therapy fails to eradicate the organism, a course of clindamycin for 10 days should be considered.

In general, the carrier state is harmless, self-limited (2–6 months), and not contagious. An attempt to eradicate the carrier state is warranted only if the patient or another family member has frequent streptococcal infections or when a family member or patient has a history of rheumatic fever or glomerulonephritis.

Treatment should be considered for carriers who live in closed or semiclosed community settings. If the patient has had three or more documented infections within 6 months, daily penicillin prophylaxis may be given during the winter season. Patients may be referred for tonsillectomy if they continue to have frequent episodes or if persistently enlarged tonsils cause chronic upper airway obstruction. “Frequent” is defined as seven episodes in 1 year, five per year for 2 years, or three per year for 3 years.

Table 17–3. Treatment of group A streptococcal pharyngitis.

Drug	Dosage	Maximum Adult Dose	Formulations	Comments
Penicillin VK	250 mg bid for 10 days, 500 mg bid or tid for adolescents & adults	1000 mg	250 mg/tsp; 250 mg tablets and 500 mg tablets	Preferred by American Heart Association (AHA)
Amoxicillin ^a	750 mg once daily for 10 days in patients older than age 3 years	750 mg	250 mg/tsp; 250 mg tablets	For poorly compliant patients
IM Benzathine penicillin	If < 27 kg, 600,000 U; if > 27 kg, 1.2 million U			If preferred by parent. AHA endorsed
For penicillin-allergic patients				
Erythromycin estolate (250/5)	20 mg/kg bid for 10 days	250 mg bid	250 mg/tsp; 250 mg tablets	Preferred by AHA
Zithromax	12 mg/kg/d for 5 days (not the otitis media dose)	500 mg on day 1 and 250 mg for 4 days more	15 ml of 100/5 mL; 15 ml of 200/5 mL; 30 ml of 200/5 mL	Expensive. For poorly compliant patients
First-generation cephalosporins	Varies with agent			These agents should not be used to treat patients with immediate-type hypersensitivity to β -lactam antibiotics

^aPreferred by some doctors for younger children because of taste.

Lan AJ, Colford JM: The impact of dosing frequency on the efficacy of 10-day penicillin or amoxicillin therapy for Streptococcal tonsillopharyngitis: A meta-analysis. *Pediatrics electronic* pages 2000;105:e19 [PMID: 10654979].

PERITONSILLAR CELLULITIS OR ABSCESS (QUINSY)

Tonsillar infection occasionally penetrates the tonsillar capsule, spreads to the surrounding tissues, and causes peritonsillar cellulitis. If untreated, necrosis occurs and a tonsillar abscess forms. This can occur at any age. The most common cause is β -hemolytic streptococcal infection. Other pathogens are group D streptococci, β -hemolytic streptococci, *S pneumoniae*, and anaerobes.

The patient complains of a severe sore throat even before the physical findings become marked. A high fever is usually present, and the process is almost always unilateral. The tonsil bulges medially, and the anterior tonsillar pillar is prominent. The soft palate and uvula on the involved side are edematous and displaced toward the uninvolved side. In cases of abscess formation, trismus, ear pain, dysphagia, and, eventually, drooling occur. The most serious complication of inadequately treated peritonsillar abscess is a lateral pharyngeal abscess. This causes fullness and tenderness of the lateral neck as well as torticollis. Without intervention, the lateral pharyngeal abscess threatens life by airway obstruction or carotid artery erosion. If airway symptoms are present, an immediate otolaryngology consultation is indicated.

It is often difficult to differentiate peritonsillar cellulitis from abscess. In some children, it is possible to aspirate the peritonsillar space to diagnose and treat an abscess. However, it is reasonable to admit a child for 12–24 hours of intravenous antimicrobial therapy, because aggressive treatment in early cases of peritonsillar cellulitis usually prevents suppuration. Therapy with penicillin or clindamycin is appropriate. Failure to respond to therapy during the first 12–24 hours indicates a high probability of abscess formation. An otolaryngologist should be consulted for incision and drainage or for aspiration under local anesthesia.

Recurrent peritonsillar abscesses are so uncommon (7%) that routine tonsillectomy for a single bout is not indicated unless other tonsillectomy indications exist. Hospitalized patients can be discharged on oral antibiotics when fever has resolved for 24 hours and dysphagia has improved.

Herzon FS, Nicklaus P: Pediatric peritonsillar abscess: Management guidelines. *Curr Probl Pediatr* 1996;26:270 [PMID: 8899288].

RETROPHARYNGEAL ABSCESS

Retropharyngeal nodes drain the adenoids, nasopharynx, and paranasal sinuses and can become infected. The most common causes are β -hemolytic streptococci and *S aureus*. If this pyogenic adenitis goes untreated, a retropharyngeal abscess forms. The process occurs most commonly during the first 2 years of life. Beyond this age, retropharyngeal abscess usually results from superinfection of a penetrating injury of the posterior wall of the oropharynx.

The diagnosis of retropharyngeal abscess should be strongly suspected in an infant with fever, respiratory symptoms, and neck hyperextension. Dysphagia, drooling, dyspnea, and gurgling respirations are also found and are due to impingement by the abscess. Prominent swelling on one side of the posterior pharyngeal wall confirms the diagnosis. Swelling usually stops at the midline because a medial raphe divides the prevertebral space. Lateral neck soft tissue films show the retropharyngeal space to be wider than the C4 vertebral body.

Although retropharyngeal abscess is a surgical emergency, frequently it cannot be distinguished from retropharyngeal adenitis. Immediate hospitalization and intravenous antimicrobial therapy with a semisynthetic penicillin or clindamycin is the first step for most cases. Immediate surgical drainage is required when a definite abscess is seen radiographically or when the airway is compromised markedly. In most instances, a period of 12–24 hours of antimicrobial therapy will help to differentiate the two entities. In the child with adenitis, fever will decrease and oral intake will increase. A child with retropharyngeal abscess will continue to deteriorate. A surgeon should incise and drain the abscess under general anesthesia to prevent its extension.

LUDWIG ANGINA

Ludwig angina is a rapidly progressive cellulitis of the submandibular space that can cause airway obstruction and death. The submandibular space extends from the mucous membrane of the floor of the mouth to the muscular and fascial attachments of the hyoid bone. This infection is encountered infrequently in infants and children. The initiating factor in over 50% of cases is dental disease, including abscesses and extraction. Some patients have a history of lacerations and injuries to the floor of the mouth. Group A streptococcus is the most common organism identified, but other pathogens cause the infection.

The manifestations are fever and tender swelling of the floor of the mouth. The tongue can become enlarged as well as tender and erythematous. Upward displacement of the tongue may cause dysphagia, drooling, and airway obstruction.

Treatment consists of giving high doses of intravenous clindamycin or ampicillin plus nafcillin until the results of cultures and sensitivity tests are available. Because the most common cause of death in Ludwig angina is sudden airway obstruction, the patient must be monitored closely in the intensive care unit and intubation provided for progressive respiratory distress. An otolaryngologist should be consulted to identify and perform a drainage procedure.

Britt JC et al: Ludwig's angina in the pediatric population: Report of a case and review of the literature. *Int J Pediatr Otorhinolaryngol* 2000;52:79.

ACUTE CERVICAL ADENITIS

Local infections of the ear, nose, and throat can spread to a regional node and cause a secondary inflammation. The typical case involves a large, unilateral, solitary, anterior cervical node. About 70% of these cases are due to β -hemolytic streptococcal infection, 20% to staphylococci, and the remainder to viruses, atypical mycobacteria, and *Bartonella henselae*. Surgeons report a higher incidence of staphylococcal infection, but they see a greater proportion of atypical cases that have failed to respond to penicillin therapy and thus require incision and drainage. The most common antecedent infection is pharyngitis. Other entry sites for cervical adenitis include a periapical dental abscess (usually producing a submandibular adenitis), facial impetigo (infected cuts or bug bites), infected acne, and otitis externa (usually producing a preauricular adenitis).

The initial evaluation of cervical adenitis should generally include a group A streptococcal diagnostic test, a complete blood count with differential (looking for atypical lymphocytes), and a purified protein derivative skin test (PPD), looking for nontuberculous mycobacteria. If no cause is found, a mononucleosis test is useful. Early treatment with antibiotics prevents many cases of pyogenic adenitis from progressing to suppuration. However, once fluctuation occurs, antibiotic therapy alone is often insufficient. When fluctuation is present, needle aspiration may promote resolution. If needle aspiration is done, the pus should be sent for a Gram stain, aerobic and anaerobic culture, an acid-fast stain for *Mycobacteria*, and an acid-fast smear and tuberculosis culture. If needle aspiration is not effective, a surgeon should incise and drain the abscess. Hospitalization is required only if the patient is toxic, dehydrated, dysphagic, or dyspneic.

Cat-scratch disease is frequently implicated in cases of chronic cervical adenopathy. The diagnosis is aided by the finding of a primary papule on the face. In over 90% of patients, cat scratches are present or there is a history of contact with kittens. The node is usually only

mildly tender, but may suppurate and drain. About one third of children have fever and malaise, and, rarely, neurologic sequelae and prolonged fever occur. Cat-scratch disease, caused by *B henselae*, can be diagnosed by serologic testing available at commercial laboratories, but testing is not always confirmatory. Blood should be drawn 2–8 weeks after onset of symptoms. Because most nodes caused by this pathogen spontaneously resorb within 1–3 months, the benefit of antibiotics is controversial. In a placebo-controlled trial, azithromycin for 5 days caused a more rapid decrease in node size. Other drugs likely to be effective include rifampin, trimethoprim–sulfamethoxazole, erythromycin, clarithromycin, doxycycline, ciprofloxacin, and gentamicin.

Cervical lymphadenitis can be caused by nontuberculous mycobacterial species or *Mycobacterium avium* complex. The adenitis is usually unilateral and indolent, but may involve several adjacent nodes. A characteristic violaceous appearance may develop over a prolonged period of time without systemic signs or much local pain. Atypical mycobacterial infections are often associated with PPD skin reactions less than 10 mm.

Once the diagnosis is suspected due to a positive PPD, a chest radiograph should be done and all family members tested for tuberculosis. The node should not be incised and drained, because that may lead to a draining sinus tract. Instead, a complete excision of all nodes should be done by an experienced surgeon. Nodes may recur, usually within 3 months of surgery. In such cases, a newer macrolide in combination with a second drug (rifampin or ethambutol) is given for 3–6 months.

Differential Diagnosis

A. NEOPLASMS AND CERVICAL NODES

Malignant tumors usually are not suspected until the adenopathy persists despite treatment. Classically, the nodes are painless, nontender, and firm to hard in consistency. They may be fixed to underlying tissues. These nodes may occur as a single node, as unilateral multiple nodes in a chain, as bilateral cervical nodes, or as generalized adenopathy. Common malignancies that may present in the neck include Hodgkin disease, non-Hodgkin lymphoma, rhabdomyosarcoma, and thyroid carcinoma.

B. IMITATORS OF ADENITIS

Several structures in the neck can become infected and resemble a node. The first three masses are of congenital origin and are listed in order of frequency.

1. Thyroglossal duct cyst—When superinfected, this congenital malformation can become acutely swollen.

Helpful findings are the fact that it is in the midline, located between the hyoid bone and suprasternal notch, and moves upward when the tongue is stuck out or during swallowing. Occasionally, the cyst develops a sinus tract and opening just lateral to the midline.

2. Branchial cleft cyst—When superinfected, this malformation can become a tender mass 3–5 cm in diameter. Aids to diagnosis are the fact that the mass is located along the anterior border of the sternocleidomastoid muscle and is smooth and fluctuant. Occasionally it is attached to the overlying skin by a small dimple or a draining sinus tract.

3. Lymphatic malformation (cystic hygroma)—Most of these lymphatic cysts are located in the posterior triangle just above the clavicle. The mass is soft and compressible and can be transilluminated. Over 60% of hygromas are noted at birth, and the remainder are usually seen by the time the child is age 2 years. If cysts become large enough, they can compromise the patient's ability to swallow and breath.

4. Parotitis—The most common pitfall in differential diagnosis of cervical adenopathy is mistaking parotitis for adenitis. However, a swollen parotid crosses the angle of the jaw, is associated with preauricular percussion tenderness, and is bilateral in 70% of cases. There may be a history of exposure to mumps, but in the United States other viruses are now the main cause. An amylase level will be elevated in parotitis.

5. Ranula—A ranula is a cyst in the floor of the mouth caused by obstruction of the ducts of the sublingual gland. A plunging ranula extends below the mylohyoid muscle and can appear as a neck mass.

6. Sternocleidomastoid muscle hematoma—This cervical mass is noted at age 2–4 weeks. On close examination, it is found to be part of the muscle body and not movable. An associated torticollis usually confirms the diagnosis.

SNORING, MOUTH BREATHING, & UPPER AIRWAY OBSTRUCTION

In April 2002, the American Academy of Pediatrics published a Clinical Practice Guideline for the diagnosis and management of uncomplicated childhood obstructive sleep apnea syndrome (OSAS). The guideline emphasizes that pediatricians should screen all children for snoring and that complex high-risk patients should be referred to a specialist.

When parents report that their child has nightly snoring and is a mouth breather even during the day, one should be suspicious of obstructive sleep apnea (OSA). Figure 17–9 is an algorithm for management of these complaints. The adenoids can be assessed by mirror examination, endoscopy, or radiographic studies. Either adenoid hypertrophy or nasal obstruction can be assumed when a child has hyponasal speech. The consonants “m,” “n,” and “ng” rely on the palate not touching the posterior pharyngeal wall. By having a child repeat the word “banana” or “ninety-nine” with the nose open or pinched closed, one may assess the nasal and nasopharyngeal airways. If the voice does not change with occlusion of the nostrils, then either adenoid or nasal obstruction is present.

Although nasal obstruction is usually due to allergic rhinitis and can be diagnosed by a careful allergy history, there are other, less common causes. Nasal polyps appear as glistening, gray to pink, jelly-like masses that are prominent just inside the anterior nares and occur singly or in clusters. They occur in cystic fibrosis and severe allergic rhinitis. Persistent mouth-breathing may also rarely be due to a nasopharyngeal tumor, or to a meningocele herniated into the nasal cavity. For male patients, if unilateral nasal obstruction and epistaxis occur frequently, juvenile angiofibroma should be suspected. If allergic rhinitis is the suspected cause of snoring, a trial of intranasal corticosteroid spray is indicated. If enlarged tonsils (Figure 17–10) or adenoids are present, a referral to an otolaryngologist or a pediatric sleep laboratory is in order.

Diagnosis

The gold standard for diagnosis of OSA is a polysomnogram. A patient's history and clinical examination cannot predict the presence or severity of OSA. An overnight oximetry study is a poor screening test for OSA. The test may detect those patients with severe disease but miss the milder cases. OSA is part of a spectrum of disorders that occur during sleep. A milder form of OSA is upper airway resistance syndrome. Patients with this syndrome have an otherwise normal polysomnogram with the only evidence of obstruction being increased respiratory effort. The criteria for diagnosing OSA differ between children and adults. An obstructive event occurs when airflow stops despite persistence of respiratory effort. A hypopnea is counted when airflow and respiratory effort decrease with an associated oxygen desaturation or arousal. Normative values are just being established. An investigation of sleep-disordered breathing in children between the ages of 6 and 11 years is the first study to evaluate clinical relevance using full polysomnograms. The study demonstrated that a respiratory disturbance index (RDI) of at least

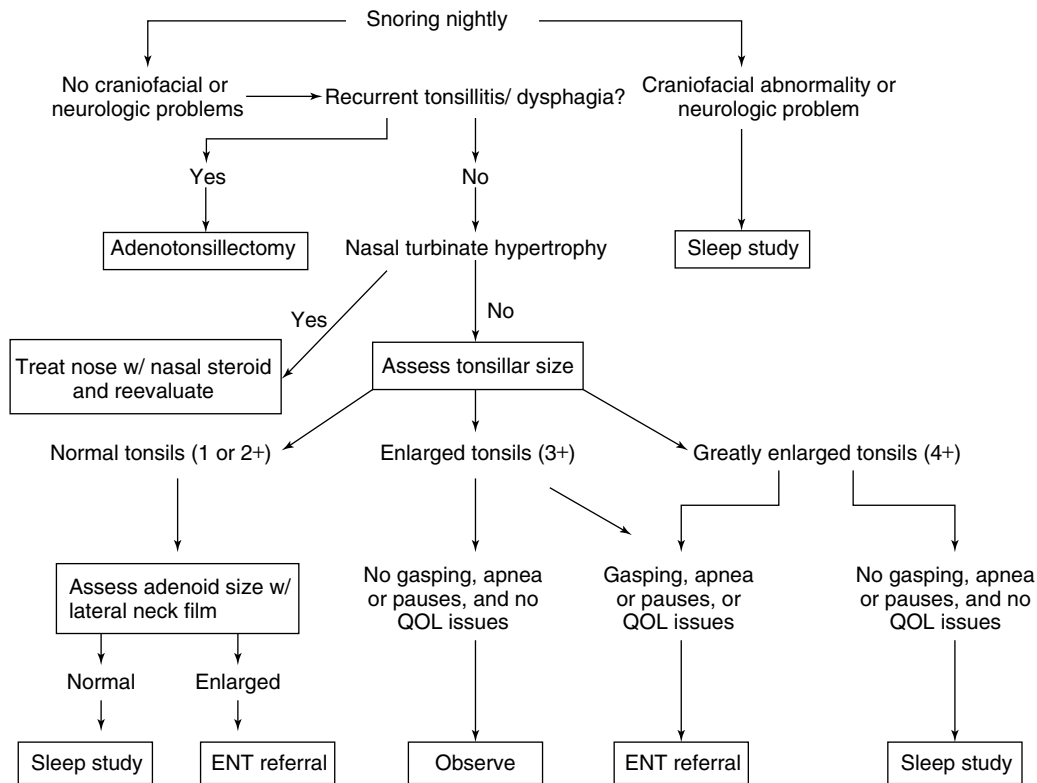

Figure 17–9. Algorithm for snoring. QOL = quality of life.

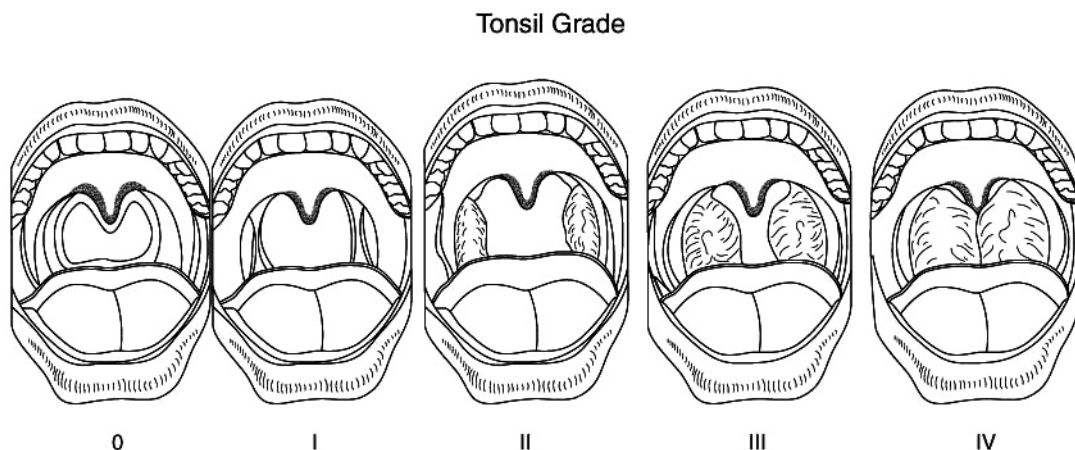

Figure 17–10. A grading scale for tonsil size that ranges from 0 to 4. With grade 0 the tonsils are small and contained within the tonsillar fossa; in grade 4 the tonsils are so large they almost touch (“kissing”). (Reprinted, with permission, from Brodsky L: Modern assessment of tonsils and adenoids. *Pediatr Clin North Am* 1989;36(6):1551.)

one event an hour when associated with a 3% oxygen desaturation was associated with daytime sleepiness and learning problems. If oxygen desaturations were absent, an RDI of five was associated with clinical symptoms. The importance of diagnosing OSA in children cannot be underestimated. Recent studies have shown that teenagers who are loud snorers exhibit impaired school performance, and that behavioral problems are associated with OSA. One should strongly consider the diagnosis of OSA in a snoring child who otherwise meets the criteria for ADHD. For those patients who have severe OSA by polysomnogram with large oxygen desaturations, obtain a chest radiograph and electrocardiogram to make sure that cor pulmonale has not developed.

National Sleep Foundation (<http://www.sleepfoundation.org/>)

TONSILLECTOMY & ADENOIDECTOMY

Tonsillectomy

A tonsillectomy with or without adenoidectomy is typically performed for either hypertrophy or recurrent infections. Adenotonsillar hypertrophy may produce upper airway obstruction, dysphagia, or dental malocclusion. Rarely, the size may produce pulmonary hypertension or cor pulmonale. Recurrent infections are present when a child has seven or more documented *S pyogenes* infections in 1 year, five per year for 2 years, or three per year for 3 years. A tonsillectomy is reasonable if fewer infections are present but the child has missed multiple school days or has a complicated course. Recurrent peritonsillar abscesses and persistent streptococcal carrier state are other indications as well as unilateral tonsil hypertrophy that appears neoplastic.

A possible new indication is FAPA syndrome (see previous discussion), in which the fever is predictable and commonly occurs every 4–8 weeks. Removal of the tonsils was shown to relieve the symptoms in five children in one recent study.

OSA is associated with loud snoring during sleep with periods of respiratory pauses terminated with gasping and agitated arousal. The American Academy of Pediatrics technical report on OSA (<http://www.pediatrics.org/cgi/content/full/109/4/e69>) suggests that primary snoring may also have developmental consequences. Other symptoms of OSA include ADHD, failure to thrive, and nocturnal enuresis.

Recently, a proliferation of new surgical techniques has occurred that can potentially reduce the morbidity associated with an adenotonsillectomy.

Sood S et al: Effectiveness of the ultrasonic harmonic scalpel for tonsillectomy. *Ear Nose Throat J* 2001;80(8):514; 518 [PMID: 11523467]

Adenoidectomy

The adenoids, composed of lymphoid tissue in the nasopharynx, are a component of the Waldeyer ring of lymphoid tissue with the palatine tonsils and lingual tonsils. Enlargement of the adenoids with or without infection can obstruct the upper airway, alter normal orofacial growth, and interfere with speech, swallowing, or eustachian tube function. Most children with prolonged mouth breathing eventually develop dental malocclusion and what has been termed an adenoidal facies. The face is pinched and the maxilla narrowed because the molding pressures of the orbicularis oris and buccinator muscles are unopposed by the tongue. The role of hypertrophy and chronic infection in the pathogenesis of sinusitis is unclear, but adenoidectomy has been shown to be effective in some patients with chronic rhinosinusitis.

Indications for adenoidectomy with or without tonsillectomy include pulmonary conditions such as chronic hypoxia related to upper airway obstruction, hypopnea, or obstructive sleep apnea; orofacial conditions such as mandibular growth abnormalities, dental malocclusion, and swallowing disorders; speech abnormalities; persistent middle ear effusion; recurrent and chronic otitis media; and chronic sinusitis. Chronic adenoiditis can seed the sinuses and cause the ongoing sinus disease.

Coyte PC et al: The role of adjuvant adenoidectomy and tonsillectomy in the outcome of the insertion of tympanostomy tubes. *N Engl J Med* 2001;344:1188 [PMID: 11390633].

Complications of Tonsillectomy & Adenoidectomy

The reported mortality rates associated with tonsillectomy & adenoidectomy (T&A) now approximate that of general anesthesia alone. The rate of hemorrhage varies between 0.1% and 8.1% depending on the definition of hemorrhage; the rate of postoperative transfusion is 0.04%. Other complications include hypernasal speech (< 0.01%), and more rarely nasopharyngeal stenosis, atlantoaxial subluxation, mandible condyle fracture, and psychologic trauma.

Contraindications to Tonsillectomy & Adenoidectomy

A. SHORT PALATE

Adenoids should not be removed completely in a child with a cleft palate or submucous cleft palate because of the risk of aggravating the velopharyngeal incompetence and causing hypernasal speech and nasal regurgitation. A superior or partial adenoidectomy can be performed in a child with marked obstructive sleep apnea who has a submucous cleft palate or ongoing conductive hearing loss from middle ear effusion.

B. BLEEDING DISORDER

If a chronic bleeding disorder is present, it must be diagnosed and treated before T&A.

C. ACUTE TONSILLITIS

An elective T&A can often be postponed until acute tonsillitis is resolved. Urgent tonsillectomy may be required for tonsillitis unresponsive to medical therapy.

DISORDERS OF THE LIPS

Labial Sucking Tubercle

A small baby may present with a small callus in the mid-upper lip. It usually is asymptomatic and disappears after cup feeding is initiated.

Cheilitis

Dry, cracked, scaling lips are usually caused by sun or wind exposure. Contact dermatitis from mouthpieces or various woodwind or brass instruments has also been reported. Licking the lips accentuates the process, and the patient should be warned of this. Liberal use of lip balms gives excellent results.

Inclusion Cyst

Inclusion (retention) cysts are due to the obstruction of mucous glands or other mucous membrane structures. In the newborn, they occur on the hard palate or gums and are called Epstein pearls. These small cysts resolve spontaneously in 1–2 months. In older children, inclusion cysts usually occur on the palate, uvula, or tonsillar pillars. They appear as taut yellow sacs varying in size from 2 mm to 10 mm. Inclusion cysts that do not resolve spontaneously should undergo incision and drainage. Occasionally a mucous cyst on the lower lip (mucocele) requires drainage for cosmetic reasons. Minor salivary glands are present at this site. Blockage of the outflow of the individual gland initiates the development.

DISORDERS OF THE TONGUE

Geographic Tongue (Benign Migratory Glossitis)

This condition of unknown cause occurs in 1–2% of the population with no age, sex, or racial predilection and is characterized by irregularly shaped areas on the tongue devoid of papillae and surrounded by parakeratotic reddish borders. The pattern changes as alternating regeneration and desquamation occurs. The lesions are generally asymptomatic and require no treatment.

Fissured Tongue (Scrotal Tongue)

This condition is marked by numerous irregular fissures on the dorsum of the tongue. It occurs in approximately 1% of the population and is usually a dominant trait. It is also frequently seen in children with trisomy 21 and other mentally delayed patients who have the habit of chewing on a protruded tongue.

Coated Tongue (Furry Tongue)

The tongue normally becomes coated if mastication is impaired and the patient is taking a liquid or soft diet. Mouth breathing, fever, or dehydration can accentuate the process.

Macroglossia

Tongue hypertrophy and protrusion may be a clue to Beckwith–Wiedemann syndrome, glycogen storage disease, cretinism, Hurler syndrome, lymphangioma, or hemangioma. Tongue reduction procedures should be considered in otherwise healthy subjects when macroglossia affects airway patency, eating, dental development, and normal mandibular growth. In trisomy

21, the normal-sized tongue protrudes because the patient's oral cavity is small.

Bezerra S, Costa I: Oral conditions in children from birth to 5 years: The findings of a children's dental program. *J Clin Ped Dent* 2000;25(1):79 [PMID: 11314357].

HALITOSIS

Bad breath is usually due to acute stomatitis, pharyngitis, sinusitis, a nasal foreign body, or dental hygiene problems. In older children and adolescents, halitosis can be a manifestation of chronic sinusitis, gastric bezoar, bronchiectasis, or lung abscess. The presence of orthodontic devices or dentures can cause halitosis if good dental hygiene is not maintained. Halitosis can also be caused by decaying food particles embedded in cryptic tonsils. In adolescents, tobacco use is a common cause. Mouthwashes and chewable breath fresheners give limited improvement. Treatment of the underlying cause is indicated, and a dental referral may be in order.

Amir E et al: Halitosis in children. *J Pediatr* 1999;134(3):338 [PMID: 10064672].

SALIVARY GLAND DISORDERS

Parotitis

A first episode of parotitis may safely be considered to be of viral origin, unless fluctuance is present. The leading cause was mumps until adoption of vaccination; now the leading viruses are parainfluenza and Epstein-Barr virus. HIV should be considered if the child is known to be at risk.

Suppurative Parotitis

Suppurative parotitis is an uncommon clinical disorder occurring chiefly in newborns and debilitated elderly patients. The parotid gland is swollen, tender, and often reddened and is usually a unilateral process. The diagnosis is made by expression of purulent material from the Stensen duct. The material should be smeared and cultured. Fever and leukocytosis may be present.

Treatment includes hospitalization and intravenous nafcillin because the most common causative organism is *S aureus*.

Recurrent Idiopathic Parotitis

Some children experience repeated episodes of parotid swelling that last 1–2 weeks and then resolve spontaneously, or can become infected and require antibiotics for resolution. There is usually pain and often no fever. The process is most often unilateral, suggesting some sort

of obstructive process, but can be associated with Sjögren syndrome, another autoimmune process, HIV infection, or a calculus in the parotid duct. Serum amylase levels are normal, which speaks against a diagnosis of viral parotitis. Many episodes may occur from age 2 years on. The problem may resolve spontaneously at puberty.

Treatment includes analgesics if pain is present and an antistaphylococcal antibiotic for prophylaxis of infection and quicker resolution at the onset of symptoms. A second attack of parotid swelling without fever should result in referral to an otolaryngologist to make the diagnosis.

Huisman TA et al: MRI of chronic recurrent parotitis in childhood. *J Comput Assist Tomogr* 2001;25:269 [PMID: 11242227].

Tumors of the Parotid Gland

Mixed tumors, hemangiomas, sarcoidosis, and leukemia can be manifested in the parotid gland as a hard or persistent mass. A cystic mass or multiple cystic masses may represent an HIV infection. Work-up may require consultation with oncology, infectious diseases, hematology, and otolaryngology.

Ranula

A ranula is a retention cyst of a sublingual salivary gland. It occurs on the floor of the mouth to one side of the lingual frenulum. Ranula has been described as resembling a frog's belly because it is thin-walled and contains a clear bluish fluid. Referral to an otolaryngologist for excision of the cyst and associated sublingual gland is the treatment of choice.

CONGENITAL ORAL MALFORMATIONS

Tongue-Tie (Ankyloglossia)

The tightness of the lingual frenulum varies greatly among normal people. A short frenulum prevents both protrusion and elevation of the tongue. Puckering of the midline of the tongue occurring with tongue movement is noted on physical examination.

When mild, treatment consists of reassurance. If the tongue cannot protrude past the teeth or alveolar ridge or move between the gums and cheek, referral to an otolaryngologist for evaluation is indicated. Frenulectomy may be recommended if there is a question of suckling difficulties, dental health (related to the inability to clear food from around the teeth), or articulation problems.

Messner AH, Lalakea ML: Ankyloglossia: Controversies in management. *Int J Pediatr Otorhinolaryngol* 2000;54:123 [PMID: 10967382].

Messner AH et al: Ankyloglossia: Incidence and associated feeding difficulties. *Arch Otolaryngol Head Neck Surg* 2000;126:36 [PMID: 10628708].

Torus Palatini

Hard midline masses on the palate are called *torus palatini*. They are bony protrusions that form at suture lines of bone. Usually they are asymptomatic and require no therapy. They can be surgically reduced if necessary.

Cleft Lip & Cleft Palate (see Chapter 33)

Submucous Cleft Palate

A bifid uvula is present in 3% of healthy children. However, a close association exists (as high as 75%) between bifid uvula and submucous cleft palate. A submucous cleft can be diagnosed by noting a translucent zone in the middle of the soft palate. Palpation of the hard palate reveals absence of the posterior bony protrusion. Affected children have a 40% risk of developing persistent middle ear effusion. They are at risk also of incomplete closure of the palate, resulting in hypernasal speech. During feeding, some of these infants experience nasal regurgitation of food. Children with sub-

mucous cleft palate causing abnormal speech or nasal regurgitation of food require referral for surgical repair.

High-Arched Palate

A high-arched palate is usually a genetic trait of no consequence. It also occurs in children who are chronic mouth breathers and in premature infants who undergo prolonged oral intubation. Some rare causes of high-arched palate are congenital disorders such as Marfan syndrome, Treacher Collins syndrome, and Ehlers–Danlos syndrome.

Robin Sequence (Pierre Robin)

This group of congenital malformation is characterized by the triad of micrognathia, cleft palate, and glossoposis. Affected children present as emergencies in the newborn period because of infringement on the airway by the tongue. The main objective of treatment is to prevent asphyxia until the mandible becomes large enough to accommodate the tongue. In some cases, this objective can be achieved by leaving the child in a prone position while unattended. In more severe cases, a tracheostomy is required. The child requires close observation and careful feeding until the problem is outgrown.

Respiratory Tract & Mediastinum

■ RESPIRATORY TRACT

Pediatric pulmonary diseases account for almost 50% of deaths in children younger than age 1 year and about 20% of all hospitalizations of children younger than age 15 years. Approximately 7% of children have some sort of chronic disorder of the lower respiratory system. Understanding the pathophysiology of many pediatric pulmonary diseases requires an appreciation of the normal growth and development of the lung.

GROWTH & DEVELOPMENT

The lung has its origins from an outpouching of the foregut during the fourth week of gestation. The development of the lung is divided into five overlapping stages. The first stage is the embryonic stage (3–7 weeks' gestation) during which the primitive lung bud undergoes asymmetrical branching and then subsequent dichotomous branching, leading to the development of the conducting airways. This stage of lung development is dependent on a complex crosstalk of various growth factors originating in both the pulmonary epithelium and the splanchnic mesenchyme. This stage also sees the development of the large pulmonary arteries from the sixth aortic arch and the pulmonary veins as outgrowths of the left atrium. Abnormalities during this stage result in congenital abnormalities such as lung aplasia, tracheoesophageal fistula, and congenital pulmonary cysts. The embryonic stage overlaps with the next stage: the pseudoglandular stage (5–17 weeks' gestation). During this stage the lung has a glandular appearance and witnesses the completion of the conducting airways (bronchi and bronchioles). The respiratory epithelium of these airways begins to differentiate, and the presence of cartilage, smooth muscle cells, and mucus glands are first seen. In addition, the pleuroperitoneal cavity divides into two distinct compartments. Abnormalities during this stage lead to pulmonary sequestration, cystic adenomatoid malformation, and congenital diaphragmatic hernia. The next stage witnesses the delineation of the pul-

monary acinus: the canalicular stage (16–26 weeks' gestation). During this stage alveolar type II cell differentiate, the pulmonary capillary network develops, and the alveolar type I cells closely approximate with the developing capillary network. Abnormalities of development during this stage include neonatal respiratory distress syndrome and lung hypoplasia. The next stage is the sacular stage (26–36 weeks' gestation), during which further branching of the terminal saccules takes place as well as a thinning of the interstitium and fusion of the type I cell and capillary basement membrane in preparation for the lungs' function as a gas-exchange organ. The final stage of lung development is the alveolar stage (36 weeks's gestation to 3–8 years of age). Controversy surrounds the length of this stage of lung development. This stage witnesses secondary septal formation, further sprouting of the capillary network, and the development of true alveoli. Abnormalities during this stage lead to lung hypoplasia and can result in the development of bronchopulmonary dysplasia.

At birth, the lung assumes the gas-exchanging function served by the placenta in utero, placing immediate stress on all components of the respiratory system. Abnormalities in the lung, respiratory muscles, chest wall, airway, respiratory controller, or pulmonary circulation may therefore be present at birth. Survival after delivery depends, for example, on the development of the surfactant system to maintain airway stability and allow gas exchange. Immaturity of the surfactant system, often seen in infants born at less than 35 weeks' gestational age, can result in severe respiratory morbidity in the immediate neonatal period as well as subsequent chronic lung disease. A lethal form of lung disease has recently been recognized in infants homozygous for abnormalities in the surfactant protein B gene. Persistent pulmonary hypertension of the newborn—failure of the normal transition to a low-resistance pulmonary circulation at birth—can complicate a number of neonatal respiratory diseases. There is mounting evidence that abnormalities during fetal and neonatal growth and development of the lung have long-standing effects into adulthood, such as reduced gas exchange, exercise intolerance, asthma, and an increased risk of COPD.

DIAGNOSTIC AIDS

PHYSICAL EXAMINATION OF THE RESPIRATORY TRACT

Assessing the rate, depth, ease, symmetry, and rhythm of respiration is critical to the detection of pulmonary disease. In young children, an elevated respiratory rate may be an initial indicator of pneumonia. Attention should be paid to tracheal position and thoracic configuration. Auscultation should assess the quality of breath sounds and detect the presence of abnormal sounds such as fine or coarse crackles, wheezing, or rhonchi. In older patients, unilateral crackles are the most valuable examination finding in pneumonia. Extrapulmonary manifestations of pulmonary disease include growth failure, altered mental status (from hypoxemia or hypercapnia), cyanosis, clubbing, and osteoarthropathy. In a study of children with respiratory illnesses, abnormalities of attentiveness, consolability, respiratory effort, color, and movement had a good diagnostic accuracy in detecting hypoxemia. Evidence of cor pulmonale (loud pulmonic component of the second heart sound, hepatomegaly, elevated neck veins, and, rarely, peripheral edema) signifies advanced lung disease.

Respiratory disorders can be secondary to disease in other systems. It is therefore important to look for other conditions such as congenital heart disease (murmur, gallop), neuromuscular disease (muscle wasting, scoliosis), immunodeficiency (rash, diarrhea), and autoimmune disease or occult malignancy (arthritis, hepatosplenomegaly).

Wipf JE et al: Diagnosing pneumonia by physical examination: Relevant or relic? *Arch Intern Med* 1999; 159:1082 [PMID: 10335685].

PULMONARY FUNCTION TESTS

Lung function tests can help to differentiate obstructive from restrictive lung diseases, measure disease severity,

define precipitants of symptoms, and evaluate response to therapy. They can help define the risks of anesthesia and surgery and assist in the planning of respiratory care in the postoperative period. However, the range of normal values for a test may be wide, and the predicted normal values change dramatically with growth. For this reason, serial determinations of lung function are often more informative than a single determination. Patient cooperation is essential for almost all physiologic assessments. Most children are not able to perform the necessary maneuvers before age 5 years. Lung functions in infants and toddlers are available at specialized centers. Despite these problems, tests of lung function are valuable in the care of children.

Spirometers are available on which forced vital capacity can be recorded either as a volume–time tracing (spirogram) or a flow–volume curve. The patient inhales maximally, holds his or her breath for a short period, and then exhales as fast as possible for at least 3 seconds. The tracing produced by the exhalation shows forced vital capacity (FVC), which is the total amount of air that is exhaled from maximum inspiration, and the forced expiratory volume (FEV) in the first second of the exhalation (FEV₁). The maximum midexpiratory flow rate (MMEF, or FEF_{25–75%}), is the mean flow rate during the middle portion of the FVC maneuver. The FEV₁/FVC ratio is calculated from these absolute values; a ratio greater than 0.85 in children and young adults shows unlimited normal airflow.

These basic tests of lung function differentiate obstructive from restrictive processes. Examples of obstructive processes include asthma, chronic bronchitis, and cystic fibrosis (CF); restrictive problems include chest wall deformities that limit lung expansion and interstitial processes due to collagen–vascular diseases, hypersensitivity pneumonitis, and interstitial fibrosis. Classically, diseases that obstruct airflow decrease the FEV₁ more than the FVC, so that the FEV₁/FVC ratio is low. In restrictive problems, however, the decreases in the FEV₁ and FVC are proportionate; thus, the ratio of FEV₁ to FVC is either normal or high. Clinical suspicion of a restrictive disease is usually an indication for referral to a specialist for evaluation.

The peak expiratory flow rate (PEFR), the maximal flow recorded during an FVC maneuver, can be assessed by handheld devices. The records of the PEFR can be helpful in following the course of pulmonary disorders that are difficult to control and require multiple medications (eg, asthma). These devices can also be used to give patients with poor perception of their disease an awareness of a decrease in lung function, thus facilitating earlier treatment.

ASSESSMENT OF OXYGENATION AND VENTILATION

Arterial blood gas determination defines the balance between respiration at the tissue level and that in the lungs. Assessment of blood gases is essential in critically ill children and may be used also for determining the severity of lung involvement in chronic conditions. Blood gas measurements are affected by abnormalities of respiratory control, gas exchange, respiratory mechanics, and the circulation. In pediatrics, hypoxia (low PaO₂) most commonly results from mismatching of ventilation and perfusion. Hypercapnia (elevated PaCO₂) results from inadequate alveolar ventilation, ie, inability to clear the CO₂ produced. This is termed *hypoventilation*. Causes include decreased central respiratory drive, paralysis of respiratory muscles, and low tidal volume breathing as seen in restrictive lung diseases, severe scoliosis, or chest wall trauma. Table 18-1 gives normal values for arterial pH, PaO₂, and PaCO₂ at sea level and at 5000 feet.

Exhaled or end-tidal CO₂ monitoring can be used to estimate arterial CO₂ content. It is used to monitor alveolar ventilation and is most accurate in patients without significant lung disease, particularly those with a good match of ventilation and perfusion and without airway obstruction. Exhaled or end-tidal CO₂ use has increased to confirm endotracheal tube placement and ensure endotracheal rather than esophageal intubation. This assessment is accurate in children who weigh more than 2 kg and have a perfusing rhythm. Exhaled CO₂ can be monitored by attaching a CO₂ detector to an endotracheal tube or to a nasal cannula. Qualitative CO₂ monitors use a chemical detector in a strip of paper that changes color when CO₂ is present. Capnography devices are quantitative and measure the concentration of CO₂ by infrared absorption detectors. These display continuous exhaled CO₂ concentration as a waveform and with a digital display of end-tidal CO₂.

Table 18-1. Normal arterial blood gas values on room air.

	pH	PaO ₂ (mm Hg)	PaCO ₂ (mm Hg)
Sea level	7.38–7.42	85–95	36–42
5000 feet	7.36–7.40	65–75	35–40

Transcutaneous gas monitoring is a noninvasive assessment of PaO₂ and PaCO₂ using electrodes that measure gas tension at the skin surface. Transcutaneous monitoring can underestimate the PaO₂ and overestimate the PaCO₂ unless skin perfusion is maximal. Thus heating of the skin site is required, and cardiac function should be stable.

Pulse oximetry (measuring light absorption by transilluminating the skin) is the most reliable and easiest form of noninvasive monitoring of oxygenation. Oxygenated hemoglobin absorbs red light at certain wavelengths. Measurement during a systolic pulse allows estimation of arterial oxygen saturation as the machine corrects for the light absorbed at the tissue level between pulses. No heating of the skin is necessary. Values of oxygen saturation are reliable as low as 80%. The pulse oximeter has reduced reliability during conditions causing reduced arterial pulsation such as hypothermia, hypotension, or infusion of vasoconstrictor drugs. Carbon monoxide bound by hemoglobin results in higher than actual oxygen saturation readings.

CULTURE OF MATERIAL FROM THE RESPIRATORY TRACT

Expectorated sputum is rarely available from patients younger than age 8 years. In older children, a Gram-stained smear of sputum showing significant numbers of organisms within neutrophils may identify a pathogen. Bacterial stains and cultures of nasopharyngeal secretions are frequently misleading.

Cultures from the lower respiratory tract can be obtained invasively by tracheal aspiration through an endotracheal tube or rigid bronchoscope, or by performing a bronchoalveolar lavage through a flexible bronchoscope. Sputum induction, performed by inhaling aerosolized hypertonic saline, is a relatively safe noninvasive means of obtaining lower airway secretions. Where thoracoscopic lung biopsy by a skilled operator is unavailable, lung puncture directed to an area of consolidation by computed tomography (CT) scan or fluoroscopy may be the best approach for a child who deteriorates after initial antibiotic therapy or who

is critically ill or immunocompromised. However, pneumothorax may result. Open-lung biopsy, though a major intervention, should be considered in the worsening or critically ill child when other approaches are unsuccessful. In skilled hands, thoracoscopic lung biopsy may avoid open biopsy and its potential complications. Thoracentesis should be performed when pleural fluid is present. Blood glucose and lactate dehydrogenase should be drawn simultaneously for comparison with pleural fluid levels. Blood cultures must be obtained in children with acute pneumonia.

Specimens obtained by invasive means should be tested for viruses, *Mycoplasma pneumoniae*, *Chlamydia*, *Legionella pneumophila*, *Bordetella pertussis*, fungi, *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*), acid-fast bacteria, and anaerobes or other bacteria. Rapid diagnostic techniques such as immunofluorescent antibody and enzyme-linked immunosorbent assay (ELISA) are best. Counterimmunoelectrophoresis of pleural fluid, serum, or concentrated urine may help identify disease due to *Streptococcus pneumoniae* or *Haemophilus influenzae*. Because these tests can be performed quickly, they may obviate further, more invasive studies.

Wood RE: Diagnostic and therapeutic procedures in pediatric pulmonary patients. In Taussig LM, Landau LI (eds): *Pediatric Respiratory Medicine*. Mosby, 1999.

IMAGING OF THE RESPIRATORY TRACT

The plain chest radiograph remains the foundation for investigating the pediatric thorax. Both frontal and lateral views should be obtained. The radiograph is useful for evaluating air trapping caused by airway obstruction, volume loss caused by pneumonia, and interstitial problems such as pulmonary edema. Hyperaeration is best demonstrated in lateral views as flattening of the diaphragm. It is often seen because young children commonly develop small airway obstruction and asthma. Parenchymal changes may cause increased interstitial markings, consolidation, air bronchograms, or loss of diaphragm or heart contours. When pleural fluid is suspected, lateral decubitus radiographs may be helpful in determining the extent and mobility of the fluid. When a foreign body is suspected, forced expiratory radiographs may show focal air trapping and shift of the mediastinum to the contralateral side. Lateral neck radiographs can be useful in assessing the size of adenoids and tonsils and also in differentiating croup from epiglottitis, the latter being associated with the "thumbprint" sign.

Barium swallow is indicated for patients with suspected aspiration to detect swallowing dysfunction, tracheoesophageal fistula, gastroesophageal reflux, and achalasia. This technique is also important in detecting vascular rings and slings, because most of these abnormalities compress the esophagus. Airway fluoroscopy is another important tool for assessing both fixed airway obstruction (eg, tracheal stenosis) and dynamic airway obstruction (eg, tracheomalacia). Fluoroscopy or ultrasound of the diaphragm can detect paralysis by demonstrating paradoxical movement of the involved hemidiaphragm.

High-resolution CT scanning is useful to evaluate diffuse infiltrative lung disease, metastatic disease, mediastinal masses, and chest wall disease. Characteristic patterns seen in interstitial lung disease (eg, honeycombing in pulmonary fibrosis) or airway disease (eg, bronchiectasis) are often missed on chest radiographs. Magnetic resonance imaging (MRI) is useful for defining subtle or complex abnormalities and vascular rings. Ventilation-perfusion scans can provide information about regional ventilation and perfusion and can help detect vascular malformations and pulmonary emboli (rare in children). Pulmonary angiography is occasionally necessary to define the pulmonary vascular bed more precisely.

LARYNGOSCOPY & BRONCHOSCOPY

The indications for laryngoscopy include undiagnosed hoarseness, stridor, symptoms of obstructive sleep apnea, and laryngeal wheezing consistent with a diagnosis of vocal cord dysfunction; indications for bronchoscopy include wheezing, suspected foreign body, pneumonia, atelectasis, chronic cough, hemoptysis, and placement of an endotracheal tube and assessment of patency. In general, the more specific the indication, the higher the diagnostic yield.

Pediatric bronchoscopy instruments are of either the flexible fiberoptic or the rigid open tube type. Flexible bronchoscopy has the following advantages:

1. With sedation and topical anesthetics, the procedure can be done at the bedside.

2. Evaluation of the upper airway can be done with little risk in patients who are awake.
3. The distal airways of intubated patients can be examined without removing the endotracheal tube.
4. The instrument can be used as an obturator to intubate a patient with a difficult upper airway.
5. Endotracheal tube placement and patency can be checked.
6. Assessment of airway dynamics is generally better.
7. It is possible to examine more distal airways.

Improved digital optics has greatly enhanced the image quality. The advantages of using a rigid instrument are (1) easier removal of foreign bodies (so rigid bronchoscopy is preferred for suspected foreign body aspiration); and (2) better airway control, allowing the patient to be ventilated through the bronchoscope. In addition, this approach to the airway allows better assessment of the subglottic space for stenosis. The choice of procedures depends largely on the expertise available.

Bronchoalveolar lavage through a flexible bronchoscope is used to detect infection in immunocompetent and immunocompromised children. Aspiration and hemorrhage are also suspected in the presence of lipid and hemosiderin-laden macrophages, respectively. Surfactant protein analysis of lavage fluid can also be completed. Transbronchial biopsy is used to look for infection and rejection in transplant patients and to diagnose other conditions such as sarcoidosis.

GENERAL THERAPY OF PEDIATRIC LUNG DISEASES

OXYGEN THERAPY

Oxygen therapy in children with respiratory disease can reduce the work of breathing, resulting in fewer respiratory symptoms; relax the pulmonary vasculature, lessening the potential for pulmonary hypertension and congestive heart failure; and improve feeding. Patients breathing spontaneously can be treated by nasal cannula, head hood, or mask (including simple, rebreathing, nonrebreathing, or Venturi masks). The general goal of oxygen therapy is to achieve an arterial oxygen

tension of 65–90 mm Hg or an oxygen saturation above 92%. The actual oxygen concentration achieved by nasal cannula or mask depends on the flow rate, the type of mask used, and the patient's age. Small changes in flow rate during oxygen administration by nasal cannula can lead to substantial changes in inspired oxygen concentration in young infants. The amount of oxygen required to correct hypoxemia may vary according to the child's activity. It is not unusual, for example, for an infant with chronic lung disease to require 0.75 L/min while awake but 1 L/min while asleep or feeding.

Although the head hood is an efficient device for delivery of oxygen in young infants, the nasal cannula is used more often because it allows the infant greater mobility. The cannula has nasal prongs that are inserted in the nares. Flow through the nasal cannula should generally not exceed 3 L/min to avoid excessive drying of the mucosa. Even at high flow rates, oxygen by nasal cannula rarely delivers inspired oxygen concentrations greater than 40–45%. In contrast, partial rebreathing and nonrebreathing masks or head hoods achieve inspired oxygen concentrations as high as 90–100%.

Because the physical findings of hypoxemia are subtle, the adequacy of oxygenation should be measured as the arterial oxygen tension, or oxygen saturation can be determined by oximetry. The advantages of the latter noninvasive method include the ability to obtain continuous measurements during various normal activities and to avoid artifacts caused by crying or breath holding during attempts at arterial puncture. For children with chronic cardiopulmonary disorders that may require supplemental oxygen therapy (eg, bronchopulmonary dysplasia or CF), frequent noninvasive assessments are essential to ensure the safety and adequacy of treatment.

INHALATION OF BRONCHODILATORS

Airway obstruction that is at least partially reversed by a bronchodilator can be seen in CF, bronchiolitis, and bronchopulmonary dysplasia as well as in acute and chronic asthma.

The β -adrenergic agonists may be delivered by metered-dose inhaler (MDI), dry powder inhaler, or nebulizer. MDIs are convenient and best combined with valved holding chambers, especially for children who lack the ability to coordinate actuation of the MDI

with inhalation. In contrast, the nebulizer is an effective method of delivering medication to infants and young children. Long-acting inhaled β_2 -adrenergic agents that are relatively selective for the respiratory tract are described in Chapter 34. Inhaled bronchodilators are as effective as injected agents for treating acute episodes of airway obstruction and have fewer side effects. These drugs can be safely administered at home as long as both the physician and the family realize that a poor response may signify the need for corticosteroids to help restore β -adrenergic responsiveness.

Anticholinergic agents may also acutely decrease airway obstruction. Furthermore, they may yield a longer duration of bronchodilation than do many adrenergic agents. Selected patients may benefit from receiving both β -adrenergic and anticholinergic agents. In general, this class of drugs is most effective in the treatment of chronic bronchitis.

AIRWAY CLEARANCE THERAPY

Chest physical therapy, with postural drainage, percussion, and forced expiratory maneuvers, has been widely used to improve the clearance of lower airway secretions even though there is limited data on the efficacy of these techniques.

Children with CF have been shown to benefit from routine airway clearance. Many airway clearance techniques exist, but only a few long-term studies have compared the various options. The various techniques currently available include chest physiotherapy, autogenic drainage, positive expiratory pressure (PEP, Flutter, or Acapella), intrapulmonary percussive ventilation (IPV), or high-frequency chest compression (Vest). The decision on which technique to use should be based on the patient's age and preference after trying different approaches. Often bronchodilators or mucolytic medications are given prior to or during airway clearance therapy. Inhaled corticosteroids and inhaled antibiotics should be given after airway clearance therapy so that the airways are first cleared of secretions, allowing the medications to maximally penetrate into the lung.

AVOIDANCE OF ENVIRONMENTAL HAZARDS

All parents or other caregivers should be counseled about environmental hazards to the lung. The list of potential hazards includes small objects that may be aspirated, allergens that can precipitate respiratory symptoms in atopic children, and cigarette smoke.

The harmful effects of smoking in the home deserve special emphasis. Children from families where the parents and others smoke have decreased lung growth as well as decreased pulmonary function in comparison with children raised in smoke-free homes. Exposure of children to tobacco smoke also leads to an increased frequency of lower respiratory tract infections and an increased incidence of respiratory symptoms, including recurrent wheezing. Health care providers must increase their efforts to educate patients and their families about the hazards of smoking.

DISORDERS OF THE CONDUCTING AIRWAYS

The conducting airways (the nose, mouth, pharynx, larynx, trachea, bronchi, and bronchioles) direct inspired air to the gas-exchange units of the lung; they do not participate in gas exchange themselves. Airflow obstruction in the conducting airways occurs by (1) external compression (eg, vascular ring, tumor), (2) abnormalities of the airway structure itself (eg, congenital defects, thickening of an airway wall due to inflammation), or

(3) material in the airway lumen (eg, foreign body, mucus).

Airway obstruction can be fixed (airflow limited in both the inspiratory and the expiratory phases) or variable (airflow limited more in one phase of respiration than in the other). Variable obstruction is common in children because their airways are more compliant and susceptible to dynamic compression. With variable extrathoracic airway obstruction (eg, croup), airflow limitation is greater during inspiration, leading to inspiratory stridor. With variable intrathoracic obstruction (bronchomalacia), limitation is greater during expiration, producing expiratory wheezing. Thus determining the phase of respiration in which obstruction is greatest may be helpful in localizing the site of obstruction.

EXTRATHORACIC AIRWAY OBSTRUCTION

Patients with abnormalities of the extrathoracic airway may present with snoring and other symptoms of obstructive apnea, hoarseness, brassy cough, or stridor. The course of the illness may be acute (eg, infectious croup), recurrent (eg, spasmodic croup), chronic (eg, subglottic stenosis), or progressive (eg, laryngeal papillomatosis). Significant risk factors are difficult delivery, ductal ligation, and intubation. Examination should determine if obstructive symptoms are present at rest or with agitation, if they are positional, or if they are related to sleep. The presence of agitation, air hunger, severe retractions, cyanosis, lethargy, or coma should alert the physician to a potentially life-threatening condition that may require immediate airway intervention. Helpful diagnostic studies in the evaluation of upper airway obstruction include chest and lateral neck radiographs, airway fluoroscopy, and barium swallow. In patients who have symptoms of severe chronic obstruction, an electrocardiogram (ECG) should be obtained to evaluate for right ventricular hypertrophy and pulmonary hypertension. Patients with obstructive sleep apnea should have polysomnography (measurements during sleep of the motion of the chest wall, airflow at the nose and mouth, heart rate, oxygen saturation, and selected electroencephalographic leads to stage sleep) to determine severity and to evaluate the need for tonsillectomy and adenoidectomy, oxygen, or continuous positive airway pressure (CPAP). In older children, pulmonary function tests can differentiate fixed from variable airflow obstruction and identify the site of variable obstruction. If noninvasive studies are unable to establish the cause, direct laryngoscopy and bronchoscopy remain the procedures of choice to establish the precise diagnosis. Treatment should be directed at relieving airway obstruction and correcting the underlying condition if possible.

Leung AK, Cho H: Diagnosis of stridor in children. *Am Fam Physician* 1999;60:2289 [PMID:10593320].

INTRATHORACIC AIRWAY OBSTRUCTION

Intrathoracic airway obstruction usually causes expiratory wheezing. The history should include the following:

1. Age at onset
2. Precipitating factors (eg, exercise, upper respiratory illnesses, allergens, choking while eating)
3. Course—acute (bronchiolitis, foreign body), chronic (tracheomalacia, vascular ring), recurrent (reactive airways disease), or progressive (CF, bronchiolitis obliterans)
4. Presence and nature of cough
5. Production of sputum
6. Previous response to bronchodilators
7. Symptoms with positional changes (vascular rings)
8. Involvement of other organ systems (malabsorption in CF)

Physical examination should include growth measurements and vital signs. The examiner should look for cyanosis or pallor, barrel-shaped chest, retractions and use of accessory muscles, and clubbing. Auscultation should define the pattern and timing of respiration, detect the presence of crackles and wheezing, and determine whether findings are localized or generalized.

Routine tests include plain chest radiographs, a sweat test, and pulmonary function tests in older children. Other diagnostic studies are dictated by the history and physical findings. Treatment should be directed toward the primary cause of the obstruction but generally includes a trial of bronchodilators.

CONGENITAL DISORDERS OF THE EXTRATHORACIC AIRWAY

LARYNGOMALACIA

Laryngomalacia is a benign congenital disorder in which the cartilaginous support for the supraglottic structures is underdeveloped. It is the most common cause of persistent stridor in infants and usually is seen in the first 6 weeks of life. Stridor has been reported to be worse in the supine position, with increased activity, with upper respiratory infections, and during feeding; however, the clinical presentation can be variable. Patients may have slight oxygen desaturation during sleep.

Gastroesophageal reflux may also be associated with laryngomalacia requiring treatment. The condition usually improves with age and resolves by age 2 years, but in some cases symptoms persist for years. The diagnosis is established by direct laryngoscopy, which shows inspiratory collapse of an omega-shaped epiglottis (with or without long, redundant arytenoids). In mildly affected patients with a typical presentation (those without stridor at rest or retractions), this procedure may not be necessary. No treatment is usually needed. However, in patients with severe symptoms of airway obstruction associated with feeding difficulties, failure to thrive, obstructive sleep apnea, or severe dyspnea, surgical epiglottoplasty may be necessary.

Olney DR et al: Laryngomalacia and its treatment. *Laryngoscope* 1999;109:1770 [PMID: 10569405].

Toynnton SC et al: Aryepiglottoplasty for laryngomalacia: 100 consecutive cases. *J Laryngol Otol* 2001;115:35 [PMID: 11233619].

OTHER CONGENITAL PROBLEMS

Other rare congenital lesions of the larynx (laryngeal atresia, laryngeal web, laryngocele and cyst of the larynx, subglottic hemangioma, and laryngeal cleft) are best evaluated by direct laryngoscopy. Laryngeal atresia obviously presents immediately after birth with severe respiratory distress and is usually fatal. Laryngeal web, representing fusion of the anterior portion of the true vocal cords, is associated with hoarseness, aphonia, and stridor. Surgical correction may be necessary depending on the degree of airway obstruction.

Congenital cysts and laryngoceles are believed to have similar origin. Cysts are more superficial, whereas laryngoceles communicate with the interior of the larynx. Cysts are generally fluid-filled, whereas laryngoceles may be air- or fluid-filled. Airway obstruction is usually prominent and requires surgery or laser therapy.

Subglottic hemangiomas are seen in infancy with signs of upper airway obstruction and are often (but not always) associated with similar lesions of the skin. Although these lesions tend to regress spontaneously, airway obstruction may require laser surgical treatment or even tracheostomy.

Laryngeal cleft is a very rare condition resulting from failure of posterior cricoid fusion. Patients with this condition may have stridor but always aspirate severely, resulting in recurrent or chronic pneumonia and failure to thrive. Barium swallow is always positive for severe aspiration, but diagnosis can be very difficult even with direct laryngoscopy. Patients often require tracheostomy and gastrostomy, because surgical correction is not always successful.

Sichel JY et al: Management of congenital laryngeal malformations. *Am J Otolaryngol* 2000;21:22 [PMID: 10668673].

ACQUIRED DISORDERS OF THE EXTRATHORACIC AIRWAY

CROUP SYNDROME

Croup describes acute inflammatory diseases of the larynx, including viral croup (laryngotracheobronchitis), epiglottitis (supraglottitis), and bacterial tracheitis. These are the main entities in the differential diagnosis for patients presenting with acute stridor, although spasmodic croup, angioneurotic edema, laryngeal or esophageal foreign body, and retropharyngeal abscess should be considered as well.

1. Viral Croup

Viral croup generally affects younger children in the fall and early winter months and is most often caused by parainfluenza virus serotypes. Other organisms causing croup include respiratory syncytial virus (RSV), influenza virus, rubeola virus, adenovirus, and *Mycoplasma pneumoniae*. Although inflammation of the entire airway is usually present, edema formation in the subglottic space accounts for the predominant signs of upper airway obstruction.

Clinical Findings

A. SYMPTOMS AND SIGNS

Usually a prodrome of upper respiratory tract symptoms is followed by a barking cough and stridor. Fever is usually absent or low-grade but may on occasion be as high as in patients with epiglottitis. Patients with mild disease may have stridor when agitated. As obstruction worsens, stridor occurs at rest, accompanied in severe cases by retractions, air hunger, and cyanosis. On examination, the presence of cough and the absence of drooling favor the diagnosis of viral croup over epiglottitis.

B. IMAGING

Lateral neck radiographs can be diagnostically helpful by showing subglottic narrowing and a normal epiglottis. This is not done routinely in the child with a classic presentation.

Treatment

Treatment of viral croup is based on the symptoms. Mild croup, signified by a barking cough and no stridor at rest, requires supportive therapy with oral hydration and minimal handling. Mist therapy is used by some physicians, although clinical studies demonstrating its effectiveness are lacking. Conversely, patients with stridor at rest require active intervention. Oxygen should be administered to patients with oxygen desaturation. Nebulized racemic epinephrine (2.25% solution; 0.05 mL/kg to a maximum of 1.5 mL diluted in sterile saline) is commonly used because it has a rapid onset of action within 10–30 minutes. Both racemic epinephrine and epinephrine hydrochloride are effective in alleviating symptoms and decreasing the need for intubation. Once controversial, the efficacy of glucocorticoids in croup is now more firmly established. Dexamethasone, 0.6 mg/kg intramuscularly as one dose, improves symptoms, reduces the duration of hospitalizations and frequency of intubations, and permits earlier discharge from the emergency room. Oral dexamethasone appears equally effective, and limited data suggest that lower doses of oral dexamethasone (0.15 mg/kg) may be as effective as the higher dose. Inhaled budesonide (2–4 mg) also improves symptoms and decreases hospital stay. Onset of action occurs within 2 hours, and this agent may be as effective as dexamethasone; however, dexamethasone is still the most cost-effective steroid of choice. If symptoms resolve within 3 hours of glucocorticoids and nebulized epinephrine, patients can safely be discharged without fear of a sudden rebound in symptoms. If, however, recurrent nebulized epinephrine treatments are required or if respiratory distress persists, patients require hospitalization for close observation, supportive care, and nebulization treatments as needed. In patients with impending respiratory failure, an airway must be established (see following paragraph). Hospitalized patients with persistent symptoms over 3–4 days despite treatment should arouse suspicion of another cause of airway obstruction.

Patients with impending respiratory failure require an artificial airway. Intubation with an endotracheal tube of slightly smaller diameter than would ordinarily be used is reasonably safe. Extubation should be accomplished within 2–3 days to minimize the risk of laryngeal injury. If the patient fails extubation, tracheostomy may be required.

Prognosis

Most children with viral croup have an uneventful course and improve within a few days. Some evidence suggests that patients with a history of croup associated with wheezing may have airway hyperreactivity, but it

has not been determined if this was present prior to the croup episode or if the croup episode itself altered airway function. Recurrence of croup occurs in some instances, implying airway hyperreactivity.

Castro-Rodriguez JA et al: Relation of two different subtypes of croup before age three to wheezing, atopy, and pulmonary function during childhood: A prospective study. *Pediatrics* 2001;170:512 [PMID: 11230591].

Stroud RH, Friedman NR: An update on inflammatory disorders of the pediatric airway: Epiglottitis, croup, and tracheitis. *Am J Otolaryngol* 2001;22:268 [PMID: 11264324].

Wright RB et al: New approaches to respiratory infections in children: Bronchiolitis and croup. *Emerg Med Clin North Am* 2002;20:93 [PMID: 11826639].

2. Epiglottitis

Epiglottitis is a true medical emergency. In published case series, it is almost always caused by *Haemophilus influenzae* type B, although other organisms such as nontypable *H influenzae*, *Streptococcus pneumoniae*, groups A and C *Streptococcus pyogenes*, *Neisseria meningitidis*, and staphylococci have been implicated. Resulting inflammation and swelling of the supraglottic structures (epiglottis and arytenoids) can develop rapidly and lead to life-threatening upper airway obstruction. The incidence has decreased dramatically since *H influenzae* conjugate vaccine was introduced.

Clinical Findings

A. SYMPTOMS AND SIGNS

Typically, patients present with a sudden onset of fever, dysphagia, drooling, muffled voice, inspiratory retractions, cyanosis, and soft stridor. They often sit in the so-called sniffing dog position, which gives them the best airway possible under the circumstances. Progression to total airway obstruction may occur and result in respiratory arrest. The definitive diagnosis is made by direct inspection of the epiglottis, a procedure that should be done by an experienced airway specialist under controlled conditions (usually the operating room). The typical findings are cherry-red and swollen epiglottis and arytenoids.

B. IMAGING

Diagnostically, lateral neck radiographs may be helpful in demonstrating a classic “thumbprint” sign. Obtaining radiographs, however, may delay important airway intervention.

Treatment

Once the diagnosis of epiglottitis is made, endotracheal intubation must be performed immediately. Most anes-

thysiologists prefer general anesthesia (but not muscle relaxants) to facilitate intubation. After an airway is established, cultures of the blood and epiglottis should be obtained and the patient started on appropriate intravenous antibiotics to cover *H influenzae* (ceftriaxone sodium or equivalent cephalosporin). Extubation can usually be accomplished in 24–48 hours, when direct inspection shows significant reduction in the size of the epiglottis. Intravenous antibiotics should be continued for 2–3 days, followed by oral antibiotics to complete a 10-day course.

If a physician who has little experience in treating airway disorders and is located far from a pediatric care facility encounters a patient with epiglottitis, the following is recommended. Start the patient on oxygen and assemble all the airway equipment available. Manipulate the patient as little as possible, and allow the child to remain sitting up. Enlist the help of the most experienced airway person available, or call a transport team. Start an intravenous line and give antibiotics. If the patient obstructs completely and experiences respiratory arrest, attempt to establish an airway by any means possible: bag and mask ventilation, intubation, transtracheal ventilation with a large-bore angiocatheter attached to a 3-mm endotracheal tube adapter and resuscitation bag, or tracheostomy.

Prognosis

Prompt recognition and appropriate treatment usually results in rapid resolution of swelling and inflammation. Recurrence is unusual.

Levy RJ, Helforr MA: Pediatric airway issues. *Crit Care Clin* 2000;16:489 [PMID: 10941587].

Rotta AT, Wiryawan B: Respiratory emergencies in children. *Respir Care* 2003;48:248 [PMID: 12667275].

3. Bacterial Tracheitis

Bacterial tracheitis (pseudomembranous croup) is a severe form of laryngotracheobronchitis. The organism most often isolated is *Staphylococcus aureus*, but organisms such as *H influenzae*, group A *Streptococcus pyogenes*, *Neisseria* species, *Moraxella catarrhalis*, and others have been reported. The disease probably represents localized mucosal invasion of bacteria in patients with primary viral croup, resulting in inflammatory edema, purulent secretions, and pseudomembranes. Although cultures of the tracheal secretions are frequently positive, blood cultures are almost always negative.

Clinical Findings

A. SYMPTOMS AND SIGNS

The early clinical picture is similar to that of viral croup. However, instead of gradual improvement, pa-

tients develop high fever, toxicity, and progressive upper airway obstruction that is unresponsive to standard croup therapy. The incidence of sudden respiratory arrest or progressive respiratory failure is high; in such instances, airway intervention is required. Findings of toxic shock and the acute respiratory distress syndrome (ARDS) may also be seen.

B. LABORATORY FINDINGS

The white cell count is usually elevated, with left shift. Cultures of tracheal secretions usually demonstrate one of the causative organisms.

C. DIAGNOSIS

Lateral neck radiographs show a normal epiglottis but often severe subglottic and tracheal narrowing. Irregularity of the contour of the proximal tracheal mucosa can frequently be seen radiographically. Bronchoscopy showing a normal epiglottis and the presence of copious purulent tracheal secretions confirm the diagnosis.

Treatment

Suspected bacterial tracheitis should be managed in a fashion similar to that for epiglottitis. Because the incidence of respiratory arrest or progressive respiratory failure is high, intubation is usually necessary. Because these patients often have thick, purulent tracheal secretions, humidification, frequent suctioning, and intensive care monitoring are required to prevent endotracheal tube obstruction. Intravenous antibiotics to cover *Staphylococcus aureus*, *H influenzae*, and the other organisms are indicated. Because thick secretions persist for several days, the required period of intubation is longer for bacterial tracheitis than for epiglottitis. Despite the severity of this illness, the reported mortality rate is very low.

VOCAL CORD PARALYSIS

Unilateral or bilateral vocal cord paralysis may be congenital or, more commonly, may result from injury to the recurrent laryngeal nerves. Risk factors for acquired paralysis include difficult delivery (especially face presentation), neck and thoracic surgery (eg, ductal ligation, repair of tracheoesophageal fistula), trauma, mediastinal masses, pulmonary hypertension, and central nervous system (CNS) disease (eg, Arnold–Chiari mal-

formation). Patients usually present with varying degrees of hoarseness, aspiration, or high-pitched stridor. Unilateral cord paralysis is more likely to occur on the left because of the longer course of the left recurrent laryngeal nerve and its proximity to major thoracic structures. Patients with unilateral paralysis are usually hoarse but rarely have stridor. With bilateral cord paralysis, the closer to midline the cords are positioned, the greater the airway obstruction; the more lateral the cords are positioned, the greater the tendency to aspirate and experience hoarseness or aphonia. If partial function is preserved (paresis), the adductor muscles tend to operate better than the abductors, with a resultant high-pitched inspiratory stridor and normal voice. Airway intervention (intubation, tracheostomy) is rarely indicated in unilateral paralysis but is often necessary for bilateral paralysis. Recovery is related to the severity of nerve injury and the potential for healing.

Portier F et al: Respiratory obstruction as a sign of brainstem dysfunction in infants with Chiari malformations. *Int J Pediatr Otorhinolaryngol* 2001;57:195 [PMID: 11223451].

SUBGLOTTIC STENOSIS

Subglottic stenosis may be congenital or, more commonly, may result from endotracheal intubation. Neonates and infants are particularly vulnerable to subglottic injury from intubation: The subglottis is the narrowest part of an infant's airway, and the cricoid cartilage, which supports the subglottis, is the only cartilage that completely encircles the airway. The clinical presentation may vary from totally asymptomatic to the typical picture of severe upper airway obstruction. Patients with signs of stridor who repeatedly fail extubation are likely to have subglottic stenosis. Subglottic stenosis should also be suspected in children with multiple, prolonged, or severe episodes of croup. As with other conditions, diagnosis is made by direct laryngoscopy and bronchoscopy. Tracheostomy is often required when airway compromise is severe. Surgical intervention is ultimately required to correct the stenosis. Depending on the type of stenosis, a cricoid split in which the cricoid cartilage is surgically opened (better for acquired than for congenital lesions) may be tried. Laryngotracheal reconstruction in which a cartilage graft from another source (eg, rib) is used to expand the airway has become the standard procedure for symptomatic subglottic stenosis in children.

Walner DL et al: Neonatal subglottic stenosis—incidence and trends. *Laryngoscope* 2001;111:48 [PMID: 11192899].

LARYNGEAL TRAUMA

Injury to the larynx may result from external trauma, such as automobile accidents, snowmobile accidents (clothesline injury), and hanging; or internal trauma, such as noxious inhalation (burns and caustic substances) and intubation. External trauma can cause laryngeal fracture, which requires an emergency tracheostomy to prevent death. After appropriate airway intervention, attention should be directed to debridement and closure of lacerations. Reduction of laryngeal fractures should be performed as soon as the patient is stabilized.

Jewett BS et al: External laryngeal trauma: Analysis of 392 patients. *Arch Otolaryngol Head Neck Surg* 1999;125:87 [PMID: 10448735].

LARYNGEAL PAPILLOMATOSIS

Papillomas of the larynx are benign, warty growths that are difficult to treat and are the most common laryngeal neoplasm in children. Human papillomaviruses 6, 11, and 16 have been implicated as causative agents. A substantial percentage of mothers of patients with laryngeal papillomas have a history of genital condylomas at the time of delivery, so the virus may be acquired during passage through an infected birth canal.

The age at onset is usually 2–4 years, but juvenile-onset recurrent respiratory papillomatosis is well documented. A younger age of onset may be a worse prognostic indicator. Patients usually develop hoarseness, voice changes, croupy cough, or stridor that can lead to life-threatening airway obstruction. Diagnosis is by direct laryngoscopy. The larynx was involved at the time of diagnosis in over 95% of patients, most of whom had only one site involved.

Treatment is directed toward relieving airway obstruction, usually by surgical removal of the lesions. Tracheostomy is necessary when life-threatening obstruction or respiratory arrest occurs. Various surgical procedures (laser, cup forceps, cryosurgery) have been used to remove papillomas, but recurrences are the rule, and frequent reoperation may be needed. The lesions occasionally spread down the trachea and bronchi, making surgical removal more difficult. The use of interferon therapy remains controversial. Fortunately, spontaneous remissions do occur, usually by puberty, so that the goal of therapy is to maintain an adequate airway until remission occurs.

CONGENITAL DISORDERS OF THE INTRATHORACIC AIRWAYS

MALACIA OF AIRWAYS

Tracheomalacia or bronchomalacia exists when the cartilaginous framework of the airway is inadequate to maintain airway patency. Because cartilage of the infant airway is normally soft, all infants may have some degree of dynamic collapse of a central airway when pressure outside the airway exceeds intraluminal pressure. In tracheomalacia, whether congenital or acquired, dynamic collapse leads to airway obstruction. The congenital variety may be isolated or associated with another developmental defect, such as tracheoesophageal fistula or vascular ring. It may be localized to part of the trachea or, more commonly, may involve the entire trachea as well as the remainder of the conducting airways. In severe cases, cartilage in the involved area may be missing or underdeveloped. The acquired variety has been associated with long-term ventilation of premature newborns that results in chronic tracheal injury.

Patients present with coarse wheezing, a prolonged expiratory phase, and a croupy cough, all of which increase with agitation and upper respiratory tract infections. Diagnosis can be made by cinefluoroscopy or bronchoscopy. Barium swallow may be indicated to rule out coexisting conditions. No treatment is usually indicated for the isolated condition, which generally improves over time. Coexisting lesions such as tracheoesophageal fistulas and vascular rings need primary repair. In severe cases of tracheomalacia, intubation or tracheostomy may be necessary, but this procedure alone is seldom satisfactory because airway collapse continues to exist below the tip of the artificial airway. CPAP through an artificial airway can sometimes stabilize the collapsing airway. When conventional therapy fails, surgical approaches to the problem (tracheopexy, aortopexy, placement of stents) may be considered.

VASCULAR RINGS & SLINGS

The most common vascular anomalies to compress the trachea or esophagus are a double aortic arch, right aortic arch with left ligamentum arteriosum or patent ductus arteriosus, pulmonary sling, anomalous innominate or left carotid artery, and aberrant right subclavian artery. All but the latter can cause tracheal compression and present in infancy with symptoms of chronic airway obstruction (stridor, coarse wheezing, and croupy cough). Symptoms are often worse in the supine position. Respiratory compromise is most severe with double aortic arch and may lead to apnea, respiratory arrest, or even death. Esophageal compression, present in all but anomalous innominate or carotid artery, may result in feeding difficulties, including dysphagia and vomiting. Barium swallow showing esophageal compression is the mainstay of diagnosis. An anomalous innominate or carotid artery is best diagnosed by cinefluoroscopy, MRI, or bronchoscopy.

Patients with significant symptoms require surgical correction, especially those with double aortic arch. Controversy exists about whether angiography is necessary to define the anatomy prior to surgery. Patients usually improve following correction but may have persistent but milder symptoms of airway obstruction due to associated tracheomalacia.

BRONCHOGENIC CYSTS

Bronchogenic cysts generally occur in the mid mediastinum (see Mediastinal Masses section) near the carina and adjacent to the major bronchi but can be found elsewhere in the lung. They range in size from 2 to 10 cm. Cyst walls are thick and may contain pus, mucus, or blood. These cysts develop from abnormal lung budding of the primitive foregut. They do not contain distal lung parenchyma and generally do not communicate with the airway.

Clinically, respiratory distress can appear acutely in early childhood or present as chronic wheezing, chronic cough, tachypnea, recurrent pneumonia, or stridor, depending on the location and size of the cysts and the degree of airway compression. On examination, the trachea may deviate from the midline, and the percussion

noted over involved lobes may be hyperresonant. Breath sounds over such areas will also be decreased. The chest radiograph shows air trapping and hyperinflation of the affected lobes. Smaller lesions or those detected early may not be seen on chest radiographs or may appear spherical. Initial assessment of a suspected bronchogenic cyst usually includes barium swallow to look for a mass. This study also helps determine whether the lesion communicates with the gastrointestinal tract. CT scans or ultrasonography can differentiate solid versus cystic mediastinal masses and define the cyst's relationship to the rest of the lung.

Treatment is by surgical resection. Postoperatively, vigorous pulmonary physiotherapy is required to prevent complications (atelectasis, infection of lung distal to the site of resection of the cyst).

ACQUIRED DISORDERS OF THE INTRATHORACIC AIRWAYS

FOREIGN BODY ASPIRATION

Aspiration of a foreign body into the respiratory tract is rarely observed, so it is the abrupt onset of cough, choking, or wheezing—especially in children who have access to high-risk objects such as peanuts, hard candy, and small toys—that suggests the diagnosis. Children age 6 months to 4 years are at highest risk, and many deaths are caused by respiratory obstruction each year.

1. Foreign Bodies in the Upper Respiratory Tract

The diagnosis is established by acute onset of cyanosis and choking along with inability to vocalize or cough (complete obstruction) or with drooling and stridor (partial obstruction).

Foreign bodies that lodge in the esophagus may compress the airway and cause respiratory distress. More typically, the foreign body lodges in the supraglottic airway, triggering protective reflexes that result in laryngospasm. Onset is generally abrupt, with a history of the child's running with food in his or her mouth or playing with seeds, small coins, toys, and the

like. Poor child-proofing in the home and cases in which an older sibling feeds age-inappropriate foods (eg, peanuts, hard candy, carrot slices) to the younger child are typical. If the obstruction is only partial, coughing, stridor, and the ability to vocalize may persist. If complete, an inability to cough or vocalize (aphonia) and cyanosis with marked distress are observed. Without treatment, progressive cyanosis, loss of consciousness, seizures, bradycardia, and cardiopulmonary arrest follow.

Treatment

The emergency treatment of upper airway obstruction due to foreign body aspiration is somewhat controversial. In general, it is recommended that if partial obstruction is present, children should be allowed to use their own cough reflex to extrude the foreign body. If after a brief observation period, the obstruction increases or the airway becomes completely obstructed, acute intervention is required. The American Academy of Pediatrics and the American Heart Association distinguish between children younger than and older than age 1 year. A choking infant younger than age 1 year should be placed face-down over the rescuer's arm, with the head positioned below the trunk. Five measured back blows are delivered rapidly between the infant's scapulas with the heel of the rescuer's hand. If obstruction persists, the infant should be rolled over and five rapid chest compressions performed (similar to cardiopulmonary resuscitation). This sequence is repeated until the obstruction is relieved. In children older than age 1 year, abdominal thrusts (Heimlich maneuver) may be performed, with special care in younger children because of concern about possible intraabdominal organ injury.

In both groups, blind probing of the airway to dislodge a foreign body is discouraged because of the risk of impaction. The airway may be opened by jaw thrust, and if the foreign body can be directly visualized, careful removal with the fingers or instruments (Magill forceps) can be attempted. Patients with persistent apnea and inability to achieve adequate ventilation may require emergency intubation, tracheostomy, or needle cricothyrotomy, depending on the setting and the rescuer's skills.

2. Foreign Bodies in the Lower Respiratory Tract

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of coughing, wheezing, or respiratory distress.
- Asymmetrical physical findings of decreased breath sounds or localized wheezing.
- Asymmetrical radiographic findings, especially with forced expiratory view.

Clinical Findings

A. SYMPTOMS AND SIGNS

Respiratory symptoms and signs vary depending on the site of obstruction and the duration following the acute episode. For example, a large or central airway obstruction may cause marked distress. The acute cough or wheezing caused by a foreign body in the lower respiratory tract may diminish over time only to recur later and present as chronic cough or persistent wheezing. Foreign body aspiration should be suspected in children with chronic cough, persistent wheezing, or recurrent pneumonia. Long-standing foreign bodies may lead to bronchiectasis or lung abscess. Hearing asymmetrical breath sounds or localized wheezing also suggests a foreign body.

B. IMAGING

Inspiratory and forced expiratory (obtained by manually compressing the abdomen during expiration) chest radiographs should be obtained if foreign body aspiration is suspected. The initial inspiratory view may show localized hyperinflation due to the ball-valve effect of the foreign body, causing distal air trapping. A positive forced expiratory study shows a mediastinal shift away from the affected side. If airway obstruction is complete, atelectasis and related volume loss will be the major radiologic findings. Chest fluoroscopy is an alternative approach for detecting air trapping and mediastinal shift.

Treatment

If the imaging is positive or if, despite negative imaging, clinical suspicion persists, a bronchoscopy is indicated. Rigid bronchoscopy under general anesthesia is recommended. Flexible bronchoscopy may be helpful for follow-up evaluations (after the foreign object has been removed).

Children with suspected acute foreign body aspiration should be admitted to the hospital for evaluation and treatment. Chest postural drainage is no longer recommended because the foreign body may become dislodged and obstruct a major central airway. Bronchoscopy should not be delayed in children with respiratory distress but should be performed as soon as the diagnosis is made—even in children with more chronic symptoms. Following the removal of the foreign body, β -adrenergic nebulization treatments followed by chest physiotherapy are recommended to help clear related mucus or bronchospasm. Failure to identify a foreign body in the lower respiratory tract can result in bronchiectasis and lung abscess. This risk justifies an aggressive approach to suspected foreign bodies in suspicious cases.

BRONCHITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cough that usually progresses from dry to productive.
- Rhonchi heard on auscultation.

General Considerations

Bronchitis is inflammation of the major conducting airways within the lung and is unusual as an isolated entity in children. However, inflammation within this section of the airways commonly occurs in viral lower respiratory tract infections, on exposure to environmental irritants including tobacco smoke, and in association

with other disease entities such as CF or primary ciliary dyskinesia. In adults, the diagnosis of chronic bronchitis is based on a history of at least 3 months of productive cough occurring for 2 or more years, but no generally acceptable criteria for this diagnosis exist in children.

Clinical Findings

A. SYMPTOMS AND SIGNS

Acute bronchitis usually begins as a nonproductive cough that may be associated with other features of an upper respiratory illness of viral origin. The longer the cough persists, the more likely it is to become productive. In general, children with uncomplicated acute bronchitis appear nontoxic, and fever, if present, is low-grade. Diffuse rhonchi are heard on auscultation. In uncomplicated acute bronchitis, mucus production decreases, and the cough disappears over a period of 7–10 days.

B. LABORATORY FINDINGS

The white blood count is usually normal and, if elevated, may suggest a viral infection. Pulmonary function tests may reveal variable degrees of airway obstruction.

C. IMAGING

Radiographic examination of the chest may be normal or may show a mild increase in bronchovascular markings.

Differential Diagnosis

Most attacks of acute bronchitis are caused by viral infections. Certain viral pathogens (eg, adenovirus) can produce a more severe clinical picture that resembles a pertussis-like illness. Bacteria that may produce disease in which bronchitis is a prominent symptom include *Bordetella pertussis*, *Mycobacterium tuberculosis*, *Corynebacterium diphtheriae*, and *Mycoplasma pneumoniae*.

Noninfectious diseases need to be considered in the evaluation of acute bronchitis that differs from the clinical picture described earlier and in cases of chronic or recurrent bronchitis. Asthma may present as a persistent cough with little or no wheezing. Sinus infections may provide a source of persistent irritation to the respiratory tract and lead to a chronic cough. CF, an immunodeficiency, or primary ciliary dyskinesia must also be considered if the bronchitis persists or recurs and if bronchiectasis is present or suspected. In the younger child, respiratory tract anomalies, foreign bodies, and recurrent aspiration must also be considered. Tobacco or marijuana smoking may contribute to this process in

older children. In patients of all ages, the potential role of irritants within the environment must also be evaluated.

Complications

In otherwise healthy children, complications of acute bronchitis are extremely uncommon. If persistent, bronchiectasis, an irreversible dilatation and destruction of the bronchial walls, can result.

Treatment

When bronchitis is secondary to an uncomplicated acute viral infection, supportive therapy is all that is necessary. Expectorants and cough suppressants, though commonly used, are seldom indicated. Avoidance of irritants during the viral infection may also decrease symptoms and morbidity. Antibiotics are indicated if a bacterial infection of the airway is suspected or proven.

BRONCHIOLITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Clinical syndrome characterized by coughing, tachypnea, labored breathing, and/or hypoxia.
- Irritability, poor feeding, vomiting.
- Wheezing and crackles on chest auscultation.

Bronchiolitis is the most common serious acute respiratory illness in infants and young children. One to three percent of infants with bronchiolitis will require hospitalization, especially during the winter months. The typical presentation is acute onset of tachypnea, cough, rhinorrhea, and expiratory wheezing. Respiratory syncytial virus (RSV) is by far the most common pathogen; parainfluenza and influenza viruses, adenovirus, *Mycoplasma*, *Chlamydia*, *Ureaplasma*, and *Pneumocystis* are less common causes of bronchiolitis during early infancy. Major concerns include not only the acute effects of bronchiolitis but also the possible development of

chronic airway hyperreactivity (asthma). Bronchiolitis due to RSV infection contributes substantially to morbidity and mortality in children with underlying medical disorders, including chronic lung disease of prematurity, CF, congenital heart disease, and immunodeficiency.

Clinical Findings

A. SYMPTOMS AND SIGNS

The usual course of RSV bronchiolitis is 1–2 days of fever, rhinorrhea, and cough, followed by wheezing, tachypnea, and respiratory distress. Typically the breathing pattern is shallow, with rapid respirations. Nasal flaring, cyanosis, retractions, and rales may be present, along with prolongation of the expiratory phase and wheezing, depending on the severity of illness. Some young infants present with apnea and few findings on auscultation but may subsequently develop rales, rhonchi, and expiratory wheezing.

B. LABORATORY FINDINGS

The peripheral white blood cell count may be normal or may show a mild lymphocytosis.

C. IMAGING

Chest radiographic findings typically include hyperinflation with mild interstitial infiltrates, but segmental atelectasis is common.

Prevention & Treatment

The most effective prevention against RSV infection is to use proper hand-washing techniques and to reduce exposure to potential environmental risk factors. Major challenges have impeded the development of an RSV vaccine, but a licensed product may be expected in the near future. Prophylaxis with a monoclonal antibody (palivizumab or Synagis) has proven effective in reducing the rate of hospitalization in high-risk premature infants and those with chronic cardiopulmonary conditions.

Although most children with RSV bronchiolitis are readily treated as outpatients, hospitalization is frequently required in young infants (younger than 6 months of age) and in patients with hypoxemia on room air, a history of apnea, moderate tachypnea with feeding difficulties, marked respiratory distress with retractions, or underlying chronic cardiopulmonary disorders. Supportive strategies including frequent suctioning and providing adequate fluids to maintain hydration form the mainstays of treatment for bronchiolitis. If hypoxemia is present, supplemental oxygen should be administered. Although bronchodilators and corticosteroids may attenuate airway obstruction, their

use remains controversial and empiric, and patients should be assessed individually to determine responsiveness.

In immunocompromised patients, especially bone marrow transplant recipients, a combination of RSV intravenous immune globulin (RSV-IVIG) and the antiviral ribavirin has been tried. Therapy for RSV, however, remains limited, controversial, and mostly supportive.

Prognosis

The prognosis for the majority of infants with acute bronchiolitis is very good. With improved supportive care and prophylaxis with palivizumab, the mortality rate among high-risk infants has decreased substantially.

BRONCHIECTASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Chronic cough with sputum production.*
- *Rhonchi and/or wheezes on chest auscultation.*
- *Diagnosis confirmed by high-resolution CT scan.*

General Considerations

Bronchiectasis is the permanent dilatation of bronchi. The dilation may be regular, with the airway continuing to have a smooth outline (cylindric bronchiectasis); irregular, with areas of dilation and constriction (varicose bronchiectasis); or marked, with destruction of structural components of the airway wall (saccular or cystic bronchiectasis).

Bronchiectasis results from airway obstruction by retained mucus secretions or inflammation in response to chronic or repeated infection. It occurs either as a consequence of a preceding illness (severe pneumonia or foreign body aspiration) or as a manifestation of an underlying systemic disorder (CF or primary ciliary dyskinesia).

Clinical Findings

A. SYMPTOMS AND SIGNS

Persons with bronchiectasis will typically have chronic cough, purulent sputum, fever, and weight loss. Recurrent respiratory infections and dyspnea on exertion are also common. Some children present with recurrent fevers. Hemoptysis occurs less frequently in children than in adults with bronchiectasis. On physical examination, finger clubbing may be seen, and there may be evidence of sinusitis. Persistent moist rales, rhonchi, and decreased air entry are often noted over the bronchiectatic area when saccular changes are present.

B. LABORATORY FINDINGS AND IMAGING

Cultures from the lower respiratory tract usually reveal normal oropharyngeal flora. These include *Streptococcus pneumoniae*, *Staphylococcus aureus*, and nontypable *H influenzae*. *Pseudomonas aeruginosa* can also be found in children with bronchiectasis, even in those without CF.

Chest radiographs may be mildly abnormal with slightly increased bronchovascular markings or areas of atelectasis, or they may demonstrate cystic changes in one or more areas of the lung. The extent of bronchiectasis is best defined by high-resolution CT scan of the lung, which often reveals far wider involvement of lung than expected from the plain chest radiograph. Contrast bronchography is rarely performed today.

Pulmonary function testing often reveals an obstructive pattern even in the absence of asthma, CF, or other disease processes leading to airway obstruction. Evaluation of lung function after use of a bronchodilator is helpful in assessing the benefit a patient may have from bronchodilators. Serial assessments of lung function help define the progression or resolution of the disease.

Differential Diagnosis

Bronchiectasis has numerous causes. It can occur following severe respiratory tract infections by bacteria (*Bordetella pertussis*), viruses (adenovirus), or other organisms (*Mycobacterium tuberculosis*). Bronchiectasis is commonly seen in patients with CF, immunodeficiency, rheumatic conditions, and primary ciliary dyskinesia. Other diagnostic considerations include foreign body aspiration, chronic aspiration of gastric or oropharyngeal contents, and allergic bronchopulmonary aspergillosis.

And though uncommon, bronchiectasis may result from defective development of bronchial cartilage (Williams–Campbell syndrome) and developmental failure of elastic and muscular tissues of the trachea and bronchi (tracheobronchomegaly, or Mounier–Kuhn syndrome).

Complications

Major concerns are severe pneumonia, hemoptysis, and cor pulmonale. Less frequent complications are abscesses of the lung, empyema, and bronchopleural fistula.

Treatment

Aggressive antibiotic therapy during pulmonary exacerbations and routine airway clearance are mainstays of treatment. Inhaled mucolytic agents and bronchodilators may also be of benefit in individual patients.

Surgical removal of an area of lung affected with severe bronchiectasis is considered when the response to medical therapy is poor. Other indications for operation include severe localized disease, repeated hemoptysis, and recurrent pneumonia in one area of lung. If bronchiectasis is widespread, surgical resection offers little advantage.

Prognosis

The prognosis depends on the underlying cause and severity of bronchiectasis, the extent of lung involvement, and the response to medical management. Good pulmonary hygiene and avoidance of infectious complications in the involved areas of lung may reverse cylindrical bronchiectasis.

Barker AF: Bronchiectasis. *N Engl J Med* 2002;346:1383 [PMID: 11986413].

Chang AB et al: Non-CF bronchiectasis: Clinical and HRCT evaluation. *Pediatr Pulmonol* 2003;35:477 [PMID: 12746947].

BRONCHIOLITIS OBLITERANS

Bronchiolitis obliterans is characterized by obstruction of bronchi and bronchioles by fibrous tissue. The disorder follows damage to the lower respiratory tract, such as inhalation of toxic gases, infections (adenovirus, influenza virus, rubeola virus, *Bordetella*, *Mycoplasma*), connective tissue diseases, transplantation, and aspiration. Bronchiolitis obliterans may also develop in children who have Stevens–Johnson syndrome with pulmonary involvement. Many cases of bronchiolitis obliterans are idiopathic. Adenovirus-induced bronchiolitis obliterans occurs more frequently in the Native-American population and in Polynesian children in New Zealand.

Clinical Findings

A. SYMPTOMS AND SIGNS

Bronchiolitis obliterans should be considered when persistent cough, wheezing, or sputum production is pre-

sent after an episode of acute pneumonia. Prolonged rales or wheezing or persistent exercise intolerance following a pulmonary insult should also suggest this disease.

B. LABORATORY FINDINGS AND IMAGING

Chest radiograph abnormalities include evidence of localized or generalized air trapping as well as (in some cases) nodular densities and alveolar opacification. Scattered areas of matched decreases in ventilation and perfusion are seen when the lung is scanned. Pulmonary angiograms reveal decreased vasculature in involved lung, and bronchograms show marked pruning of the bronchial tree. An assessment of lung function demonstrates an obstructive process that may be combined with evidence of restriction. Inhaled bronchodilators or corticosteroids provide little improvement in lung function.

Differential Diagnosis

Poorly treated asthma, CF, and bronchopulmonary dysplasia must be considered in children with persistent airway obstruction. A trial of medications (including bronchodilators and corticosteroids) may help to determine the reversibility of the process when the primary differential is between asthma and bronchiolitis obliterans. Although the results of imaging and pulmonary function testing are very suggestive, the most definitive way to establish a diagnosis is by lung biopsy.

Complications

Sequelae of bronchiolitis obliterans include persistent airway obstruction, recurrent wheezing, bronchiectasis, chronic atelectasis, recurrent pneumonia, and unilateral hyperlucent lung syndrome.

Treatment

Supplemental oxygen should be given to patients with oxygen desaturation during normal activities or sleep. In addition, early treatment should be directed at preventing ongoing airway damage due to problems such as aspiration, which may be either the primary insult or an acquired problem secondary to marked hyperinflation. The effectiveness of other forms of treatment may be more difficult to evaluate. Oral and inhaled bronchodilators may reverse airway obstruction if the disease has a reactive component. Many children also receive at least one course of corticosteroid treatment in an attempt to reverse the obstruction or prevent ongoing damage. Antibiotics should be used as indicated for pneumonia.

Prognosis

Prognosis may depend in part on the underlying cause as well as the age at which the insult occurred. The course varies from mild asthma-like symptoms to rapidly fatal deterioration despite therapy.

BRONCHOPULMONARY DYSPLASIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Acute respiratory distress in first week of life.*
- *Required oxygen therapy or mechanical ventilation, with persistent oxygen requirement at 36 weeks' gestational age.*
- *Persistent respiratory abnormalities, including physical signs and radiographic findings.*

General Considerations

Bronchopulmonary dysplasia (BPD) remains one of the most significant sequelae of acute respiratory distress in the neonatal intensive care unit, with an incidence of about 30% for infants with a birth weight of less than 1000 g. This disease was first characterized in 1967 when Northway and coworkers reported the clinical, radiologic, and pathologic findings in a group of premature newborns that required prolonged mechanical ventilation and oxygen therapy to treat hyaline membrane disease. The progression from acute hyaline membrane disease to chronic lung disease was divided into four stages: acute respiratory distress shortly after birth, usually hyaline membrane disease (stage I); clinical and radiographic worsening of the acute lung disease, often due to increased pulmonary blood flow secondary to a patent ductus arteriosus (stage II); and progressive signs of chronic lung disease (stages III and IV). The pathologic findings and clinical course of BPD in recent years have changed due to a combination of new therapies (surfactants, prenatal glucocorticoids, and different ventilation strategies) and increased survival of infants born at earlier gestational ages. Al-

though the incidence of BPD has not changed, the severity of the lung disease has decreased. Pathologically this “new” BPD is characterized by a reduction in inflammation, decreased alveolar number, and a dysmorphic vascular structure.

A recent summary of a National Institutes of Health workshop on BPD proposes a definition of the disease that includes oxygen requirement for more than 28 days, a history of positive pressure ventilation or continuous positive airway pressure, and gestational age. The new definition accommodates several key observations regarding the disease, including: (1) Although most of these children were premature and had hyaline membrane disease, full-term newborns with such disorders as meconium aspiration or persistent pulmonary hypertension can also develop bronchopulmonary dysplasia; (2) some extremely preterm newborns require minimal ventilator support yet subsequently develop a prolonged oxygen requirement despite the absence of severe acute manifestations of respiratory failure; (3) newborns dying within the first weeks of life can already have the aggressive, fibroproliferative pathologic lesions that resemble bronchopulmonary dysplasia; and (4) physiologic abnormalities (increased airway resistance) and biochemical markers of lung injury (altered protease and antiprotease ratios, increased inflammatory cells and mediators), which may be predictive of bronchopulmonary dysplasia, are already present in the first week of life.

The precise mechanism that results in the development of BPD is unclear. The premature lung makes insufficient functional surfactant; furthermore, the antioxidant defense mechanisms are not sufficiently mature to protect the lung from the toxic oxygen metabolites generated from hyperoxia. Lungs destined to develop BPD show early inflammation and hypercellularity followed by healing with fibrosis. Thus abnormal lung mechanics due to structural immaturity, surfactant deficiency, atelectasis, and pulmonary edema—plus lung injury secondary to hyperoxia and mechanical ventilation—lead to further abnormalities of lung function, causing increases in ventilator and oxygen requirements and resulting in a vicious cycle that compounds the progression of lung injury. Excessive fluid administration, patent ductus arteriosus, pulmonary interstitial emphysema, pneumothorax, infection, pulmonary hypertension, and inflammatory stimuli secondary to lung injury or infection also play important roles in the pathogenesis of the disease. Although the exact mechanisms leading to chronic lung disease are not completely understood, bronchopulmonary dysplasia represents the consequences of lung injury caused by oxygen toxicity, barotrauma, and inflammation superimposed on a susceptible, generally immature lung.

Differential Diagnosis

The radiologic appearance of BPD is changing, and severe chronic lung findings of fibrosis with infiltrate are less common. The changes in severe BPD necessitate ruling out meconium aspiration syndrome, congenital infection (eg, with cytomegalovirus [CMV] or *Ureaplasma*), cystic adenomatoid malformation, recurrent aspiration, pulmonary lymphangiectasia, total anomalous pulmonary venous return, overhydration, and idiopathic pulmonary fibrosis.

Clinical Course & Treatment

The clinical course of infants with bronchopulmonary dysplasia ranges from a mild increased oxygen requirement that gradually resolves over a few months to more severe disease requiring chronic tracheostomy and mechanical ventilation for the first 2 years of life. In general, patients show slow, steady improvements in oxygen or ventilator requirements but can have frequent respiratory exacerbations leading to frequent and prolonged hospitalizations. Clinical management generally includes careful attention to growth, nutrition (caloric requirements of infants with oxygen dependence and respiratory distress are quite high), metabolic status, developmental and neurologic status, and related problems, along with the various cardiopulmonary abnormalities described in a later discussion.

Short courses of postnatal glucocorticoid therapy has been helpful in increasing the success of weaning from the ventilator. This therapy is controversial, however, because data show decreased alveolarization in preterm and postnatal animals given long courses of corticosteroids. Longer courses of postnatal glucocorticoids have been linked to an increased incidence of cerebral palsy. Inhaled glucocorticoids may help reduce the need for systemic steroids, but the overall incidence of bronchopulmonary dysplasia has not been affected. Early use of surfactant therapy increases the chance for survival without bronchopulmonary dysplasia and can decrease the overall mortality and reduce the need for ventilation. Thus early interventions are important prior to the development of bronchopulmonary dysplasia to decrease morbidity and mortality. Ongoing studies on the imbalance of proteolytic enzymes, elastolytic lung damage, and the role of specific antiinflammatory medications during the early development of bronchopulmonary dysplasia are needed.

Because increased airway resistance and bronchial hyperreactivity are common in affected infants, inhaled corticosteroids together with occasional use of β -adrenergic agonists are commonly part of the treatment plan. Part of the rationale for the use of corticosteroids is to decrease lung inflammation and enhance responsiveness

to β -adrenergic drugs, as in the treatment of severe asthma. β -Adrenergic agonists followed by chest physiotherapy are often used for the thick secretions that may contribute to airway obstruction or recurrent atelectasis.

Although bronchial hyperreactivity in affected infants is well recognized, structural lesions (eg, subglottic stenosis, vocal cord paralysis, tracheal stenosis, tracheomalacia, bronchial stenosis, and granulomatous bronchial polyps) often contribute to airflow limitation. Children with significant stridor, sleep apnea, chronic wheezing, or excessive respiratory distress need diagnostic bronchoscopy. In addition, the contribution of gastroesophageal reflux and aspiration should be considered in the face of worsening chronic lung disease.

Infants often have recurrent pulmonary edema, which may be due to increased permeability of the injured pulmonary circulation or to increases in hydrostatic pressure if left ventricular dysfunction is present. Salt and water retention secondary to chronic hypoxemia, hypercapnia, or other stimuli may be present. Chronic or intermittent diuretic therapy is commonly used if rales or signs of persistent pulmonary edema are present and clinical studies show acute improvement in lung function. Unfortunately, diuretics often have adverse effects, including severe volume contraction, hypokalemia, alkalosis, and hyponatremia. Potassium and arginine chloride supplements are commonly required.

Infants with BPD are at risk of developing pulmonary hypertension, and in many of these children even mild hypoxemia can cause significant elevations of pulmonary arterial pressure. To minimize the harmful effects of hypoxemia, the SaO_2 should be kept above 93%, with care to avoid hyperoxia during retinal vascular development. Electrocardiographic and echocardiographic studies should be performed to monitor for the development of right ventricular hypertrophy. If hypertrophy persists or if it develops where it was not previously present, intermittent hypoxemia should be considered and further assessments of oxygenation pursued, especially while the infant sleeps. Even intermittent hypoxia contributes to the development or progression of pulmonary hypertension and cor pulmonale; therefore, noninvasive assessments of oxygenation must be made during all activities, including the infant's waking, sleeping, and feeding periods. Infants with a history of intubation can develop obstructive sleep apnea secondary to a high-arched palate or subglottic narrowing. Barium swallow, esophageal pH probe studies, bronchoscopy, and cardiac catheterization will diagnose unsuspected cardiac or pulmonary lesions that contribute to the underlying pathophysiology, such as aspiration, tracheomalacia, obstructive sleep apnea, and anatomic cardiac lesions. Long-term care should include monitoring for systemic hyperten-

sion and the development of left ventricular hypertrophy.

Nutritional problems in infants may be due to increased oxygen consumption, feeding difficulties, gastroesophageal reflux, and chronic hypoxemia. Hypercaloric formulas and gastrostomies are often required to ensure adequate intake while avoiding overhydration. Influenza vaccine is recommended. With the onset of acute wheezing secondary to suspected viral infection, rapid diagnostic testing for RSV infection may facilitate early treatment. Immune prophylaxis of RSV reduces the morbidity of bronchiolitis in infants with bronchopulmonary dysplasia.

For children who remain ventilator-dependent, attempts should be made to maintain PaCO_2 below 60 mm Hg—even when pH is normal—because of the potential adverse effects of hypercapnia on salt and water retention, cardiac function, and perhaps pulmonary vascular tone. Changes in ventilator settings in children with severe lung disease should be slow, because the effects of many of the changes may not be apparent for days. These signs may include poor feeding, irritability, weight loss, vomiting, increased retractions, wheezing, increased somnolence, and CO_2 retention. Medical staff should meet frequently with the parents to review progress and changes in treatment plans and thereby ease some of the family stresses involved in caring for a child who has a chronic disease. Patience, continued family support, attention to developmental issues, and speech and physical therapy help to improve the long-term outlook.

Prognosis

Surfactant replacement therapy has had a significant effect on reducing morbidity and mortality from bronchopulmonary dysplasia. Infants of younger gestational age are surviving in greater numbers. Surprisingly, the effect of neonatal care has not decreased the incidence of bronchopulmonary dysplasia significantly, as half the survivors go on to develop this diagnosis. The disorder typically develops in the most immature infants, but the long-term outlook for most survivors is generally favorable. Long-term follow-up studies suggest that lung function may be altered for life. Hyperinflation and damage to small airways has been reported in children 10 years out from the first signs of bronchopulmonary dysplasia. In addition, these infants are at a higher risk for developing such sequelae as persistent airway hyperreactivity, exercise intolerance, pulmonary hypertension, increased risk for COPD, and perhaps abnormal lung growth. As smaller, more immature infants survive, abnormal neurodevelopmental outcomes become more likely. The incidence of cerebral palsy, hearing loss, vision abnormalities, spastic diplegia, and develop-

mental delays is increased. Feeding abnormalities, behavior difficulties, and increased irritability have all been reported. Finally, children with bronchopulmonary dysplasia frequently develop airway obstruction, hyperreactive airways, and decreased oxygen saturation during exercise. This should be taken into account for children residing at higher altitudes. A focus on good nutrition, prophylaxis against respiratory pathogens and airway hyperreactivity, and attention to school performance continue to provide the best outcomes.

CYSTIC FIBROSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Sweat chloride* > 60 mmol/L.
- *Mutated CFTR protein.*

- *Pulmonary, gastrointestinal, or hepatic dysfunction.*

General Considerations

Cystic fibrosis is the most common lethal genetic disease in the United States, with an incidence of 1:3000–1:4000 among Caucasians. It is a major cause of pulmonary and gastrointestinal morbidity in children and a leading cause of death in early adulthood. Although CF is characterized by abnormalities in the hepatic, gastrointestinal, and male reproductive systems, lung disease is the major cause of morbidity and mortality. Almost all patients develop obstructive lung disease associated with chronic infection that leads to progressive loss of pulmonary function. The prognosis has improved steadily over the past 20 years, so that the median survival is now 33 years—perhaps because of antibiotics, better treatment of malabsorption, and development of a network of CF clinical care centers. The centers usually emphasize a multidisciplinary approach to patient care (www.cff.org).

The gene for CF is on the long arm of human chromosome 7 and codes for the cystic fibrosis transmembrane conductance regulator (CFTR) protein. CFTR functions as an ion channel and controls the movement of salt and water into and out of epithelial cells where it is expressed. Over 1000 mutations in the CF gene have been identified. The most common mutation, called delta F508, is a deletion of three base pairs at position 508 in the gene. These gene mutations lead to defects or deficiencies in CFTR, causing cells to produce abnormally thick mucus.

Clinical Findings & Treatment

A. CLINICAL PRESENTATIONS AND DIAGNOSIS

Approximately 15% of newborns with CF present at birth with meconium ileus, a severe intestinal obstruction resulting from inspissation of tenacious meconium in the terminal ileum. In the past, surgical removal of the meconium was common and often led to resection of bowel. Improved techniques of enema administration under radiologic observation have reduced the need for surgery.

Roughly 50% of patients with CF present in infancy with failure to thrive, respiratory compromise, or both. The age at presentation, however, can be variable; some patients are not diagnosed until adulthood. Newborn screening based on elevations of immunoreactive trypsinogen (IRT), a pancreatic enzyme precursor, in

the blood is an alternative method of case identification.

In the presence of clinical symptoms such as meconium ileus, failure to thrive, or recurrent respiratory infections, or with elevated IRT levels, the diagnosis of CF is confirmed by a sweat chloride level above 60 mEq/L or by the presence of two known CF mutations. The most acceptable sweat testing procedure is the quantitative pilocarpine iontophoresis sweat test. Measurements of electrical conductivity alone can be unreliable.

B. GASTROINTESTINAL AND NUTRITIONAL FINDINGS AND TREATMENT

Patients with untreated CF have abdominal distention and discomfort; bulky, greasy stools; and increased flatulence secondary to exocrine pancreatic insufficiency and malabsorption. Some infants present with hypoalbuminemia, anemia, edema, and hepatomegaly. Infants with severe protein-calorie malnutrition have particularly difficult courses, with high morbidity and mortality rates. Children and adults with CF are subject to intestinal blockage from inspissated stool. This so-called meconium ileus equivalent is now most often treated with cathartics and enemas and only rarely requires surgery. Persons with CF are more prone to intussusception (especially of the appendix) than are those without the disease.

The cornerstone of gastrointestinal treatment is pancreatic enzyme supplementation. Patients are required to take the enzyme capsules with each meal and with snacks. Newer enzyme preparations contain more lipase per capsule than older preparations; therefore, patients take fewer capsules, making administration easier. Occasionally, enzyme supplementation alone does not control the malabsorption, and antacids are added to the regimen.

Individuals with CF may have fat-soluble vitamin deficiency, hypoalbuminemia, and poor growth with decreased stores of body fat. In the past, fat-restricted diets were recommended. It is now recognized that persons with CF need all the calories they can take, and unrestricted diets are the norm in most centers. Moreover, caloric supplements, such as high-calorie commercial supplements or formulas or food modules (including Polycose and medium-chain triglycerides), are often added to the patient's diet. In patients who do not respond to oral supplementation, night-time nasogastric feeding or feeding by means of gastrostomy or jejunostomy has been tried. Although there is general agreement that quality of life is enhanced by improved nutrition, it is not known whether aggressive nutritional treatment increases longevity. The goals of nutritional treatment are to achieve normal height and weight. Patients may require many more calories than predicted

because of stool loss of fat and protein and ongoing pulmonary infection and inflammation.

C. PULMONARY FINDINGS AND TREATMENT

Infants with CF frequently have respiratory symptoms severe enough to require hospitalization. Cough, tachypnea, rales, and wheezing are common findings. RSV infection is associated with added morbidity in early infancy. Some patients develop cough only later in childhood or adolescence, but by adulthood almost all persons with CF have productive coughs. In more advanced disease, hemoptysis due to bronchiectasis, exercise limitation, and cor pulmonale may be present. Rales may be heard on physical examination. Clubbing also develops as the lung disease progresses.

Pulmonary function abnormalities initially show obstructive patterns with diminished flow rates and increased lung volumes. As the disease progresses, vital capacity is also affected. The incidence of airway reactivity in CF has been estimated to be 25–50%, several times the incidence in the general population. Initially, the airway is colonized with *Staphylococcus aureus*, but in most persons *Pseudomonas aeruginosa* eventually becomes the predominant pathogen. Acquisition of the characteristic mucoid *Pseudomonas* is associated with a more rapid decline in pulmonary function. In addition, infection with *Burkholderia cepacia* has been associated with rapid deterioration and death. Pathologically, the earliest lesions involve hyperplasia of the mucus glands of the bronchial epithelium and mucosal and submucosal cellular infiltrates. Bronchiolectasis and bronchiectasis throughout all lung fields usually follow.

Airway clearance therapy and aggressive antibiotic use form the mainstays of treatment for CF lung disease. Two evidence-based medications that are now routinely used in many persons with CF are inhaled recombinant human DNase (Pulmozyme) and inhaled tobramycin (TOBI). These therapies have been shown to maintain lung function and reduce the need for hospitalizations and intravenous antibiotics. Bronchodilators and antiinflammatory therapies are also frequently used.

Although corticosteroids have been shown to be effective in maintaining lung function in persons with CF, adverse effects, including glucose intolerance, frank diabetes, and decreased linear growth, have limited their use. Persons with CF derive hope from the range of agents being evaluated for restoring CFTR function. Gene therapy trials are also under way.

A subgroup of patients with CF have frequent pulmonary exacerbations characterized by difficult breathing, increased sputum production, decreased exercise tolerance, and diminished pulmonary function. These patients often benefit from hospital treatment, includ-

ing intensified airway clearance therapy, intravenous antibiotics, bronchodilators, and concentrated efforts at nutritional rehabilitation. Increasingly, outpatient intravenous therapy is being used to shorten or eliminate the hospital stay.

D. HEPATIC DISEASE

Although most patients with CF have cirrhosis at autopsy, only a small percentage develop portal hypertension. In these individuals, however, the clinical findings of the liver disease may be severe, with esophageal varices leading to life-threatening gastrointestinal bleeding and hypersplenism requiring splenic embolization.

E. REPRODUCTIVE TRACT INVOLVEMENT

Failure of development of the vas deferens leaves more than 95% of males with CF infertile. CF is occasionally diagnosed through infertility evaluations in men with relatively mild involvement of the respiratory and gastrointestinal tracts. In general, women with CF are fertile, but pregnancy may place considerable stress on patients with limited pulmonary function.

Prognosis

The rate of progression of lung involvement usually determines survival. Most patients now reach adulthood. Lung transplant for end-stage disease is an accepted treatment. In addition, new treatments, including gene therapy trials, are being developed based on improved understanding of the disease at the cellular and molecular levels.

CONGENITAL MALFORMATIONS OF THE LUNG

What follows is a brief description of selected congenital pulmonary malformations.

PULMONARY AGENESIS & HYPOPLASIA

With unilateral pulmonary agenesis (complete absence of one lung), the trachea continues into a main bronchus and often has complete tracheal rings. The left lung is affected more often than the right. With compensatory postnatal growth, the remaining lung often herniates into the contralateral chest. Chest radi-

ographs show a mediastinal shift toward the affected side, and vertebral abnormalities may be present. Absent or incomplete lung development may be associated with other congenital abnormalities, such as absence of one or both kidneys or fusion of ribs, and the outcome is primarily related to the severity of associated lesions. About 50% of patients survive; the mortality rate is higher with agenesis of the right lung than of the left lung. This difference is probably not related to the higher incidence of associated anomalies but rather to a greater shift in the mediastinum that leads to tracheal compression and distortion of vascular structures.

Pulmonary hypoplasia is incomplete development of one or both lungs, characterized by a reduction in alveolar number and a reduction in airway branches. Pulmonary hypoplasia is present in up to 10–15% of perinatal autopsies. The hypoplasia can be a result of an intrathoracic mass, resulting in lack of space for the lungs to grow; decreased size of the thorax; decreased fetal breathing movements; decreased blood flow to the lungs; or possibly a primary mesodermal defect affecting multiple organ systems. Congenital diaphragmatic hernia is the most common cause, with an incidence of 1:2200 births. Other causes include extralobar sequestration, diaphragmatic eventration or hypoplasia, thoracic neuroblastoma, fetal hydrops, and fetal hydrochlothorax. Chest cage abnormalities, diaphragmatic elevation, oligohydramnios, chromosomal abnormalities, severe musculoskeletal disorders, and cardiac lesions may also result in hypoplastic lungs. Postnatal factors may play important roles. For example, infants with advanced bronchopulmonary dysplasia can have pulmonary hypoplasia.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical presentation is highly variable and is related to the severity of hypoplasia as well as associated abnormalities. Lung hypoplasia is often associated with pneumothorax. Some newborns present with perinatal stress, severe acute respiratory distress, and persistent pulmonary hypertension of the newborn secondary to primary pulmonary hypoplasia (without associated anomalies). Children with lesser degrees of hypoplasia may present with chronic cough, tachypnea, wheezing, and recurrent pneumonia.

B. LABORATORY FINDINGS AND IMAGING

Chest radiographic findings include variable degrees of volume loss in a small hemithorax with mediastinal shift. Pulmonary agenesis should be suspected if tracheal deviation is evident on the chest radiograph. The chest CT scan is the optimal diagnostic imaging procedure if the chest radiograph is not definitive. Ventila-

tion-perfusion scans, angiography, and bronchoscopy are often helpful in the evaluation, demonstrating decreased pulmonary vascularity or premature blunting of airways associated with the maldeveloped lung tissue. The degree of respiratory impairment is defined by analysis of arterial blood gases.

Treatment & Prognosis

Treatment is supportive. The outcome is determined by the severity of underlying medical problems, the extent of the hypoplasia, and the degree of pulmonary hypertension.

PULMONARY SEQUESTRATION

Pulmonary sequestration is nonfunctional pulmonary tissue that does not communicate with the tracheo-bronchial tree and receives its blood supply from one or more anomalous systemic arteries. This abnormality originates during the embryonic period of lung development. It is classified as either extralobar or intralobar. Extralobar sequestration is a mass of pulmonary parenchyma anatomically separate from the normal lung, with a distinct pleural investment. Its blood supply derives from the systemic circulation (more typical), from pulmonary vessels, or from both. Rarely it communicates with the esophagus or stomach. Pathologically, extralobar sequestration appears as a solitary thoracic lesion near the diaphragm. Abdominal sites are rare. Size varies from 0.5 to 12 cm. The left side is involved in over 90% of cases. In contrast to intralobar sequestrations, venous drainage is usually through the systemic or portal venous system.

Histologic findings include uniformly dilated bronchioles, alveolar ducts, and alveoli. Occasionally the bronchial structure appears normal; however, often the cartilage in the wall is deficient, or no cartilage-containing structures can be found. Lymphangiectasia is sometimes found within the lesion. Extralobar sequestration

can be associated with other anomalies, including bronchogenic cysts, heart defects, and diaphragmatic hernia, the latter occurring in over half of cases.

Intralobar sequestration is an isolated segment of lung within the normal pleural investment that often receives blood from one or more arteries arising from the aorta or its branches. Intralobar sequestration is usually found within the lower lobes (98%), two thirds are found on the left side, and it is rarely associated with other congenital anomalies (less than 2% versus 50% with extralobar sequestration). It rarely presents in the newborn period (unlike extralobar sequestration). Some researchers have hypothesized that intralobar sequestration is an acquired lesion secondary to chronic infection. Clinical presentation includes chronic cough, wheezing, or recurrent pneumonias. Rarely, patients with intralobar sequestration can present with hemoptysis. Diagnosis is often made by angiography, which shows large systemic arteries perfusing the lesion. Recently, spiral CT scans with contrast, or magnetic resonance angiography, have proven useful in identifying anomalous systemic arterial supply to the lung. Treatment is usually by surgical resection.

CONGENITAL LOBAR EMPHYSEMA

Patients with congenital lobar emphysema—also known as infantile lobar emphysema, congenital localized emphysema, unilobar obstructive emphysema, congenital hypertrophic lobar emphysema, or congenital lobar overinflation—present most commonly with severe neonatal respiratory distress or progressive respiratory impairment during the first year of life. Rarely the mild or intermittent nature of the symptoms in older children or young adults results in delayed diagnosis. Most patients are white males. Although the cause of congenital lobar emphysema is not well understood, some lesions show bronchial cartilaginous dysplasia due to abnormal orientation or distribution of

the bronchial cartilage. This leads to expiratory collapse, producing obstruction and the symptoms outlined in the following discussion.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical features include tachypnea, cyanosis, wheezing, retractions, and cough. Breath sounds are reduced on the affected side, perhaps with hyperresonance to percussion, mediastinal displacement, and bulging of the chest wall on the affected side.

B. IMAGING

Radiologic findings include overdistention of the affected lobe (usually an upper or middle lobe; > 99%), with wide separation of bronchovascular markings, collapse of adjacent lung, shift of the mediastinum away from the affected side, and a depressed diaphragm on the affected side. The radiographic diagnosis may be confusing in the newborn because of retention of alveolar fluid in the affected lobe causing the appearance of a homogeneous density. Other diagnostic studies include chest radiograph with fluoroscopy, ventilation–perfusion study, and chest CT scan followed by bronchoscopy, angiography, and exploratory thoracotomy.

Differential Diagnosis

The differential diagnosis of congenital lobar emphysema includes pneumothorax, pneumatocele, atelectasis with compensatory hyperinflation, diaphragmatic hernia, and congenital cystic adenomatoid malformation. The most common site of involvement is the left upper lobe (42%) or right middle lobe (35%). Evaluation must differentiate regional obstructive emphysema from lobar hyperinflation secondary to an uncomplicated ball-valve mechanism due to extrinsic compression from a mass (ie, bronchogenic cyst, tumor, lymphadenopathy, foreign body, pseudotumor or plasma cell granuloma, vascular compression) or intrinsic obstruction from a mucus plug due to infection and inflammation from various causes.

Treatment

When respiratory distress is marked, a segmental or complete lobectomy is usually required. Less symptomatic older children may do equally well with or without lobectomy.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION

Patients with congenital cystic adenomatoid malformations (CAMs), which are unilateral hamartomatous lesions, generally present with marked respiratory distress within the first days of life. This disorder accounts for 95% of cases of congenital cystic lung disease.

Right and left lungs are involved with equal frequency. These lesions originate during the first 4–6 weeks of gestation during the embryonic period of lung development. These lesions appear as gland-like space-occupying masses or have an increase in terminal respiratory structures, forming intercommunicating cysts of various sizes, lined by cuboidal or ciliated pseudostratified columnar epithelium. They may have polypoid formations of mucosa, with focally increased elastic tissue in the cyst wall beneath the bronchial type of epithelium. Air passages appear malformed and tend to lack cartilage.

There are three types of such malformations. Type 1 is most common (55%) and consists of single or multiple large cysts (> 2 cm in diameter) with features of mature lung tissue. Type 1 is amenable to surgical resection. A mediastinal shift is evident on examination or chest radiograph in 80% of patients and can mimic infantile lobar emphysema. Approximately 75% of type 1 lesions are on the right side. A survival rate of 90% is generally reported.

Type 2 lesions (40% of cases) consist of multiple small cysts (< 2 cm) resembling dilated simple bronchioles and are often (60%) associated with other anomalies, especially renal agenesis or dysgenesis, cardiac malformations, and intestinal atresia. Approximately 60% of type 2 lesions are on the left side. Mediastinal shift is evident less often (10%) than in type 1, and the survival rate is worse (40%).

Type 3 lesions consist of small cysts (< 0.5 cm). They appear as a bulky, firm mass. The reported survival rate is 50%.

Recently, two additional types have been described: type 0, a malformation of the proximal tracheobronchial tree (incompatible with life), and type 4, a

malformation of the distal acinus. Both types are extremely uncommon.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinically, respiratory distress is noted soon after birth. Expansion of the cysts occurs with the onset of breathing and produces compression of normal lung areas with mediastinal herniation. Breath sounds are decreased. With type 3 lesions, dullness to percussion may be present. Older patients can present with a spontaneous pneumothorax or with pneumonia-like symptoms.

B. IMAGING

With type 1 lesions, chest radiograph shows an intrapulmonary mass of soft tissue density with scattered radiolucent areas of varying sizes and shapes, usually with a mediastinal shift and pulmonary herniation. Placement of a radiopaque feeding tube into the stomach helps in the differentiation from diaphragmatic hernia. Type 2 lesions appear similar except that the cysts are smaller. Type 3 lesions may appear as a solid homogeneous mass filling the hemithorax and causing a marked mediastinal shift. Differentiation from sequestration is not difficult because congenital cystic adenomatoid malformations have no systemic blood supply.

Treatment

Treatment of types 1 and 3 lesions involves surgical removal of the affected lobe. Resection is often indicated because of the risk of infection and air trapping, since the malformation communicates with the tracheobronchial tree but mucous clearance is compromised. Because type 2 lesions are often associated with other severe anomalies, management may be more complex. Segmental resection is not feasible because smaller cysts may expand after removal of the more obviously affected area. CAMs have been reported to have malignant potential; therefore, expectant management with observation alone should proceed with caution. Recent development of intrauterine surgery for congenital malformations has led to promising results.

ACQUIRED DISORDERS INVOLVING ALVEOLI

BACTERIAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Fever, cough, dyspnea.*
- *Abnormal chest examination (rales or decreased breath sounds).*
- *Abnormal chest radiograph (infiltrates, hilar adenopathy, pleural effusion).*

General Considerations

Bacterial pneumonia is inflammation of the lung classified according to the infecting organism. It usually develops when one or more of the defense mechanisms normally protecting the lung is inadequate. Patients with the following problems are particularly predisposed to this disease: aspiration, immunodeficiency or immunosuppression, congenital anomalies (intrapulmonary sequestration, tracheoesophageal fistula, cleft palate), abnormalities in clearance of mucus (CF, ciliary dysfunction, tracheomalacia, bronchiectasis), congestive heart failure, and perinatal contamination.

Clinical Findings

A. SYMPTOMS AND SIGNS

The bacterial pathogen, severity of the disease, and age of the patient may cause substantial variations in the presentation of acute bacterial pneumonia. Infants may have few or nonspecific findings on history and physical examination. Immunocompetent older patients may not be extremely ill. Some patients may present with fever only or only with signs of generalized toxicity. Others may have additional symptoms or signs of lower respiratory tract disease (respiratory distress, cough, sputum production), pneumonia (rales, decreased breath sounds, dullness to percussion, abnormal tactile or vocal fremitus), or pleural involvement (splinting, pain, friction rub, dullness to percussion). Some patients may have additional extrapulmonary findings, such as meningismus or abdominal pain, due to pneumonia itself. Others may have evidence of infection at other sites due to the same organism causing their pneumonia: meningitis, otitis media, sinusitis, pericarditis, epiglottitis, or abscesses.

B. LABORATORY FINDINGS

Elevated white blood cell counts ($> 15,000/\mu\text{L}$) frequently accompany bacterial pneumonia. However, a low white blood count ($< 5000/\mu\text{L}$) can be an ominous finding in this disease.

C. IMAGING

Chest radiographic findings (lateral and frontal views) define bacterial pneumonia. Patchy infiltrates, atelectasis, hilar adenopathy, or pleural effusion may be observed. Radiographs should be taken in the lateral decubitus position to identify pleural fluid. Complete lobar consolidation is not a common finding in infants and children. Severity of disease may not correlate with radiographic findings. Clinical resolution precedes resolution apparent on chest radiograph.

D. SPECIAL EXAMINATIONS

Invasive diagnostic procedures (transtracheal aspiration, bronchial brushing or washing, lung puncture, or open or thoracoscopic lung biopsy) should be undertaken in critically ill patients when other means do not adequately identify the cause (see Culture of Material from the Respiratory Tract section).

Differential Diagnosis

The differential diagnosis of pneumonia varies with the age and immunocompetence of the host. The spectrum of potential pathogens to be considered includes aerobic, anaerobic, and acid-fast bacteria as well as *Chlamydia trachomatis* and *C. psittaci*, *Rickettsia quintana* (Q fever), *Pneumocystis jiroveci*, *Bordetella pertussis*, *Mycoplasma pneumoniae*, *Legionella pneumophila*, and respiratory viruses.

Noninfectious pulmonary disease (including gastric aspiration, foreign body aspiration, atelectasis, congenital malformations, congestive heart failure, malignant growths, tumors such as plasma cell granuloma, chronic interstitial lung diseases, and pulmonary hemosiderosis) should be considered in the differential diagnosis of localized or diffuse infiltrates. When effusions are present, additional noninfectious disorders such as collagen diseases, neoplasm, and pulmonary infarction should also be considered.

Complications

Empyema may occur frequently with staphylococcal, pneumococcal and group A β -hemolytic streptococcal disease. Distal sites of infection—meningitis, otitis media, sinusitis (especially of the ethmoids), and septicemia—may be present, particularly with disease due to *S. pneumoniae* or *H. influenzae*. Certain immunocompromised patients, such as those who have undergone

splenectomy or who have hemoglobin SS or SC disease or thalassemia, are especially prone to overwhelming sepsis with these organisms. Distal infection of the bones, joints, or other organs (eg, liver abscess) may occur in certain hosts with specific organisms.

Treatment

Antimicrobial therapy should be guided by Gram stain of sputum, tracheobronchial secretions, or pleural fluid if available; radiographic findings; age and known or suspected immunocompetence of the host; and local epidemiologic information. Reasonable coverage for pneumonia in the sick, immunocompromised, or debilitated patient, pending the results of bronchoalveolar lavage or thoracoscopic biopsy, should include cef-tazidime, clindamycin, vancomycin, erythromycin for *Legionella* and *Mycoplasma*, and possibly trimethoprim-sulfamethoxazole for *P. jiroveci*. Depending on the circumstances and the level of illness, empiric antifungal or antiviral therapy may be considered. In specific circumstances such as aspiration due to neurologic impairment or in patients with tracheostomies, clindamycin is indicated, pending culture and sensitivity studies, owing to the likely presence of resistant anaerobes.

Less severe pneumonias can often be treated with oral antibiotics based on the patient's age and suspected organism. Lobar pneumonias presumed to be due to *S. pneumoniae* can be treated initially with oral β -lactams, including cefuroxime axetil, amoxicillin, or amoxicillin-clavulanate. However, persistence or worsening of symptoms within 3–5 days suggests the presence of a resistant organism, and newer quinolones, clindamycin, or vancomycin may be required. When possible, therapy can be guided by the antibiotic sensitivity pattern of the organisms isolated.

Whether a child should be hospitalized depends on his or her age, the severity of illness, the suspected organism, and the anticipated reliability of compliance at home. Home treatment is adequate for most older children. With febrile pneumonias, infants generally—and toddlers often—require admission. Moderate to severe respiratory distress, apnea, hypoxemia, poor feeding, clinical deterioration on treatment, or associated complications (large effusions, empyema, or abscess) indicate the need for immediate hospitalization. Careful follow-up within 12 hours to 5 days is often indicated in those not admitted. Cefuroxime or a macrolide, depending on the clinical picture, may be appropriate initial therapy for patients in this category.

Additional therapeutic considerations include oxygen, humidification of inspired gases, hydration and electrolyte supplementation, and nutrition. Removal of pleural fluid for diagnostic purposes is indicated ini-

tially to guide antimicrobial therapy. Many feel that early chest tube drainage of empyema fluid due to *S aureus* is indicated. Empyema due to group A β -hemolytic streptococci, *S pneumoniae* or *H influenzae* can also necessitate chest tube drainage. Repeat pleural taps should be considered in the patient who has persistent high fever for more than 10 days in association with significant pleural effusions. The persistence of organisms in this fluid or the persistence of toxicity, malaise, anorexia, and wasting in the patient suggests the potential need for pleural decortication, a procedure that can be made less morbid by thoracoscopy in skilled hands.

Endotracheal intubation or mechanical ventilation may be indicated in patients with respiratory failure or in those too debilitated or overwhelmed to handle their secretions.

Prognosis

For the immunocompetent host in whom bacterial pneumonia is adequately recognized and treated, the survival rate is high. For example, the mortality rate from uncomplicated pneumococcal pneumonia is less than 1%. If the patient survives the initial illness, persistently abnormal pulmonary function following empyema is surprisingly uncommon, even when treatment has been delayed or inappropriate.

VIRAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Upper respiratory infection prodrome (fever, coryza, cough, hoarseness).
- Wheezing or rales.
- Myalgia, malaise, headache (older children).

General Considerations

Most pneumonias in children are caused by viruses. RSV, parainfluenza (1, 2, and 3) viruses, and influenza (A and

B) viruses are responsible for more than 75% of cases. Severity of disease, height of fever, radiographic findings, and the characteristics of cough or lung sounds do not reliably differentiate viral from bacterial pneumonias. Furthermore, such infections may coexist. However, substantial pleural effusions, pneumatoceles, abscesses, lobar consolidation with lobar volume expansion, and “round” pneumonias are generally inconsistent with viral disease.

Clinical Findings

A. SYMPTOMS AND SIGNS

An upper respiratory infection frequently precedes the onset of lower respiratory disease due to viruses. Although wheezing or stridor may be prominent in viral disease, cough, signs of respiratory difficulty (retractions, grunting, nasal flaring), and physical findings (rales, decreased breath sounds) may not be distinguishable from those in bacterial pneumonia.

B. LABORATORY FINDINGS

The peripheral white blood cell count can be normal or slightly elevated and is not useful in distinguishing viral from bacterial disease. A markedly elevated neutrophil count, however, indicates that viral disease is less likely.

Rapid viral diagnostic methods—such as fluorescent antibody tests or ELISA for RSV or other viruses—should be performed on nasopharyngeal secretions to confirm this diagnosis in high-risk patients and for epidemiology or infection control. Rapid diagnosis of RSV infection does not preclude the possibility of concomitant infection with other pathogens.

C. IMAGING

Chest radiographs frequently show perihilar streaking, increased interstitial markings, peribronchial cuffing, or patchy bronchopneumonia. Lobar consolidation may occur, however, as in bacterial pneumonia. Patients with adenovirus disease may have severe necrotizing pneumonias, resulting in the development of pneumatoceles. Hyperinflation of the lungs may occur when involvement of the small airways is prominent.

Differential Diagnosis

The differential diagnosis of viral pneumonia is the same as for bacterial pneumonia. Patients with prominent wheezing may have asthma, airway obstruction caused by foreign body aspiration, acute bacterial or viral tracheitis, or parasitic disease.

Complications

Bronchiolitis obliterans or severe chronic respiratory failure may follow adenovirus pneumonia. Bronchiolitis

or viral pneumonia may contribute to persistent reactive airway disease in some patients. Bronchiectasis, persistent interstitial lung diseases (fibrosis and desquamative interstitial pneumonitis), and unilateral hyperlucent lung (Swyer–James syndrome) may follow measles, adenovirus, and influenza pneumonias. Viral pneumonia or laryngotracheobronchitis may predispose the patient to subsequent bacterial tracheitis or pneumonia as immediate sequelae. Plasma cell granuloma may develop as a rare sequel to viral or bacterial pneumonia.

Treatment

General supportive care for viral pneumonia does not differ from that for bacterial pneumonia. Patients can be quite ill and should be hospitalized according to the level of their illness. Because bacterial disease often cannot be definitively excluded, antibiotics may be indicated.

Patients at risk for life-threatening RSV infections (eg, those with bronchopulmonary dysplasia or other severe pulmonary conditions, congenital heart disease, or significant immunocompromise) should be hospitalized and given ribavirin. Rapid viral diagnostic tests may be a useful guide for such therapy (see Bronchiolitis section regarding prevention). These high-risk patients should be immunized annually against influenza A and B viruses. Despite immunization, however, influenza can still occur. When available epidemiologic data indicate an active influenza A infection in the community, rimantadine, amantadine hydrochloride, or oseltamivir phosphate should be considered early for high-risk infants and children who appear to be infected. Children with suspected viral pneumonia should be placed in respiratory isolation.

Prognosis

Although most children with viral pneumonia recover uneventfully, worsening reactive airway disease, abnormal pulmonary function or chest radiographs, persistent respiratory insufficiency, and even death may occur in high-risk patients such as newborns or those with underlying lung, cardiac, or immunodeficiency disease. Patients with adenovirus infection or those concomitantly infected with RSV and second pathogens such as influenza, adenovirus, CMV, or *P jiroveci* also have a poorer prognosis.

CHLAMYDIAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cough, tachypnea, rales, few wheezes, and no fever.
- Appropriate age: 2–12 weeks.
- Inclusion conjunctivitis, eosinophilia, and elevated immunoglobulins can be seen.

General Considerations

Pulmonary disease due to *C trachomatis* usually evolves gradually as the infection descends the respiratory tract. Infants may appear quite well despite the presence of significant pulmonary illness. Infant infections are now at epidemic proportions in urban environments worldwide. Other sexually transmitted organisms such as *Ureaplasma urealyticum* may also be widespread and contribute to lung disease in infants.

Clinical Findings

A. SYMPTOMS AND SIGNS

About 50% of patients with chlamydial pneumonia have active inclusion conjunctivitis or a history of it. Rhinopharyngitis with nasal discharge or otitis media may have occurred or may be currently present. Female patients may have vulvovaginitis.

Cough is usually present. It can have a staccato character and resemble the cough of pertussis. The infant is usually tachypneic. Scattered inspiratory rales are commonly heard, but wheezes rarely. Significant fever suggests a different or additional diagnosis.

B. LABORATORY FINDINGS

Although patients may frequently be hypoxemic, CO₂ retention is not common. Peripheral blood eosinophilia (400 cells/μL) has been observed in about 75% of patients. Serum immunoglobulins are usually abnormal. IgM is virtually always elevated, IgG is high in many, and IgA is less frequently abnormal. *C trachomatis* can usually be identified in nasopharyngeal washings using fluorescent antibody or culture techniques.

C. IMAGING

Chest radiographs may reveal diffuse interstitial and patchy alveolar infiltrates, peribronchial thickening, or focal consolidation. A small pleural reaction can be pre-

sent. Despite the usual absence of wheezes, hyperexpansion is commonly present.

Differential Diagnosis

Bacterial, viral, and fungal (*P jiroveci*) pneumonias should be considered. Premature infants and those with bronchopulmonary dysplasia may also have chlamydial pneumonia.

Treatment

Erythromycin or sulfisoxazole therapy should be administered for 14 days. Hospitalization may be required for infants with significant respiratory distress, coughing paroxysms, or posttussive apnea. Oxygen therapy may be required for prolonged periods in some patients.

Prognosis

An increased incidence of obstructive airway disease and abnormal pulmonary function tests may occur for at least 7–8 years following infection.

MYCOPLASMAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever.
- Cough.
- Appropriate age: older than 5 years.

General Considerations

M pneumoniae is a common cause of symptomatic pneumonia in older children. Endemic and epidemic infection can occur. The incubation period is long (2–3 weeks), and the onset of symptoms is slow. Although the lung is the primary infection site, extrapulmonary complications sometimes occur.

Clinical Findings

A. SYMPTOMS AND SIGNS

Fever, cough, headache, and malaise are common symptoms as the illness evolves. Although cough is usually dry at the onset, sputum production may develop as the illness progresses. Sore throat, otitis media, otitis externa, and bullous myringitis may occur. Rales are frequently present on chest examination; decreased breath sounds or dullness to percussion over the involved area may be present.

B. LABORATORY FINDINGS

The total and differential white blood cell counts are usually normal. The cold hemagglutinin titer can be determined and may be elevated during the acute presentation. A titer of 1:64 or higher supports the diagnosis. Acute and convalescent titers for *M pneumoniae* demonstrating a fourfold or greater rise in specific antibodies confirm the diagnosis.

C. IMAGING

Chest radiographs usually demonstrate interstitial or bronchopneumonic infiltrates, frequently in the middle or lower lobes. Pleural effusions are extremely uncommon.

Complications

Extrapulmonary involvement of the blood, CNS, skin, heart, or joints can occur. Direct Coombs-positive autoimmune hemolytic anemia, occasionally a life-threatening disorder, is the most common hematologic abnormality that can accompany *M pneumoniae* infection. Coagulation defects and thrombocytopenia can also occur. Cerebral infarction, meningoencephalitis, Guillain-Barré syndrome, cranial nerve involvement, and psychosis all have been described. A wide variety of skin rashes, including erythema multiforme and Stevens-Johnson syndrome, can occur. Myocarditis, pericarditis, and a rheumatic fever-like illness can also occur.

Treatment

Antibiotic therapy with a macrolide for 7–10 days usually shortens the course of illness. Ciprofloxacin is a possible alternative. Supportive measures, including hydration, antipyretics, and bed rest, are helpful.

Prognosis

In the absence of the less common extrapulmonary complications, the outlook for recovery is excellent. The extent to which *M pneumoniae* can initiate or exacerbate chronic lung disease is not well understood.

Kim CK et al: Late abnormal findings on high-resolution computed tomography after *Mycoplasma pneumoniae*. *Pediatrics* 2000;105:372 [PMID: 10654958].

TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Positive tuberculin skin test or anergic host.
- Positive culture for *Mycobacterium tuberculosis*.

General Considerations

There is a resurgence of tuberculosis in all age groups, including children. The clinical spectrum of tuberculosis includes a positive tuberculin skin test without evident disease, asymptomatic primary infection, the Ghon complex, bronchial obstruction with secondary collapse or obstructed airways, segmental lesions, calcified nodules, pleural effusions, progressive primary cavitating lesions, contiguous spread into adjacent thoracic structures, acute miliary tuberculosis, ARDS, overwhelming reactivation infection in the immunocompromised host, occult lymphohematogenous spread, and metastatic extrapulmonary involvement at almost any site. Symptoms of airway obstruction, sometimes with secondary bacterial pneumonia resulting from hilar adenopathy, are common presenting features in children.

Clinical Findings

A. SYMPTOMS AND SIGNS

The most important aspect of the history is contact with an individual with tuberculosis—often an elderly relative, a caregiver, or a person previously residing in a region where tuberculosis is endemic—or a history of travel to or residence in such an area. Homeless and extremely impoverished children are also at high risk, as are those in contact with high-risk adults (acquired immunodeficiency syndrome [AIDS] patients, residents or employees of correctional institutions or nursing homes, drug users, and health care workers). Once exposed, pediatric patients at risk for developing active disease include infants and those with malnutrition, AIDS, diabetes mellitus, or immunosuppression (cancer chemotherapy, corticosteroids). In suspected cases, the patient, immediate family, and suspected carriers

should be tuberculin-tested. Spread is mainly respiratory, so isolated pulmonary parenchymal tuberculosis constitutes more than 95% of presenting cases. The primary focus (usually single) and associated nodal involvement may not be seen radiographically. Because healing—rather than progression—is the usual course in the uncompromised host, a positive tuberculin test may be the only manifestation. However, for patients born outside the United States, a positive test may indicate only a previous bacille Calmette–Guérin (BCG) immunization.

The tuberculous complications listed previously most often occur during the first year of infection. Thereafter, infection remains quiescent until adolescence, when reactivation of pulmonary tuberculosis is common. At any stage, chronic cough, anorexia, weight loss or failure to gain weight, and fever are useful clinical signs if present. Except in cases with complications or advanced disease, physical findings are few. Most children with pulmonary tuberculosis are asymptomatic.

B. LABORATORY FINDINGS

A positive tuberculin skin test is defined as 10 mm or more of induration 48–72 hours after intradermal injection of 5 tuberculin units of purified protein derivative (PPD). Tine tests should not be used. Appropriate control skin tests, such as those for hypersensitivity to diphtheria–tetanus, mumps, or *Candida albicans*, should be applied at the same time PPD is applied. If the patient fails to respond to PPD and all of the controls, the possibility of tuberculosis is not excluded.

Anteroposterior and lateral chest radiographs should be obtained in all suspected cases. Culture for *M tuberculosis* is critical for proving the diagnosis and for defining drug susceptibility. Early morning gastric lavage following an overnight fast should be performed on three occasions in infants and children with suspected active pulmonary tuberculosis before treatment is started, when the severity of illness allows. Although stains for acid-fast bacilli on this material are of little value, this is the ideal culture site. Despite the increasing importance of isolating organisms because of multiple drug resistance, only 40% of children will yield positive cultures.

Sputum cultures from older children and adolescents are similarly useful. Stains and cultures of bronchial secretions are useful if bronchoscopy is performed as part of the patient's evaluation. When pleural effusions are present, pleural biopsy for cultures and histopathologic examination for granulomas or organisms provide diagnostic information. Meningeal involvement is a possibility in young children, and lumbar puncture should be considered in their initial evaluation.

Differential Diagnosis

Fungal diseases that affect mainly the lungs, such as histoplasmosis, coccidioidomycosis, cryptococcosis, and North American blastomycosis, may resemble tuberculosis and in doubtful cases should be excluded by appropriate serologic studies. Atypical tuberculous organisms may involve the lungs, especially in the immunocompromised patient. Depending on the presentation, diagnoses such as lymphoreticular and other malignancies, collagen–vascular disorders, or other pulmonary infections may be considered.

Complications

In addition to those complications listed in the General Considerations and Clinical Findings sections, lymphadenitis, meningitis, osteomyelitis, arthritis, enteritis, peritonitis, and renal, ocular, middle ear, and cutaneous disease may occur. The infant born to tuberculous parents is at great risk for developing illness. The possibility of life-threatening airway compromise must always be considered in patients with large mediastinal or hilar lesions.

Treatment

Because the risk of hepatitis due to isoniazid is extremely low in children, this drug is indicated in those with a positive tuberculin skin test. This greatly reduces the risk of subsequent active disease and complications with minimal morbidity. Isoniazid plus rifampin treatment for 6 months, plus pyrazinamide during the first 2 months, is indicated when the chest radiograph is abnormal or when extrapulmonary disease is present. Without pyrazinamide, isoniazid plus rifampin must be given for 9 months. In general, the more severe tuberculous complications are treated with a larger number of drugs. Enforced, directly observed therapy (twice weekly or more often) is indicated when noncompliance is suspected. Recommendations for antituberculosis chemotherapy, based on disease stage, are continuously being updated. The most current edition of the *AAP Red Book* is a reliable source for these protocols.

Corticosteroids are used to control inflammation in selected patients with potentially life-threatening airway compression by lymph nodes, acute pericardial effusion, massive pleural effusion with mediastinal shift, or, perhaps, miliary tuberculosis with respiratory failure.

Prognosis

In patients with an intact immune system, modern antituberculous therapy offers good potential for recovery. The outlook for patients with immunodeficiencies, organisms resistant to multiple drugs, poor drug compli-

ance, or advanced complications is guarded. Organisms resistant to multiple drugs are increasingly common. Resistance emerges either because the physician prescribes an inadequate regimen or because the patient discontinues medications. When resistance to or intolerance of isoniazid and rifampin prevents their use, cure rates are 50% or less.

ASPIRATION PNEUMONIA

Patients whose anatomic defense mechanisms are impaired are at risk of aspiration pneumonia (Table 18–2). Acute disease is commonly caused by bacteria present in the mouth (especially gram-negative anaerobes). Chronic aspiration often causes recurrent bouts of acute febrile pneumonia. It may also lead to chronic focal infiltrates, atelectasis, illness resembling asthma or interstitial lung disease, or failure to thrive.

Clinical Findings

A. SYMPTOMS AND SIGNS

Acute onset of fever, cough, respiratory distress, or hypoxemia in a patient at risk suggests aspiration pneumonia. Chest physical findings, such as rales, rhonchi, or decreased breath sounds, may initially be limited to the lung region into which aspiration occurred. Although any region may be affected, the right side—especially the right upper lobe in the supine patient—is commonly affected. In patients with chronic aspiration,

Table 18–2. Risk factors for aspiration pneumonia.

Seizures
Depressed sensorium
Recurrent gastroesophageal reflux, emesis, or gastrointestinal obstruction
Neuromuscular disorders with suck–swallow dysfunction
Anatomic abnormalities (laryngeal cleft, tracheoesophageal fistula, vocal cord paralysis)
Debilitating illnesses
Occult brainstem lesions
Near-drowning
Nasogastric, endotracheal, or tracheostomy tubes
Severe periodontal disease

diffuse wheezing may occur. Generalized rales may also be present. Such patients may not develop acute febrile pneumonias.

B. LABORATORY FINDINGS AND IMAGING

Chest radiographs may reveal lobar consolidation or atelectasis and focal or generalized alveolar or interstitial infiltrates. In some patients with chronic aspiration, perihilar infiltrates with or without bilateral air trapping may be seen.

In severely ill patients with acute febrile illnesses, a bacteriologic diagnosis should be made. In addition to blood cultures, cultures of tracheobronchial secretions and bronchoalveolar lavage or lung puncture specimens may be desirable (see Culture of Material from the Respiratory Tract section).

In patients with chronic aspiration pneumonitis, solid documentation of aspiration as the cause of illness may be elusive. Barium contrast studies may provide evidence of suck–swallow dysfunction, laryngeal cleft, occult tracheoesophageal fistula, or gastroesophageal reflux. Overnight or 24-hour esophageal pH probe studies may also help establish the latter. Although radionuclide scans are commonly used, the yield from such studies is disappointingly low. Rigid bronchoscopy in infants or flexible bronchoscopy in older children can be useful in more definitively excluding tracheoesophageal fistula and obtaining bronchoalveolar lavage specimens to search for lipid-laden macrophages, which can suggest chronic aspiration.

Differential Diagnosis

In the acutely ill patient, bacterial and viral pneumonias should be considered. In the chronically ill patient, the differential diagnosis may include disorders causing recurrent pneumonia (eg, immunodeficiencies, ciliary dysfunction, foreign body), chronic wheezing, or interstitial lung disorders (see Interstitial Lung Disease section), depending on the presentation.

Complications

Empyema or lung abscess may result from acute aspiration pneumonia. Chronic disease may result in bronchiectasis.

Treatment

Antimicrobial therapy for acute aspiration pneumonia includes coverage for gram-negative anaerobic organisms. In general, clindamycin is appropriate initial coverage. However, in some hospital-acquired infections, additional coverage for multiply resistant *P aeruginosa*, streptococci, and other organisms may be required.

Treatment of recurrent and chronic aspiration pneumonia may include the following: surgical correction of anatomic abnormalities; improved oral hygiene; improved hydration; and inhaled bronchodilators, chest physical therapy, and suctioning. In patients with compromise of the CNS, exclusive feeding by gastrostomy and (in some) tracheostomy may be required to control airway secretions. Gastroesophageal reflux, often requiring surgical correction, is commonly present in such patients.

Prognosis

The outlook is directly related to the disorder causing aspiration.

PNEUMONIA IN THE IMMUNOCOMPROMISED HOST

Pneumonia in an immunocompromised host may be due to any common bacteria (streptococci, staphylococci, *M pneumoniae*) or less common pathogens such as *Toxoplasma gondii*, *P jiroveci*, *Aspergillus* species, *Mucor*, *Candida* species, *Cryptococcus neoformans*, gram-negative enteric and anaerobic bacteria, *Nocardia*, *Legionella pneumophila*, mycobacteria, and viruses (CMV, varicella-zoster, herpes simplex, influenza virus, RSV, adenovirus). Multiple organisms are commonly present.

Clinical Findings

A. SYMPTOMS AND SIGNS

Patients often present with subtle signs such as mild cough, tachypnea, or low-grade fever that can rapidly progress to high fever, respiratory distress, and hypoxemia. An obvious portal of infection, such as an intravascular catheter, may predispose to bacterial or fungal infection.

B. LABORATORY FINDINGS AND IMAGING

Fungal, parasitic, or bacterial infection, especially with antibiotic-resistant bacteria, should be suspected in the neutropenic child. Cultures of peripheral blood, sputum, tracheobronchial secretions, urine, nasopharynx or sinuses, bone marrow, pleural fluid, biopsied lymph

nodes, or skin lesions or cultures through intravascular catheters should be obtained as soon as infection is suspected.

Invasive methods are commonly required to make a diagnosis. Appropriate samples should be obtained soon after a patient with pneumonia fails to respond to initial treatment. The results of these procedures usually lead to important changes in empiric preoperative therapy. Sputum is often unavailable. Bronchoalveolar lavage frequently provides the diagnosis of one or more organisms and should be done early in evaluation. The combined use of a wash, brushing, and lavage has a high yield. In patients with rapidly advancing disease, lung biopsy becomes more urgent. The morbidity and mortality rates of this procedure can be reduced by a thoracoscopic approach by a skilled operator. Because of the multiplicity of organisms that may cause disease, a comprehensive set of studies should be done on lavage and biopsy material. These consist of rapid diagnostic studies, including fluorescent antibody studies for *Legionella*; rapid culture and antigen detection for viruses; Gram, acid-fast, and fungal stains; cytologic examination for viral inclusions; cultures for viruses, anaerobic and aerobic bacteria, fungi, mycobacteria, and *Legionella*; and rapid immunofluorescent studies for *P jiroveci*.

Chest radiographs may be useful. In *P jiroveci* pneumonia, dyspnea and hypoxemia may be marked despite minimal radiographic abnormalities.

Differential Diagnosis

The organisms causing disease vary with the type of immunocompromise present. For example, the splenectomized patient may be overwhelmed by infection with *S pneumoniae* or *H influenzae*. The infant receiving adrenocorticotropic hormone therapy may be more likely to have *P jiroveci* infection. The febrile neutropenic child who has been receiving adequate doses of intravenous broad-spectrum antibiotics may have fungal disease. The key to diagnosis is to consider all possibilities of infection.

Depending on the form of immunocompromise, perhaps only one half to two thirds of new pulmonary infiltrates in such patients represent infection. The remainder are caused by pulmonary toxicity of radiation, oxygen, chemotherapy, or other drugs; pulmonary disorders, including hemorrhage, embolism, atelectasis, aspiration, or ARDS; recurrence or extension of primary malignant growths or immunologic disorders; transfusion reactions, leukostasis, or tumor cell lysis; or interstitial lung disease, such as lymphocytic interstitial pneumonitis with human immunodeficiency virus (HIV) infection.

Complications

Respiratory failure, shock, multiple organ damage, disseminated infection, and death commonly occur in the infected immunocompromised host.

Treatment

Broad-spectrum intravenous antibiotics are indicated early in febrile, neutropenic, or immunocompromised children. Trimethoprim–sulfamethoxazole (for *Pneumocystis*) and erythromycin (for *Legionella*) are also indicated early in the treatment of immunocompromised children before an organism is identified. Further therapy should be based on studies of specimens obtained from bronchoalveolar lavage or lung biopsy.

Prognosis

Prognosis is based on the severity of the underlying immunocompromise, appropriate early diagnosis and treatment, and the infecting organisms.

HYPERSENSITIVITY PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of exposure (eg, birds, organic dusts, or molds).
- Interstitial infiltrates on chest radiograph or diffuse rales.
- Recurrent cough, fever, wheezing, or weight loss can occur.

General Considerations

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, is a T-cell-mediated disease involving the peripheral airways, interstitium, and alveoli. Both acute and

chronic forms may occur. In children, the most common forms are brought on by exposure to domestic and occasionally wild birds or bird droppings (eg, pigeons, parakeets, parrots, doves). Inhalation of almost any organic dust, however (moldy hay, compost, logs or tree bark, sawdust, or aerosols from humidifiers), can cause disease. Methotrexate-induced hypersensitivity has also been described in a child with juvenile rheumatoid arthritis. A high level of suspicion and a thorough history are required for diagnosis.

Clinical Findings

SYMPTOMS AND SIGNS

Episodic cough and fever can occur with acute exposures. Chronic exposure results in weight loss, fatigue, dyspnea, cyanosis, and, ultimately, respiratory failure.

B. LABORATORY FINDINGS

Acute exposure may be followed by polymorphonuclear leukocytosis with eosinophilia and evidence of airway obstruction on pulmonary function testing. Chronic disease results in a restrictive picture on lung function tests. Arterial blood gases may reveal hypoxemia with a decreased PaCO₂ and normal pH.

The serologic key to diagnosis is the finding of precipitins (precipitating IgG antibodies) to the organic dusts that contain avian proteins or fungal or bacterial antigens. Ideally, to identify avian proteins, the patient's sera should be tested with antigens from droppings of the suspected species of bird. However, exposure may invoke precipitins without causing disease.

Differential Diagnosis

Patients with mainly acute symptoms must be differentiated from those with atopic asthma. Patients with chronic symptoms must be distinguished from those with collagen-vascular, immunologic, or primary interstitial pulmonary disorders.

Complications

Prolonged exposure to offending antigens may result in pulmonary hypertension due to chronic hypoxemia, cor pulmonale, irreversible restrictive lung disease due to pulmonary fibrosis, or respiratory failure.

Treatment

Complete elimination of exposure to the offending antigens is required. Corticosteroids may hasten recovery.

Prognosis

With appropriate diagnosis and avoidance of offending antigens, the prognosis is excellent. A good prognosis, however, is dependent on early diagnosis before pulmonary damage is irreversible.

Grech V et al: Pigeon breeder's lung in childhood: Varied clinical picture at presentation. *Pediatr Pulmonol* 2000;30:145 [PMID: 10922137].

INTERSTITIAL LUNG DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Tachypnea, dyspnea, retractions, or hypoxemia.*
- *Cough or rales.*
- *Bilateral pulmonary infiltrates.*

General Considerations

Interstitial disorders in children are commonly caused by infection, immunodeficiency, aspiration, cardiac disease, or pulmonary vascular disease. Genetic causes such as SP-B and SP-C mutations are now also identified. Children are less likely than adults to have primary (idiopathic) pulmonary interstitial lung disorders (eg, desquamative, usual, or lymphocytic interstitial pneumonitis), hypersensitivity pneumonitis, or collagen-vascular diseases.

Clinical Findings

A. SYMPTOMS AND SIGNS

Children may present with a chronic dry cough or a history of dyspnea on exertion. The child with more advanced disease may have increased dyspnea, tachypnea, retractions, cyanosis, clubbing, failure to thrive, or weight loss. Physical examination may reveal these findings, and dry ("Velcro") rales may be present on chest auscultation, especially at the lung bases.

B. LABORATORY FINDINGS AND IMAGING

Chest radiographs are normal in up to 10–15% of patients. More commonly, diffuse or perihilar bilateral reticular interstitial infiltrates are present. Nodular and reticulonodular diseases are uncommon in children except in HIV infection. Bilateral disease is the rule except

cept in cases of infection and aspiration-related disorders, which may be unilateral.

On pulmonary function testing, interstitial disorders often show a restrictive pattern of decreased lung volumes, compliance, and diffusing capacity for carbon monoxide, whereas the FEV₁/FVC ratio may be normal or increased. However, exercise-induced hypoxemia is often the earliest detectable abnormality of lung function. Blood gas abnormalities include hypoxemia, a low PaCO₂, and normal pH.

Many chronically ill patients can be investigated in a sequence of (1) serologic, (2) bronchoscopic, and (3) biopsy steps. Although bronchoalveolar lavage may be useful in identifying patients who have pulmonary hemosiderosis (hemosiderin-laden macrophages), aspiration (lipid-laden macrophages), and infectious disorders, lung biopsy is the most reliable method for definitive diagnosis.

During the initial phase, the following diagnostic studies may be considered: radiographs, barium swallow, pulmonary function tests, skin tests (see Tuberculosis section); complete blood count and erythrocyte sedimentation rate; sweat chloride test for CF; ECG or echocardiogram; serum immunoglobulins and other immunologic evaluations; sputum studies (see Pneumonia in the Immunocompromised Host section); and studies for Epstein–Barr virus, CMV, *M pneumoniae*, *Chlamydia*, *Pneumocystis*, and *U urealyticum*.

During the second phase, bronchoscopy should be performed to exclude anatomic abnormalities and obtain multiple bronchial biopsies or brushings to examine cilia. At the same procedure, bronchoalveolar lavage should be done for microbiologic and cytologic testing. In some instances, an SP-B protein analysis should also be performed. In patients with static or slowly progressing disease, one can then await results of bronchoscopic studies. In patients with acute, rapidly progressive disease, this stage should be combined with thoracoscopic biopsy. Special stains and cultures, immunofluorescence for immune complexes, and electron microscopy should be ordered. Genomic analysis of tissue or blood for SP-B and SP-C should be sought if clinically indicated. Although transbronchial biopsy may be useful in diagnosing a few disorders (eg, sarcoidosis), its overall usefulness in pediatrics is limited.

Differential Diagnosis

Malignant disorders (histiocytosis X, disseminated carcinoma), congenital disorders (Gaucher disease, neurofibromatosis, tuberous sclerosis, familial interstitial lung disease), pulmonary hemosiderosis, pulmonary telangiectasia or lymphangiectasia, bronchiolitis obliterans, sarcoidosis, and ciliary dyskinesia should be con-

sidered in addition to the groups of disorders mentioned earlier.

Complications

Respiratory failure or pulmonary hypertension with cor pulmonale may occur.

Treatment

Therapy for interstitial lung disease due to infection, aspiration, or cardiac disorders should be directed toward the primary disorder. Most of the primary pulmonary interstitial disorders are treated initially with prednisone (2 mg/kg/d) for 6 weeks to 6 months depending on the severity of disease and the response. Many patients require even more protracted therapy with alternate-day prednisone. Chloroquine (5–10 mg/kg/d) may be useful in selected disorders such as desquamative interstitial pneumonitis. In refractory cases, azathioprine and cyclophosphamide may be tried. Pulse steroids given intravenously in doses of 10 to 30 mg/kg for 1 to 3 days have shown benefit in case reports of children with pulmonary fibrosis. Newer antifibrotic agents such as interferon gamma, being investigated in adult patients with interstitial pulmonary fibrosis, have not been tried in children to date. Addition of cytotoxic drugs (azathioprine, cyclophosphamide) has not been shown to be more beneficial than prednisone alone.

Prognosis

The prognosis is guarded in children with interstitial lung disease due to collagen–vascular and primary pulmonary interstitial diseases, immunodeficiency diseases, surfactant protein mutations, and cancer.

EOSINOPHILIC PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pulmonary infiltrates, often migratory, seen on chest radiograph.
- Persistent cough; wheezes or rales on chest auscultation.

- Increased eosinophils in peripheral blood or in lung biopsy specimens.

General Considerations

A spectrum of diseases should be considered under this heading: (1) allergic bronchopulmonary helminthiasis (ABPH), (2) pulmonary eosinophilia with asthma (allergic bronchopulmonary aspergillosis and related disorders), (3) hypereosinophilic mucoid impaction, (4) bronchocentric granulomatosis, and (5) collagen-vascular disorders. The old term, Löffler syndrome (transient migratory pulmonary infiltrates and eosinophilia), is no longer used because most patients had undiagnosed ABPH, medication reactions (www.pneumotox.com), or allergic bronchopulmonary aspergillosis. Many of these disorders occur in children with personal or family histories of allergies or asthma. APBH may be related to hypersensitivity to migratory parasitic nematodes (*Ascaris*, *Strongyloides*, *Ancylostoma*, *Toxocara*, *Trichuris*) and larval forms of filariae (*Wuchereria bancrofti*). Allergic bronchopulmonary aspergillosis is related to hypersensitivity to the fungus *Aspergillus*. Hypersensitivity to other fungi has also been documented. Eosinophilic pneumonias are rare but can be associated with drug hypersensitivity, sarcoidosis, Hodgkin disease or other lymphomas, and bacterial infections, including brucellosis and those caused by *M tuberculosis* and atypical mycobacteria.

Clinical Findings

A. SYMPTOMS AND SIGNS

Cough, wheezing, and dyspnea are common presenting complaints. In ABPH, fever, malaise, sputum production, and, rarely, hemoptysis may be present. In allergic bronchopulmonary aspergillosis, patients may present all of these findings and occasionally produce brown mucus plugs. Anorexia, weight loss, night sweats, and clubbing can also occur.

B. LABORATORY FINDINGS AND IMAGING

Elevated absolute peripheral blood eosinophil counts (3000/ μ L and often exceeding 50% of leukocytes) are present in APBH and allergic bronchopulmonary aspergillosis. Serum IgE levels as high as 1000–10,000 IU/mL are common. In allergic bronchopulmonary aspergillosis, the serum IgE concentration appears to correlate with activity of the disease. Stools should be examined for ova and parasites—often several times—to clarify the diagnosis. Isohemagglutinin titers are often markedly elevated in APBH.

In allergic bronchopulmonary aspergillosis and related disorders, patients may show central bronchiectasis on chest radiograph (so-called tramlines) or CT scan. Saccular proximal bronchiectasis of the upper lobes is pathognomonic. Although the chest radiograph may be normal, peribronchial haziness, focal or plate-like atelectasis, or patchy to massive consolidation can occur. Positive immediate skin tests, serum IgG precipitating antibodies, or IgE specific for the offending fungus is present.

Differential Diagnosis

These disorders must be differentiated from exacerbations of asthma, CF, or other underlying lung disorders that cause infiltrates to appear on chest radiographs. Allergic bronchopulmonary aspergillosis can occur in patients with CF.

Complications

Delayed recognition and treatment of allergic bronchopulmonary aspergillosis may cause progressive lung damage and bronchiectasis. Lesions of the conducting airways in bronchocentric granulomatosis can extend into adjacent lung parenchyma and pulmonary arteries, resulting in secondary vasculitis.

Treatment

Therapy for the specific parasite causing ABPH should be given, and corticosteroids may be required when illness is severe. Treatment of disease due to microfilariae is both diagnostic and therapeutic. Allergic bronchopulmonary aspergillosis and related disorders are treated with prolonged courses of oral corticosteroids, bronchodilators, and chest physical therapy. In patients with CF, itraconazole may decrease steroid doses for those with allergic bronchopulmonary aspergillosis. Pulmonary vasculitis associated with collagen vascular disease usually is treated with high-dose steroids or cytotoxic agents.

LUNG ABSCESS

Lung abscesses are most likely to occur in immunocompromised patients; in those with severe infections elsewhere (embolic spread); or in those with recurrent aspiration, malnutrition, or blunt chest trauma. Although organisms such as *S aureus*, *H influenzae*, *S pneumoniae*, and viridans streptococci more commonly affect the previously normal host, anaerobic and gram-negative organisms as well as *Nocardia*, *Legionella* species, and fungi (*Candida*, *Aspergillus*) should also be considered in the immunocompromised host.

Clinical Findings

A. SYMPTOMS AND SIGNS

High fever, malaise, and weight loss are often present. Symptoms and signs referable to the chest may or may not be present. In infants, evidence of respiratory distress can be present.

B. LABORATORY FINDINGS AND IMAGING

Elevated peripheral white blood cell count with a neutrophil predominance or an elevated erythrocyte sedimentation rate may be present. Blood cultures are rarely positive except in the overwhelmed host.

Chest radiographs usually reveal single or multiple thick-walled lung cavities. Air–fluid levels can be present. Local compressive atelectasis, pleural thickening, or adenopathy may also occur. Chest CT scan may provide better localization and understanding of the lesions.

In patients producing sputum, stains and cultures may provide the diagnosis. Direct percutaneous aspiration of material for stains and cultures guided by fluoroscopy or ultrasonography should be considered in the severely compromised or ill.

Differential Diagnosis

Loculated pyopneumothorax, an *Echinococcus* cyst, neoplasms, plasma cell granuloma, and infected congenital cysts and sequestrations should be considered.

Complications

Although complications due to abscesses are now rare, mediastinal shift, tension pneumothorax, and spontaneous rupture can occur. Diagnostic maneuvers such as lung puncture may also cause complications (pneumothorax).

Treatment

Because of the risks of lung puncture, uncomplicated abscesses are frequently conservatively treated in the un-

compromised host with appropriate broad-spectrum antibiotics directed at *S aureus*, *H influenzae*, and streptococci. Additional coverage for anaerobic and gram-negative organisms should be provided for others. Prolonged therapy (3 weeks or more) may be required. Attempts to drain abscesses via bronchoscopy have caused life-threatening airway compromise. Surgical drainage or lobectomy is occasionally required, primarily in immunocompromised patients. However, such procedures may themselves cause life-threatening complications.

Prognosis

Although radiographic resolution may be very slow, resolution occurs in most patients without risk factors for lower respiratory tract infections or loss of pulmonary function. In the immunocompromised host, the outlook depends on the underlying disorder.

Wali SO et al: Percutaneous drainage of pyogenic lung abscess. *Scand J Infect Dis* 2002;34:673 [PMID: 12374359].

PULMONARY TUMORS

Primary tumors of the airway and parenchyma of the lung are unusual in pediatrics. Most intrathoracic tumors occur in or close to the mediastinum (see Mediastinal Masses section). Other pulmonary tumors may be classified as benign, malignant, or metastatic. Benign pulmonary tumors include plasma cell granulomas, hamartomas, adenomas, papillomas, angiomas, leiomyomas, lipomas, and neurogenic tumors. The most common malignant tumor in children, a bronchogenic carcinoma, is also very rare. Other malignant tumors include fibrosarcomas and leiomyosarcomas. Metastatic tumors in childhood include Wilms tumor; hepatoblastoma; and osteogenic, chondrosarcoma, Ewing, reticulum cell, and soft tissue sarcomas. Lung tumors in children are more often metastatic than primary.

Clinical Findings

A. SYMPTOMS AND SIGNS

Symptoms, when they occur, may include pain, fever, cough, wheezing, weight loss, malaise, anemia, anorexia, and hemoptysis. On physical examination, signs of a pleural effusion, volume loss, or consolidation may be present if the tumor has led to significant airway obstruction.

B. LABORATORY FINDINGS AND IMAGING

In addition to frontal and lateral chest radiographs, fluoroscopy, CT scans, and angiography may be helpful in

defining and delineating the tumor. Sputum cultures and cytology, as well as tuberculin and fungal skin tests plus fungal serology, may be needed to exclude other conditions.

Differential Diagnosis

The differential diagnosis includes acute, recurrent, or persistent viral and bacterial pneumonia, tuberculosis, and pulmonary infiltrates due to fungal infections. In infants, congenital malformations (pulmonary sequestration, cystic adenomatoid malformation) may also present as mass lesions.

Treatment & Prognosis

The appropriate therapy and the response to therapy depend on the type and location of the tumor. Benign lesions may be cured with surgical resection, but the prognosis is more guarded with both primary and metastatic malignant lesions.

Brooks JW, Krummel TM: Tumors of the chest. In Chernick V, Boat TF (eds): *Kendig's Disorders of the Respiratory Tract in Children*, 6th ed. WB Saunders, 1998.

DISEASES OF THE PULMONARY CIRCULATION

PULMONARY HEMORRHAGE

Pulmonary hemorrhage is caused by a spectrum of disorders affecting the large and small airways and alveoli. It can occur as an acute or chronic process. Hemorrhage involving the alveoli is termed diffuse alveolar hemorrhage. If pulmonary hemorrhage is subacute or chronic, hemosiderin-laden macrophages are found in the sputum and tracheal or gastric aspirate. Many cases are secondary to infection (bacterial, mycobacterial, parasitic, viral, or fungal), lung abscess, bronchiectasis (CF or other causes), foreign body, coagulopathy (often with overwhelming sepsis), or elevated pulmonary venous pressure (secondary to congestive heart failure or anatomic heart lesions). Other causes include lung contusion from trauma, arteriovenous fistula, multiple telangiectasia, pulmonary sequestration, agenesis of a single pulmonary artery, and esophageal duplication or bronchogenic cyst. Rarer causes are tumors (eg, bronchial adenoma or left atrial myxoma) and pulmonary infarction secondary to pulmonary embolus.

Diffuse alveolar hemorrhage may be idiopathic or drug-related or may occur in Goodpasture syndrome, rapidly progressive glomerulonephritis, and systemic vasculitides (often associated with such collagen–vascu-

lar diseases as systemic lupus erythematosus, rheumatoid arthritis, Wegener granulomatosis, polyarteritis nodosa, Henoch–Schönlein purpura, and Behçet disease). Idiopathic pulmonary hemosiderosis refers to the accumulation of hemosiderin in the lung, especially the alveolar macrophage, as a result of chronic or recurrent hemorrhage (usually from pulmonary capillaries) that is not associated with the previously listed causes. Children and young adults are mainly affected, with the age at onset ranging from 6 months to 20 years. This group of disorders includes milk allergy in young infants (Heiner syndrome).

Several cases of pulmonary hemorrhage and pulmonary hemosiderosis have been reported in infants exposed to a toxigenic mold, *Stachybotrys chartarum*, and other fungi. This association was initially noted in Cleveland, Ohio. The infants were primarily African American, living in older homes, and often the homes had recent water damage. Environmental tobacco smoke was also frequently present in the environment. Other forms of hypersensitivity pneumonitis have also been reported to cause pulmonary bleeding.

Clinical Findings

A. SYMPTOMS AND SIGNS

Pulmonary hemorrhage has as many symptoms as it has causes. Large airway hemorrhage presents with hemoptysis and symptoms of the underlying cause, such as infection, foreign body, or bronchiectasis in CF. Hemoptysis from larger airways is often bright red or contains clots. Idiopathic pulmonary hemosiderosis usually presents with nonspecific respiratory symptoms (cough, tachypnea, retractions) with or without hemoptysis, poor growth, and fatigue. Some children or young adults may present with massive hemoptysis, marked respiratory distress, stridor, or a pneumonia-like syndrome. Fever, abdominal pain, digital clubbing, and chest pain may be reported. Jaundice and hepatosplenomegaly may be present with chronic bleeding. Physical examination often reveals decreased breath sounds, rales, rhonchi, or wheezing.

B. LABORATORY FINDINGS AND IMAGING

Laboratory studies vary depending on the cause of hemorrhage. Following long-standing idiopathic pulmonary hemorrhage, iron deficiency anemia and heme-positive sputum are present. Nonspecific findings may include lymphocytosis and an elevated erythrocyte sedimentation rate. Peripheral eosinophilia is present in up to 25% of patients. Chest radiographs demonstrate a range of findings, from transient perihilar infiltrates to large, fluffy alveolar infiltrates with or without atelectasis and mediastinal adenopathy. Pulmonary function testing generally reveals restrictive impairment, with

low lung volumes, poor compliance, and an increased diffusion capacity. Hemosiderin-laden macrophages are found in bronchial or gastric aspirates. The diagnostic usefulness of lung biopsy is controversial.

Diffuse alveolar hemorrhage with underlying systemic disease such as systemic lupus erythematosus, Wegener granulomatosis, and occasionally Goodpasture syndrome can occur with the histologic entity known as necrotizing pulmonary capillaritis. On lung biopsy the alveolar septa are infiltrated with neutrophils, and alveolar hemorrhage is acute or chronic. The septa can fill with edema or fibrinoid necrosis. Idiopathic pulmonary hemosiderosis may represent a mild form of capillaritis associated with alveolar hemorrhage. It might represent a process that waxes and wanes, and capillaritis may be focal or mild. Likewise, an immune-mediated process may cause idiopathic pulmonary hemosiderosis, although no serologic marker has yet been identified. Although capillaritis has been described without evidence of underlying systemic disease, the search for collagen-vascular disease, vasculitis, or pulmonary fibrosis should be exhaustive.

The investigation should include serologic studies such as antineutrophil cytoplasmic antibodies (c-ANCA) for Wegener granulomatosis, p- (perinuclear) or c-ANCA for microscopic polyangiitis, antinuclear antibodies for systemic lupus erythematosus, and antibasement membrane antibodies for Goodpasture syndrome. α 1-Antitrypsin deficiency has been associated with vasculitides and should be considered.

Suspected cases of cow's milk-induced pulmonary hemosiderosis can be confirmed by laboratory findings that include high titers of serum precipitins to multiple constituents of cow's milk and positive intradermal skin tests to various cow's milk proteins. Improvement after an empiric trial of a diet free of cow's milk also supports the diagnosis.

Differential Diagnosis

The search for the site of respiratory bleeding, underlying systemic illness, and cardiac or vascular abnormalities will help define the diagnosis. When gross hemoptysis is present, large airway bronchiectasis, epistaxis, foreign body, and arteriovenous or pulmonary malformations should be ruled out. MRI or CT-assisted angiography can localize abnormal or systemic arterial flow.

Alveolar bleeding with hemoptysis is often frothy and pink. The differential diagnosis includes the disorders causing diffuse alveolar hemorrhage listed earlier. In contrast to idiopathic pulmonary hemosiderosis, Goodpasture syndrome occurs in a slightly older age group (15–35 years), tends to have a more aggressive pulmonary course, and has renal involvement (crescentic proliferative glomerulonephritis and circulating antiglomerular basement membrane antibody).

Wegener granulomatosis also has renal involvement (granulomatous glomerulitis with necrotizing vasculitis, but renal biopsy may be nonspecific) and other systemic manifestations, especially with upper and lower respiratory tract inflammation. Upper tract involvement includes sinusitis, rhinitis, recurrent epistaxis, otitis media, saddle nose deformity, and subglottic stenosis. Wegener granulomatosis may occur without renal involvement early in the course of the disease. The diagnosis can be made by biopsy or an elevated c-ANCA titer.

Treatment

Therapy should be aimed at direct treatment of the underlying disease. Supportive measures, including iron therapy, supplemental oxygen, and blood transfusions, may be needed. A diet free of cow's milk should be tried in infants. Systemic corticosteroids have been used for various causes of diffuse alveolar hemorrhage and have been particularly successful in those secondary to collagen-vascular disorders and vasculitis. Case reports have been published on the variable effectiveness of steroids, chloroquine, cyclophosphamide, and azathioprine for idiopathic pulmonary hemosiderosis.

Prognosis

The outcome of idiopathic pulmonary hemosiderosis is variable, characterized by a waxing and waning course of intermittent intrapulmonary bleeds and the gradual development of pulmonary fibrosis over time. The severity of the underlying renal disease contributes to the mortality rates associated with Goodpasture syndrome and Wegener granulomatosis. Diffuse alveolar hemorrhage is considered a lethal pulmonary complication of systemic lupus erythematosus.

PULMONARY EMBOLISM

Although pulmonary embolism is apparently rare in children, the incidence is probably underestimated because it is often not considered in the differential diagnosis of respiratory distress. It occurs most commonly in children with sickle cell anemia as part of the acute chest syndrome and with rheumatic fever, infective endocarditis, schistosomiasis, bone fracture, dehydration, polycythemia, nephrotic syndrome, atrial fibrillation, and other conditions. A recent report suggests that a majority of children with pulmonary emboli referred for hematology evaluation have coagulation regulatory protein abnormalities and antiphospholipid antibodies. Emboli may be single or multiple, large or small, with clinical signs and symptoms dependent on the severity of pulmonary vascular obstruction.

Clinical Findings

A. SYMPTOMS AND SIGNS

Pulmonary embolism usually presents clinically as an acute onset of dyspnea and tachypnea. Heart palpitations or a sense of impending doom may be reported.

Pleuritic chest pain and hemoptysis may be present (not common), along with splinting, cyanosis, and tachycardia. Massive emboli may be present with syncope and cardiac arrhythmias. Physical examination is usually normal (except for tachycardia and tachypnea) unless the embolism is associated with an underlying disorder. Mild hypoxemia, rales, focal wheezing, or a pleural friction rub may be found.

B. LABORATORY FINDINGS AND IMAGING

Radiographic findings may be normal, but a peripheral infiltrate, small pleural effusion, or elevated hemidiaphragm can be present. If the emboli are massive, differential blood flow and pulmonary artery enlargement may be appreciated. The ECG is usually normal unless the pulmonary embolus is massive. Echocardiography is useful in detecting the presence of large proximal embolus. A negative D-dimer has a greater than 95% negative predictive value for an embolus. Ventilation–perfusion scans show localized areas of ventilation without perfusion. Spiral CT with contrast may be helpful, but

pulmonary angiography is the gold standard. Further evaluation may include Doppler ultrasound studies of the legs to search for deep venous thrombosis. Coagulation studies, including assessments of antithrombin III and protein C or S deficiencies or defective fibrinolysis, may be indicated. Antiphospholipid antibodies and other coagulation regulatory proteins (protein C and S, and factor V Leiden) should be checked as abnormalities have been demonstrated in 70% of the hematology referrals in one pediatric institution.

Treatment

Acute treatment includes supplemental oxygen, sedation, and anticoagulation. Current recommendations include heparin administration to maintain an activated partial thromboplastin time that is one and one-half or more times the control value for the first 24 hours. Urokinase (2000–4000 U/kg for 36 hours) can be used to help dissolve the embolus. Tissue plasminogen activator (t-PA) is another option via central or peripheral administration. These therapies should be followed by warfarin therapy for at least 6 weeks with an INR of greater than 2. In patients with identifiable deep venous thrombosis of the lower extremities and significant pulmonary emboli (with hemodynamic compromise despite anticoagulation), inferior vena caval interruption may be necessary. Long-term prospective data regarding this latter therapy are lacking, however.

PULMONARY EDEMA

Pulmonary edema is excessive accumulation of extravascular fluid in the lung. This occurs when fluid is filtered into the lungs faster than it can be removed, leading to changes in lung mechanics such as decreased lung compliance, worsening hypoxemia from ventilation–perfusion mismatch, bronchial compression, and, if ad-

vanced, decreased surfactant function. There are two basic types of pulmonary edema: increased pressure (cardiogenic or hydrostatic) and increased permeability (noncardiogenic or primary). Hydrostatic pulmonary edema is usually due to excessive increases in pulmonary venous pressure, which is most commonly due to congestive heart failure from multiple causes. In contrast, many lung diseases, especially ARDS, are characterized by the development of pulmonary edema secondary to changes in permeability due to injury to the alveolocapillary barrier. In these settings, pulmonary edema occurs independently of the elevations of pulmonary venous pressure.

Clinical Findings

A. SYMPTOMS AND SIGNS

Cyanosis, tachypnea, tachycardia, and respiratory distress are commonly present. Physical findings include rales, diminished breath sounds, and (in young infants) expiratory wheezing. More severe disease is characterized by progressive respiratory distress with marked retractions, dyspnea, and severe hypoxemia.

B. IMAGING

Chest radiographic findings depend on the cause of the edema. Pulmonary vessels are prominent, often with diffuse interstitial or alveolar infiltrates. Heart size is usually normal in permeability edema but enlarged in hydrostatic edema.

Treatment

Although specific therapy depends on the underlying cause, supplemental oxygen therapy and, if needed, ventilator support for respiratory failure are indicated. Diuretics, digoxin, and vasodilators may be indicated for congestive heart failure along with restriction of salt and water. Recommended interventions for permeability edema are reduction of vascular volume and maintenance of the lowest central venous or pulmonary arterial wedge pressure possible without sacrificing cardiac output or causing hypotension (see following discussion). β -Adrenergic agonists such as terbutaline have been shown to increase alveolar clearance of lung water, perhaps through the action of a sodium-potassium channel pump. Maintaining normal albumin levels and a hematocrit of greater than 30 maintains the filtration of lung liquid toward the capillaries, avoiding low oncotic pressure.

CONGENITAL PULMONARY LYMPHANGIECTASIA

Structurally, congenital pulmonary lymphangiectasia appears as dilated subpleural and interlobular lymphatic channels and may present as part of a generalized lymphangiectasis (in association with obstructive cardiovascular lesions—especially total anomalous pulmonary venous return) or as an isolated idiopathic lesion. Pathologically, the lung appears firm, bulky, and non-compressible, with prominent cystic lymphatics visible beneath the pleura. On cut section, dilated lymphatics are present near the hilum, along interlobular septa, around bronchovascular bundles, and beneath the pleura. Histologically, dilated lymphatics have a thin endothelial cell lining overlying a delicate network of elastin and collagen.

Clinical Findings

Congenital pulmonary lymphangiectasia is a rare, usually fatal disease that generally presents as acute or persistent respiratory distress at birth. Although most patients do not survive the newborn period, some survive longer, and there are isolated case reports of its diagnosis later in childhood. It may be associated with features of Noonan syndrome, asplenia, total anomalous pulmonary venous return, septal defects, atrioventricular canal, hypoplastic left heart, aortic arch malformations, and renal malformations. Chylothorax has been reported. Chest radiographic findings include a ground-glass appearance, prominent interstitial markings suggesting lymphatic distention, diffuse hyperlucency of the pulmonary parenchyma, and hyperinflation with depression of the diaphragm.

Prognosis

Although the onset of symptoms may be delayed for as long as the first few months of life, prolonged survival is extremely rare. Most deaths occur within weeks after birth. Rapid diagnosis is essential in order to expedite the option of pulmonary transplant.

DISORDERS OF THE CHEST WALL

EVENTRATION OF THE DIAPHRAGM

Eventration of the diaphragm occurs when striated muscle is replaced with connective tissue and is demonstrated on radiograph by elevation of part or all of the diaphragm. This congenital disorder is thought to represent incomplete formation of the diaphragm in utero. When defects are small, there is no paradoxical movement of the diaphragm and little symptomatology. Small eventrations may be detected on a chest radiograph taken for another reason. When defects are large, there may or may not be paradoxical movement of the diaphragm, depending on the nature of the tissue replacing the normal diaphragm. The degree of respiratory distress depends in large part on the amount of paradoxical motion of the diaphragm. When the diaphragm moves upward during inspiration, instability of the inferior border of the chest wall increases the work of breathing and can lead to respiratory muscle fatigue. Treatment for respiratory distress is surgical plication, which stabilizes the diaphragm.

The differential diagnosis of eventration includes phrenic nerve injury and partial diaphragmatic hernia. The former can result from birth or other trauma and may also be seen following cardiac surgery. In most cases, only one phrenic nerve is involved. An elevated hemidiaphragm is noted on chest radiograph, and paradoxical motion of the diaphragm may be seen by fluoroscopy or ultrasonography. Patients often cannot be extubated or have persistent respiratory compromise, particularly with feeding. If symptoms persist for 2–4 weeks, the diaphragm is surgically plicated as described previously. Function returns to the diaphragm in about 50% of cases of phrenic nerve injury whether or not plication was performed. Recovery periods of up to 100 days have been reported in these cases.

SCOLIOSIS

Scoliosis—lateral curvature of the spine—can, if uncorrected, lead to severe restrictive lung disease and death from cor pulmonale. Most cases of idiopathic scoliosis occur in adolescent girls and are corrected before significant pulmonary impairment occurs. Congenital scoliosis of severe degree or with other major abnormalities carries a more guarded prognosis. Scoliosis may also occur in patients with progressive neuromuscular dis-

ease, such as Duchenne muscular dystrophy, and can be a major contributor to respiratory failure.

PECTUS EXCAVATUM

Pectus excavatum is anterior depression of the chest wall that may be symmetrical or asymmetrical with respect to the midline. Reports of exercise testing and pulmonary function testing in patients with pectus excavatum are controversial as to whether this disorder causes physiologic limitations. Therefore, the decision to repair the deformity may be based on cosmetic or physiologic considerations. Care of patients following pectus excavatum repair requires mechanical ventilation and careful respiratory monitoring because of the weak chest wall following surgery.

Borowitz D et al: Pulmonary function and exercise response in patients with pectus excavatum after Nuss repair. *J Pediatr Surg* 2003;38:544 [PMID: 12677562].

Fonkalsrud EW: Current management of pectus excavatum. *World J Surg* 2003;27:502 [PMID: 12715210].

Malek MH et al: Ventilatory and cardiovascular responses to exercise in patients with pectus excavatum. *Chest* 2003;124:870 [PMID: 12970011].

PECTUS CARINATUM

Pectus carinatum is a bowing out of the sternum, usually apparent at birth. The abnormality may be associated with systemic diseases such as the mucopolysaccharidoses. As with pectus excavatum, pulmonary function tests are not usually abnormal in the absence of other disorders. The decision to repair this deformity is based primarily on cosmetic grounds. Postoperative care similarly requires careful monitoring because of chest wall instability produced by the repair.

Williams AM, Crabbe DC: Pectus deformities of the anterior chest wall. *Paediatr Respir Rev* 2003;4:237 [PMID: 12880759].

NEUROMUSCULAR DISORDERS

Weakness of the respiratory and pharyngeal muscles leads to chronic or recurrent pneumonia secondary to aspiration and infection, atelectasis, hypoventilation,

and respiratory failure in severe cases. Scoliosis, which frequently accompanies long-standing neuromuscular disorders, may further compromise respiratory function. Typical physical findings are a weak cough, decreased air exchange, rales, wheezing, and dullness to percussion. Signs of cor pulmonale (loud pulmonary component to the second heart sound, hepatomegaly, elevated neck veins) may be evident in advanced cases. Chest radiographs generally show small lung volumes. If chronic aspiration is present, increased interstitial infiltrates and areas of atelectasis or consolidation may be present. Arterial blood gases demonstrate hypoxemia in the early stages and compensated respiratory acidosis in the late stages. Typical pulmonary function abnormalities include low lung volumes and decreased inspiratory force generated against an occluded airway. Treatment is supportive and includes vigorous pulmonary toilet, antibiotics with infection, and oxygen to correct hypoxemia. Unfortunately, despite aggressive medical therapy, many neuromuscular conditions progress to respiratory failure and death. The decision to intubate and ventilate is a difficult one; it should be made only when there is real hope that deterioration, though acute, is potentially reversible or when chronic ventilation is wanted. Chronic mechanical ventilation using either noninvasive or invasive techniques is being used more frequently in patients with chronic respiratory insufficiency.

DISORDERS OF THE PLEURA & PLEURAL CAVITY

The visceral pleura covers the outer surface of the lungs, and the inner surface of the chest wall is the parietal pleura. Disease processes can lead to accumulation of air or fluid in the pleural space. Pleural effusions are classified as transudates or exudates. Transudates occur when there is imbalance between hydrostatic and oncotic pressure, so that fluid filtration exceeds reabsorption (eg, congestive heart failure). Exudates form as a result of inflammation of the pleural surface leading to

increased capillary permeability (eg, parapneumonic effusions). Other pleural effusions include chylothorax and hemothorax.

Thoracentesis is helpful in characterizing the fluid and providing definitive diagnosis. Recovered fluid is considered an exudate (as opposed to a transudate) if any of the following are found: a pleural fluid to serum protein ratio greater than 0.5, a pleural fluid to serum lactic dehydrogenase (LDH) ratio greater than 0.6, or a pleural fluid LDH greater than 200 units/L. Important additional studies on pleural fluid include cell count; pH and glucose; Gram, acid-fast, and fungal stains; cultures; counterimmunoelectrophoresis for specific organisms; and, occasionally, amylase concentration. Cytologic examination of pleural fluid should be performed to rule out leukemia or other neoplasm.

Hilliard TN et al: Management of parapneumonic effusion and empyema. *Arch Dis Child* 2003;88(10):915 [PMID: 14500314].

PARAPNEUMONIC EFFUSION & EMPYEMA

Bacterial pneumonia is often accompanied by pleural effusion. Some of these effusions harbor infection, and others are inflammatory reactions to pneumonia. The nomenclature in this area is somewhat confusing. Some use the term *empyema* for grossly purulent fluid and *parapneumonic effusion* for nonpurulent fluid. It is clear, however, that some nonpurulent effusions will also contain organisms and represent either partially treated or early empyema. It is probably best to refer to all effusions associated with pneumonia as parapneumonic effusions, some of which are infected and some not.

The most common organism associated with empyema is *S pneumoniae*. Other common organisms include *H influenzae* and *S aureus*. Less common causes are group A streptococci, gram-negative organisms, anaerobic organisms, and *M pneumoniae*. Effusions associated with tuberculosis are almost always sterile and constitute an inflammatory reaction.

Clinical Findings

A. SYMPTOMS AND SIGNS

Patients usually present with typical signs of pneumonia, including fever, tachypnea, and cough. They may have chest pain, decreased breath sounds, and dullness to percussion on the affected side and may prefer to lie on the affected side. With large effusions, there may be tracheal deviation to the contralateral side.

B. LABORATORY FINDINGS

The white blood cell count is often elevated, with left shift. Blood cultures are sometimes positive. The tuberculin skin test is positive in most cases of tuberculosis. Thoracentesis reveals findings consistent with an exudate. Cells in the pleural fluid are usually neutrophils in bacterial disease and lymphocytes in tuberculous effusions. In bacterial disease, pleural fluid pH and glucose are often low. pH less than 7.2 suggests active bacterial infection. The pH of the specimen should be determined in a blood gas syringe sent to the laboratory on ice. Extra heparin should not be used in the syringe since it can falsely lower the pH. Although in adults the presence of low pH and glucose necessitates aggressive and thorough drainage procedures, the prognostic significance of these findings in children is unknown. Gram stain, cultures, and counterimmunoelectrophoresis are often positive for the offending organism.

C. IMAGING

The presence of pleural fluid is suggested by a homogeneous density on chest radiograph that obscures the underlying lung. Large effusions may cause a shift of the mediastinum to the contralateral side. Small effusions may only blunt the costophrenic angle. Lateral decubitus radiographs may help to detect freely movable fluid by demonstrating a layering-out effect. If the fluid is loculated, no such effect is perceived. Ultrasonography can be extremely valuable in localizing the fluid and detecting loculations, especially when thoracentesis is contemplated.

Treatment & Prognosis

After initial thoracentesis and identification of the organism, appropriate intravenous antibiotics and adequate drainage of the fluid remain the mainstay of therapy. Although there is a trend toward managing smaller pneumococcal empyemas without a chest tube, most larger effusions require chest tube drainage. Often the empyema has been present for more than 7 days, increasing the chance for loculation of fluid. Aggressive management with drainage of pleural cavity fluid and release of adhesions is often sought in many institutions as a first line approach after thoracentesis, allowing the chest tube to be placed in the operating room under anesthesia. Some evidence suggests that thoroscopically aided debridement may be beneficial in terms of morbidity and length of hospital stay. Early decortication using thoroscopic techniques may reduce morbidity and the need for prolonged hospitalization.

The prognosis is related to the severity of disease but is generally excellent, with complete or nearly complete recovery expected in most instances.

Rodgers BM: The role of thoracoscopy in pediatric surgical practice. *Semin Pediatr Surg* 2003;12(1):62 [PMID: 12520474].

HEMOTHORAX

Accumulation of blood in the pleural space can be caused by surgical or accidental trauma, coagulation defects, and pleural or pulmonary tumors. With blunt trauma, hemopneumothorax may be present. Symptoms are related to blood loss and compression of underlying lung parenchyma. There is some risk of secondary infection, resulting in empyema. Drainage of a hemothorax is required when significant compromise of pulmonary function is present, as with hemopneumothorax. In uncomplicated cases, observation is indicated because blood is readily absorbed spontaneously from the pleural space.

Thoracoscopy with video assist has been used successfully in the management of hemothorax. Chest CT scan is helpful to select patients who may require surgery, as identification of blood and the volume of blood may be more predictive by this method than by chest radiograph.

Bliss D, Silen M: Pediatric thoracic trauma. *Crit Care Med* 2002;30 (11 Suppl):S409 [PMID: 12528782].

CHYLOTHORAX

The accumulation of chyle in the pleural space usually results from accidental or surgical trauma to the thoracic duct. In the newborn, chylothorax can be congenital or secondary to birth trauma. This condition also occurs as a result of superior vena caval obstruction secondary to central venous lines and following Fontan procedures for tricuspid atresia. Symptoms of chylothorax are related to the amount of fluid accumulation and the degree of compromise of underlying pulmonary parenchyma. Thoracentesis reveals typical milky fluid (unless the patient has been fasting) containing chiefly T lymphocytes.

Treatment should be conservative because many chylothoraces resolve spontaneously. Oral feedings with medium-chain triglycerides reduce lymphatic flow through the thoracic duct. Drainage of chylous effusions should be performed only for respiratory compromise because the fluid often rapidly reaccumulates. Repeated or continuous drainage may lead to protein malnutrition and T-cell depletion, rendering the patient relatively immunocompromised. If reaccumulation of fluid persists, surgical ligation of the thoracic

duct or sclerosis of the pleural space can be attempted, though the results may be less than satisfactory.

Beghetti M et al: Etiology and management of pediatric chylothorax. *J Pediatr* 2000;136:653 [PMID: 10802499].

Romero S: Nontraumatic chylothorax. *Curr Opin Pulm Med* 2000;6:287 [PMID: 10912634].

PNEUMOTHORAX & RELATED AIR LEAK SYNDROMES

Pneumothorax can occur spontaneously in newborns and in older children or, more commonly, as a result of birth trauma, positive-pressure ventilation, underlying obstructive or restrictive lung disease, and rupture of a congenital or acquired lung cyst. Pneumothorax can also occur as an acute complication of tracheostomy. Air usually dissects from the alveolar spaces into the interstitial spaces of the lung. Migration to the visceral pleura ultimately leads to rupture into the pleural space. Associated conditions include pneumomediastinum, pneumopericardium, pneumoperitoneum, and subcutaneous emphysema. These conditions are more commonly associated with dissection of air into the interstitial spaces of the lung with retrograde dissection along the bronchovascular bundles toward the hilum.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical spectrum can vary from asymptomatic to severe respiratory distress. Associated symptoms include cyanosis, chest pain, and dyspnea. Physical examination may reveal decreased breath sounds and hyperresonance to percussion on the affected side with tracheal deviation to the opposite side. When pneumothorax is under tension, cardiac function may be compromised, resulting in hypotension or narrowing of the pulse pressure. Pneumopericardium is a life-threatening condition that presents with muffled heart tones and shock. Pneumomediastinum rarely causes symptoms by itself.

B. IMAGING

Chest radiographs usually demonstrate the presence of free air in the pleural space. If the pneumothorax is large and under tension, compressive atelectasis of the underlying lung and shift of the mediastinum to the opposite side may be demonstrated. Cross-table lateral and lateral decubitus radiographs can aid in the diagnosis of free air. Pneumopericardium is identified by the presence of air completely surrounding the heart, whereas in patients with pneumomediastinum, the heart and mediastinal structures may be outlined with air but the air does not involve the diaphragmatic cardiac border.

Differential Diagnosis

Acute deterioration of a patient on a ventilator can be caused by tension pneumothorax, obstruction or dislodgment of the endotracheal tube, or ventilator failure. Radiographically, pneumothorax must be distinguished from diaphragmatic hernia, lung cysts, congenital lobar emphysema, and cystic adenomatoid malformation, but this task is usually not difficult.

Treatment

Small or asymptomatic pneumothoraces usually do not require treatment and can be managed with close observation. Larger or symptomatic ones usually require drainage, although inhalation of 100% oxygen to wash out blood nitrogen can be tried.

Needle aspiration should be used to relieve tension acutely, followed by chest tube or pigtail catheter placement. Pneumopericardium requires immediate identification and, if clinically symptomatic, needle aspiration to prevent death, followed by pericardial tube placement.

In older patients with spontaneous pneumothorax, recurrences are common; sclerosing and surgical procedures are often required.

DISORDERS OF THE CONTROL OF BREATHING

PEDIATRIC SLEEP APNEA

Sleep apnea has become recognized as a major public health problem in adults, with the risk of excessive daytime sleepiness, driving accidents, poor work performance, and effects on mental health. Pediatric sleep disorders are less commonly recognized because the presentation, risks, and outcome all differ from that in adults. Sleep apnea is defined as cessation of breathing and can be classified as central (the lack of effort to breathe) or obstructive (the attempt to breathe through an obstructed airway). Obstructive sleep apnea occurs in normal children with an incidence of about 2%, increasing in children with craniofacial abnormalities, neuropathies, or other medical problems. The incidence also increases when children are medicated with hypnotics, sedatives, or anticonvulsants. Central apnea, often seen in premature infants, may indicate abnormal-

ities of the central control of breathing in the brainstem; however, with long-term obstructive sleep apnea, central components, or so-called mixed apnea, can develop.

The presentation of sleep apnea in children varies with age. It can present with life-threatening apnea in infants, hyperactivity and behavioral abnormalities in the sleep-deprived toddler, or with mood changes and sleepiness in the teenager. Unlike chronic snoring adults who tend to be obese, children with sleep apnea may present with failure to thrive, and a work-up of apnea is always indicated in these children. Another complication in childhood obstructive sleep apnea is the occurrence of partial obstruction, or hypopnea, which can cause long episodes of nighttime hypoventilation without arousal from sleep. This can also occur without clues such as snoring or noisy breathing. Sleep apnea should be suspected whenever a child presents with witnessed apnea, labored breathing, frequent nighttime arousals, failure to thrive, oxygen desaturation, life-threatening events, behavior abnormalities, obesity, or craniofacial abnormalities.

When sleep apnea is suspected, the polysomnogram is the diagnostic test of choice. This test measures sleep state with electroencephalographic leads, plus breathing rate, airflow at the nose, heart rate and rhythm, oxygen saturation, with other data including esophageal pH, end-tidal CO₂, body position, muscle activity, and optional additions. The test allows diagnosis of various forms of apnea, sleep fragmentation, or other sleep disorders of children.

First-line therapy for obstructive sleep apnea in children is adenotonsillectomy, which improves the clinical status of most children with normal craniofacial structure. Even children with underlying structural abnormalities of the face may benefit, although additional treatment with continuous positive airway pressure may be indicated. Additional therapy is also helpful for children with obstructive apnea and obesity, for whom adenotonsillectomy may be only partially beneficial. Central hypoventilation, either primary or secondary to long-standing obstructive apnea, requires treatment with positive airway pressure and a rated tidal volume. This can be accomplished with tracheostomy and ventilation, or noninvasively with bilevel positive airway pressure using a mask.

Because the differential diagnosis of sleepiness is quite varied among children, pediatric sleep disorder centers are the referral of choice for testing and initiation of therapy. Treatment of young or developmentally delayed children with apnea also presents several challenges.

APPARENT LIFE-THREATENING EVENTS IN INFANCY

Apparent life-threatening events (ALTEs) are characterized as being frightening to the observer and commonly include some combination of obstructive or central apnea, color change (usually cyanosis or pallor), a marked change in muscle tone (usually extreme limpness), choking, or gagging. The observer sometimes fears the infant has died. A substantial number of infants are brought to medical attention following ALTEs. The 50% of infants in whom no explanation for the episode can be found are said to have apnea of infancy. There is a relationship between apnea of infancy and sudden infant death syndrome (SIDS), with a small percentage of patients with apnea of infancy at risk for sudden death. In addition, only a small percentage of infants succumbing to SIDS have prior episodes of apnea.

The mechanism for ALTEs is unknown, but because they don't occur after infancy, immaturity is felt to play a major role. Indeed, classic studies on the nervous system, reflexes, and responses to apnea or hypoxia during sleep show profound cardiovascular compromise in infants during stimulation of the immature autonomic nervous system; adults would not be affected.

The following section describes an approach to the patient who has undergone an ALTE, taking note of the very broad differential diagnosis and uncertainties in both evaluation and treatment.

Differential Diagnosis

Table 18-3 classifies disorders associated with ALTEs. A careful history is often the most helpful part of the evaluation. It is useful to determine whether the infant has been chronically ill or essentially well. A history of several days of poor feeding, temperature instability, or respiratory or gastrointestinal symptoms suggests an infectious process. Reports of "struggling to breathe" or "trying to breathe" imply airway obstruction. Association of the episodes with feeding implies disorganized swallowing, gastroesophageal reflux, or airway obstruction. Episodes that typically follow crying may be related to breath-holding. Association of episodes with

Table 18–3. Potential causes of apparent life-threatening events.

Infectious	Viral: respiratory syncytial virus and other respiratory viruses Bacterial: sepsis, pertussis, chlamydia
Gastrointestinal	Gastroesophageal reflux with or without obstructive apnea
Respiratory	Airway abnormality; vascular rings, pulmonary slings, tracheomalacia Pneumonia
Neurologic	Seizure disorder Central nervous system infection: meningitis, encephalitis Vasovagal response Leigh encephalopathy Brain tumor
Cardiovascular	Congenital malformation Dysrhythmias Cardiomyopathy
Nonaccidental trauma	Battering Drug overdose Munchausen-by-proxy syndrome
No definable cause	Apnea of infancy

sleeping may also suggest gastroesophageal reflux, apnea of infancy, or sleep-disordered breathing. Attempts should be made to determine the duration of the episode, but this is often difficult. It is helpful to role-play the episode with the family. Details regarding the measures taken to resuscitate the infant and the infant's recovery from the episode are often useful in determining severity.

The physical examination provides further direction in pursuing the diagnosis. Fever or hypothermia suggests infection. An altered state of consciousness implies a postictal state or drug overdose. Respiratory distress implies cardiac or pulmonary lesions.

Most patients are hospitalized for observation in order to reduce stress on the family and allow prompt completion of the evaluation. Laboratory evaluation includes a complete blood count for evidence of infection. Serum electrolytes are usually obtained. Elevations in serum bicarbonate suggest chronic hypoventilation, whereas decreases suggest acute acidosis, perhaps due to hypoxia during the episode. Chronic acidosis suggests an inherited metabolic disorder. The chest radiograph is examined for infiltrates suggesting acute infection or chronic aspiration and for cardiac size as a clue to intrinsic cardiac disease. Arterial blood gas studies provide

an initial assessment of oxygenation and acid–base status, and low PaO₂ or elevated PaCO₂ (or both) implies cardiorespiratory disease. A significant base deficit suggests that the episode was accompanied by hypoxia or circulatory impairment. Oxygen saturation measurements in the hospital assess oxygenation status during different activities and are more comprehensive than a single blood gas sample.

Because apnea has been associated with respiratory infections, diagnostic studies for RSV and other viruses, pertussis, and *Chlamydia* may help with diagnosis. The apnea occurring with infection often precedes other physical findings. If the episode might have involved airway obstruction, the airway should be examined either directly, by fiberoptic bronchoscopy, or radiographically, by CT or barium swallow. Barium swallow is a useful tool to rule out the possibility of anatomic abnormalities such as vascular ring and tracheoesophageal fistula. This study may also demonstrate reflux and aspiration. If reflux is suspected, it should be documented by esophageal pH monitoring coupled with respiratory pattern recording. Most infants with reflux and apnea can be given medical antireflux treatment. Infants with reflux and repeated episodes of apnea may benefit from a surgical antireflux procedure.

ALTEs occur in the same age group as infants who die of sudden death (2–4 months is the peak age). Sleep-disordered breathing has been implicated as a possible cause of ALTEs and perhaps sudden death. Polysomnograms are used to determine abnormalities of cardiorespiratory function, sleep state, oxygen saturation, CO₂ retention, and seizure activity. This tool can be used in conjunction with pH monitoring to determine the contribution of reflux to apnea. Esophageal pressure manometry can be useful to detect subtle changes in respiratory effort related to partial obstructive breathing (hypopnea). Infants may be at more risk of adverse events from sleep-disordered breathing due to their immature nervous system.

There are several neurologic causes of ALTEs. Apnea as the sole manifestation of a seizure disorder is unusual but may occur. In cases of repeated episodes, 24-hour electroencephalographic monitoring may be helpful in detecting a seizure disorder. Leigh disease, a brainstem disorder characterized pathologically by neuronal dropout, may present with apneic episodes.

Apneic episodes have been linked to child abuse in several ways. Head injury following nonaccidental trauma may be first brought to medical attention because of apnea. Other signs of abuse are usually immediately apparent in such cases. Drug overdose, either accidental or intentional, may also present with apnea. Several series document that apneic episodes may be falsely reported by parents seeking attention (ie, Munchausen-by-proxy syndrome). Parents may physically

interfere with a child's respiratory efforts, in which case pinch marks on the nares are sometimes found.

Treatment

Therapy is directed at the underlying cause if one is found. After blood cultures are taken, antibiotics should be given to infants who appear toxic. Seizure disorders are treated with anticonvulsants. Vascular rings and pulmonary slings must be corrected surgically because of severe morbidity and high mortality rates when untreated.

The approach to care of infants with ALTEs where no definable cause can be ascertained is controversial. Home monitoring has been used in the past as treatment, but the efficacy of monitoring has not been demonstrated in controlled trials. With over 20 years of home monitoring, the sudden infant death rate did not change due to this intervention. Yet a rationale for the use of monitors is that infants at risk for subsequent severe episodes can be identified. Although monitors can detect apnea or bradycardia, they do not predict which children will have future ALTEs. Parents should be taught cardiopulmonary resuscitation prior to discharge. They should also be aware of the possibility of frequent false alarms. It must be noted that many parents cannot handle the stress associated with having a monitor in the home.

The decision to monitor these infants involves the participation of the family. Infants with severe initial episodes or repeated severe episodes are now thought to be at significant increased risk and should probably be monitored in the home. Episodes in these children are so severe that the parents want to know the infant's condition at all times. The decision to discontinue monitoring is usually based on the infant's ability to go several months without triggering the alarm.

Oxygen has been used as therapy for ALTEs for several reasons. First, it reduces periodic breathing of infancy, an immature pattern of breathing that can cause some degree of oxygen desaturation. Second, infants have small chest capacities with increased chest wall compliance that reduces lung volume. Oxygen can increase the baseline saturation, reducing the severity of desaturation with short apneas. Respiratory stimulants such as caffeine and aminophylline have been used in specific cases of central apnea or periodic breathing.

SUDDEN INFANT DEATH SYNDROME

SIDS is defined as the sudden death of an infant younger than age 1 year that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history. The postmortem examination is an important feature of the definition because approximately 20% of cases of sudden death can be explained by autopsy findings. The incidence of SIDS in the United States has recently declined to less than 1:1000 live births. The part of the decline that has occurred since 1994 is likely due to alterations of risk factors (see following discussion).

Epidemiologic and pathologic data constitute most of what is known about SIDS. The number of deaths peaks between ages 2 and 4 months, and most deaths occur in infants a few weeks to 6 months of age. Most deaths occur between midnight and 8 AM, while the infant and often the caregiver are sleeping. In fact, the only unifying features of all SIDS cases are age and sleep. Previous studies showed a peak in SIDS during the respiratory virus season, but the association becomes weaker when the data are controlled for risk factors such as tobacco exposure. SIDS is more common among ethnic and racial minorities and socioeconomically disadvantaged populations. There is a 3:2 male predominance in most series. Other risk factors include low birth weight, teenage or drug-addicted mothers, maternal smoking, and a family history of SIDS. Most of these risk factors are associated with a two- to three-fold elevation of incidence but are not specific enough to be useful in predicting which infants will die unexpectedly. Recent immunization is not a risk factor.

Since 1990, SIDS rates have declined more than 60% worldwide. Population studies in New Zealand and Europe identified risk factors, which when changed had a major effect on the incidence of SIDS. Since 1994 the AAP's "Back-to-Sleep" campaign has promoted education about SIDS risk factors in the United States. Modifiable risk factors include sleeping position, bottle feeding, maternal smoking, and infant overheating; sleeping position and smoke exposure may have the largest influence. The prone sleep position could contribute to SIDS through decreased arousal during sleep or during hypoxia, rebreathing of exhaled gases, or effects on the immature autonomic nervous system. The side position, often used in hospitals, also shows increased risk of SIDS compared with the supine position.

Maternal smoking, especially prenatal maternal smoking, increases the risk of SIDS. Investigations of tobacco effects on the autonomic nervous system of the developing fetus, pulmonary growth and function of the newborn, or its combination with viral infection all point to differences in SIDS compared with control subjects.

The most consistent pathologic findings are intrathoracic petechiae and mild inflammation and congestion of the respiratory tract. Subtler pathologic findings include brainstem gliosis, extramedullary hematopoiesis, and increases in periadrenal brown fat. These latter findings suggest that infants who succumb to SIDS have had intermittent or chronic hypoxia before death.

The mechanism or mechanisms of death in SIDS are unknown. For example, it is unknown whether the initiating event at the time of death is cessation of breathing, cardiac arrhythmia, or asystole. Suggested hypotheses have included upper airway obstruction, catecholamine excess, brainstem immaturity or injury, and increased fetal hemoglobin. It has been recognized that some infants who presented with apneic episodes subsequently died from SIDS; however, study of these infants and prospective studies of large numbers of newborns have indicated that most infants with apnea do not die from SIDS and that most infants with SIDS have no identifiable episodes of apnea (see Apparent Life-Threatening Events section).

A history of mild symptoms of upper respiratory infection before death is not uncommon, and SIDS victims are sometimes seen by physicians a day or so before death. When infants are discovered blue, cold, and motionless by parents or caregivers, they are most commonly taken to the emergency room, where resuscitation usually fails. Families must then be supported following the death. The National SIDS Resource Center (<http://www.sidscenter.org/>) provides information about psychosocial support groups and counseling for families of SIDS victims. The postmortem examination is essential for the diagnosis of SIDS and may help the family by excluding other possible causes of death. A death scene investigation is also important in determining the cause of sudden unexpected deaths in infancy.

The health care provider is instrumental in parental education regarding the modifiable risk factors for SIDS. Education includes promotion of the supine sleeping position, breast-feeding, avoidance of overheating, and smoking cessation (even prenatally). Hospitals should set an example by placing infants in the supine position. With education, the mortality rate, and perhaps the incidence of ALTEs, may continue to decline.

■ MEDIASTINUM

MEDIASTITIS

Acute infection of the mediastinum in children is usually due to traumatic perforation of the esophagus. The trauma may be self-induced (foreign body, puncture injury to the pharynx with a sharp object) or iatrogenic (endoscopy, attempted endotracheal intubation). Vomiting can perforate the esophagus and lead to mediastinitis but this is rare. In addition, acute suppurative mediastinitis without trauma does occur but is unusual.

Clinical Findings

A. SYMPTOMS AND SIGNS

The early symptoms and signs of acute mediastinitis may be vague and include the gradual onset of fever, chills, and dysphagia with substernal pain. Dyspnea and cough may also be present. Inspiration may be accompanied by discomfort due to stretching of inflamed mediastinal structures, leading to a pattern of spasmodic or halting inspiration. On physical examination, evidence of obstruction of venous return may be present, with substernal pain elicited on palpation of the structures of the thorax. In addition, subcutaneous emphysema may be appreciated in the thoracic and cervical areas.

B. LABORATORY FINDINGS AND IMAGING

The neutrophil and band count is usually high in mediastinitis. The chest radiograph may show widening of the upper mediastinum; the lateral view shows anterior displacement of the trachea and the esophagus. Medi-

astinal emphysema, pleural effusions, and pyopneumothorax may also be present.

Differential Diagnosis

The differential diagnosis includes bacterial pneumonia, septicemia, and retropharyngeal abscesses.

Complications

Untreated mediastinitis can progress rapidly to death from infection or tracheal obstruction. Mediastinal abscess is a possible complication.

Treatment

Intravenous antibiotics should be given urgently. If significant tracheal obstruction is present, an airway must be provided. Drainage of abscesses in the mediastinum may also be indicated.

Sztajnbok J et al: Descending suppurative mediastinitis: Nonsurgical approach to this unusual complication of retropharyngeal abscesses in childhood. *Pediatr Emerg Care* 1999;15:341 [PMID: 10532666].

MEDIASTINAL MASSES

Mediastinal masses may present because of symptoms produced by pressure on the esophagus, airways, nerves, or vessels within the mediastinum or may be discovered on a routine chest radiograph. Once the mass is identified, localization to one of four mediastinal compartments aids in the differential diagnosis. The superior mediastinum is the area above the pericardium that is bordered inferiorly by an imaginary line from the manubrium to the fourth thoracic vertebra. The anterior mediastinum is bordered by the sternum anteriorly and the pericardium posteriorly, and the posterior mediastinum is defined by the pericardium and diaphragm anteriorly and the lower eight thoracic vertebrae posteriorly. The middle mediastinum is surrounded by these three compartments.

Clinical Findings

A. SYMPTOMS AND SIGNS

Respiratory symptoms, when present, are due to pressure on an airway (cough, wheezing) or an infection (unresolving pneumonia in one area of lung). Hemoptysis can also occur but is an unusual presenting symptom. Dysphagia may occur secondary to compression of the esophagus. Pressure on the recurrent laryngeal

nerve can cause hoarseness due to paralysis of the left vocal cord. Superior vena caval obstruction can lead to dilation of neck vessels and other signs and symptoms of obstruction of venous return from the upper part of the body (superior mediastinal syndrome).

B. LABORATORY FINDINGS AND IMAGING

The mass is initially defined by frontal and lateral chest radiographs together with thoracic CT scans and perhaps MRI. A barium swallow may also help define the extent of a mass. Other studies that may be required include angiography (to define the blood supply to large tumors), electrocardiography, echocardiography, ultrasound of the thorax, fungal and mycobacterial skin tests, and urinary catecholamine assays. MRI or myelography may be necessary in children suspected of having a neurogenic tumor in the posterior mediastinum.

Differential Diagnosis

The differential diagnosis of mediastinal masses is determined by their location. Within the superior mediastinum, one may find cystic hygromas, vascular or neurogenic tumors, thymic masses, teratomas, intrathoracic thyroid tissue, and esophageal lesions. A mediastinal abscess may also be found in this region. Within the anterior mediastinum, thymic tissue (thymomas, hyperplasia, cysts) and teratomas, vascular tumors, and lymphatic tissue (lymphomas, reactive lymphadenopathy) give rise to masses. An intrathoracic thyroid and a pleuropericardial cyst may also be found in this region. Within the middle mediastinum one may again find lymphomas and hypertrophic lymph nodes, granulomas, bronchogenic or enterogenous cysts, metastases, and pericardial cysts. Abnormalities of the great vessels and aortic aneurysms may also present as masses in this compartment. Within the posterior mediastinum, neurogenic tumors, enterogenous cysts, thoracic meningoceles, or aortic aneurysms may be present.

In some series, more than 50% of mediastinal tumors occur in the posterior mediastinum and are mainly neurogenic tumors or enterogenous cysts. Most neurogenic tumors in children younger than age 4 years are malignant (neuroblastoma, neuroganglioblastoma), whereas a benign ganglioneuroma is the most common histologic type in older children. In the middle and anterior mediastinum, tumors of lymphatic origin (lymphomas) are the primary concern. Bulky anterior mediastinal tumors that compress the trachea and the great vessels can lead to a superior mediastinal syndrome, which presents a diagnostic problem because of anesthesia hazards. Definitive diagnosis in most instances relies on surgery to obtain the mass or a part of the mass for histologic examination. In cases of lymphoma, the scalene nodes may also contain tumor, and a biopsy

should be performed in an attempt to establish a diagnosis.

Treatment & Prognosis

The appropriate therapy and the response to therapy depend on the cause of the mediastinal mass.

Anji T. Yetman, MD, Shelley D. Miyamoto, MD, Henry M. Sondheimer, MD

Cardiovascular disease is a significant cause of death and chronic illness in childhood. In North America 8 in 1000 infants are born with a congenital heart defect. In addition, acquired heart disease, including Kawasaki disease, myocarditis, rheumatic heart disease, and others, remains a significant cause of pediatric morbidity and mortality. With advances in medical and surgical care, more than 85% of children with congenital heart defects will live into adulthood. It is therefore important that attention be paid not only to the diagnosis and treatment of congenital cardiac lesions but also to the prevention of secondary comorbidities, namely, hyperlipidemia and atherosclerosis. Maintenance pediatric health visits must focus on the diagnosis and prevention of hypercholesterolemia and hypertension. Counseling regarding the hazards of smoking and the benefits of regular exercise should be part of routine pediatric care. Subspecialty clinics designed to address the needs of the young adult with congenital heart disease will be needed to service this growing patient population. Previously rare clinical dilemmas, including the impact of pregnancy on congenital cardiac lesions, risks of anticoagulation during pregnancy, and vocational choices will need to be addressed.

■ DIAGNOSTIC EVALUATION

The presence of a heart murmur may suggest the possibility of heart disease. The murmur may be a functional or innocent one, however. Not all serious cardiovascular disorders are accompanied by an easily detectable murmur.

Sequence of Evaluation

1. History
2. Physical examination
3. Electrocardiogram
4. Chest radiograph
5. Echocardiogram
6. Other ancillary studies, including cardiopulmonary stress testing, 24-hour Holter or other ambulatory ECG monitoring devices, cardiac catheterization,

angiocardigraphy, nuclear imaging studies, and cardiac magnetic resonance imaging (MRI)

HISTORY

In obtaining a medical history from the family or the patient, one must keep in perspective the patient's age and activity level. Most congenital defects will lead to either decreased pulmonary blood flow or increased pulmonary blood flow with pulmonary congestion (see Table 19–10). Symptoms will vary according to the alteration in pulmonary blood flow (Table 19–1)

The presence of other cardiovascular symptoms such as palpitations and chest pain should also be determined by history in the older child, paying particular attention to the timing (rest or activity related), onset and termination (gradual vs sudden), and precipitating and relieving factors.

PHYSICAL EXAMINATION

General

The examination should begin with a careful inspection to note activity (agitation, lethargy), skin perfusion, and skin color. Heart rate, respiratory rate, blood pressure (in all four extremities), and oxygen saturation are required. Many congenital cardiac defects occur as part of a genetic syndrome (Table 19–2), and the overall assessment should include examination for dysmorphic features that may provide clues to the associated cardiac defect.

1. Cardiovascular Examination

Inspection & Palpation

The conformation of the chest should be noted by observing the supine patient from the end of the examining table. A left precordial bulge indicates long-standing cardiomegaly, which may be seen in association with dilated cardiomyopathy, or right or left heart obstructive lesions.

Palpation may reveal increased precordial activity, RV lift, or left-sided heave; a diffuse point of maximal impulse; or a thrill caused by a greater than grade III/VI murmur. Thrills are located where the murmur is most

Table 19–1. Symptoms of increased and decreased pulmonary blood flow.

Decreased Pulmonary Blood Flow	Increased Pulmonary Blood Flow
Infant/Toddler:	
Cyanosis	Tachypnea with activity/feeds
Squatting	Diaphoresis
Loss of consciousness	Poor weight gain
Older child:	
Dizziness	Exercise intolerance
Syncope	Dyspnea on exertion, Diaphoresis

intense and can sometimes be felt at the point of radiation. For example, a thrill in the suprasternal notch or carotid thrill is associated with aortic stenosis. In patients with severe pulmonary hypertension, palpable pulmonary closure is frequently noted at the upper left sternal border. A palpable fourth heart sound may be seen in association with a hypertrophied, noncompliant ventricle as in hypertrophic cardiomyopathy.

Auscultation

A. HEART SOUNDS

The first heart sound (S_1) is the sound of AV valve closure. It is best heard at the lower left sternal border and is usually medium-pitched. Although S_1 has multiple components, usually only one of these (M_1) is heard with a stethoscope.

The second heart sound (S_2) is the sound of semilunar valve closure. It is best heard along the mid and

Table 19–2. Cardiac defects in common syndromes.

Genetic Syndrome	Commonly Associated Cardiac Defect
Down syndrome	AVSD
Turner’s syndrome	Bicuspid aortic valve, coarctation
Noonan’s syndrome	Dysplastic pulmonic valve, HCM
Williams–Beuren syndrome	Supravalvular aortic stenosis, PPS
Marfan’s syndrome	MVP, MR, dilated aortic root
Fetal alcohol syndrome	VSD, ASD
Maternal rubella	PDA, PPS

AVSD = atrioventricular septal defect; HCM = hypertrophic cardiomyopathy; MVP = mitral valve prolapse; MR = mitral regurgitation; VSD = ventricular septal defect; ASD = atrial septal defect; PDA = patent ductus arteriosus; PPS = peripheral pulmonary stenosis.

upper left sternal border. S_2 has two component sounds, A_2 and then P_2 (aortic and pulmonary valve closure). Splitting of S_2 varies with respiration, widening with inspiration and narrowing with expiration. It is best heard at the second left intercostal space at the sternal border. Abnormal splitting of S_2 may provide clues to the presence of cardiac disease (Table 19–3).

The third heart sound (S_3) is the sound of rapid filling of the LV. It occurs in early diastole, after S_2 , and is medium- to low-pitched. When heard in healthy children, the sound diminishes or disappears when the position changes from supine to sitting or standing. It is usually intermittent. A persistent S_3 is often heard in the presence of a dilated LV caused by a cardiomyopathy or large left-to-right shunt.

The fourth heart sound (S_4) is associated with atrial contraction and increased atrial pressure and has a low pitch similar to that of S_3 . It occurs just prior to S_1 and is not normally audible. It is heard in the presence of atrial contraction into a noncompliant ventricle as is present in hypertrophic or restrictive cardiomyopathy or a hypertrophied LV from other causes.

Ejection clicks are high-pitched and are usually related to dilated great vessels or valve abnormalities. They can be heard throughout ventricular systole and are classified as early, mid, or late. Early ejection clicks at the mid left sternal border are usually of pulmonary origin. Aortic clicks are typically best heard at the apex. In contrast to aortic clicks, pulmonic clicks vary with respiration, becoming louder during inspiration. A mid to late ejection click at the apex is most typically caused by mitral valve prolapse. Early clicks may also be heard with a closing ventricular septal defect (VSD).

B. MURMURS

Murmurs are the most common cardiovascular finding leading to a cardiology referral. Innocent, or functional, heart murmurs are extremely common. Between 40% and 45% of children have an innocent murmur at some time during childhood.

Table 19–3. Abnormal splitting of S_2 .

Causes of wide split S_2
RV volume overload: ASD, anomalous pulmonary venous return, PI
RV pressure overload: Pulmonary valve stenosis
Delayed RV conduction: RBBB
Causes of narrow split S_2
Pulmonary hypertension
Single semilunar valve (aortic atresia, pulmonary atresia, truncus arteriosus)

RV = right ventricle; ASD = atrial septal defect; PI = pulmonic insufficiency; RBBB = right bundle branch block.

1. Characteristics—All murmurs should be described based on the following characteristics:

a. Location and radiation. Where the murmur is best heard and where the sound extends.

b. Relationship to cardiac cycle and duration. Systolic ejection (immediately following S_1 with a crescendo/decrecendo change in intensity), pansystolic (occurring throughout most of systole and of constant intensity), diastolic, and continuous. The timing of the murmur provides valuable clues as to underlying pathology (Table 19–4).

c. Intensity. Classified as grade I, soft and heard with difficulty; grade II, soft but easily heard; grade III, loud but without a thrill; grade IV, loud and associated with a precordial thrill; grade V, loud, with thrill, and audible with the edge of the stethoscope; or grade VI, very loud and audible with the stethoscope off the chest.

d. Quality. Harsh, musical, or rough; high, medium, or low in pitch.

e. Variation with position. Audible when the patient is supine, sitting, standing, or squatting.

2. Functional murmurs—The six most common functional murmurs of childhood are:

a. Newborn murmur. Heard in the first few days of life, this murmur is at the lower left sternal border, without significant radiation. It has a soft, short, vibratory grade I–II/VI quality that often subsides when mild pressure is applied to the abdomen. It usually disappears by age 2–3 weeks.

b. Functional murmur of peripheral arterial pulmonary stenosis. This is frequently heard in newborns and is caused by the normal mild bending of the branches of the pulmonary artery. It is heard with equal intensity at the upper left sternal border, at the back, and in both axillae. It is a soft, short, high-pitched, grade I–II/VI systolic ejection murmur and usually disappears by age 4. This murmur must be differentiated from true peripheral pulmonary stenosis (Williams syn-

drome or rubella syndrome), coarctation of the thoracic aorta, valvular pulmonary stenosis, and atrial septal defect (ASD).

c. Still murmur. This is the most common innocent murmur of early childhood. It is most typically heard from age 2 years until preadolescence. Still's murmur is loudest midway between the apex and the lower left sternal border and often is transmitted to the remainder of the precordium. Still's murmur is a musical or vibratory, short, high-pitched, grade I–III early systolic murmur. It is loudest when the patient is in the supine position; it diminishes or disappears with inspiration, when the patient sits or stands, or during the Valsalva maneuver. Still's murmur will be louder in patients with fever or tachycardia.

d. Pulmonary ejection murmur. This is the most common innocent murmur in older children. It is heard throughout childhood from age 3 years onward. It is usually a soft, systolic ejection murmur, grade I–II in intensity and well localized to the upper left sternal border. The murmur becomes louder when the patient is supine or when cardiac output is increased and softens with standing or during the Valsalva maneuver. The pulmonary ejection murmur must be differentiated from other murmurs, such as those associated with pulmonary stenosis, coarctation of the aorta, ASD, and peripheral pulmonary artery stenosis.

e. Venous hum. This murmur is usually heard after age 2 years, is located in the left and right infraclavicular areas, and is usually louder on the right. It is a continuous musical hum of grade I–II intensity and it may be accentuated in diastole and with inspiration. This murmur is best heard with the child sitting. Turning the child's neck, placing him or her in a supine position, and compressing the jugular vein obliterates the venous hum. Venous hum is produced by turbulence at the confluence of the subclavian and jugular veins.

f. Innominate or carotid bruit. This murmur is more common in the older child and adolescent. It is heard in the right supraclavicular area. This is a long systolic ejection murmur, somewhat harsh and of grade

Table 19–4. Pathologic murmurs.

Systolic Ejection	Pansystolic	Diastolic	Continuous
Semilunar valve stenosis (AS/PS/truncal stenosis)	VSD AVVR (MR/TR)	Semilunar valve regurgitation (A/PI/truncal insufficiency)	Runoff lesions (PDA/AVM/aortopulmonary collaterals)
ASD		AV valve stenosis (MS/TS)	
Coarctation			

VSD = ventricular septal defect; AS/PS = aortic stenosis/pulmonic stenosis; MR/TR = mitral regurgitation/tricuspid regurgitation; A/PI = aortic insufficiency/pulmonic insufficiency; PDA/AVM = patent ductus arteriosus/arteriovenous malformation; ASD = atrial septal defect; AV = atrioventricular; MS/TS = mitral stenosis/tricuspid stenosis.

II–III intensity. The bruit can be accentuated by light pressure on the carotid artery and must be differentiated from all types of aortic stenosis.

When functional murmurs are found in a child, the physician should assure the parents that these are normal heart sounds of the developing child and that they do not represent structural abnormality of the heart.

2. Extracardiac Examination

Arterial Pulse

A. RATE AND RHYTHM

Cardiac rate and rhythm can vary greatly during infancy and childhood, so multiple determinations should be made. This caution is particularly important for infants (Table 19–5), whose heart rate varies with activity. In children, the rhythm may be regular, or there may be a phasic variation in the heart rate with respiration (sinus arrhythmia), which is normal.

B. QUALITY AND AMPLITUDE OF PULSE

The pulses of the upper and lower extremities should be compared. A bounding pulse is characteristic of run-off lesions, including patent ductus arteriosus (PDA), aortic regurgitation, arteriovenous malformation (AVM), or any condition with a low diastolic pressure (fever, anemia, septic shock). These conditions may also be associated with palpable palmar pulses, which otherwise are not normally present. Narrow or thready pulses are found in patients with reduced cardiac output as seen in cardiomyopathy, myocarditis, pericardial tamponade, or severe aortic stenosis. A reduction in pulse amplitude or blood pressure (> 10 mm Hg) with inspiration is referred to as pulsus paradoxus and is a telltale sign of pericardial tamponade. With inspiration, venous return is increased to the right side of the heart. Because of a fixed pericardial constraint, an increase in right heart volume must be accompanied by a reduction in left heart volume and thus a reduction in cardiac output during the inspiratory phase of respiration. The femoral pulse should be palpable and equal in amplitude and simultaneous with the brachial pulse. A

femoral pulse that is absent, or weak, or that is delayed in comparison with the brachial pulse, suggests coarctation of the aorta. An absent or diminished femoral pulse may be the only clue to the presence of this important clinical problem.

C. ARTERIAL BLOOD PRESSURE

Blood pressures should be obtained in the upper and lower extremities. Systolic pressure in the lower extremities should be greater than or equal to that in the upper extremities. The cuff must cover the same relative area of the arm and leg. Measurements should be repeated several times.

D. VENOUS PRESSURE & PULSE

The level of the distended jugular vein above the suprasternal notch, when the patient is placed at a 45-degree angle to the examination table, is a measure of venous pressure. Normally, one may observe the transition between collapsed and distended jugular vein approximately 1–2 cm above the notch. Although the venous pulse may not be helpful when examining infants and young children because of their short neck and increased subcutaneous tissue in this region, it may be a helpful adjunctive tool in the cardiac assessment of the older child.

E. EXTREMITIES

1. Cyanosis—Cyanosis is the result of an increased concentration (4–5 g/dL) of reduced hemoglobin in the blood. Bluish skin color is usually, but not always, a sign. Anemic patients may not appear blue, and patients with polycythemia may appear cyanotic, even though blood oxygen content is normal. Visible cyanosis accompanies low cardiac output, hypothermia, and systemic venous congestion, even in the presence of adequate oxygenation. Cyanosis should be judged only by the color of the mucous membranes (lips and nail beds). Bluish discoloration around the mouth (acrocyanosis) is a feature of skin that has not been exposed to sun, and it does not correlate with cyanosis.

2. Clubbing of fingers and toes—Clubbing implies the presence of fairly severe cyanotic congenital heart disease. It usually does not appear until after age 1 year. The first sign of clubbing is softening of the nail beds, followed by rounding of the fingernails and then by thickening and shininess of the terminal phalanx, with loss of creases.

Hypoxemia producing cyanosis is by far the most common cause of digital clubbing, but it also occurs in patients with infective endocarditis, chronic liver disease, inflammatory bowel diseases, chronic pulmonary insufficiency (PI), and lung abscess. Digital clubbing may be a benign genetic variant.

Table 19–5. Resting heart rates.

Age	Low	High
< 1 month	80	160
1–3 months	80	200
2–24 months	70	120
2–10 years	60	90
11–18 years	40	90

3. Edema—Edema of dependent areas (lower extremities in the older child and the face and sacrum in the younger child) is characteristic of elevated right heart pressures, which may be seen with tricuspid valve pathology, or RV dysfunction from a variety of causes (right heart failure).

F. ABDOMEN

Hepatomegaly is the cardinal sign of right heart failure in the infant and child. Presystolic pulsation of the liver may occur with right atrial hypertension and systolic pulsation with tricuspid insufficiency. Apparent hepatomegaly may also be seen in the child with pulmonary edema from lesions causing left-to-right shunting or left heart failure. Pulmonary congestion and associated lymphatic engorgement lead to lung hyperexpansion, pushing the liver further below the costal margin. Splenomegaly may be present in patients who have had long-standing congestive heart failure (CHF), and it is a characteristic feature of infective endocarditis. Ascites is also a feature of chronic right heart failure. Physical examination may be notable for shifting dullness or a fluid wave on abdominal examination.

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) is an essential part of the evaluation of the cardiovascular system. A consistent approach to the ECG will allow for interpretation of even the most complex and initially confusing ECG recording. The heart rate should first be determined (Is it appropriate for the patient's age and state of well-being?), then the rhythm (Is the patient in a normal sinus rhythm or other rhythm as evidenced by a P wave with a consistent PR interval before every QRS complex?), and then the axis (Are the P and QRS axes normal for the patient's age?). Once this initial assessment of rate, rhythm, and axis is performed, attention can be directed toward assessment of chamber enlargement and finally to assessment of cardiac intervals and ST segments.

Age-Related Variations

The ECG evolves with age and thus must be interpreted according to age-related norms. The rate gradually decreases and intervals increase with age. The dom-

inance of ventricles changes from RV dominance in the newborn to LV dominance in the older infant, child, and adult. The normal ECG of the 1-week-old infant would be highly abnormal for a 1-year-old child, and the ECG of a 5-year-old child is abnormal for an adult.

Electrocardiographic Interpretation

Figure 19–1 defines the events recorded by the ECG.

A. RATE

The paper speed at which ECGs are normally obtained is 25 mm/s. Each small square is 1 mm, and each large square, 5 mm. Therefore, five large squares represent 1 second, one large square 0.2 second, and one small square 0.04 second. A common method of estimating the ventricular rate is to count the number of small squares between two QRS complexes (see following discussion) and to divide this number into 1500. If QRS complexes appear at a rate of one per 5 small squares, the ventricular rate is 300; if QRS complexes appear every 12 small squares, the ventricular rate is 125, and so on.

B. RHYTHM

Sinus rhythm should always be present in normal children. In contrast to adults, premature atrial and ventricular contractions are uncommon during childhood.

C. AXIS

P wave axis: The P wave is generated from atrial contraction beginning in the high right atrium at the site of the sinus node. The impulse proceeds leftward and inferiorly, thus leading to a positive deflection in all left-sided and inferior leads (II, III and aVF). Conversely, the P wave in patients in normal sinus rhythm should be negative in lead aVR.

QRS axis: The net voltage should be positive in leads I and aVF in children with a normal axis. In the young child, RV dominance may persist, leading to a negative net deflection in lead I. Several congenital cardiac lesions are associated with alterations in the normal QRS axis (Table 19–6)

D. P WAVE

In the pediatric patient, the amplitude of the P wave is normally no greater than 2.5 mm or more than 0.08 second in duration. The P wave is usually best seen in leads II and V₁.

E. PR INTERVAL

This interval is measured from the beginning of the P wave to the beginning of the QRS complex. It increases with age and with slower rates. The PR interval ranges from a minimum of 0.11 second in infants to a maximum of 0.18 second in older children with slow rates.

Figure 19-1. Complexes and intervals of the ECG.

The PR interval is commonly prolonged in patients who have rheumatic heart disease and by digitalis.

F. QRS COMPLEX

This represents ventricular depolarization, and its amplitude and direction of force (axis) reveal the relative size of (viable) ventricular mass in hypertrophy, hypoplasia, and infarction. Abnormal ventricular conduction (eg, right bundle branch block [RBBB], anterior fascicular block) is also revealed.

G. QT INTERVAL

This interval is measured from the beginning of the QRS complex to the end of the T wave. The QT dura-

tion may be prolonged as a primary condition or secondarily due to drugs or electrolyte imbalances (Table 19-7) The normal QT duration is rate-related and must be corrected using the Bazett formula:

$$QTc = \frac{QT\ interval(s)}{\sqrt{R - R\ interval(s)}}$$

The normal QTc is less than 0.44 second or less than 0.46 second in postpubertal females.

H. ST SEGMENT

This segment, lying between the end of the QRS complex and the beginning of the T wave, is affected by drugs, electrolyte imbalances, or myocardial injury.

I. T WAVE

The T wave represents myocardial repolarization and is altered by electrolytes, myocardial hypertrophy, and ischemia.

J. IMPRESSION

The ultimate impression of the ECG is derived from a systematic analysis of the features described earlier as

Table 19-6. QRS axis deviation.

Right Axis Deviation	Left Axis Deviation
Tetralogy of Fallot	Atrioventricular septal defect
Dextro transposition of the great arteries	Pulmonary atresia with intact ventricular septum
Total anomalous pulmonary venous return	Tricuspid atresia
Atrial septal defect	

Table 19–7. Causes of QT prolongation.*

Cardiac Medications
Antiarrhythmics: IA (quinidine, procainamide, disopyramide) class III (amiodarone, sotalol)
Inotropic Agents: dobutamine, dopamine, epinephrine, isoproterenol
Noncardiac medications
Antibiotics/Antivirals: azithromycin, clarithromycin, levofloxacin, amantadine
Antipsychotics: risperidol, thioridazine, lithium, haloperidol
Other: albuterol, levalbuterol, ondansetron, phenytoin, pseudoephedrine
Sedatives: chloral hydrate, methadone
Electrolyte disturbances: hypokalemia, hypomagnesemia, hypocalcemia

CHEST RADIOGRAPH

Evaluation of the chest radiograph for cardiac disease should focus on: (1) position of the cardiac apex, (2) position of the abdominal viscera, (3) cardiac size, (4) cardiac configuration, and (5) character of the pulmonary vasculature.

A segmental approach is used when evaluating cardiac anatomy, either by chest radiograph or by echocardiography. The position of the cardiac apex should be noted as either levocardia (apex points to the left), dextrocardia (cardiac apex to the right), or mesocardia (cardiac apex in the middle). The position of the liver and stomach bubble should be noted as either in the normal position (abdominal situs solitus), in reverse position with stomach bubble on the right (abdominal situs inversus), or a variable stomach position with midline liver (abdominal situs ambiguous). The heart appears relatively large in normal newborns and decreases on the chest radiograph with age. The heart size should be less than 50% of the chest diameter in children older than age 1 year. The cardiac configuration on chest radiograph may provide useful diagnostic information, as certain cardiac lesions have a characteristic radiographic appearance (Tables 19–8 and 19–9).

Table 19–8. Radiographic changes with cardiac chamber enlargement.

Chamber Enlarged	Change in Cardiac Silhouette on Anteroposterior Film
Right ventricle	Apex of the heart is tipped upward
Left ventricle	Apex of the heart is tipped downward
Left atrium	Double shadow behind cardiac silhouette
	Increase in subcarinal angle
Right atrium	Prominence of right atrial border of the heart

The pulmonary vasculature should be assessed in every patient. The presence of increased or decreased pulmonary blood flow provides a useful clue to cardiac diagnosis, particularly in the cyanotic infant (Table 19–10)

The standard posteroanterior and left lateral chest radiographs are used (Figure 19–2).

Dextrocardia

Dextrocardia is a radiographic term used when the heart is on the right side of the chest. When dextrocardia occurs with reversal of position of the other important organs of the chest and abdomen (eg, liver, lungs, and spleen), the condition is called situs inversus totalis, and the heart is usually completely normal. When dextrocardia occurs with otherwise normal organs (situs solitus), the heart usually has severe defects.

Table 19–9. Lesion-specific chest radiographic findings.

Diagnosis	Chest radiograph appearance
Dextrotransposition of the great arteries	Egg on a string
Tetralogy of Fallot	Boot-shaped heart
Unobstructed total anomalous pulmonary venous drainage	Snowman
Obstructed total anomalous pulmonary venous drainage	Small heart with congested lungs
Coarctation	Figure 3 sign + rib notching

Table 19–10. Alterations in pulmonary blood flow in cyanotic cardiac lesions.

Increased Pulmonary Blood Flow	Decreased Pulmonary Blood Flow
Total anomalous pulmonary venous return	Pulmonic stenosis
TA/large ventricular septal defect	Tricuspid atresia/restrictive ventricular septal defect
Complete transposition of great arteries	Tetralogy of Fallot
Truncus arteriosus	Pulmonary atresia with intact ventricular septum
	Hypoplastic left heart syndrome

Rarely, the abdominal organs and lungs are neither in situs solitus nor situs inversus. These states are called situs ambiguus. The liver is central and anterior in the upper abdomen, with the stomach pushed posteriorly. Bilateral right-sidedness (asplenia syndrome) or bilateral left-sidedness (polysplenia syndrome) may occur, but, in virtually all cases of situs ambiguus, congenital heart disease is present.

ECHOCARDIOGRAPHY

Echocardiography is a useful noninvasive method for diagnosing congenital heart defects and is used to further define anatomy, function, chamber size, vessel size, and valve abnormalities following cardiac examination, chest radiograph, and ECG. In most cases two-dimensional echocardiography is sufficient for the accurate diagnosis of congenital cardiac lesions, and no further

testing is required prior to initial medical or surgical intervention. Two-dimensional echocardiography with Doppler ultrasonography (color, pulsed, or continuous-wave ultrasound measurements) is used to assess cardiac output, magnitude of regurgitant and stenotic lesions, diastolic LV relaxation, and pulmonary artery pressure. Stress echocardiography allows for quantification of ventricular systolic and diastolic function and assessment of myocardial wall motion abnormalities in patients after exercise or pharmacologic stress with dobutamine infusion.

Two-dimensional echocardiography should be performed with a systematic series of steps to define the intracardiac anatomy:

1. Position of the cardiac apex
2. Position of the abdominal vessels (inferior vena cava [IVC] and aorta)
3. Relationship between the atria and ventricles
4. Relationship between the ventricles and great vessels
5. Evaluation of intracardiac defects

The relationship between the atria and ventricles is noted. If the morphologic right atrium empties into a morphologic right ventricle (RV) and, similarly, the morphologic left atrium empties into a morphologic LV, atrioventricular concordance is present. If the atria correspond to the wrong ventricle (eg, right atrium emptying into LV), atrioventricular discordance is present. Other possible atrioventricular (AV) relationships include double-inlet LV (both atria empty into the LV), double-inlet RV, and atresia of a right or left AV valve with associated single inlet (eg, tricuspid atresia). Similarly, the relationship between the ventricles and great vessels is noted. Normally, the pulmonary artery (PA) arises from the RV and the aorta from the LV and ventriculoarterial concordance is present. If the relationships are reversed (ie, aorta from RV and PA from

Figure 19–2. Position of cardiovascular structures in principal radiograph views. Ao = aorta, IVC = inferior vena cava, LA = left atrium, LA APP = left atrial appendage, LV = left ventricle, PA = pulmonary artery, RA = right atrium, RV = right ventricle, SVC = superior vena cava.

LV), then ventriculoarterial discordance is present (as in complete transposition of the great arteries [TGA]). Other possible ventriculoarterial relationships include double-outlet RV, double-outlet LV, and atresia of one outlet (eg, pulmonary or aortic atresia). If both AV discordance and ventriculoarterial discordance are present, the patient has what is referred to as congenitally corrected transposition.

NUCLEAR CARDIOLOGY

Nuclear imaging may be used in patients with VSDs and other lesions with left-to-right shunting to noninvasively quantify the degree of shunting and thereby avoid cardiac catheterization.

Nuclear imaging may also be useful as an adjunct to cardiopulmonary exercise testing in assessing both fixed and reversible areas of myocardial ischemia. This testing is valuable in evaluating myocardial perfusion in patients with Kawasaki disease, repaired anomalous left coronary artery or other coronary anomalies, myocardial bridging in the setting of hypertrophic cardiomyopathy or chest pain in association with ECG changes with exercise.

MAGNETIC RESONANCE IMAGING

MRI is a valuable tool in the evaluation and noninvasive follow-up of many congenital heart defects. It is particularly useful in imaging the vascular structures of the thorax, which are difficult to image by transthoracic echocardiogram. The addition of cardiac gated imaging allows dynamic evaluation of the structure and blood flow in the heart and great vessels. MRI is invaluable in the initial assessment and long-term follow-up of coarctation of the aorta, in following the progression of aortic dilation in patients with Marfan syndrome, in quantification of regurgitant lesions such as PI following repair of tetralogy of Fallot (ToF), and in quantification of ventricular function in patients whose echocardiographic images are inadequate. Because it allows the operator to move the heart and great vessels on the computer screen, three-dimensional MRI is an ideal method of noninvasive reconstruction of the entire heart and useful for both assessing intracardiac anatomy and analyzing great vessel anatomy and relationships. MRI combined with pharmacologic stress testing (dobutamine infusions) may allow for evaluation of cardiac reserve in patients who cannot undergo standard exercise testing because of size or disability.

Boxt LM, Rozenshtein A: MR imaging of congenital heart disease. *Magn Reson Imaging Clin North Am* 2003;11(1):27 [PMID: 12797509].

Cardiopulmonary Stress Testing

Most children with heart disease are capable of normal activity, and data on cardiac function after exercise are essential to preventing the unnecessary restriction of activities. The response to exercise is valuable in determining the timing of, and need for, cardiovascular surgery as well as a useful objective outcome measure for the evaluation of medical and surgical interventions.

Bicycle ergometers or treadmills can be used to test children as young as age 5 years. The addition of a metabolic cart enables one to assess whether exercise impairment is secondary to cardiac limitation, pulmonary limitation, deconditioning, or lack of effort. Exercise variables include the ECG, blood pressure response to exercise, oxygen saturation, ventilation, maximal oxygen consumption, and peak work load attained. Cardiopulmonary stress testing is routine in children with congenital cardiac lesions to ascertain limitations, develop exercise prescriptions, assess the effect of therapies, and decide on the need for cardiac transplantation. Stress testing is also employed in children with structurally normal hearts to rule out cardiac or pulmonary pathology in children with chest pain, syncope, or shortness of breath on exertion. Significant stress ischemia or dysrhythmias warrant physical restrictions or appropriate therapy. Children with poor performance due to suboptimal conditioning benefit from a planned exercise program.

McManus A, Leung M: Maximizing the clinical use of exercise gaseous exchange testing in children with repaired cyanotic congenital heart defects: The development of an appropriate test strategy. *Sports Med* 2000;29(4):229 [PMID: 10783899].

ARTERIAL BLOOD GASES

Quantitating the arterial PO₂ or O₂ saturation (eg, by pulse oximetry) during the administration of 100% oxygen is the most useful method of distinguishing cyanosis produced primarily by heart disease or by lung disease in sick infants. In cyanotic heart disease, PaO₂ increases very little when 100% oxygen is administered over the values obtained while breathing room air. However, PaO₂ usually increases very significantly when oxygen is administered to a patient who has lung disease. Table 19–11 illustrates the responses seen in patients with heart or lung disease during the hyperoxic test. Routine pulse oximetry has been advocated as an adjunct to the current newborn screening evaluation as it is a simple, cost-effective means of screening for major cardiac defects prior to hospital discharge.

Table 19–11. Examples of responses to 10 minutes of 100% oxygen in lung disease and heart disease.

	Lung Disease		Heart Disease	
	Room Air	100% O ₂	Room Air	100% O ₂
Color	Blue	→ Pink	Blue	→ Blue
Oximetry	60%	→ 99%	60%	→ 62%
Pao ₂ (mm Hg)	35	→ 120	35	→ 38

Koppel RI et al. Effectiveness of pulse oximetry screening for congenital heart disease in asymptomatic newborns. *Pediatrics* 2003;111:451 [PMID: 12612220].

CARDIAC CATHETERIZATION & ANGIOCARDIOGRAPHY

Cardiac catheterization precisely defines the anatomic and physiologic abnormalities in simple and complex cardiac malformations. Cardiac catheterization, may be performed for diagnostic purposes when further anatomic or physiologic data are needed prior to a therapeutic decision or may be performed for therapeutic purposes when the cardiac condition can be palliated or treated in the catheterization laboratory.

Therapeutic Cardiac Catheterization

Therapeutic procedures performed during cardiac catheterization include coil embolization of a PDA, balloon aortoplasty of aortic coarctation, balloon atrial septostomy, valvuloplasty of stenotic aortic or pulmonary valves, and placement of ASD and VSD devices. Cardiac catheterization is also performed to evaluate the effects of pharmaceutical therapy. An example of this use of catheterization is monitoring acute changes in pulmonary vascular resistance during the administration of nitric oxide or prostacyclin in a child with primary pulmonary hypertension. Electrophysiologic evaluation and ablation of abnormal electrical pathways in children can be performed by qualified personnel in the pediatric catheterization laboratory.

The risks of cardiac catheterization (morbidity and mortality) must be explained to the patient’s family. Although the risks are very low for elective studies in older children (< 0.1%), the risk of major complications in distressed infants is about 2%. Interventional procedures such as balloon valvuloplasties increase these risks further.

Cardiac Catheterization Data

Figure 19–3 shows oxygen saturation (in percent) and pressure (in mm Hg) values obtained at cardiac catheterization from the chambers and great arteries of the heart. These values are within the normal range for a child.

A. OXYGEN CONTENT AND SATURATION; PULMONARY (Q_p) AND SYSTEMIC (Q_s) BLOOD FLOW (CARDIAC OUTPUT)

In most laboratories, left-to-right shunting is determined by changes of blood oxygen content or saturation during sampling through the right side of the heart. A significant increase in oxygen saturation between one right chamber and the other indicates the presence of a left-to-right shunt at the site of the increase. The oxygen saturation of the peripheral arterial blood should always be determined during cardiac catheterization. Normal arterial oxygen saturation is 95–97% at sea level and 92–94% at 5280 feet. Subnormal saturations suggest the presence of a right-to-left shunt, underventilation, or pulmonary disease.

Figure 19–3. Pressures (in mm Hg) and oxygen saturation (in percent) obtained by cardiac catheterization in a healthy child. 3 = mean pressure of 3 mm Hg in the right atrium, 5 = mean pressure of 5 mm Hg in the left atrium.

The size of a left-to-right shunt is usually expressed as a ratio of pulmonary to systemic blood flow (Q_p/Q_s) or as liters per minute as determined by the Fick principle:

$$\text{Cardiac output (L/min)} = \frac{\text{Oxygen consumption (mL/min)}}{\text{Arteriovenous difference (mL/L)}}$$

B. PRESSURES

Pressures should be determined in all chambers and major vessels entered. Pressures should be recorded as a catheter is pulled back from a distal chamber or vessel into a more proximal chamber. It is not normal for systolic pressure in the ventricles to exceed systolic pressure in the great arteries or mean diastolic pressure in the atria to exceed end-diastolic pressure in the ventricles. If a gradient in pressure exists, an obstruction is present, and the severity of the gradient is one criterion for the necessity of operative repair or catheter intervention. An RV systolic pressure of 100 mm Hg and a pulmonary artery systolic pressure of 20 mm Hg yield a gradient of 80 mm Hg. In this case, the patient would be classified as having severe pulmonary stenosis requiring balloon dilation of the pulmonic valve or surgery if valvuloplasty fails to reduce the gradient to less than 20 mm Hg.

C. PULMONARY AND SYSTEMIC VASCULAR RESISTANCE

The vascular resistance is calculated from the following formula and reported in units or in dynes \times cm⁻⁵/m²:

$$\text{Resistance} = \frac{\text{Pressure}}{\text{Flow}}$$

The pressure drop used to determine pulmonary vascular resistance is calculated by subtracting the mean pulmonary artery wedge or left atrial pressure from the mean pulmonary artery pressure. This pressure drop is divided by pulmonary blood flow per square meter of body surface area. (Pulmonary blood flow is determined by thermodilution or from the Fick principle, as noted earlier.) Similarly, systemic vascular resistance is determined by subtracting the mean central venous pressure from the mean systemic arterial pressure and dividing this pressure drop by systemic blood flow.

Normally, the pulmonary vascular resistance ranges from 1 to 3 units/m², or from 80 to 240 dynes \times cm⁻⁵/m². Systemic vascular resistance ranges from 15 to 20 units/m², or from 1200 to 1600 dynes \times cm⁻⁵/m². If pulmonary resistance is greater than 10 units or the ratio of pulmonary to systemic resistance is greater than 0.5, all other diagnostic findings should be reviewed carefully to confirm the presence of pulmonary hyper-

tension that is so severe as to render the patient inoperable.

Freedom RM et al: *Congenital Heart Disease: Textbook of Angiography*. Futura, 1997.

Simpson JM et al: Cardiac catheterization of low birth weight infants. *Am J Cardiol* 2001;87:1372 [PMID: 11397356].

PERINATAL & NEONATAL CIRCULATION

At birth, two events occur that affect the cardiovascular and pulmonary system: (1) the umbilical cord is clamped, removing the placenta from the maternal circulation; and (2) breathing commences. As a result, marked changes in the circulation occur. During fetal life, the placenta offers low resistance to blood flow. In contrast, the pulmonary arterioles are markedly constricted and offer high resistance to the flow of blood into the lungs. Pulmonary vascular resistance is high in the fetus, and pulmonary blood flow accounts for only 7–10% of the combined in utero ventricular output. At birth, pulmonary blood flow dramatically increases 8- to 10-fold with a progressive fall in pulmonary vascular resistance and pressure. Mechanisms responsible for maintenance of high pulmonary vascular resistance include physical factors (lack of an air–liquid interface or ventilation), relative low oxygen tension, and perhaps vasoactive mediators such as elevated endothelin peptide levels or leukotrienes. Clamping the cord causes a sudden increase in resistance to flow in the systemic circuit. As the lung becomes the organ of respiration, the oxygen tension (PO₂) increases in the vicinity of the small pulmonary arterioles, resulting in a decrease in their constriction and thus a significant decrease in the pulmonary vascular resistance. Increased oxygen tension, rhythmic lung distention, and production of nitric oxide as well as prostacyclin likely play major roles in the fall in pulmonary vascular resistance at birth. The pulmonary vascular resistance shortly after birth falls below that of the systemic circuit, resulting in a change in blood flow across the ductus arteriosus to left to right.

Because of the changes in resistance, most of the RV outflow now passes into the lungs rather than through the ductus arteriosus into the descending aorta. In fact, functional closure of the ductus arteriosus begins to develop shortly after birth. The ductus arteriosus usually remains patent for 3–5 days. During the first hour after birth, a small right-to-left shunting is present (as in the fetus). However, after 1 hour, bidirectional shunting occurs, with the left-to-right direction predominating. In most cases, right-to-left shunting disappears completely by 8 hours. In patients with severe hypoxia (eg, in the syndrome of persistent pulmonary hypertension of the newborn), the pulmonary vascular resistance re-

mains elevated, resulting in a continued right-to-left shunt. The cause of the functional closure of the ductus arteriosus is not completely known. Evidence indicates that the increased PO_2 of the arterial blood causes spasm of the ductus. Although flow through the ductus arteriosus usually is gone within 5 days, the vessel does not close anatomically for 7–14 days.

In fetal life, the foramen ovale serves as a one-way valve, permitting shunting of blood from the inferior vena cava through the right atrium into the left atrium. At birth, because of the changes in the pulmonary and systemic vascular resistance and the increase in the quantity of blood returning from the pulmonary veins to the left atrium, the left atrial pressure rises above that of the right atrium. This functionally closes the flap of the one-way valve, essentially preventing flow of blood across the septum. The foramen ovale remains patent in 10–15% of adults.

Persistent pulmonary hypertension is a clinical syndrome that occurs in full-term infants. The neonate develops tachypnea, cyanosis, and clinical evidence of pulmonary hypertension during the first 8 hours after delivery. These infants have massive right-to-left ductal or foramen shunting (or both) for 3–7 days because of high pulmonary vascular resistance. The clinical course is one of progressive hypoxia and acidosis, terminating in early death unless the pulmonary resistance can be lowered. Instituting appropriate means to increase alveolar pO_2 —hyperventilation, alkalosis, paralysis, surfactant administration, high-frequency ventilation, and cardiac pressors—can usually reverse the resistance. Inhaled nitric oxide is a selective pulmonary vasodilator that produces a sustained improvement in oxygenation and reduces the use of extracorporeal membrane oxygenation. Postmortem findings include increased thickness of the pulmonary arteriolar media.

In the normal newborn, pulmonary vascular resistance and the pulmonary arterial pressure continue to fall during the first few months of life. This phenomenon results from the involution of the pulmonary arteriole from a relatively thick-walled, small-lumen vessel to a thin-walled, large-lumen vessel. Adult levels of pulmonary resistance and pressure are normally achieved by age 2 months. It is at this time typically that signs and symptoms of pulmonary overcirculation associated with moderate or large left-to-right shunting appear.

Fineman JR, Soifer SJ: The fetal and neonatal circulations. In Rudolph AR: *Congenital Diseases of the Heart: Clinical Physiologic Considerations*, 2nd ed. Futura, 2001.

CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) is the clinical condition in which the heart fails to meet the circulatory and

metabolic needs of the body. Almost all infants who develop CHF from congenital heart lesions do so by age 6 months. Common causes of CHF include VSD, PDA, coarctation of the aorta, AV septal defect, large arteriovenous malformations (AVM), and chronic atrial tachyarrhythmias. CHF due to acquired cardiac conditions, such as myocarditis, may occur at any age. Patients present with symptoms of pulmonary congestion as noted in Table 19–1.

Treatment

The therapy of CHF should be directed toward the underlying cause as well as the symptoms. Irrespective of the cause, neurohormonal activation occurs early when ventricular systolic dysfunction is present. Plasma catecholamine levels increase and account for the patient's symptoms. Increased plasma norepinephrine causes tachycardia and diaphoresis and indirectly, through activation of the renin–angiotensin system, causes peripheral vasoconstriction and salt and water retention. Increased metabolic demands cause increased caloric expenditure and failure to thrive. Inotropic agents, diuretics, afterload-reducing agents, and β -blockers may be used, together with supportive measures (oxygen, sedation, mechanical ventilation, and intravenous nutrition) in the treatment of the child with CHF.

Inpatient Management of Congestive Heart Failure

Patients with cardiac decompensation may require hospital admission for initiation or augmentation of anti-congestive therapies. Patients are routinely admitted to a cardiac intensive care unit where telemetry and invasive hemodynamic monitoring (arterial and central venous lines) are used to deliver and assess response to therapy. Table 19–12 demonstrates intravenous inotropic agents used to augment cardiac output and their relative effect on heart rate, systemic vascular resistance, and cardiac index. The drug used will depend in part on the cause of the CHF.

A. INTRAVENOUS INOTROPIC SUPPORT

1. Afterload reduction—

a. **Milrinone.** This selective phosphodiesterase inhibitor increases the level of cyclic adenosine monophosphate (cAMP), thereby improving the inotropic state of the heart. In addition to a dose-dependent increase in cardiac contractility, the drug is a systemic and pulmonary vasodilator and thus an effective agent in cases of right or left ventricular systolic dysfunction for increasing contractility and reducing afterload. Milrinone has been associated with a reduction in incidence of low cardiac output syndrome

Table 19–12. Intravenous inotropic agents.

Drug	Dose	Renal Perfusion	Heart Rate	Cardiac Index	SVR
Dopamine	2–5 $\mu\text{g}/\text{kg}/\text{min}$	\uparrow via vasodilation	0	0	0
	5–10	\uparrow via \uparrow cardiac index	\uparrow	\uparrow	0
	> 10	\downarrow	\uparrow	\uparrow	\uparrow
Dobutamine	2.5–10 $\mu\text{g}/\text{kg}/\text{min}$	\uparrow via \uparrow cardiac index	\uparrow	\uparrow	$\uparrow\downarrow$
Epinephrine	0.2–2.0 $\mu\text{g}/\text{kg}/\text{min}$	\downarrow	\uparrow	\uparrow	\uparrow
Norepinephrine	0.05–0.1 $\mu\text{g}/\text{kg}/\text{min}$	\downarrow	0	\uparrow	$\uparrow\uparrow$
Isoproterenol	0.05–2.0 $\mu\text{g}/\text{kg}/\text{min}$	0	$\uparrow\uparrow$	\uparrow	$\downarrow\downarrow$

after cardiac surgery. The usual dosage range is 0.25–0.75 $\mu\text{g}/\text{kg}/\text{min}$.

b. Nitroprusside. This vasodilator acts directly on vascular smooth muscle, causing both venous and arterial vasodilation at dosages of 0.5–4.0 $\mu\text{g}/\text{kg}/\text{min}$. It is useful in the management of postoperative hypertension. Prolonged use should be carefully monitored as thiocyanate toxicity may occur.

c. Nitroglycerin. Nitroglycerin functions primarily as a dilator of venous capacitance vessels and causes a reduction of right and left atrial pressure. Systemic blood pressure may also fall, and reflex tachycardia may occur. Nitroglycerin is used to improve coronary blood flow and has been shown to be useful in the setting of low cardiac output following congenital heart surgery. Usual intravenous dosage range is 1–3 $\mu\text{g}/\text{kg}/\text{min}$.

2. Extracorporeal membrane oxygenator (ECMO)—

Mechanical support devices including membrane oxygenators may be used in children with myocardial dysfunction following cardiac surgery or in children with refractory CHF secondary to cardiomyopathy or myocarditis. In all cases, mechanical support is used for a limited time while cardiac function improves, or as a bridge to cardiac transplantation. A cannula is placed in the right atrium, either through direct mediastinal cannulation, or through the internal jugular vein. An arterial catheter is placed either directly into the aorta or into an extrathoracic arterial site such as the common carotid artery. Flow from the venous return catheter passes through a membrane oxygenator and then is delivered back to the patient via the arterial catheter. Flow rates are adjusted to maintain adequate systemic perfusion, as judged by mean arterial blood pressure, acid–base status, end-organ function, and mixed venous oxygen saturation. The patient is monitored closely for return of cardiac contractility, and ECMO flows are adjusted accordingly. Risks are significant and include severe internal and external bleeding, infection, thrombosis, and pump failure.

Outpatient Congestive Heart Failure Management

A. MEDICATIONS

1. Digitalis—Digitalis is a primary drug for the treatment of CHF. The desired effect is improvement in myocardial performance (inotropic effect) with an associated decrease in systemic vascular resistance. The standard preparation used in pediatrics is digoxin, which may be administered intravenously, intramuscularly, or orally depending on how rapidly a therapeutic response is needed. The clinical urgency of the individual case dictates how quickly digitalization should be accomplished. Children require higher doses of digoxin on a per kilogram basis than adults, because of their superior renal function.

a. Digitalization. The routine schedule consists of giving one half of the total digitalizing dose initially, then one quarter of the total digitalizing dose at 6 and 12 hours of therapy (Table 19–13). Twenty-four hours after the last digitalizing dose, maintenance therapy is started.

Serum digoxin levels are not routinely monitored unless there are concerns regarding compliance or toxicity.

b. Digitalis toxicity. Any dysrhythmia that occurs during digitalis therapy should be attributed to the drug until proven otherwise. Ventricular bigeminy and first-, second-, or third-degree AV block are characteristic of digitalis toxicity. A trough level should be obtained if digitalis toxicity is suspected.

Table 19–13. Digitalis dosing schedule.

Age	Parenteral	Oral
Premature	0.035 mg/kg	0.04 mg/kg
1 week to 2 years	0.05 mg/kg	0.06 mg/kg
< 1 week or > 2 years	0.04 mg/kg	0.05 mg/kg

c. Digitalis poisoning. This is an acute emergency that must be treated without delay. Digitalis poisoning most commonly occurs in toddlers who have taken their parents' or grandparents' medications. The child's stomach should be emptied immediately even if several hours have passed since ingestion. Patients who have ingested massive amounts of digitalis should receive large doses of activated charcoal. Induction of vomiting or gastric lavage may be indicated but should not be performed if the patient is obtunded. In advanced heart block, atropine or temporary ventricular pacing may be beneficial. Digoxin immune Fab can be used to reverse potentially life-threatening intoxication. Antiarrhythmic agents may be useful.

2. Diuretics—Diuretics are almost always used in the treatment of CHF, either with or without digoxin.

a. Furosemide. This rapidly acting loop diuretic may be given intravenously or orally. Furosemide removes large amounts of potassium and chloride from the body, producing hypochloremic metabolic alkalosis when used chronically. Electrolytes should be monitored during long-term therapy.

b. Thiazides The thiazides are distal tubular diuretics used to complement furosemide in severe cases of CHF.

c. Spironolactone Spironolactone is a potassium-sparing aldosterone inhibitor diuretic. It is used frequently in conjunction with furosemide or thiazides for its enhanced diuretic function. Because it spares potassium, supplemental potassium may be avoided. Spironolactone may also be used as a neurohormonal antagonist with benefit in CHF irrespective of its diuretic effect. In adults with CHF, it has been associated with LV remodeling and improved life expectancy.

d. Metolozone. This potent oral loop diuretic is frequently used in patients who have become refractory to conventional doses of the other diuretics. Due to the marked diuresis that can be associated with this agent, electrolytes must be followed closely as even minor alterations in potassium may precipitate an arrhythmia in a patient with preexisting myocardial dysfunction.

3. Afterload-reducing agents—Oral afterload-reducing agents improve cardiac output by decreasing systemic vascular resistance. Angiotensin-converting enzyme (ACE) inhibitors (captopril, enalapril, lisinopril) are used in patients requiring long-term treatment. These agents, which block angiotensin II-mediated systemic vasoconstriction, are particularly useful in children with structurally normal hearts but reduced LV myocardial function (ie, myocarditis or dilated cardiomyopathies). These agents are also useful in ameliorating mitral and aortic insufficiency and have a role in controlling refractory CHF in patients with large left-

to-right shunts in whom systemic vascular resistance is elevated.

4. Fluid restriction—Restricting fluids is a useful adjunct to medical therapy in children with CHF. When restricting fluids in infants and toddlers it is often necessary to fortify the formula and increase its caloric density in order to maintain adequate caloric intake at reduced volumes.

5. Beta blockade— β -blockers are a useful adjunctive therapy in children with refractory CHF already taking diuretics and ACE inhibitors. Carvedilol and other β -blockers, through their antirenin and anticatecholamine effects, decrease myocardial afterload and improve ventricular systolic function in some patients.

CONGENITAL HEART DISEASE

Congenital heart disease occurs in 0.8% of North American and European populations, making this the most common category of congenital structural malformation. Curative or palliative surgical correction is now available for virtually all patients with congenital heart disease.

Etiology

Congenital heart disease often has a genetic basis. The commonest abnormality now recognized is a microdeletion in the long arm of chromosome 22 (22q11) associated with the DiGeorge, Shprintzen, and conotruncal anomaly face syndromes. These children tend to have either interrupted aortic arch or conotruncal abnormalities such as ToF or double-outlet RV. Intrauterine factors such as maternal diabetes, alcohol consumption, progesterone use, viral infection, and other maternal teratogen exposure are associated with an increased incidence of malformations. These factors probably represent environmental triggers in persons susceptible or predisposed to congenital heart defects. Even acquired heart diseases, such as rheumatic fever, appear to be under strong genetic control. Atherosclerosis clearly oc-

curs in families although in some circumstances it can also be influenced by diet, drugs, or lifestyle.

Genetic diagnosis may allow for a more accurate prediction of the risk of recurrence of a congenital heart disease in a subsequent pregnancy.

NONCYANOTIC CONGENITAL HEART DISEASE

1. Atrial Septal Defect of the Ostium Secundum Variety

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *RV heave.*
- *S₂ widely split and usually fixed.*
- *Grade I–III/VI ejection systolic murmur at the pulmonary area.*
- *Widely radiating systolic murmur mimicking peripheral pulmonary artery stenosis (common in infancy).*
- *Diastolic flow murmur at the lower left sternal border (if the shunt is significant in size).*
- *ECG with rsR' in lead V₁.*

General Considerations

An ASD is an opening in the atrial septum permitting the shunting of blood between the atria. There are three major types: (1) The ostium secundum type (discussed here) is the most common and is in the middle of the septum in the region of the foramen ovale. (2) The sinus venosus type is positioned high in the atrial septum, is the least common, and is frequently associated with partial anomalous pulmonary venous return. (3) The ostium primum type is low in position and is a form of AV septal defect. It is discussed in that section.

ASD of the ostium secundum variety occurs in approximately 10% of patients with congenital heart disease and is twice as common in females as in males. Diagnosis in infancy is becoming more common. Pulmonary hypertension and growth failure are uncommon but occur occasionally in infancy and childhood. After the third decade, pulmonary vascular disease may develop; left-to-right shunting then decreases, and

right-to-left shunting becomes the major clinical abnormality.

Clinical Findings

A. SYMPTOMS AND SIGNS

Infants with ASD rarely present with CHF. Children with ASDs most often have no cardiovascular symptoms. Some patients remain asymptomatic throughout life; others develop easy fatigability as older children or adults. Cyanosis does not occur unless pulmonary hypertension develops.

The peripheral pulses are normal and equal. The heart is usually hyperactive, with an RV heave felt best at the mid to lower left sternal border. No thrills are usually present. S₂ at the pulmonary area is widely split and often fixed. The pulmonary component is normal in intensity. A grade II–III/VI ejection-type systolic murmur is heard best at the left sternal border in the second intercostal space. This murmur is caused by increased flow across the pulmonic valve. No murmur is heard from the flow across the ASD. A middiastolic murmur can often be heard in the fourth intercostal space at the left sternal border. This murmur is caused by increased flow across the tricuspid valve during diastole. The presence of this murmur suggests a high flow with a pulmonary to systemic blood flow ratio greater than 2:1.

B. IMAGING

Radiographs show cardiac enlargement. The main pulmonary artery may be dilated and pulmonary vascular markings increased owing to the increased pulmonary blood flow.

C. ELECTROCARDIOGRAPHY

The usual ECG shows right axis deviation with a clockwise loop in the frontal plane. In the right precordial leads, a rsR' pattern is usually present.

D. ECHOCARDIOGRAPHY

Echocardiography shows a dilated RV. Direct visualization of the ASD by two-dimensional echocardiography, plus demonstration of a left-to-right shunt through the defect by color-flow Doppler, confirms the diagnosis and has eliminated the need for cardiac catheterization prior to open-heart surgery or catheter closure of the defect. During the echocardiography evaluation, a careful assessment of the entry of all of the pulmonary veins into the left atrium is made to rule out associated anomalous pulmonary venous return.

E. CARDIAC CATHETERIZATION

Oximetry reveals a significant increase in oxygen saturation at the atrial level. The pulmonary artery pressure is

usually normal, as is pulmonary vascular resistance. The ratio of pulmonary to systemic blood flow may vary from 1.5:1 to 4:1. Cardiac catheterization is rarely needed for diagnostic purposes; however, placement of a device to close the ostium secundum ASD during cardiac catheterization is becoming increasingly common.

Treatment

Surgical or catheterization laboratory closure with an interventional device is generally recommended for ostium secundum ASDs in which the ratio of pulmonary to systemic blood flow is greater than 2:1. Closure is performed electively in patients between ages 1 and 3 years. The mortality rate for surgical closure is less than 1%. When closure is performed by age 3 years, late complications of RV dysfunction and significant dysrhythmias are avoided. Early surgery is always indicated in infants with CHF or significant pulmonary hypertension. Surgical repair can now be safely performed via a “mini” median sternotomy or posterior thoracotomy approach. Many defects are amenable to nonoperative device closure in the cardiac catheterization laboratory, but the defect must have adequate tissue rims on either side on which to anchor the device.

Course and Prognosis

Patients usually tolerate an ASD well in the first two decades of life. Occasionally a patient may never develop symptoms, but exercise intolerance is common in adulthood. Pulmonary hypertension and reversal of the shunt are rare late complications. Infective endocarditis is uncommon. Spontaneous closure occurs, most frequently in children with a defect originally estimated as less than 4 mm in diameter. Exercise tolerance and oxygen consumption in surgically corrected children are generally normal, and restriction of physical activity is unnecessary. Of all the forms of congenital heart disease, ostium secundum ASD is the most likely to present in middle to late adulthood, either with increased fatigue or with atrial tachyarrhythmias.

2. Ventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Small- to moderate-sized left-to-right shunt without pulmonary hypertension:

- Acyanotic, relatively asymptomatic.
- Grade II–IV/VI pansystolic murmur, maximal along the lower left sternal border.
- P_2 not accentuated.

Large left-to-right shunt:

- Acyanotic.
- Easy fatigability.
- CHF in infancy (often).
- Hyperactive heart; biventricular enlargement.
- Grade II–IV/VI pansystolic murmur, maximal at the lower left sternal border.
- P_2 usually accentuated.
- Diastolic flow murmur at the apex.

Insignificant left-to-right shunt or bidirectional shunt with pulmonary hypertension:

- Quiet precordium with RV lift.
- Palpable P_2 .
- Short ejection systolic murmur along the left sternal border; single accentuated S_2 .
- Systemic arterial oxygen desaturation may be present; pulmonary arterial pressure and systemic arterial pressures are equal; little or no oxygen saturation increase at the RV level by catheterization.

General Considerations

Simple VSD is the most common congenital heart malformation, accounting for about 30% of all cases of congenital heart disease. Defects in the ventricular septum occur both in the membranous portion of the septum (most common) and in the muscular portion. VSDs follow one of four courses:

A. SMALL, HEMODYNAMICALLY INSIGNIFICANT VENTRICULAR SEPTAL DEFECTS

Between 80% and 85% of all VSDs are small (< 3 mm in diameter) at birth, and will close spontaneously. In general, small defects in the muscular interventricular septum will close sooner than those in the membranous

interventricular septum. In most cases, a small VSD never requires surgical closure. Fifty percent of small VSDs will close by age 2 years, and 90% will close by age 6 years. The remaining 10% will close during the school years, and parents should be told at the time of diagnosis and echocardiographic confirmation that all small VSDs will eventually close.

B. MODERATE VENTRICULAR SEPTAL DEFECTS

Asymptomatic patients with moderate VSDs (3–5 mm in diameter) account for only 3–5% of children with VSDs. In general these children do not have CHF or pulmonary hypertension, the two indicators for surgical closure. In those who have cardiac catheterization, the ratio of pulmonary to systemic blood flow is usually less than 2:1, and serial cardiac catheterizations demonstrate that the shunts get progressively smaller. If there is neither CHF nor pulmonary hypertension, these defects can be followed until spontaneous closure.

C. LARGE VENTRICULAR SEPTAL DEFECTS WITH NORMAL PULMONARY VASCULAR RESISTANCE

These defects are usually 6–10 mm in diameter. Unless they become markedly smaller within a few months after birth, they will require surgery. The timing of surgery depends on the clinical situation. Many infants with large VSDs and normal pulmonary vascular resistance will develop CHF and failure to thrive by age 3–6 months, and require correction at that time. In all cases, surgery before age 2 years is required so that the risk of pulmonary vascular disease can be minimized.

D. LARGE VENTRICULAR SEPTAL DEFECTS WITH PULMONARY VASCULAR OBSTRUCTIVE DISEASE

The vast majority of patients with inoperable pulmonary hypertension develop the condition progressively. The combined data of the multicenter National History Study indicate that almost all cases of irreversible pulmonary hypertension can be prevented by surgical repair of a large VSD before age 2 years.

Clinical Findings

A. SYMPTOMS AND SIGNS

Patients with small or moderate left-to-right shunts usually have no cardiovascular symptoms. Patients with large left-to-right shunts are usually ill early in infancy. Such patients have frequent upper and lower respiratory infections. They grow slowly and gain weight slowly. Dyspnea, exercise intolerance, and fatigue are common. CHF develops between 1 and 6 months. Patients who survive the first year usually improve, although easy fatigability may persist. With severe pulmonary hypertension (Eisenmenger syndrome), cyanosis is present.

1. Small left-to-right shunt—Usually no lifts, heaves, or thrills are present. The first sound at the apex is normal, and the second sound at the pulmonary area is split physiologically. The pulmonary component is normal. A grade II–IV/VI, medium- to high-pitched, harsh pansystolic murmur is heard best at the left sternal border in the third and fourth intercostal spaces. The murmur radiates over the entire precordium. No diastolic murmurs are heard.

2. Moderate left-to-right shunt—Slight prominence of the precordium is common. Moderate LV heave is evident. A systolic thrill may be palpable at the lower left sternal border between the third and fourth intercostal spaces. The second sound at the pulmonary area is most often split but may be single. A grade III–IV/VI, harsh pansystolic murmur is heard best at the lower left sternal border in the fourth intercostal space. A mitral diastolic flow murmur indicates that the pulmonary venous return is large and that the pulmonary-to-systemic blood flow ratio is at least 2:1.

3. Large ventricular septal defects with pulmonary hypertension—The precordium is prominent, and the sternum bulges. An LV thrust and an RV heave are palpable. S_2 may be felt at the pulmonary area. A thrill may be present at the lower left sternal border. S_2 is usually single or narrowly split, with accentuation of the pulmonary component. The murmur ranges from grade II to grade IV/VI and is usually harsh and pansystolic. Occasionally, when the defect is large, a murmur is difficult to hear. A diastolic flow murmur may be heard, depending on the size of the shunt.

B. IMAGING

Chest radiographic findings vary depending on the size of the shunt. In patients with small shunts, the radiograph may be normal. Patients with large shunts usually show significant cardiac enlargement involving both the left and right ventricles and the left atrium. The aorta is small to normal in size, and the main pulmonary artery segment is dilated. The pulmonary vascular markings are increased in patients with large shunts.

C. ELECTROCARDIOGRAPHY

The ECG is normal in patients with small left-to-right shunts. Left ventricular hypertrophy (LVH) usually occurs in patients with large left-to-right shunts and normal pulmonary vascular resistance (moderate-sized defects). Combined ventricular hypertrophy (both right and left) occurs in patients with pulmonary hypertension caused by increased flow, increased resistance, or both. Pure RV hypertrophy occurs in patients with pulmonary hypertension secondary to pulmonary vascular obstruction (Eisenmenger syndrome).

D. ECHOCARDIOGRAPHY

Two-dimensional echocardiography can reveal defects that are 2 mm or larger and often can be used to pinpoint the anatomic location of the defect. The addition of color-flow Doppler allows detection of even the smallest VSDs. Multiple defects can be detected by combining two-dimensional and color-flow imaging. Doppler can aid in the evaluation of VSDs by estimating the pressure difference between the left and right ventricles. A pressure difference greater than 50 mm Hg indicates the absence of severe pulmonary hypertension. The combination of excellent visualization of the VSD using echocardiography and Doppler plus the ability to estimate right-sided heart pressures by knowing the systemic blood pressure, and using the pressure drop by Doppler from the left to the right ventricle, allows many VSDs to be repaired surgically without cardiac catheterization and angiocardiography.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Cardiac catheterization and angiocardiography is rarely required for evaluation of an isolated VSD. The pulmonary artery pressure may vary from normal to systemic levels (equal to the aortic pressure). Left atrial pressure (pulmonary wedge pressure) may be normal to increased. Pulmonary vascular resistance varies from normal to markedly increased. Angiocardiographic examination defines the number, size, and location of the defects.

Treatment

A. MEDICAL MANAGEMENT

Patients who develop CHF should receive vigorous treatment with anticongestive measures (see Congestive Heart Failure section). If the patient does not respond to vigorous anticongestive measures, or if he or she shows signs of progressive pulmonary hypertension, surgery is indicated without delay. Transcatheter closure of muscular VSDs is currently being used in selected cases.

B. SURGICAL TREATMENT

The indications for surgical closure of a VSD are CHF combined with failure to thrive and pulmonary hypertension. Primary closure of the defect with a synthetic patch is used. The age at which elective surgery is performed has decreased in most pediatric cardiology centers; most defects are closed in infancy. Patients with cardiomegaly, poor growth, poor exercise tolerance, or other clinical abnormalities who have a significant shunt (> 2:1) without significant pulmonary hypertension typically undergo surgical repair at age 3–6 months. Pa-

tients with pulmonary artery pressures equal to systemic pressure (pulmonary hypertension) undergo surgical repair well before age 2 years to avoid pulmonary vascular disease. In most centers these children have surgery before age 1 year. As a result of this management, the incidence of VSD with pulmonary vascular disease and right-to-left shunting (Eisenmenger syndrome) has been virtually eliminated. In all cases of VSD, the surgical mortality rate is below 2%.

Course & Prognosis

Significant late dysrhythmias are uncommon. Functional exercise capacity and oxygen consumption are usually normal, and physical restrictions are unnecessary. Adults with corrected defects have a normal quality of life. With complete VSD closure, antibiotic prophylaxis for bacterial endocarditis can be discontinued 6 months after surgery.

Thanopoulos B et al: Transcatheter closure of perimembranous ventricular septal defects with the Amplatzer asymmetric ventricular septal defect occluder: Preliminary experience in children. *Heart* 2003;89(8):918 [PMID: 12860872].

Thanopoulos B et al: Transcatheter closure of muscular ventricular septal defects with the Amplatzer ventricular septal defect occluder: Initial clinical applications in children. *J Am Coll Cardiol* 1999;33(5):1395 [PMID: 10193744].

3. Atrioventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Murmur often inaudible in neonates.*
- *Loud pulmonary component of S₂.*
- *Common in infants with Down syndrome.*
- *ECG with left axis deviation.*

General Considerations

AV septal defect is a congenital cardiac abnormality resulting from incomplete fusion of the embryonic endocardial cushions. The endocardial cushions help to form the lower portion of the atrial septum, the membranous portion of the ventricular septum, and the septal leaflets of the tricuspid and mitral valves. These defects are not very common. They account for about 4% of all cases of congenital heart disease. Forty-five percent of children with Down syndrome have congenital heart disease. Of these, 20–25% have AV septal defects.

AV septal defects are divided into partial and complete forms. The complete form consists of a posterior-inlet VSD, an ostium primum ASD that is continuous with the ventricular defect, and a cleft in the anterior leaflet of the mitral valve. In the partial form, any one of these components may be present. The most common partial form of AV septal defect is the ostium primum type of ASD with a cleft in the mitral valve and little or no VSD.

The complete form results in large left-to-right shunts at both the ventricular and atrial levels, tricuspid and mitral regurgitation, and pulmonary hypertension, usually with some increase in pulmonary vascular resistance. When pulmonary hypertension is present, the shunts may be bidirectional. The hemodynamics in the partial form depend on the lesions present.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical picture varies depending on the severity of the defect. In the partial form, patients may be clinically indistinguishable from children with ostium secundum ASDs. They are often asymptomatic. Patients with complete AV septal defect usually are severely affected. CHF often develops in infancy, and recurrent bouts of pneumonia are common.

In the neonate with the complete form, the murmur may be inaudible. After 4–6 weeks, a nonspecific systolic murmur develops. The murmur is usually not as harsh as that of an isolated VSD. The heart is significantly enlarged (both the right and left sides). S_2 is split, with an accentuated pulmonary component. A pronounced diastolic flow murmur may be heard at the apex and the lower left sternal border.

When severe pulmonary vascular obstructive disease is present, dominant RV enlargement usually occurs. S_2 can be palpated at the pulmonary area. No thrill is felt. S_2 is markedly accentuated and single. A nonspecific short systolic murmur is heard at the lower left sternal border. No diastolic flow murmurs are heard. Cyanosis is detectable in severe cases with predominant right-to-left shunts.

The physical findings in the incomplete form depend on the lesions. In the most common variety (ostium primum ASD with mitral regurgitation), the findings are similar to those of ostium secundum ASD with or without findings of mitral regurgitation.

B. IMAGING

Cardiac enlargement is always present. In the complete form, all four chambers are enlarged. The pulmonary vascular markings are increased. In patients with pulmonary vascular obstructive disease, only the main pulmonary artery segment and its branches are prominent.

The peripheral pulmonary vascular markings are usually decreased.

C. ELECTROCARDIOGRAPHY

In all forms of AV septal defect, left axis deviation with a counterclockwise loop in the frontal plane is present. The mean axis varies from approximately -30 to -90 degrees. Because left axis deviation is present in all patients with this condition, the ECG is an important diagnostic tool. Only 5% of isolated VSDs have this ECG abnormality. First-degree heart block is present in over 50% of patients. Right, left, or combined ventricular hypertrophy is present depending on the particular type of defect and the presence or absence of pulmonary hypertension.

D. ECHOCARDIOGRAPHY

Echocardiography is the diagnostic technique of choice. The anatomy can be visualized directly by two-dimensional echocardiography, noting both AV valves to be at the same level. A primum ASD and an inlet VSD are present. AV valve regurgitation may be present. The LV outflow tract is elongated and has been likened to a “goose-neck.” The LV outflow tract may be obstructed.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Cardiac catheterization is not routinely used in the diagnostic assessment of AV septal defects but may be of value in assessing pulmonary artery pressures in the older infant with Down syndrome as this patient group is predisposed to early-onset pulmonary hypertension, which may prohibit surgical closure. If any anatomic questions still need to be answered, cardiac catheterization is of value. The results of cardiac catheterization vary with the type of defect. The catheter is easily passed across the atrial septum in its lowest portion and frequently enters the LV directly from the right atrium. This catheter course is a result of the very low ASD and the cleft in the mitral valve. Increased oxygen saturation in the RV or the right atrium identifies the level of the shunt. Angiocardiography reveals the characteristic goose-neck deformity of the LV outflow tract in the complete form.

Treatment

Treatment consists of anticongestive measures; since spontaneous improvement does not occur, surgery is always required. In the partial form, surgery carries a low mortality rate (1–2%), but patients require ongoing follow-up because of the risk of late occurring LV outflow tract obstruction and mitral valve dysfunction. The complete form is associated with a somewhat higher mortality rate, but complete correction in the first year

of life, prior to the onset of irreversible pulmonary hypertension, is obligatory. Patients with Down syndrome tend to have a lower incidence of associated mitral valve dysplasia and have a lesser risk of reoperation. Pulmonary artery banding procedures are rarely used for AV septal defects. Primary correction should be performed when the child is well and, if possible, weighs more than 5 kg. At corrective surgery, transesophageal echocardiography is useful in assessing the adequacy of repair in the operating room at the completion of cardiopulmonary bypass.

PATENT DUCTUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Variable murmur, with active precordium and full pulses, in newborn premature infants.*
- *Continuous murmur and full pulses in older infants.*

General Considerations

PDA is the persistence of the normal fetal vessel that joins the pulmonary artery to the aorta. It closes spontaneously in normal full-term infants at 3–5 days of age. It is a common abnormality, accounting for about 10% of all cases of congenital heart disease. The incidence of PDA is higher in infants born at high altitudes (over 10,000 ft). It is twice as common in females as in males. In preterm infants weighing less than 1500 g, the frequency of PDA ranges from 20 to 60%.

The defect occurs as an isolated abnormality, but associated lesions sometimes occur. Coarctation of the aorta and VSD are commonly associated with PDA. Even more important to recognize are those patients with murmurs of PDA but without readily apparent findings of other associated lesions who are being kept alive by the patent ductus (eg, a patient with PDA with unsuspected pulmonary atresia).

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical findings and the clinical course depend on the size of the shunt and the degree of pulmonary hypertension.

1. Typical patent ductus arteriosus—The pulses are bounding, and pulse pressure is widened. S_1 is normal. S_2 is usually narrowly split. Rarely, in large shunts, S_2 is paradoxically split; that is, S_2 closes on inspiration and splits on expiration. The paradoxical splitting is caused by the volume overload of the LV and the prolonged ejection of blood from this chamber.

The murmur is quite characteristic. It is a very rough “machinery” murmur that is maximal at the second intercostal space at the left sternal border and inferior to the left clavicle. It begins shortly after S_1 , rises to a peak at S_2 , and passes through the S_2 into diastole, where it becomes a decrescendo murmur and fades before the S_1 . The murmur tends to radiate fairly well over the lung fields anteriorly but relatively poorly over the lung fields posteriorly. A diastolic flow murmur is often heard at the apex.

2. Patent ductus arteriosus with pulmonary hypertension—The physical findings depend on the cause of the pulmonary hypertension. If pulmonary hypertension is primarily the result of an increase in blood flow and only a slight increase in pulmonary vascular resistance, the physical findings are similar to those listed earlier. The significant difference is the presence of an accentuated pulmonary component of S_2 . Bounding pulses and a loud continuous heart murmur are present. In patients with increased pulmonary vascular resistance, the findings are quite different. S_2 is single and accentuated, and no significant heart murmur is present. The pulses are normal rather than bounding.

3. Patent ductus arteriosus in the premature neonate with associated respiratory distress syndrome—A preterm neonate during or after respiratory distress syndrome may have a significant PDA that is difficult to detect by auscultation but which may still be clinically significant. A soft, nonspecific systolic murmur or no murmur is heard rather than the classic continuous murmur. Increase in peripheral pulses may be a helpful sign. Increasing oxygen requirement and increased need for respiratory support or CHF may be signs that a PDA is causing significant left-to-right shunting. The chest radiograph may show cardiomegaly. Echocardiography is always required to confirm the presence or absence of a PDA in the premature infant with lung disease.

B. IMAGING

In simple PDA, the radiographic appearance depends on the size of the shunt. If the shunt is relatively small,

the heart is not enlarged. If the shunt is large, both left atrial and LV enlargement may be present. The aorta and the main pulmonary artery segment may be prominent.

C. ELECTROCARDIOGRAPHY

The ECG may be normal or may show LVH, depending on the size of the shunt. In patients with pulmonary hypertension caused by increased blood flow, biventricular hypertrophy usually occurs. In those with pulmonary vascular obstructive disease, pure right ventricular hypertrophy (RVH) occurs.

D. ECHOCARDIOGRAPHY

Echocardiography provides direct visualization of the ductus and confirmation of the direction and degree of shunting. Preterm infants with a suspected PDA should have a complete echocardiographic evaluation to make a definitive diagnosis, assess the magnitude of the left-to-right shunt, and rule out associated, particularly ductal-dependent, lesions.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Children with PDA never require a cardiac catheterization for diagnostic reasons. However, children with a small PDA routinely have the ductus closed in the catheterization laboratory. This is the sole indication for cardiac catheterization in PDA.

Treatment

Treatment is surgical when the PDA is large, except in patients with pulmonary vascular obstructive disease. Patients with large left-to-right shunts and pulmonary hypertension should be operated on by age 1 year to prevent the development of progressive pulmonary vascular obstructive disease. A symptomatic PDA with normal pulmonary artery pressure can be safely coil-occluded during cardiac catheterization after the child has reached 5 kg.

Patients with nonreactive pulmonary vascular obstruction who have resistance greater than 10 units and a ratio of pulmonary-to-systemic resistance greater than 0.7 despite vasodilator therapy (eg, nitric oxide) should not be operated on. These patients are made worse by closure of the ductus, because the ductus serves as an escape route for their pulmonary hypertension.

Symptomatic PDA is a common problem in preterm infants. Indomethacin, a potent inhibitor of prostaglandin synthesis, is routinely used to close the PDA in premature infants. Indomethacin does not close the PDA of full-term infants or children. The success of indomethacin therapy is as high as 80–90% in premature infants with a birth weight over 1200 g, but

it is less successful in smaller infants. Indomethacin (0.1–0.3 mg/kg orally every 8–24 hours or 0.1–0.3 mg/kg parenterally every 12 hours) can be used if adequate renal, hematologic, and hepatic function is demonstrated. Management during indomethacin therapy includes fluid restriction with or without diuretics and close observation of the urinary output because of indomethacin's tendency to rapidly decrease renal function. If indomethacin is not successful and the ductus remains hemodynamically significant, surgical ligation should be performed without hesitation. If the ductus closes substantially so that it is no longer hemodynamically significant even with some residual flow from left to right, surgery is not needed, and a second course of indomethacin may complete ductal closure. Recent studies from Europe indicate that ibuprofen may be as effective as indomethacin for the medical closure of the preterm PDA.

Course & Prognosis

Patients with simple PDA and small-to-moderate shunts usually do well without surgery. However, in the third or fourth decade of life, symptoms of easy fatigability, dyspnea on exertion, and exercise intolerance appear, usually as a consequence of the development of pulmonary hypertension or CHF.

Spontaneous closure of a PDA may occur up to age 1 year. This is especially true in preterm infants. After age 1 year, spontaneous closure is rare. Because infective endocarditis is a potential complication, closure by coil embolization or surgery is recommended if the defect persists beyond age 1 year.

The prognosis for patients with large shunts or pulmonary hypertension is not as good. Poor growth and development, frequent episodes of pneumonia, and the development of CHF occur in these children. Therefore, patients with PDA and large shunts who are beyond the newborn period should have immediate surgical ligation of their PDA.

MALFORMATIONS ASSOCIATED WITH OBSTRUCTION TO BLOOD FLOW ON THE RIGHT SIDE OF THE HEART

1. Valvular Pulmonary Stenosis with Intact Ventricular Septum

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- No symptoms with mild and moderately severe cases.
- Cyanosis and a high incidence of right-sided CHF in very severe cases in infancy.
- RV lift; systolic ejection click at the pulmonary area in mild to moderately severe cases.
- S_2 widely split with soft to inaudible P_2 ; grade I–VI/VI obstructive systolic murmur, maximal at the pulmonary area.
- Dilated pulmonary artery on posteroanterior chest radiograph.

General Considerations

Pulmonic valve stenosis accounts for 10% of all cases of congenital heart disease. In the usual case, the cusps of the pulmonary valve are fused to form a membrane or diaphragm with a hole in the middle that varies from 2 to 10 mm in diameter. Occasionally, only two cusps may fuse, producing a bicuspid pulmonary valve. In the more severe cases, a secondary infundibular stenosis is present. The pulmonary valve annulus is usually small. Moderate to marked poststenotic dilation of the main and left pulmonary arteries is usually evident. Patent foramen ovale is fairly common.

Obstruction to blood flow across the pulmonary valve results in an increase in pressure developed by the RV to maintain an adequate output across that valve. Pressures greater than systemic are potentially life-threatening and are associated with critical obstruction. Because of the increased work required of the RV, severe RVH and eventual RV failure can occur. In contrast to patients with severe pulmonic valve stenosis, patients with this obstruction who also have a large VSD (ie, ToF) are not at risk for heart failure. In this situation, the septal defect limits the pressure developed in the RV to systemic pressure, making heart failure extremely uncommon.

When obstruction is severe and the ventricular septum is intact, a right-to-left shunt will often occur at the atrial level through a patent foramen ovale. Thus, patients with this condition may have cyanosis, which always indicates a severe degree of valvular obstruction.

Clinical Findings

A. SYMPTOMS AND SIGNS

The history varies with the severity of the obstruction. Patients with mild or even moderate valvular pulmonary stenosis are completely asymptomatic. Patients with more severe valvular obstruction may develop cyanosis very early—even as neonates. Hypoxemic spells characterized by a sudden onset of marked cyanosis and dyspnea occur, but are much less common than in ToF.

Patients with mild to moderate obstruction are acyanotic. These patients are usually well developed and well nourished. They are not prone to lung infections. The pulses are normal. Clubbing may occur in severe cases in which cyanosis has persisted for a long time. On examination of the heart, the precordium may be prominent. An RV heave can frequently be palpated. A systolic thrill is often palpated in the pulmonary area and occasionally in the suprasternal notch. S_1 is normal. In patients with mild to moderate stenosis, a prominent ejection click of pulmonary origin is heard best at the third left intercostal space. This click varies with respiration. It is much more prominent during expiration than inspiration. In patients with severe stenosis, the click tends to merge with S_1 . S_2 also varies with the degree of stenosis. In mild valvular stenosis, S_2 is normal. In moderate degrees of obstruction, S_2 is more widely split and the pulmonary component is softer. In severe pulmonary stenosis, S_2 is single because the pulmonary component cannot be heard. An ejection-type, rough, obstructive systolic murmur is best heard at the second interspace at the left sternal border. It radiates very well to the back. With severe obstruction of the valve, the murmur is usually short and peaks in late systole. No diastolic murmurs are audible.

B. IMAGING

In the mild form of pulmonary stenosis, the heart is normal in size. Poststenotic dilation of the main pulmonary artery segment and the left pulmonary artery often occurs. In moderate to severe cases, slight RV enlargement may occur, and poststenotic dilation of the main pulmonary artery may or may not be present. In cyanotic patients, the pulmonary vascular markings may be decreased.

C. ELECTROCARDIOGRAPHY

Electrocardiography is usually normal in patients with mild obstruction. RVH is present in patients with

moderate to severe valvular obstruction. In severe obstruction, RV hypertrophy and the RV strain pattern (deep inversion of the T wave) are seen in the right precordial leads. In the most severe form, right atrial hypertrophy is also present. Right axis deviation also occurs in the moderate to severe forms. Occasionally, the axis is as great as +180 degrees.

D. ECHOCARDIOGRAPHY

The pulmonary valve may be unusually thickened with reduced valve leaflet excursion. The valve may bulge forward in systole. The transvalvular pressure gradient can be estimated accurately by Doppler echocardiography.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Oxygen saturation or oxygen content does not increase in the right side of the heart. In more severe cases, a right-to-left shunt occurs at the atrial level. Pulmonary artery pressure is normal in milder cases and decreased in moderate to severe cases. RV pressure is always higher than pulmonary artery pressure. The gradient across the pulmonary valve varies from 10 to 200 mm Hg. In severe cases, the right atrial pressure is often elevated, with a predominant a wave. Cineangiography after injection of contrast material into the RV shows thickening of the pulmonary valve and the very narrow opening of the pulmonary valve. This produces a jet of contrast from the RV into the pulmonary artery. Infundibular hypertrophy may be present. Diagnostic catheterization is rarely performed because pulmonic stenosis can be diagnosed easily using physical examination, the ECG, and echocardiography. Catheterization is performed only when balloon pulmonic valvotomy is planned.

Treatment

Relief of pulmonic stenosis is recommended for children with RV systolic pressures greater than 60 mm Hg or higher than two thirds of systemic pressure. Immediate correction is indicated for patients with systemic or suprasystemic RV pressure. Percutaneous balloon valvuloplasty is the procedure of choice in most institutions. It appears to be as effective as surgery in relieving obstruction and causes less valve insufficiency. Surgery is needed to treat pulmonic valve stenosis only when balloon pulmonic valvuloplasty is unsuccessful.

Course & Prognosis

Patients with mild pulmonary stenosis live normal lives. Those with stenosis of moderate severity rarely are symptomatic. Those with severe valvular obstruction may develop severe cyanosis and CHF in infancy.

After balloon pulmonic valvuloplasty or surgery, most patients have good voluntary maximum exercise capacity unless they have significant PI after valvuloplasty. Patients with isolated PI, a common occurrence after surgical pulmonary valvotomy, may be significantly limited in exercise performance. Severe PI leads to progressive RV dilation and dysfunction, which may precipitate ventricular arrhythmias or right heart failure in adulthood. Patients with severe PI may benefit from surgical placement of a pulmonic valve to restore RV outflow tract competence. If relief of valvular obstruction occurs before age 20 years, longevity is normal. Limitation of physical activity is unwarranted. The quality of life of adults with successfully treated pulmonary stenosis, and minimal PI is normal.

Yetman AT et al: Comparison of exercise performance in patients after pulmonary valvulotomy for pulmonary stenosis and tetralogy of Fallot. *Am J Cardiol* 2002;90(12) 1412 [PMID: 12480060].

2. Infundibular Pulmonary Stenosis Without Ventricular Septal Defect

Pure infundibular pulmonary stenosis is rare. One should suspect infundibular pulmonary stenosis when mild to moderate pulmonary stenosis, an intact ventricular septum, no audible pulmonary ejection click, and a murmur that is maximal in the third and fourth intercostal spaces rather than in the second intercostal space are present. The clinical picture is identical to that of pulmonic valve stenosis. Intervention, if indicated, is always surgical because this condition does not improve with balloon catheter dilation.

3. Distal Pulmonary Stenosis

Supravalvular Pulmonary Stenosis

Supravalvular pulmonary stenosis, a relatively rare condition, is caused by narrowing of the main pulmonary artery. The clinical picture may be identical to that of valvular pulmonary stenosis, although the murmur is maximal in the first intercostal space at the left sternal border and in the suprasternal notch. No ejection click is audible. S₂ is usually narrowly split, and the pulmonary component is quite loud as a result of closure of the pulmonary valve under high pressure. The murmur radiates into the neck and over the lung fields. This condition occurs most often in children with Noonan syndrome.

Peripheral Pulmonary Branch Stenosis

In peripheral pulmonary branch stenosis, multiple narrowings of the branches of the pulmonary artery occur

at the bifurcation of the main pulmonary artery or in the periphery of the lung. Systolic murmurs may be heard over both lung fields, both anteriorly and posteriorly. Transient pulmonary branch stenosis murmurs of infancy are innocent. The three most common causes of significant pulmonary artery branch stenosis are Williams–Beuren syndrome, Alagille syndrome, and congenital rubella syndrome. Surgery is often unsuccessful. Transvenous balloon angioplasty is currently being used to treat this condition, with moderate success.

4. Other Congenital Right Heart Lesions

Ebstein Malformation of the Tricuspid Valve

In the Ebstein malformation of the tricuspid valve, the tricuspid valve is displaced downward so that the septal leaflet of the valve is attached to the RV wall (inside the RV) rather than to the tricuspid annulus. As a result, the upper portion of the RV is physiologically within the right atrium. The so-called atrialized portion of the RV is thin-walled and does not contribute to RV output. The portion of the ventricle below the displaced tricuspid valve is diminished in volume and represents the functioning RV. This is an uncommon condition.

Clinical Findings

A. SYMPTOMS & SIGNS

The degree of displacement of the tricuspid valve is variable, and the clinical significance of Ebstein malformation varies with this displacement. In the most extreme form, the septal leaflet is markedly displaced into the RV outflow tract, leading to significant reduction in antegrade flow to the pulmonary artery. Patients are cyanotic shortly after birth because of poor pulmonary artery flow. At the opposite extreme, symptoms may not develop until adulthood when tachyarrhythmias in association with right atrial dilatation or an associated reentrant pathway occur. These older patients typically have minimal displacement of the septal leaflet of the tricuspid valve.

B. IMAGING

The chest radiograph usually shows cardiomegaly with prominence of the right heart border. The degree of cardiomegaly is influenced by the degree of tricuspid valve displacement and by the presence and size of the atrial level shunt. Massive cardiomegaly with a “wall to wall heart” occurs in the setting of severe displacement and a restrictive atrial level defect.

C. ECG

ECG may be normal but more typically shows right atrial enlargement. RBBB and LV enlargement may be found. A delta wave from coexisting Wolff–Parkinson–White syndrome (WPW) may be seen.

D. ECHOCARDIOGRAPHY

Echocardiography is necessary to confirm the diagnosis and may aid in predicting outcome. The degree of displacement, the size of the right atrium, the presence of an associated atrial level shunt, and LV systolic function all affect outcome. The ratio of the atrialized area of the right heart to the area of the remainder of the heart is determined by echocardiography. The greater the ratio, the worse the prognosis.

E. COURSE AND PROGNOSIS

In cyanotic neonates, prostaglandin E infusion is used to maintain pulmonary blood flow until pulmonary vascular resistance decreases, facilitating antegrade pulmonary artery flow. If the patient remains significantly cyanotic, surgical intervention is required in the neonatal period.

Surgical repair consists of an annuloplasty to modify the level of the tricuspid orifice and diminish tricuspid insufficiency. The success rate of this procedure is highly variable. Late arrhythmias are common. Postoperative exercise tolerance increases but remains lower than that for age-related normals. If a significant Ebstein malformation is not treated, atrial tachyarrhythmias will frequently begin during adolescence.

Absence of a Pulmonary Artery

Absence of a pulmonary artery (left or right) may be an isolated malformation or may occur in association with other congenital heart diseases. It occurs occasionally in patients with ToF.

Absence of the Pulmonary Valve

Absence of the pulmonary valve is a rare abnormality usually associated with VSD. In about 50% of cases, infundibular pulmonary stenosis is also present (ToF with absent pulmonary valve).

Driscoll DJ et al: Spectrum of exercise intolerance in 45 patients with Ebstein's anomaly and observations on exercise tolerance in 11 patients after surgical repair. *J Am Coll Cardiol* 1988;11(4):831 [PMID: 3351151].

MALFORMATIONS ASSOCIATED WITH OBSTRUCTION TO BLOOD FLOW ON THE LEFT SIDE OF THE HEART

1. Coarctation of the Aorta

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Pulse lag in lower extremities.*
- *Systolic blood pressure of 20 mm Hg or greater in the upper than in the lower extremities.*
- *Blowing systolic murmur in the left axilla.*

General Considerations

Coarctation is common, accounting for about 6% of all congenital heart disease. Three times as many males as females are affected. Many, though not all, affected females have 45 XO Turner syndrome. Coarctation usually occurs in the thoracic portion of the descending aorta distal to the takeoff of the left subclavian artery in the juxtaductal region. The abdominal aorta is rarely involved. The term “Shone syndrome” refers to multiple levels of left heart obstructive disease, including mitral stenosis, bicuspid aortic valve with or without aortic stenosis, tubular hypoplasia of the aortic isthmus, and coarctation of the aorta. The incidence of an associated bicuspid aortic valve with coarctation is 80–85%.

Clinical Findings

A. SYMPTOMS AND SIGNS

The cardinal physical finding is diminution or absence of femoral pulses. Infants with severe coarctation have equal upper and lower extremity pulses from birth to 2 days of age. Unequal pulses and clinical symptoms develop between 4 and 10 days of age as the ductus arteriosus closes. Approximately 40% of children with coarctation will present at this young age. Coarctation alone, or in combination with VSD, ASD, or other congenital cardiac anomalies, is the leading cause of CHF in the first month of life.

Coarctation presents more insidiously in the 60% of children with no symptoms in infancy. Their coarctation is diagnosed by a pulse discrepancy between the arms and legs on physical exam or by arm hypertension on blood pressure measurement. Normally, the systolic blood pressure in the upper extremities is slightly lower

than in the lower extremities. The actual level of blood pressure in the arms may be elevated only moderately, even in severe coarctation, or it may be elevated significantly. In any case, the pulses in the legs are diminished or absent in affected infants. The left subclavian artery is occasionally involved in the coarctation, in which case the left brachial pulse is also weak. An ejection systolic murmur of grade II/VI intensity is often heard at the aortic area and the lower left sternal border along with an apical ejection click from the bicuspid aortic valve. The pathognomonic murmur of coarctation is heard in the left axilla and the left back. The murmur is usually systolic but may spill into diastole. If the coarctation is complicated by other malformations, murmurs associated with these other abnormalities will be audible.

B. IMAGING

In the older child, radiographic findings may show a normal sized heart, although there is usually some evidence of LV enlargement. The aorta proximal to the coarctation is prominent. The aortic outline indents at the level of the coarctation. The poststenotic segment is dilated. This combination of abnormalities results in the “Figure 3” sign on chest radiograph. Notching or scalloping of the ribs caused by marked enlargement of the intercostal collaterals can be seen. MRI has become extremely useful for determining noninvasively the anatomy of the coarctation. In patients with a severe coarctation and associated CHF, marked cardiac enlargement and pulmonary venous congestion occur.

C. ELECTROCARDIOGRAPHY

ECGs in older children may be normal or may show slight LVH. ECG usually shows RVH in infants with severe coarctation.

D. ECHOCARDIOGRAPHY

Two-dimensional echocardiography and color-flow Doppler are used to visualize the coarctation directly, and continuous-wave Doppler may estimate the degree of obstruction. Diastolic run-off flow is found by continuous-wave Doppler if the obstruction is severe. If the ductus arteriosus is patent, echocardiography may not detect the coarctation. Associated lesions such as a bicuspid aortic valve or mitral abnormalities may suggest the presence of a coarctation. In the face of poor LV systolic function, the coarctation may be difficult to visualize. Flow velocities will not be obviously increased at the coarctation site due to reduced flow across the obstruction. A high index of suspicion of coarctation is required in such a patient.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

These studies demonstrate the position, anatomy, and severity of the coarctation and will assess the adequacy of collateral circulation. Cardiac catheterization and angiocardiology are rarely performed for infants or children with coarctation unless an interventional procedure to dilate the coarctation is planned.

Treatment

Infants with coarctation of the aorta and CHF may present in extremis secondary to LV dysfunction and associated low cardiac output. Resuscitative measures should include initiation of prostaglandin infusion at a dose of 0.025–1.0 µg/kg/min to reopen the ductus arteriosus as well as initiation of inotropic support. Surgical repair should not be delayed by undue medical interventions. Once stabilized, the infant should undergo corrective repair. Some centers perform primary balloon dilation aortoplasty in infants with coarctation, but this is not universally standard. Infant surgery using either the modified end-to-end anastomosis technique or the left subclavian approach has a high success rate, but there is a significant incidence (20–30%) of re-coarctation after repair. Fortunately, recurrent coarctation is highly amenable to balloon aortoplasty in the catheterization laboratory. Coarctation of the aorta in patients who do not have CHF in infancy is corrected electively. In elective coarctation repair, either surgery or primary balloon aortoplasty can be used. In the older patient, particularly when of adult size, aortic stent placement is effective.

Course & Prognosis

Children with coarctation of the aorta who survive the neonatal period without developing CHF do quite well throughout childhood and adolescence. Fatal complications (eg, hypertensive encephalopathy, intracranial bleeding) occur uncommonly in childhood. Infective endocarditis (actually endarteritis in this condition) is rare before adolescence.

Children with coarctation corrected after age 5 years are at increased risk for systemic hypertension and myocardial dysfunction even with successful surgery. Careful exercise testing is mandatory for these children prior to their participation in athletic activities.

Ovaert C et al. Balloon angioplasty of native coarctation: Clinical outcomes and predictors of success. *J Am Coll Cardiol* 2000;35(4):988 [PMID: 10732899].

2. Aortic Stenosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Systolic ejection murmur at the upper right sternal border.*
- *Thrill in the carotid arteries.*
- *Systolic click at the apex.*
- *Dilation of the ascending aorta on chest radiograph.*

General Considerations

Aortic stenosis is an obstruction to the outflow from the LV at or near the aortic valve that causes a systolic pressure gradient of more than 10 mm Hg between the LV and the aorta. Aortic stenosis accounts for approximately 7% of all cases of congenital heart disease. Anatomically, congenital aortic stenosis is divided into three types:

A. VALVULAR AORTIC STENOSIS (75%)

In critical aortic stenosis presenting in infancy, the aortic valve usually consists of a unicuspid diaphragm-like structure without well-defined commissures. Preschool and school-age children more commonly have a bicuspid aortic valve. Teenagers and young adults characteristically have a tricuspid valve with partially fused leaflets. This lesion is more common in males than in females.

B. SUBVALVULAR AORTIC STENOSIS (23%)

In this condition, a membranous or fibrous ring occurs just below the aortic valve. The ring forms a diaphragm with a hole in the middle and results in obstruction to LV outflow. The aortic valve itself and the anterior leaflet of the mitral valve are often deformed.

C. SUPRAVALVULAR AORTIC STENOSIS (1–2%)

In this type of aortic stenosis, constriction of the ascending aorta occurs just above the coronary arteries. This condition is often familial, and two different genetic patterns are associated, one with an abnormal facies and mental retardation (Williams–Beuren syndrome) and one with normal facies and without developmental delay.

Clinical Findings

A. SYMPTOMS AND SIGNS

Most patients with aortic stenosis have no cardiovascular symptoms. Except in the most severe cases, the patient may do well until the third to fifth decades of life, although some patients have mild exercise intolerance and fatigability. A small percentage of patients have significant symptoms (ie, dizziness and syncope) in the first decade. Sudden death, although uncommon, may occur in all forms of aortic stenosis, the greatest risk by far being in adolescents with hypertrophic cardiomyopathy.

Although isolated valvular aortic stenosis seldom causes symptoms in infancy, severe heart failure occasionally occurs when critical obstruction is present at birth. The response to medical management is poor; therefore, an aggressive approach using interventional catheterization or surgery is required. The physical findings vary depending on the anatomic type of lesion:

1. Valvular aortic stenosis—Affected patients are well developed and well nourished. The pulses are usually normal and equal throughout. If the stenosis is severe and a gradient of greater than 80 mm Hg exists, the pulses are diminished with a slow upstroke. Examination of the heart reveals an LV thrust at the apex. A systolic thrill at the right base, the suprasternal notch, and both carotid arteries accompanies moderate disease.

S_1 is normal. A prominent aortic ejection click is best heard at the apex. The click corresponds to the opening of the aortic valve at the conclusion of the isovolumic contraction phase of systole. It is separated from S_1 by a short but appreciable interval. It does not vary with respiration. S_2 at the pulmonary area is normal. The aortic component of S_2 is of good intensity. A grade III–V/VI, rough, medium- to high-pitched ejection-type systolic murmur is evident, loudest at the first and second intercostal spaces, and radiates well into the suprasternal notch and along the carotids. The murmur also radiates fairly well down the lower left sternal border and can be heard at the apex. The grade of the murmur correlates well with the severity of the stenosis.

2. Discrete membranous subvalvular aortic stenosis—The findings are essentially the same as those of valvular aortic stenosis except for the absence of a click. The murmur and thrill are usually somewhat more intense at the left sternal border in the third and fourth intercostal spaces than at the aortic area. Frequently, however, the murmur is equally intense at both areas. A diastolic murmur of aortic insufficiency is commonly heard after age 5 years.

3. Supravalvular aortic stenosis—The thrill and murmur are characteristically best heard in the suprasternal notch and along the carotids, although

they are well transmitted over the aortic area and near the mid left sternal border. A difference in pulses and blood pressure between the right and left arms may be found, with the more prominent pulse and pressure in the right arm (Coanda effect).

B. IMAGING

In most cases the heart is not enlarged. The LV, however, is slightly prominent. In valvular aortic stenosis, dilation of the ascending aorta is frequently seen.

C. ELECTROCARDIOGRAPHY

Patients with mild aortic stenosis have normal ECGs. Patients with severe obstruction frequently demonstrate evidence of LVH and LV strain, but many do not. In about 25% of severe cases, the ECG is normal. Progressive increase in LVH on serial ECGs indicates a significant degree of obstruction. LV strain is an indication for surgery.

D. ECHOCARDIOGRAPHY

This has become a reliable noninvasive technique for the initial diagnosis and follow-up evaluation of all forms of aortic stenosis. Doppler accurately predicts the transvalvular gradient.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Left heart catheterization demonstrates the pressure differential between the LV and the aorta and the level at which the gradient exists. Echocardiography is now the standard method for following the severity of aortic valve stenosis, and cardiac catheterization is reserved for patients whose resting gradient has reached 60–80 mm Hg and in whom intervention is planned. For those with valvar aortic stenosis, balloon valvuloplasty is usually the first option. In subvalvular or supravalvular aortic stenosis, interventional catheterization is not useful and decisions must be made about surgical intervention.

Treatment

Because operation offers less than a cure, surgical repair should be considered only in patients with symptoms, a large resting gradient (60–80 mm Hg) despite balloon angioplasty, or coexisting aortic insufficiency. In many cases, the gradient cannot be significantly diminished without producing aortic insufficiency. Percutaneous balloon valvuloplasty is now accepted as standard initial treatment. Patients who develop significant aortic insufficiency following the procedure will require surgical intervention to repair or replace the valve with either a prosthetic valve or with the patient's own pulmonic valve (Ross procedure). In the Ross procedure, an RV-to-PA conduit is used to replace the pulmonic valve. Discrete subvalvular aortic stenosis is usually surgically

repaired at a lesser gradient because continued trauma to the aortic valve by the subvalvular jet may damage the valve and produce aortic insufficiency. Unfortunately, simple resection is followed by recurrence in more than 25% of patients with subvalvular aortic stenosis. All patients should have close follow-up, and those older than age 6 years should undergo yearly exercise testing. If exercise testing is normal, restriction of physical activity may not be necessary in patients with mild to moderate aortic stenosis.

Course & Prognosis

All forms of LV outflow tract obstruction tend to be progressive. However, regression of the obstruction has been documented in a few patients with supralvalvular obstruction. Pediatric patients with LV outflow tract obstruction—with the exception of those with critical aortic stenosis of infancy—are usually asymptomatic. Symptoms accompanying severe unoperated obstruction (angina, syncope, CHF) are all rare because of detection and surgical or catheter intervention. Preoperative or postoperative children whose obstruction is mild to moderate appear to have above-average oxygen consumption and maximum voluntary working capacity. Children in this category with normal heart size and normal resting and exercising ECG may safely participate in vigorous physical activity, including nonisometric competitive sports. Children with severe aortic stenosis may demonstrate ventricular dysrhythmias.

Rao PS. Long-term follow-up results after balloon dilation of pulmonary stenosis, aortic stenosis and coarctation of the aorta: A review. *Prog Cardiovasc Dis* 1999;42(1):59 [PMID: 10505493].

3. Mitral Valve Prolapse

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Midsystolic click best heard with the patient in the standing or squatting position.*
- *Occasional late systolic murmur.*

General Considerations

Mitral valve prolapse (MVP) is a common entity associated with abnormal auscultatory findings in older pedi-

atric patients. It is secondary to redundant valve tissue or abnormal tissue comprising the mitral valve apparatus. The mitral valve prolapses, moving posteriorly or superiorly into the left atrium during ventricular systole as the mitral valve returns to its closed position. A midsystolic click occurs at the time of this movement and is the clinical hallmark of this entity. Mitral insufficiency may occur late in systole, causing an atypical, short, late systolic murmur with variable radiation. MVP occurs in about 2% of thin adolescent females, a minority of whom have concomitant mitral insufficiency. Although MVP is most commonly an isolated lesion, it can occur in association with other conditions, namely Marfan syndrome and Ehlers–Danlos syndrome. These coexisting conditions should be ruled out by clinical examination.

Clinical Findings

A. SYMPTOMS AND SIGNS

The majority of patients with MVP are asymptomatic. Chest pain, palpitations, and dizziness may be reported, but it is unclear whether these symptoms are more common in affected patients than in the normal population. Significant dysrhythmias have been reported, including increased ventricular ectopy and nonsustained ventricular tachycardia. If significant associated mitral regurgitation is present, atrial arrhythmias may also occur. The standard approach to auscultation must be modified to diagnose MVP. Auscultation should be performed with the patient placed in various positions. Clicks, with or without systolic murmur, are elicited more commonly in the standing and squatting positions than in the supine and sitting positions. The systolic click occurs earlier in children than in adults; that is, it tends to be midsystolic rather than late systolic. Although it is usually heard at the apex, it may be audible at the left sternal border. A midsystolic or systolic murmur after the click implies mitral insufficiency and is much less common than isolated prolapse. The murmur is usually not typical of mitral insufficiency in that it is not pansystolic and radiates to the sternum rather than to the left axilla. Occasionally, a systolic “honk” is heard.

B. IMAGING

In the rare case of significant mitral insufficiency, the left atrium may be enlarged. Left atrial enlargement may produce a “double shadow” seen best on the AP chest radiograph. In significant mitral regurgitation, the subcarinal angle will be increased to greater than 90 degrees. Most chest radiographs are normal, and their use is therefore largely unwarranted.

C. ELECTROCARDIOGRAPHY

The ECG may be normal. Diffuse flattening or inversion of T waves may be seen in the precordial leads. U waves are prominent. Chest pain on exertion is rare and should be assessed with cardiopulmonary stress testing

D. ECHOCARDIOGRAPHY

Significant posterior systolic movement of the mitral valve leaflets to the atrial side of the mitral annulus during systole is diagnostic. Echocardiography will assess the degree of myxomatous change of the mitral valve and the degree of associated mitral insufficiency.

E. OTHER TESTING

Invasive procedures are rarely indicated. Holter monitoring or event recorders may be useful in establishing the presence of ventricular dysrhythmias in patients with palpitations.

Treatment & Prognosis

Oral propranolol may be effective in treatment of coexisting arrhythmias. Prophylaxis for infectious endocarditis is indicated only in individuals with significant myxomatous change on echocardiography or with associated mitral insufficiency.

The natural course of this condition is largely unknown. Twenty years of observation indicate that isolated MVP in childhood is usually a benign entity. Surgery for clinically significant mitral insufficiency is very rarely needed.

Freed LA et al: Prevalence and clinical outcome of mitral valve prolapse. *N Engl J Med* 1999;341(1):1 [PMID: 10387935].

4. Other Congenital Left Heart Valvular Lesions

Congenital Mitral Stenosis

In congenital mitral stenosis, a rare disorder, the valve leaflets are thickened and fused to produce a diaphragm-like or funnel-like structure with a central opening. When mitral stenosis is seen in conjunction with other left-sided obstructive lesions, such as subaortic stenosis and coarctation of the aorta, the complex is known as Shone syndrome. Most patients develop symptoms early in life with symptoms such as tachypnea, dyspnea, and failure to thrive. Physical examination reveals an accentuated S₁ and a loud pulmonary closure sound. No opening snap can be heard. In most cases, a presystolic crescendo murmur is heard at the

apex. Occasionally, only a middiastolic murmur can be heard. Rarely, no murmur at all is present. ECG shows right axis deviation, biatrial enlargement, and RVH. Radiograph reveals left atrial enlargement and frequently pulmonary venous congestion. Echocardiography shows abnormal mitral valve structures with reduced excursion and left atrial enlargement. Cardiac catheterization reveals an elevated pulmonary capillary wedge pressure and pulmonary hypertension.

Mitral valve repair or mitral valve replacement with a prosthetic mitral valve may be performed even in the young infant. Mitral valve repair is the preferred surgical option as mitral valve replacement is associated with a poor outcome in very young children.

Cor Triatriatum

Cor triatriatum is a rare abnormality in which the pulmonary veins join together in their confluence but the confluence is not completely integrated into the left atrium. The chamber communicates with the left atrium through an opening of variable size. The physiologic consequences of this condition are similar to those of mitral stenosis. The clinical findings depend on the size of the opening, and the size and position of any associated atrial septal defect. If the opening is extremely small, symptoms develop very early in life. If the opening is larger, patients may be asymptomatic for a considerable time. Echocardiography reveals a linear density in the left atrium with a gradient between the pulmonary venous chamber and the left atrium proper. Cardiac catheterization may be needed if the diagnosis is in doubt. Finding a high pulmonary wedge pressure and a low left atrial pressure (if the catheter can be passed through the foramen ovale into the true left atrial chamber) confirms the diagnosis. Angiocardiographic studies will identify both the proximal and distal left atrium. Surgical repair is always required in the presence of an obstructive membrane, and long-term results are good. Coexisting mitral valve abnormalities may be noted, including a supravalvular mitral ring or a dysplastic mitral valve.

Congenital Mitral Regurgitation

Congenital mitral regurgitation is a relatively rare abnormality usually associated with other congenital heart lesions, such as congenitally corrected TGA, AV septal defect, and anomalous left coronary artery. Isolated congenital mitral regurgitation is very rare. It is sometimes present in patients with Marfan syndrome, usually associated with a myxomatous prolapsing mitral valve. Occasionally, congenital dilation of the valve ring occurs with an otherwise normal valve. In other cases, the chordae tendineae are malformed, resulting in mitral regurgitation.

Congenital Aortic Regurgitation

Congenital aortic regurgitation is rare. The most common causes are bicuspid aortic valve, either uncomplicated or with coarctation of the aorta; VSD with aortic cusp prolapse and resultant aortic insufficiency; and fenestration of the aortic valve cusp (one or more holes in the cusp).

Eble BK et al: Mitral valve replacement in children: Predictors of long-term outcome. *Ann Thorac Surg* 2003;76(3):853 [PMID: 12963215].

DISEASES OF THE AORTA

Aortic dilation and dissection may occur in childhood. Although the aorta may not be dilated at birth, the structural abnormality that predisposes to dilation is presumed to be congenital in origin. Patients at risk for progressive aortic dilation, and possible dissection, include those with isolated bicuspid aortic valve, Marfan syndrome, Turner syndrome, and type IV Ehlers–Danlos syndrome.

Bicuspid Aortic Valve

Patients with bicuspid aortic valves have an increased incidence of aortic dilation and dissection, irrespective of the presence of aortic stenosis. Histologic examination demonstrates cystic medial degeneration of the aortic wall, probably as a result of smooth muscle cell apoptosis. Patients with isolated bicuspid aortic valve therefore require regular follow-up even in the absence of aortic insufficiency or aortic stenosis. Significant aortic root dilation requiring surgical intervention, in the absence of aortic stenosis, typically does not occur until adulthood.

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder of connective tissue secondary to a mutation in the fibrillin-1 gene. The incidence of spontaneous mutations is 25%, and thus family history is not always helpful. Patients are diagnosed by the Ghent criteria and must have, at a minimum, major involvement of two body systems plus involvement of a third body system or a positive family history. Body systems that may be involved include cardiovascular, ocular, musculoskeletal, pulmonary, and integumentary. Cardiac manifestations include aortic root dilation and MVP, which may even be present at birth. Patients are at risk for aortic dilation and dissection and are restricted from competitive athletics, contact sports, and isometric activities. Beta-blockers or ACE inhibitors are used to lower blood pressure and slow the rate of aortic dilation. Elective surgical

intervention is performed in patients of adult size when the aortic root dimension reaches 50–55 mm. The ratio of actual to expected aortic root dimension is used to determine the need for surgery in the young child. Surgical options include replacement of the dilated aortic root with a composite valve graft (Bentall technique) or a David procedure, wherein the patient's own aortic valve is spared and a Dacron tube graft is used to replace the dilated ascending aorta. Although young age at diagnosis was previously thought to confer a poor prognosis, early diagnosis in association with close follow-up and early initiation of medical therapy has been associated with a favorable outcome in most patients. Ventricular dysrhythmias may contribute to the increased mortality seen in this patient group.

Turner Syndrome

Cardiovascular abnormalities are common in patients with Turner syndrome. Patients are at risk for aortic dissection, typically during adulthood. Risk factors for aortic dissection are usually present and include hypertension irrespective of cause, aortic dilation, bicuspid aortic valve, and coarctation of the aorta. There have been rare reports of aortic dissection occurring in adult Turner syndrome patients in the absence of any risk factors. Patients with Turner syndrome require routine follow-up during adolescence and adulthood to monitor this potentially lethal complication.

CORONARY ARTERY ABNORMALITIES

A number of anomalies involve the origin, course, and distribution of the coronary arteries. The only abnormality seen with any regularity, which has disastrous consequences if unrecognized, is anomalous origin of the left coronary artery.

1. Anomalous Origin of the Left Coronary Artery

In this condition, the left coronary artery arises from the pulmonary artery rather than the aorta. In the

neonatal period, while the pulmonary arterial pressure is relatively high, the perfusion of the left coronary artery is adequate and the child is asymptomatic. However, by age 2 months, the pulmonary arterial pressure falls, resulting in a progressive decrease in the myocardial perfusion supplied by the left coronary artery. Ischemia and infarction of the LV occur. These infants present at age 2–4 months with severe CHF due to LV dysfunction and mitral insufficiency. Immediate surgery is needed, after the child is stabilized with anti-congestive therapy, to bring aortic flow into the left coronary system. The surgery is relatively high risk, especially if infarction of the papillary muscles supporting the mitral apparatus has occurred. Mitral valve replacement is sometimes needed.

Clinical Findings

A. SYMPTOMS AND SIGNS

Patients appear healthy at birth. Growth and development are relatively normal for a few months, although detailed questioning of the parents often discloses a history of intermittent episodes of abdominal pain, pallor, and sweating, especially during or after feeding. These episodes are often thought to be secondary to colic but in fact are anginal attacks similar to those seen in adults.

On physical examination, the patients are usually well developed and well nourished. The pulses are typically weak but equal throughout. A prominent left precordial bulge is present. The pansystolic murmur of mitral regurgitation is frequently present, although a murmur need not be present to make this diagnosis.

B. IMAGING

Chest radiographs show cardiac enlargement and left atrial enlargement and may show pulmonary venous congestion.

C. ELECTROCARDIOGRAPHY

The ECG is very helpful. There are T wave inversions in leads I and aVL. The precordial leads show T wave inversions from V₄ to V₇. Deep, and often wide, Q waves are present in leads I, aVL, and sometimes in V₄–V₆. These findings of myocardial infarction are similar to those in adults.

D. ECHOCARDIOGRAPHY

The diagnosis can be made with two-dimensional techniques by visualizing a single large right coronary artery arising from the aorta in infants with severe LV dysfunction and mitral insufficiency. The anomalous left coronary artery may be seen arising from the main pulmonary artery. The presence of flow reversal confirms the presence of an anomalous left coronary artery.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

A small left-to-right shunt (a result of the flow of blood from the right through the left coronary artery and into the pulmonary artery) can sometimes be detected. Cineangiocardio-graphy after injection of contrast into the root of the aorta fails to show the origin of the left coronary artery. A large right coronary artery fills directly from the aorta, and the contrast material flows from the right coronary system via collaterals into the left coronary arteries and finally into the pulmonary artery.

Treatment & Prognosis

Medical management with anticongestives and afterload reduction fails to correct the anatomic defect and should not delay surgical intervention. Early surgery is required to give a two coronary system. Simple ligation of the left coronary artery or subclavian to coronary artery anastomosis (without cardiopulmonary bypass) offer poor long-term results. Because survival after coronary surgery is highly dependent on the degree of mitral insufficiency, a decision must be made prior to bypass whether to leave or replace the mitral valve.

The prognosis is guarded. No therapeutic modality has been shown to be superior in follow-up studies of survivors.

CYANOTIC CONGENITAL HEART DISEASE

Tetralogy Of Fallot

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cyanosis after the neonatal period.
- Hypoxemic spells during infancy.
- Right-sided aortic arch in 25% of patients.
- Systolic ejection murmur at the upper left sternal border.

General Considerations

In ToF, a VSD is present and obstruction to RV outflow occurs so that the intracardiac shunt is typically

from right to left. This is the most common cyanotic lesion, accounting for 10% of all cases of congenital heart disease. The VSD is usually located in the membranous portion of the septum but may be surrounded completely by muscular tissue, and it is quite large. The obstruction to RV outflow may be primarily at the infundibular level (in 25–50% of cases), at the valvular level alone (rarely), or at both levels (most commonly). The primary embryologic abnormality is in the septation of the conus and truncus arteriosus with anterior deviation of the conus into the RV outflow tract, resulting in an enlarged overriding aorta and hypoplasia of the pulmonary outflow. Experimental lesions in specific loci of ectodermal (neural crest) tissue that migrate to the conus can reproduce the defects seen in ToF. The term “tetralogy” has been used to describe this combination of lesions, because RVH is always present and a varying degree of overriding of the aorta occurs in addition to the VSD and pulmonic and subpulmonic pulmonic stenosis. The overriding is caused by the anterior deviation of the conus, which brings the anterior wall of the aorta forward with it. A right-sided aortic arch is present in 25% of cases, and an ASD occurs in 15%.

Obstruction to RV outflow plus a large VSD results in a right-to-left shunt at the ventricular level and desaturation of the arterial blood. The degree of desaturation depends on the resistance to outflow from the RV, and the systemic vascular resistance. The greater the obstruction, and the lower the systemic vascular resistance, the greater the right-to-left shunting. Although the patient may be deeply cyanotic, the amount of pressure the RV can develop is limited to that of the systemic (aortic) pressure because the VSD is unrestrictive. The RV is usually able to maintain this level of pressure without developing heart failure. A high association between ToF and deletions in the long arm of chromosome 22 (22q11) has now been established, and as many as 15% of children with tetralogy appear to have this genetic abnormality.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical findings vary depending on the degree of RV outflow obstruction. Patients with a mild degree of obstruction are only minimally cyanotic or may even be acyanotic. Those with maximal obstruction are deeply cyanotic from birth. Few children are asymptomatic. Most have cyanosis by age 4 months, and the cyanosis usually is progressive. Growth and development are not typically retarded, but easy fatigability and dyspnea on exertion are common. When these children learn to walk, they frequently squat suddenly to increase systemic vascular resistance to ward off cyanotic spells.

Hypoxemic spells, also called cyanotic spells or (Tet) tetralogy spells, are one of the hallmarks of severe ToF and are characterized by the following signs and symptoms: (1) sudden onset of cyanosis or deepening of cyanosis; (2) sudden onset of dyspnea; (3) alterations in consciousness, encompassing a spectrum from irritability to syncope; and (4) decrease in intensity or even disappearance of the systolic murmur. These episodes may begin in the neonatal period, but most commonly they start at age 4–6 months. Acute treatment of cyanotic spells consists of giving oxygen and placing the patient in the knee-chest position. Acidosis, if present, should be corrected with intravenous sodium bicarbonate. Morphine sulfate should be administered cautiously by a parenteral route in a dosage of 0.1 mg/kg. Propranolol, 0.1–0.2 mg/kg intravenously, is useful. Chronic (daily) prophylaxis of cyanotic spells with propranolol, 1 mg/kg orally every 4 hours while awake, remains controversial; however, in a significant number of patients, this regimen has prevented subsequent spells and made it possible to delay surgery. The degree of cyanosis in ToF is variable. The fingers and toes show varying degrees of clubbing depending on the age of the child and the severity of cyanosis.

On examination of the heart, an RV lift is palpable. S_1 is normal; occasionally, an ejection click is evident at the apex that is aortic in origin. S_2 is predominantly aortic and single. A grade II–IV/VI, rough, ejection-type systolic murmur is present that is maximal at the left sternal border in the third intercostal space and that radiates well to the back.

B. LABORATORY FINDINGS

The hemoglobin, hematocrit, and red blood cell count are usually elevated, depending on the degree of arterial oxygen desaturation.

C. IMAGING

Chest radiographs show a heart of normal size. Indeed, the radiograph is sometimes interpreted as entirely normal. However, the RV is hypertrophied, which is often shown in the posteroanterior projection by an upturning of the apex (boot-shaped heart). The main pulmonary artery segment is usually concave, and a right aortic arch is present in 25% of cases, with the aortic knob to the right of the trachea. The pulmonary vascular markings are usually decreased.

D. ELECTROCARDIOGRAPHY

The cardiac axis is to the right, ranging from +90 to +180 degrees. The P waves are usually normal, although evidence may indicate slight right atrial hypertrophy. RVH is always present, but RV strain patterns are rare.

E. ECHOCARDIOGRAPHY

Two-dimensional imaging is diagnostic, revealing thickening of the RV wall, with overriding of the aorta and a large subaortic VSD. Furthermore, obstruction at the level of the infundibulum and pulmonary valve can be identified, and the size of the proximal pulmonary arteries can be measured. The anatomy of the coronary arteries may be visualized.

F. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Cardiac catheterization reveals the presence of a right-to-left shunt in most cases. Arterial desaturation of varying degrees is present. The right-to-left shunt occurs at the ventricular level. The RV pressure is at systemic levels, and the pressure tracing in the RV is identical to that of the LV. The pulmonary artery pressure is low. The pressure gradients may be noted at the valvular level or the infundibular level (or both).

Cineangiography is helpful. Injection of contrast into the RV reveals the RV outflow obstruction and the right-to-left shunt at the ventricular level. The major indications for cardiac catheterization are to establish coronary artery and distal pulmonary artery anatomy. In addition, some patients may be palliated by balloon dilation of the RV outflow tract during infancy to improve the pulmonary blood flow, thereby delaying surgical intervention.

Treatment

A. PALLIATIVE TREATMENT

Palliative treatment is performed at some centers for small infants who have severe symptoms (severe cyanosis, frequent severe hypoxic spells) and in whom complete correction is deemed too risky. Medical (chronic oral β -blocking agents) or, more often, surgical (creation of a systemic arterial to pulmonary arterial anastomosis) palliation can be used. Balloon angioplasty is being used for palliation in some centers. In this procedure the pulmonic valve and the entire RV outflow tract are dilated in order to reduce RV outflow tract obstruction and improve pulmonary artery growth. The most common surgical palliation is the creation of a GoreTex shunt from the subclavian artery to the ipsilateral pulmonary artery (modified Blalock–Taussig shunt). This operation can be done with very low likelihood of mortality and with no significant distortion of the pulmonary arteries.

B. TOTAL CORRECTION

The timing of open-heart surgery for repair of ToF ranges from birth to age 2 years, varying with the experience of each treatment center. The current surgical

trend is toward earlier repair based on the severity of symptoms. Patients may be repaired in the neonatal period, although, if asymptomatic, surgery is deferred until 6–8 months of age. During surgery, the VSD is closed and the obstruction to RV outflow removed. The surgical death rate varies from 1% to 3%. The major limiting anatomic feature of total correction is the size of the pulmonary arteries.

Course & Prognosis

Infants with the most severe form of ToF are usually deeply cyanotic at birth. Hypoxemic spells may occur during the neonatal period. Death is extremely rare during a severe hypoxemic spell. These children require early surgery, either a Blalock–Taussig shunt or primary correction.

All children with ToF require open-heart surgery. Complete repair before age 5 years usually results in fair to good function, although patients occasionally die as a result of ventricular dysrhythmias. A competent pulmonary valve without a dilated RV appears to diminish arrhythmias and enhance exercise performance.

PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

This condition consists of complete atresia of the pulmonary valve in association with VSD. Essentially, it is an extreme form of ToF. Because there is no antegrade flow from the RV into the pulmonary artery, the pulmonary blood flow must be derived either from a PDA or from aortopulmonary collateral arteries.

The clinical picture depends entirely on the size of the ductus and the collateral channels. If they are large, patients may be quite stable. If pulmonary blood flow is low, severe hypoxia results, and immediate palliation is required. Newborns are stabilized with intravenous prostaglandin E₁ (PGE₁) to maintain patency of the ductus arteriosus while being prepared for surgery. Once the child is stabilized, a decision must be made about whether to do a palliative Blalock–Taussig shunt

or to proceed with primary correction. In most centers, a shunt is performed in the newborn period, with open-heart surgery planned for age 9–18 months.

Echocardiography or cardiac catheterization and angiography are diagnostic. A corrective surgical procedure that has been successful in patients with adequate-sized pulmonary arteries consists of closing the VSD and inserting a homograft from the RV to the main pulmonary artery. Success depends on precise definition of pulmonary arterial and collateral blood supply to the lung and, if needed, prior unifocalization of segments with dual arterial blood supply into a single pulmonary arterial tree.

Mair DD, Puga FJ: Management of pulmonary atresia with ventricular septal defect. *Curr Treat Options Cardiovasc Med* 2003;5(5):409 [PMID: 12941209].

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Cyanosis at birth.*
- *Chest radiograph with a concave pulmonary artery segment and the apex tilted upward.*

General Considerations

In this uncommon condition, the pulmonary valve is atretic. The pulmonic annulus usually has a small diaphragm consisting of the fused valve cusps. The ventricular septum is intact. The main pulmonary artery segment is somewhat hypoplastic but almost always present. Although the RV is always reduced in size in this condition, the degree of reduction is variable. This factor is critical because some children with pulmonic atresia may have an adequate ventricle for ultimate “two-ventricular” repair; therefore, the assessment of the adequacy of the RV is important. The RV has three component parts (inlet, trabecular, and outlet), and the absence of any one of these three components makes the ultimate use of the RV extremely unlikely. Even with all three components, some RVs are inadequate.

Following birth, the pulmonary circulation is maintained by the PDA. Although a bronchial–pulmonary collateral network may be present, it is usually insufficient to maintain the pulmonary circulation. Accordingly, a continuous infusion of PGE₁ must be started as soon as possible after birth to maintain ductal patency.

Clinical Findings

A. SYMPTOMS AND SIGNS

Although patients may be normal at birth, they are usually cyanotic. Cyanosis progresses as the ductus arteriosus closes. A blowing systolic murmur resulting from the associated PDA may be heard at the pulmonary area. In addition, a pansystolic murmur is often heard at the lower left sternal border, because most of these children develop significant tricuspid insufficiency.

B. IMAGING

The heart size may vary from small to markedly enlarged, depending on the degree of tricuspid insufficiency. With striking tricuspid insufficiency, right atrial enlargement may be massive and the cardiac silhouette may virtually fill the chest.

C. ELECTROCARDIOGRAPHY

ECG reveals an axis that is leftward for age (45–90 degrees) in the frontal plane. Evidence for right atrial enlargement is usually striking. There is LV dominance for age with reduced RV forces.

D. ECHOCARDIOGRAPHY

Echocardiography shows absence of the pulmonary valve, with varying degrees of hypoplasia of the RV cavity and tricuspid annulus. The severity of tricuspid regurgitation correlates with RV size.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

RV pressure is high and is almost always suprasystemic. A cineangiogram in the RV reveals no filling of the pulmonary artery from the RV. It also demonstrates the size of the RV chamber, relative hypoplasia of the components of the tripartite RV, and the presence or absence of tricuspid regurgitation. Approximately 15% of children with pulmonic atresia and intact ventricular septum have sinusoids between the RV and the coronary arteries. The presence of these sinusoids indicates that the coronary circulation may depend on RV flow; this situation is associated with a high risk for sudden death.

Treatment & Prognosis

As in pulmonary atresia with VSD, a PGE₁ infusion is used to stabilize the patient and maintain patency of the ductus until surgery can be performed. Surgery should be undertaken as soon as possible. A Rashkind balloon atrial septostomy is performed, depending on RV size, to open up the communication across the atrial septum. If the RV is tripartite and an eventual two-chamber repair is planned, the pulmonary valve

plate is opened during cardiac catheterization in the newborn period to allow antegrade flow from the RV to the pulmonary artery and to encourage RV cavity growth. If the RV is inadequate, significant sinusoids are present, or the pulmonic valve cannot be opened successfully in the catheterization laboratory, an immediate Blalock–Taussig shunt is performed to establish pulmonary blood flow. Later in infancy, a communication between the RV and pulmonary artery can be created on bypass in an attempt to stimulate RV cavity growth. If RV dimensions or function are inadequate for a two-ventricular repair, a one-ventricular systemic venous to pulmonary artery palliation is indicated (Fontan procedure). Children with significant sinusoids receive a Blalock–Taussig shunt as immediate treatment, but they are often considered for cardiac transplantation if they are deemed at risk for coronary insufficiency and sudden death.

The prognosis in this condition remains guarded. Our overall experience strongly favors opening the atretic valve in the catheterization laboratory in the newborn period if possible. If this is impossible, a Blalock–Taussig shunt should be placed. Ultimate plans for a two-ventricular repair, a Fontan procedure, or cardiac transplantation depend on the anatomy.

Powell AJ et al: Outcome in infants with pulmonary atresia, intact ventricular septum, and right ventricular-dependent coronary circulation. *Am J Cardiol* 2000;86(11):1272 [PMID: 11090809].

TRICUSPID ATRESIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Marked cyanosis present from birth.*
- *ECG with left axis deviation, right atrial enlargement, and LVH.*

General Considerations

This relatively rare condition (< 1% of cases of congenital heart disease) is characterized by complete atresia of the tricuspid valve. As a result, no direct communica-

tion exists between the right atrium and the RV. Tricuspid atresia is divided into two types, depending on the relationship of the great vessels (Table 19–14).

Because no direct communication exists between the right atrium and the RV, the entire systemic venous return must flow through the atrial septum (either an ASD or patent foramen ovale) into the left atrium. Thus the left atrium receives both the systemic venous return and the pulmonary venous return. Complete mixing occurs in the left atrium, resulting in a greater or lesser degree of arterial desaturation.

As a result of the lack of direct communication, the development of the RV depends on the presence of a left-to-right shunt at the ventricular level. Therefore, severe hypoplasia of the RV occurs in those forms in which there is no VSD or in which the VSD is small.

Clinical Findings

A. SYMPTOMS AND SIGNS

In most patients with tricuspid atresia, symptoms develop early in infancy. Except in patients whose pulmonary blood flow is high, cyanosis is present at birth. Growth and development are poor, and the infant usually exhibits fatigability on feeding, tachypnea, dyspnea, anoxic spells, and evidence of right heart failure. Patients with marked increase in pulmonary blood flow—types 1(c) and 2(b)—may develop evidence of left heart failure as well.

Digital clubbing is present in older children. S₁ is normal. S₂ is most often single. A murmur is usually present, although it is variable. It ranges from grade II to grade III/VI in intensity and usually is a harsh blowing murmur heard best at the lower left sternal border.

Table 19–14. Tricuspid atresia.

Type 1: Without transposition of the great arteries	Type 2: With transposition of the great arteries
(a) No ventricular septal defect; hypoplasia or atresia of the pulmonary artery; patent ductus arteriosus	(a) With ventricular septal defect and pulmonary stenosis
(b) Small ventricular septal defect; pulmonary stenosis; hypoplastic pulmonary artery	(b) With ventricular septal defect but without pulmonary stenosis
(c) Large ventricular septal defect and no pulmonary stenosis; normal-sized pulmonary artery	

B. IMAGING

Chest radiographic findings are variable. The heart is slightly to markedly enlarged. The main pulmonary artery segment is usually small or absent. The size of the right atrium varies from moderately to massively enlarged, depending on the size of the communication at the atrial level. The pulmonary vascular markings are usually decreased, although in types 1(c) and 2(b) they are increased.

C. ELECTROCARDIOGRAPHY

The ECG is usually helpful. It shows left axis deviation with a counterclockwise loop in the frontal plane. The P waves are tall and peaked, indicative of right atrial hypertrophy. LVH or LV dominance is found in almost all cases. RV forces on the ECG are usually low or absent.

D. ECHOCARDIOGRAPHY

M-mode and two-dimensional methods are diagnostic and show absence of the tricuspid valve, the relationship between the great arteries, and the size of the pulmonary arteries.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

This technique reveals the large right-to-left shunt at the atrial level and desaturation of the left atrial blood. Because of the complete mixing in the left atrium, oxygen saturations in the LV, RV, pulmonary artery, and aorta are identical to the that in left atrium. The right atrial pressure is increased. LV and systemic pressures are normal. The catheter cannot be passed through the tricuspid valve from the right atrium to the RV. A balloon atrial septostomy is performed if a restrictive foramen ovale is present.

Treatment & Prognosis

In infants with high pulmonary artery flow, conventional anticongestive therapy should be given until the infant begins to outgrow the VSD. Occasionally, a pulmonary artery band is needed to protect the pulmonary bed in preparation for a Fontan procedure. A Fontan procedure (connection of the systemic venous return to the pulmonary artery) is performed when increasing cyanosis occurs, typically at age 2–4 years.

In infants with diminished pulmonary blood flow, PGE₁ is infused until an aortopulmonary shunt can be performed. The Fontan procedure is frequently performed in stages; a Glenn procedure (superior vena cava to pulmonary artery anastomosis) is performed with concomitant ligation of the aortopulmonary shunt at age 3–9 months, and a completion Fontan procedure is performed at age 1–4 years.

The prognosis for all patients with tricuspid atresia depends on the achievement of a balance of pulmonary blood flow that permits adequate oxygenation of the tissues without producing CHF. The long-term prognosis for children treated by the Fontan procedure is unknown. In the short term, the best results for the Fontan procedure occur in children with low pulmonary artery pressures prior to open-heart surgery.

Mair DD et al: The Fontan procedure for tricuspid atresia: Early and late results of a 25-year experience with 216 patients. *J Am Coll Cardiol* 2001;37(3):933 [PMID: 11693773].

HYPOPLASTIC LEFT HEART SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Mild cyanosis at birth. Minimal auscultatory findings.*
- *Rapid onset of shock with ductal closure.*

General Considerations

Hypoplastic left heart syndrome includes a number of conditions in which lesions of the left heart result in hypoplasia of the LV. The syndrome occurs in 1.4–3.8% of infants with congenital heart disease.

The most common lesions making up this syndrome are mitral atresia, aortic atresia, or both. Following birth, survival depends on a PDA because the antegrade flow into the systemic circulation is inadequate and the ductus arteriosus provides flow to the aorta. Children with hypoplastic left heart syndrome are usually stable at birth, but they deteriorate rapidly as the ductus starts to close later in the first week of life. Untreated, the average age at death is 5–7 days. In rare instances, the ductus will remain widely patent on its own, and children will survive for months without PGE₁ therapy.

Clinical Findings

A. SYMPTOMS AND SIGNS

Children with hypoplastic left heart syndrome appear stable at birth, because the ductus is widely patent. They deteriorate rapidly when the ductus starts to close

with findings first of CHF, followed almost immediately by clinical shock with acidosis secondary to inadequate systemic perfusion.

B. IMAGING

Chest radiographic findings at presentation are those of cardiac enlargement with severe pulmonary venous congestion.

C. ELECTROCARDIOGRAPHY

The ECG demonstrates right axis deviation, right atrial hypertrophy, and RVH with relative paucity of LV forces and absence of a Q wave in lead V_6 . A QR pattern is often seen in lead V_1 .

D. ECHOCARDIOGRAPHY

Echocardiography is diagnostic and eliminates the need for cardiac catheterization. A diminutive aorta and LV with an atretic mitral valve in the presence of a normal and easily definable tricuspid valve are diagnostic. The systemic circulation depends on the PDA. Color-flow Doppler imaging shows retrograde flow in the ascending aorta.

Treatment & Prognosis

PGE_1 infusion is essential initially because systemic circulation depends on a PDA. Further management depends on balancing pulmonary and systemic blood flow because the RV provides both. Within a few days of birth, the pulmonary resistance falls, favoring pulmonary overcirculation and compromised systemic perfusion. Therapy must be directed to increasing pulmonary vascular tone using hypoxia or hypercapnic ventilation. We now use nitrogen to decrease the inspired oxygen content below 21%. This therapy, which must be carefully monitored, results in an increase in pulmonary arterial tone and systemic perfusion. Nitrogen is blended with room air, and the delivered O_2 content is monitored continuously. We typically start at 16–17% inspired oxygen with a goal of maintaining systemic O_2 saturation at 65–80% to balance the pulmonary and systemic blood flows.

Shortly after birth a decision must be made between several surgical options. In the Norwood procedure, the RV is used as the systemic ventricle while an aortopulmonary bypass is created for pulmonic flow. Alternatively, the child can be listed for orthotopic cardiac transplantation. Children who have a Norwood procedure (and subsequent Glenn anastomosis and completion Fontan procedure) or who are listed for receipt of a donor heart have a 50–60% chance for 5-year survival at the best centers. Although this is a major improvement over nonsurgical intervention, hypoplastic left

heart syndrome remains one of the most challenging lesions in pediatric cardiology.

TRANSPOSITION OF THE GREAT ARTERIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cyanotic newborn without respiratory distress.
- More common in males.

General Considerations

Transposition of the great arteries (d-TGA or complete TGA) is the second most common cyanotic congenital heart disease, accounting for 5% of all cases of congenital heart disease. The male-to-female ratio is 3:1. The disorder is caused by an embryologic abnormality in the spiral division of the truncus arteriosus, in which the aorta arises from the RV and the pulmonary artery from the LV. In 60% of cases only the two usual newborn cardiac connections (patent foramen ovale and PDA) are present, but VSDs, pulmonic stenosis, coarctation of the aorta, or aortic stenosis occurs in a significant number of patients. Left unrepaired, transposition is associated with a high incidence of early pulmonary vascular obstructive disease. TGA can be classified into two types (Table 19–15).

Because the aorta arises directly from the RV, survival would be impossible without mixing between the systemic and pulmonary circulations. Oxygenated blood from the pulmonary veins must reach the systemic arterial circuit. In patients with an intact ventricular septum, mixing occurs at the atrial and ductal levels. However, in most patients, these communications are small, and the ductus arteriosus closes shortly after birth. These patients are therefore severely cyanotic. Patients with a VSD may have better mixing and less cyanosis. Patients with a VSD and pulmonary stenosis

Table 19–15. Complete (D) transposition of the great arteries.

Type 1: With intact ventricular septum	Type 2: With ventricular septal defect
(a) Without pulmonary stenosis	(a) With pulmonary stenosis
(b) With pulmonary stenosis subvalvular or valvular (or both)	(b) With pulmonary vascular obstruction
	(c) Without pulmonary vascular obstruction (normal pulmonary vascular resistance)

(types 2[a] and 2[b]) are usually severely cyanotic because of the limited blood flow to the lungs. Patients with a VSD and normal pulmonary vascular resistance (type 2[c]) have the least cyanosis but often develop heart failure early because of high pulmonary blood flow.

Clinical Findings

A. SYMPTOMS AND SIGNS

Many of the neonates are large, some weighing 4 kg at birth, and most are severely cyanotic at birth. Infants with an intact ventricular septum are often quite striking in appearance because of their profound cyanosis (unresponsive to increasing the ambient O_2), the absence of a significant murmur, their lack of respiratory distress, and their large size. Only infants with a large VSD will be less cyanotic, and they usually have a prominent murmur. The findings on cardiovascular examination depend on the intracardiac defects. Patients with type 1(a) defects have only soft murmurs or none at all. S_1 is usually normal in these patients. S_2 is single and accentuated as the aortic valve is anterior. Patients with type 1(b) defects have loud obstructive systolic murmurs that are maximal at the second and third intercostal spaces and the left sternal border, radiating well to the first and second intercostal spaces. Patients with type 2(a) defects have a murmur of pulmonary stenosis (obstructive systolic murmur at the base of the heart, best heard to the right of the sternum). Those with type 2(c) defects have a systolic murmur along the lower sternal border and a mitral diastolic flow murmur at the apex.

B. IMAGING

The chest radiograph in transposition is often nonspecific. Sometimes, however, there is an “egg on a string” appearance because the aorta is directly anterior to the main pulmonary artery, giving the image of a narrow mediastinum.

C. ELECTROCARDIOGRAPHY

Because the newborn ECG normally has RV predominance, the ECG in transposition is of little help.

D. ECHOCARDIOGRAPHY

Two-dimensional imaging and Doppler evaluation accurately describe the anatomy and physiology of transposition. The abnormal relationship of the great arteries is the hallmark of transposition on echocardiography. If clinically indicated, the balloon atrial septostomy may be performed with echocardiographic guidance.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Cardiac catheterization is both diagnostic and therapeutic in this malformation. If complete transposition of the great arteries exists and if there are two well-developed ventricles, a Rashkind balloon atrial septostomy is performed to open the atrial septum unless a true ASD exists. The coronary anatomy is delineated by ascending aortography.

Treatment

Early corrective surgery is recommended for transposition. The arterial switch operation (ASO) is performed at age 4–7 days. The arteries are switched in the anterior chest, and the coronaries are reimplanted into the neo-aorta. Small associated VSDs may be left to close on their own, but large VSDs are always closed at this time. The atrial septum is also closed. The ASO has replaced the atrial switch procedures (Mustard and Senning operations), which were previously performed. Because the ASO must be performed while the LV musculature can still support systemic blood flow, it is rarely delayed beyond age 14 days in infants with an intact ventricular septum or small VSD. If a large, unrestrictive VSD is present that maintains LV pressure at systemic levels, corrective surgery can be delayed for a few months. Surgery should still be performed by age 3–4 months because of the high risk of early pulmonary vascular disease associated with transposition.

Survival after the ASO is now greater than 95% in major centers. In addition, the switch procedure greatly shortens the time that the child remains severely cyanotic before corrective surgery. Early relief of cyanosis may improve the developmental outcome for children with transposition. Finally, the switch procedure leaves the LV as the systemic ventricle. The older atrial corrective procedures (Senning and Mustard procedures) put the RV in this role, there was a significant incidence of late RV failure. Since the LV is designed for systemic pressures, late failure of the LV after the ASO has not been reported.

CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

Congenitally corrected transposition of the great arteries (ccTGA or l-TGA) is a relatively uncommon form of congenital heart disease that may present with cyanosis depending on the presence of associated lesions. In ccTGA, both AV and VA discordance occurs, such that the right atrium connects to a morphologic LV, which supports the pulmonary artery. Conversely, the left atrium empties via a tricuspid valve, into a morphologic RV, which supports the aorta. Commonly associated lesions include VSDs and pulmonary stenosis. A dysplastic left-sided tricuspid valve is almost always present. Previously, surgical repair was directed at VSD closure and relief of pulmonary outflow tract obstruction. This surgical technique maintained the RV as the systemic ventricle supporting the aorta. It is now recognized that these patients have a reduced lifespan, and thus other surgical techniques have been advocated. The double-switch procedure is one such technique. In this procedure, an atrial level switch (Mustard or Senning technique) is performed, and an arterial switch operation then restores the morphologic LV to its position of systemic ventricle. In the absence of associated lesions, patients with ccTGA most often are undiagnosed until the adult years, when they present with either left-sided AV valve insufficiency or arrhythmias. Patients with ccTGA have an increased incidence of spontaneous complete heart block estimated at 1% per year with an overall frequency of 50%.

Graham TP et al: Long-term outcome in congenitally corrected transposition of the great arteries. *J Am Coll Cardiol* 2000;36(1):255 [PMID: 10898443].

DOUBLE-OUTLET RIGHT VENTRICLE

In this uncommon malformation, both great arteries arise from the RV. There is always a VSD that allows blood to flow from the LV. The presentation depends on the relationship of the VSD to the semilunar valves.

If the VSD is subaortic and no pulmonary stenosis is present, a large left-to-right shunt is present and the clinical picture resembles that of a large VSD. Early primary correction, with the VSD patch fashioned to the anterior aortic root, is very successful. If a subaortic VSD and pulmonic and subpulmonic stenosis are present, the physiology and the clinical management are the same as in ToF. However, if the VSD is subpulmonic (Taussig–Bing malformation), the presentation and management are analogous to those of an infant with transposition and an unrestrictive VSD.

In all forms of double-outlet RV, echocardiography with Doppler flow assessment is useful in clarifying the anatomy and physiology. Preoperative cardiac catheterization and angiocardiology are used if questions remain about the pulmonary or coronary arteries, or in children with the Taussig–Bing malformation who have severe cyanosis requiring balloon atrial septostomy for atrial mixing.

TOTAL ANOMALOUS PULMONARY VENOUS RETURN WITH OR WITHOUT OBSTRUCTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cyanosis.
- Systolic ejection murmur with lower left sternal border flow rumble and accentuated P_2 .
- Right atrial and RVH.
- Abnormal pulmonary venous connection.

General Considerations

This malformation accounts for approximately 2% of all congenital heart lesions. The pulmonary venous blood drains into a confluence behind the left atrium, but the confluence is not connected to the left atrium. The pulmonary venous blood therefore finds another route to rejoin the circulation via the systemic veins. This leads to complete mixing at the level of the right

atrium. The clinical presentation of total anomalous pulmonary venous return (TAPVR) depends on the method of return and whether that return to the systemic veins is unrestricted or restricted.

This malformation is classified by the site of entry of the pulmonary veins into the right side of the heart. Although the most common form of TAPVR is unobstructed via the left superior vena cava, three other distinct types exist:

Type 1 (50%): Entry into the left superior vena cava (persistent anterior cardinal vein) or right superior vena cava, unobstructed or obstructed.

Type 2 (20%): Entry into the right atrium directly or via the coronary sinus, unobstructed.

Type 3 (20%): Entry below the diaphragm (usually into the portal vein), almost always obstructed.

Type 4 (10%): Multiple sites of entry (mixed TAPVR).

Because the entire venous drainage from the body comes to the right atrium, a right-to-left shunt is always present at the atrial level. This may take the form of either an ASD or a patent foramen ovale. Occasionally the atrial septum is a restrictive foramen ovale, and a Rashkind procedure is needed at birth to allow filling of the left heart. Complete mixing of the systemic and pulmonary venous return occurs in the right atrium, so that the left atrial and the systemic arterial saturation levels approximately equal that of the right atrial saturation.

Clinical Findings

A. WITH UNOBSTRUCTED PULMONARY VENOUS RETURN

This large group includes all children (type 2) with pulmonary venous return to the right atrium and most children with supracardiac TAPVR. These patients tend to have a high total pulmonary flow typically present with cardiomegaly and early CHF rather than cyanosis. Oxygen saturations in the high 80s or low 90s are common. Most patients in this group have mild to moderate elevation of the pulmonary artery pressure owing to the elevated pulmonary blood flow. In most instances, the pressure does not reach systemic levels.

1. Symptoms and signs—These patients may have a history of mild cyanosis in the neonatal period and during early infancy. Thereafter, they do relatively well except for frequent respiratory infections. They are usually rather small and thin and resemble patients with very large ASDs.

Careful examination discloses duskeness of the nail beds and mucous membranes, but definite cyanosis and

digital clubbing are usually absent. The arterial pulses are normal. An RV heave is palpable.

The pulmonary component of the second sound is usually increased. A grade II–III/VI ejection-type systolic murmur is heard at the pulmonary area. It radiates over the lung fields anteriorly and posteriorly. An early to middiastolic flow murmur is often heard at the lower left sternal border in the third and fourth intercostal spaces (tricuspid flow murmur).

2. Imaging—Chest radiography reveals cardiac enlargement primarily involving the right heart and pulmonary artery. Pulmonary vascular markings are markedly increased. A characteristic cardiac contour called a “snowman” or “figure of 8” is often seen when the anomalous veins drain via a persistent left superior vena cava to the innominate vein and then the right superior vena cava. This radiographic appearance is not present until approximately 3 months of age because it requires time for the vertical vein and innominate vein to dilate.

3. Electrocardiography—ECG shows right axis deviation and varying degrees of right atrial and right ventricular hypertrophy. A QR pattern is often evident over the right precordial leads.

4. Echocardiography—Demonstration by echocardiography of a chamber posterior to the left atrium is strongly suggestive of the diagnosis. However, echocardiographic discrimination between anomalies of pulmonary venous return and persistence of pulmonary fetal circulation can be challenging. The availability of two-dimensional echocardiography plus color-flow Doppler has increased the diagnostic accuracy.

B. WITH OBSTRUCTED PULMONARY VENOUS RETURN

This group includes all patients with subdiaphragmatic TAPVR and a few of the patients in whom the venous drainage is into a systemic vein above the diaphragm.

1. Symptoms and signs—These infants usually present shortly after birth with severe cyanosis and require early corrective surgery. Cardiac examination discloses a striking RV impulse. S_1 is accentuated. S_2 is markedly accentuated and single. A grade I–III/VI ejection-type systolic murmur is frequently heard over the pulmonary area with radiation over the lung fields. Diastolic murmurs are uncommon. In many cases, no murmur is heard at all.

2. Imaging—In the most severe cases, the heart is small and pulmonary venous congestion is marked. In less severe cases, the heart size may be normal or slightly enlarged with slight pulmonary venous congestion.

3. Electrocardiography—The ECG shows right axis deviation, right atrial hypertrophy, and RVH.

4. Echocardiography—Echocardiography shows a combination of a small left atrium and LV and a vessel lying parallel and anterior to the descending aorta and to the left of the inferior vena cava. Color-flow Doppler echocardiography is useful in establishing the diagnosis and is often diagnostic. Right-to-left atrial shunting occurs.

5. Cardiac catheterization and angiocardiography—These procedures are diagnostic. Cardiac catheterization and cineangiography demonstrate TAPVR and identify the site of entry of the anomalous veins. They also demonstrate the ratio of pulmonary to systemic blood flow and the degree of pulmonary hypertension and pulmonary vascular resistance.

Treatment

Surgery is always required for TAPVR. If pulmonary venous return is obstructed, surgery must be performed during the immediate newborn period. In infants with unobstructed TAPVR, surgery is more elective and may be delayed for weeks to months. The timing of surgery can then be determined by the child's weight gain and the risk of pulmonary infection. If early surgery is not planned and the atrial septum is restrictive, a balloon atrial septostomy should be performed in the newborn period. The results of surgery are excellent.

Course & Prognosis

Most children with TAPVR do very well after surgery. However, approximately 5% of surgical survivors develop late stenosis of the pulmonary veins. This devastating condition is difficult to treat either with interventional catheterization or surgery, and it has a very poor prognosis. Pulmonary vein stenosis, when it occurs, is most often seen in children who initially had obstructed total veins, but it occurs occasionally in children whose initial presentation was unobstructed. A new surgical technique involving sutureless *in situ* pericardial repair of the recurrent pulmonary venous obstruction holds great promise. By avoiding direct suturing at the pulmonary venous ostia, the chance of recurrent stenosis at the anastomotic site is lessened.

TRUNCUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Early CHF*
- *Mild or no cyanosis.*
- *Systolic ejection click.*

General Considerations

Truncus arteriosus accounts for less than 1% of congenital heart malformations. A single great artery arises from the heart giving rise to the systemic, pulmonary, and coronary circulations. Truncus develops embryologically as a result of complete lack of formation of the spiral ridges that divide the primitive common truncus arteriosus into the aorta and the pulmonary artery. A high VSD is always present. The number of valve leaflets varies from two to six, and the valve may be sufficient, insufficient, or stenotic.

Although rare, truncus arteriosus is divided into four types by the anatomy of the pulmonary circulation:

Type 1 (48%): A main pulmonary artery arises from the base of the trunk just above the semilunar valve and runs parallel with the ascending aorta for a short time before dividing.

Type 2 (29%): Two pulmonary arteries arise side by side from the posterior aspect of the truncus.

Type 3 (11%): Two pulmonary arteries arise independently from either side of the trunk.

Type 4 (12%): No demonstrable main left and right pulmonary arteries are present. Pulmonary circulation is derived from bronchials arising from the descending thoracic aorta.

In this condition, blood leaves the heart through a single common exit. Therefore, the saturation of the blood in the pulmonary artery is the same as that in the systemic arteries. The degree of systemic arterial oxygen saturation depends on the ratio of pulmonary to systemic blood flow. If pulmonary vascular resistance is normal, the pulmonary blood flow is greater than the systemic blood flow and the saturation is relatively high. If pulmonary vascular resistance is elevated because of pulmonary vascular obstructive disease or very small pulmonary arteries, pulmonary blood flow is reduced and oxygen saturation is low. The systolic pressures are systemic in both ventricles.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical picture depends on the degree of pulmonary blood flow.

1. High pulmonary blood flow—This is the most common presentation in truncus arteriosus. Patients with high pulmonary blood flow are usually acyanotic. Their clinical presentation resembles that of patients with large VSDs. Early CHF occurs. Examination of the heart reveals a hyperactive precordium. A systolic thrill is common at the lower left sternal border. S_1 is normal. A loud early systolic ejection click is commonly heard. S_2 is single and accentuated. A grade III–IV/VI pansystolic murmur is audible at the lower left sternal border. A diastolic flow murmur can often be heard at the apex (mitral flow murmur).

2. Low pulmonary blood flow—Patients with decreased pulmonary blood flow are cyanotic early and do poorly. The most common manifestations are growth retardation, easy fatigability, dyspnea on exertion, and CHF. The heart is not hyperactive. S_1 and S_2 are single and loud. A systolic grade II–IV/VI murmur is heard at the lower left sternal border. No diastolic flow murmur is heard. A continuous heart murmur is uncommon except in type 4, in which the large bronchial collateral vessels cause the continuous murmur. A loud systolic ejection click is commonly heard.

B. IMAGING

The most common radiographic findings are a boot-shaped heart, absence of the main pulmonary artery segment, and a large aorta that has a right arch 30% of the time. The pulmonary vascular markings vary with the degree of pulmonary blood flow.

C. ELECTROCARDIOGRAPHY

The axis is usually normal. RVH or combined ventricular hypertrophy is commonly present. LVH as an isolated finding is rare.

D. ECHOCARDIOGRAPHY

A characteristic image shows override of a single great artery (similar to ToF). The origin of the pulmonary arteries and the degree of truncal valve abnormality can be seen. Color-flow Doppler can aid in the description of pulmonary flow and the function of the truncal valve, both of which are critical to management.

E. ANGIOCARDIOGRAPHY

Cardiac catheterization is not routinely performed but may be of value in the older infant in whom pulmonary vascular disease must be ruled out. Injection of contrast

material into either ventricle demonstrates the VSD and the single great artery arising from the heart. The exact type of truncus, however, is often best imaged from an injection in the truncal root itself. This will also allow for evaluation of truncal insufficiency.

Treatment

Anticongestive measures are needed for patients with high pulmonary blood flow and congestive failure. Surgery is always required in this condition. Because of the severe CHF, surgery is usually performed in the neonatal period. The VSD is closed to allow LV egress to the truncal valve as in ToF. The pulmonary artery (type 1) or arteries (types 2–3) are separated from the truncus as a block, and a conduit is fashioned from the RV to the pulmonary circulation. The conduit may be valved or nonvalved, but most surgeons prefer a valved allograft for this repair. Children with type 4 truncus arteriosus are usually stable in infancy with adequate saturations and without CHF. This is fortunate, because their ultimate surgery depends on finding and joining together (unifocalizing) their pulmonary artery segments prior to attempted surgical correction.

Course & Prognosis

Children with truncus types 1–3 with good surgical results do well. They almost always outgrow the RV to pulmonary conduit that is placed in infancy and require a revision of the conduit in later childhood. The rare child with type 4 truncus arteriosus will need staged preparation of the pulmonary arteries prior to corrective surgery. For children with types 1–3 truncus arteriosus the risk of early pulmonary vascular obstructive disease is high, and a decision to delay open-heart surgery beyond age 4–6 months, even if the child is clinically stable, must take this into account.

McElhinney DB et al: Reinterventions after repair of common arterial trunk in neonates and young infants. *J Am Coll Cardiol* 2000;35(5):1317 [PMID: 10758975].

ACQUIRED HEART DISEASE

RHEUMATIC FEVER

Rheumatic fever still occurs regionally in the United States. Availability of penicillin, improvements in the standard of living and hygiene, and greater availability of medical care have greatly reduced the incidence of this disease since the 1950s. Acute rheumatic fever has had a resurgence in several regions of the United States

(the Midwest in 1984 and the intermountain West since 1987). The character of the illness has changed, however. The reason for these regional epidemics is unknown. In both the Salt Lake City and Denver pediatric referral centers, 30–50 new cases are now seen each year.

Group A β -hemolytic streptococcal infection of the upper respiratory tract is the essential trigger that acts on predisposed individuals. The latest attempts to define host susceptibility implicate immune response (I_r) genes, which are present in approximately 15% of the population. The immune response triggered by colonization of the pharynx with group A streptococci consists of (1) sensitization of B lymphocytes by streptococcal antigens, (2) formation of antistreptococcal antibody, (3) formation of immune complexes that cross-react with cardiac sarcolemma antigens, and (4) myocardial and valvular inflammatory response.

The peak period of risk in the United States is age 5–15 years. The disease is slightly more common in girls and in African Americans, perhaps a reflection of socioeconomic factors. The annual death rate from rheumatic heart disease in school-age children (whites and nonwhites) recorded in the 1980s was less than 1:100,000.

The modified Jones criteria are used to diagnose acute rheumatic fever. Two major or one major and two minor manifestations (plus supporting evidence of streptococcal infection) are needed (Table 19–16).

Table 19–16. Jones criteria (modified) for diagnosis of rheumatic fever.

Major manifestations

Carditis
Polyarthriti
Sydenham's chorea
Erythema marginatum
Subcutaneous nodules

Minor manifestations

Clinical
Previous rheumatic fever or rheumatic heart disease
Polyarthralgia
Fever

Laboratory

Acute phase reaction: elevated erythrocyte sedimentation rate, C-reactive protein, leukocytosis
Prolonged PR interval

Plus

Supporting evidence of preceding streptococcal infection, that is, increased titers of antistreptolysin O or other streptococcal antibodies, positive throat culture for group A *Streptococcus*

Sydenham Chorea

Sydenham chorea is characterized by emotional instability and involuntary movements. These findings become progressively worse and may be accompanied by ataxia and slurring of speech. Muscular weakness becomes apparent following the onset of the involuntary movements. The attack of chorea is self-limiting, although it may last up to 3 months. Sometimes only one side is involved. Chorea may not be apparent for months to years after the acute episode of rheumatic fever.

Polyarthriti

The large joints (knees, hips, wrists, elbows, shoulders) are most commonly involved. Joint swelling and associated limitation of movement should be present. Arthralgia alone is not a major criterion.

Erythema Marginatum

A macular erythematous rash with a circinate border appears primarily on the trunk and the extremities. The face is usually spared.

Subcutaneous Nodules

These usually occur only in severe cases, and then most commonly over the joints, scalp, and spinal column. They vary from a few millimeters to 2 cm in diameter and are nontender and freely movable under the skin.

Essential Manifestation

Except in cases of rheumatic fever manifesting solely as Sydenham chorea or long-standing carditis, there should be clear evidence of a streptococcal infection such as scarlet fever, a positive throat culture for group A β -hemolytic *Streptococcus*, and increased antistreptolysin O or other streptococcal antibody titers. The antistreptolysin O titer is significantly higher in rheumatic fever than in uncomplicated streptococcal infections.

Treatment & Prophylaxis

A. TREATMENT OF THE ACUTE EPISODE

1. Anti-infective therapy—Eradication of the streptococcal infection is essential. Long-acting benzathine penicillin is the drug of choice. Depending on the age and weight of the patient, give a single intramuscular injection of 0.6–1.2 million units; alternatively, give penicillin V, 125–250 mg orally four times a day for 10 days. Erythromycin, 250 mg orally four times a day, may be substituted if the patient is allergic to penicillin.

2. Anti-inflammatory agents—

a. Aspirin. Currently, 30–60 mg/kg/d is given in four divided doses. This dosage is often more than sufficient to effect dramatic relief of the arthritis and fever. In general, higher dosages carry a greater risk of side effects, and there are no proven short- or long-term benefits of high doses to produce salicylate blood levels of 20–30 mg/dL. The duration of therapy must be tailored to meet the needs of the patient, but use of aspirin for 2–6 weeks, with reduction in dosage toward the end of the course, is usually sufficient. Other nonsteroidal antiinflammatory agents are commonly used because of the concerns about Reye syndrome, but they appear to be less effective.

b. Corticosteroids. Corticosteroids are rarely indicated. However, in the unusual patient with severe carditis and CHF, steroid therapy may be not only effective but also lifesaving. Corticosteroids may be given as follows: prednisone, 2 mg/kg/d orally for 2 weeks (or comparable doses of other corticosteroids); reduce prednisone to 1 mg/kg/d during the third week, and begin aspirin, 50 mg/kg/d; stop prednisone at the end of 3 weeks, and continue aspirin for 8 weeks or until the C-reactive protein is negative and the sedimentation rate is falling.

3. Therapy of congestive heart failure—See Congestive Heart Failure section.

4. Bed rest and ambulation—Bed rest is not required for patients with arthritis and mild carditis without CHF. Indoor activity followed by modified outdoor activity may be ordered when symptoms have disappeared but clinical and laboratory evidence of rheumatic activity remains. Modified bed rest for 2–6 weeks is generally adequate. Children should not return to school while there is clear evidence of rheumatic activity. Most acute episodes of rheumatic fever are managed on an outpatient basis.

B. TREATMENT AFTER THE ACUTE EPISODE

1. Prevention—The patient who has had a bout of rheumatic fever has a greatly increased risk of developing rheumatic fever after the next inadequately treated group A β -hemolytic streptococcal infection. Prevention is thus the most important aim for the physician to emphasize. The purpose of follow-up visits after the acute episode is not so much to evaluate the evolution of mitral or aortic insufficiency murmurs as to reinforce the physician's advice about the necessity for prophylaxis with regular long-acting benzathine penicillin. The physician should stress that protection is better with intramuscular than oral medication and that failure to comply with regular medication programs increases the risk for recurrence of rheumatic fever. If myocardial or valvular disease persists, antibacterial prophylaxis is a

lifelong commitment. More commonly with transient cardiac involvement, 3–5 years of therapy or discontinuance at adolescence is a practical and effective approach.

The following preventive regimens are in current use:

a. Penicillin G. benzathine 1.2 million units intramuscularly every 21–28 days, is the drug of choice.

b. Sulfadiazine. 500 mg daily as a single oral dose for patients weighing over 27 kg is the drug of second choice. Blood dyscrasias and a lesser effectiveness in reducing streptococcal infections make this drug less satisfactory than penicillin benzathine G.

c. Penicillin V. 250,000 units orally twice daily offers approximately the same protection afforded by sulfadiazine but is much less effective than intramuscular penicillin benzathine G (5.5 vs 0.4 streptococcal infections per 100 patient-years).

d. Erythromycin. 250 mg orally twice a day may be given to patients who are allergic to both penicillin and sulfonamides.

2. Residual valvular damage—Chronic CHF may follow a single severe episode of acute rheumatic carditis or, more commonly, may follow repeated episodes. In the United States, the typical manifestations of residual valvular damage in children are heart murmurs of mitral and aortic insufficiency. Murmurs are not accompanied by CHF in most children as long as repeated attacks are prevented.

Methods of managing CHF have been discussed previously. Children with severe valvular damage that cannot be managed adequately on a medical regimen must be considered for valve replacement before the myocardium is irreversibly damaged.

RHEUMATIC HEART DISEASE

Mitral Insufficiency

Mitral insufficiency is the most common valvular residual of acute rheumatic carditis. There are reports from all over the world of silent mitral insufficiency with echocardiographic findings characteristic of acute rheumatic fever.

Mitral Stenosis

Mitral stenosis after acute rheumatic fever is rarely encountered in the United States until 5–10 years after the first episode. Thus, mitral stenosis is much more commonly seen in adults than in children. Interventional cardiovascular balloon dilation of mitral stenosis is now being used in many patients prior to consideration of mitral valve replacement.

Aortic Insufficiency

This early decrescendo diastolic murmur is occasionally encountered as the sole valvular manifestation of rheumatic carditis. It is the second most common valve affected in polyvalvular as well as in single valvular disease. It appears that the aortic valve is involved more often in males and in African Americans.

Aortic Stenosis

Dominant aortic stenosis of rheumatic origin does not occur in pediatric patients. In one large study, the shortest length of time observed for a patient to develop dominant aortic stenosis secondary to rheumatic heart disease was 20 years.

KAWASAKI DISEASE

Kawasaki disease was first described in Japan in 1967 and was initially called mucocutaneous lymph node syndrome. The cause of Kawasaki disease is unclear, and a specific diagnostic test does not exist. Eighty percent of affected patients are younger than age 5 years, and the male-to-female ratio is 1.5:1. The diagnostic criteria include fever for more than 5 days and at least four of the following features: (1) bilateral, painless, nonexudative conjunctivitis, (2) lip or oral cavity changes (eg, lip cracking and fissuring, strawberry tongue, inflammation of the oral mucosa), (3) cervical lymphadenopathy (≥ 1.5 cm in diameter and usually unilateral), (4) polymorphous exanthema, and (5) extremity changes (redness and swelling of the hands and feet with subsequent desquamation). Clinical features not part of the diagnostic criteria, but frequently associated are shown in Table 19–17.

The potential for adverse cardiovascular effects is the most serious aspect of Kawasaki disease. Cardiovascular complications during the acute illness include myocarditis, pericarditis, valvular heart disease (usually mitral or aortic regurgitation), and coronary arteritis. Patients with fever but fewer than four of the diagnostic features can be diagnosed with atypical Kawasaki disease if they have coronary artery abnormalities.

Coronary artery lesions range from mild transient dilation of a coronary artery to large aneurysm forma-

Table 19–17. Noncardiac manifestations of Kawasaki disease.

System	Associated Signs and Symptoms
Gastrointestinal	Vomiting, diarrhea, gallbladder hydrops, elevated transaminases
Blood	Elevated ESR or CRP, leukocytosis, hypoalbuminemia, mild anemia in acute phase and thrombocytosis in subacute phase (usually second to third week of illness)
Renal	Sterile pyuria, proteinuria
Respiratory	Cough, rhinorrhea, infiltrate on chest radiograph
Joint	Arthralgia and arthritis
Neurologic	Mononuclear pleocytosis of cerebrospinal fluid, irritability, facial palsy

ESR = erythrocyte sedimentation rate; CRP = creatinine phosphokinase.

tion. Untreated patients have an approximately 25% risk of developing an aneurysm of the coronary arteries. Those at greatest risk of aneurysm formation are males, young children (< 6 months) and those not treated with intravenous immunoglobulin (IVIG).

Although the gold standard for diagnosing coronary artery aneurysms is angiography, two-dimensional echocardiography is highly sensitive and is the current standard screening test in children with Kawasaki disease. Fortunately, most coronary artery aneurysms resolve within 5 years of diagnosis. However, as aneurysms resolve, associated obstruction or stenosis (19% of all aneurysms) may develop, which may result in coronary ischemia. Giant aneurysms (> 8 mm) are much less likely to resolve, and nearly 50% eventually become stenotic. Of additional concern, acute thrombosis of an aneurysm can occur, resulting in a myocardial infarction, which is fatal in approximately 20% of cases.

The immediate management of Kawasaki disease consists of therapy with IVIG and high-dose aspirin. This therapy is effective in decreasing the incidence of coronary artery dilation and aneurysm formation. The currently recommended therapeutic regimen consists of 2 g/kg of IVIG administered over 10–12 hours and 80–100 mg/kg/d of aspirin in four divided doses until the patient is afebrile. In an effort to prevent acute thrombosis of coronary aneurysms, 3–5 mg/kg of aspirin daily is prescribed throughout the subacute phase of the illness (6–8 weeks) or until coronary artery abnormalities resolve. If fever recurs within 48–72 hours of the initial treatment course and no other source of the fever is detected, a repeat dose of IVIG is often rec-

ommended; however, the effectiveness of this approach has not been clearly demonstrated. Currently, corticosteroids are not felt to be effective in Kawasaki disease.

During the acute and subacute phases of the illness, patients should be monitored closely by serial electrocardiography, chest radiograph, and echocardiography. Selective coronary angiography is recommended in patients with evidence of myocardial ischemia. In 1994, the American Heart Association published guidelines for the long-term management of Kawasaki disease. The risk stratification and recommended follow-up can be reviewed in Table 19–18.

CARDIOMYOPATHY

As in adults, three patterns of cardiomyopathy are recognized in children: (1) dilated, (2) hypertrophic, and (3) restrictive.

1. Dilated Cardiomyopathy

The most frequent of the childhood cardiomyopathies occurs with an annual incidence of 4–8 cases per 100,000 population in the United States and Europe.

Although often idiopathic, known causes include acute or chronic myocarditis, long-standing untreated tachyarrhythmias, unrecognized left heart obstructive lesions, anthracycline toxicity, and genetic and metabolic diseases (including inborn errors of fatty acid oxidation and mitochondrial oxidative phosphorylation defects). Genetic causes include abnormalities of the dystrophin gene as in Duchenne and Becker muscular dystrophy.

Clinical Findings

A. SIGNS AND SYMPTOMS

As the heart dilates, cardiac output falls, and affected children exhibit signs and symptoms of CHF. The child experiences decreased exercise tolerance, failure to thrive, diaphoresis, and tachypnea. As the heart deteriorates, the pulses and perfusion become weaker, hepatomegaly and rales become prominent, and the cardiac examination shows a prominent gallop.

B. IMAGING

The chest radiograph shows generalized cardiomegaly with or without pulmonary venous congestion.

C. ELECTROCARDIOGRAPHY

Sinus tachycardia with ST-T segment changes are commonly seen on ECG. The criteria for right and left ventricular hypertrophy may also be met. One must ensure that a narrow complex tachycardia seen in this instance is in fact sinus tachycardia with a normal P wave axis as opposed to an atrial tachyarrhythmia that may be the underlying cause of the cardiomyopathy.

Table 19–18. Long-term management in Kawasaki disease.

Risk Level	Definition	Management Guidelines
I	No coronary artery changes at any stage of the illness	No ASA is needed beyond the subacute phase (6–8 weeks). No follow-up beyond the first year
II	Transient ectasia of coronary arteries during the acute phase	Same as above, or clinical follow-up ± ECG every 3–5 years
III	Single small to medium coronary aneurysm	ASA until abnormality resolves. Annual follow-up with ECG and echo if < 10 years old and every other year stress testing if > 10 years
IV	Giant aneurysm or multiple small to medium aneurysms without obstruction	Long term ASA ± warfarin. Annual follow-up with ECG, echo and stress testing (in those > 20 years)
V	Coronary artery obstruction	Long-term ASA ± warfarin ± calcium channel blocker to reduce myocardial oxygen consumption. Echo and ECG every 6 months. Stress testing and Holter exam annually

ASA = acetyl salicylic acid; ECG = electrocardiogram; Echo = echocardiogram.

D. ECHOCARDIOGRAPHY

The echocardiogram shows LV and left atrial enlargement with decreased LV shortening fraction. The calculated end diastolic and end-systolic dimensions are increased. With more advanced disease, mitral insufficiency will occur as the LV dilates.

E. OTHER TESTING

Catheterization is most often done to obtain a biopsy evidence of myocarditis. In addition, polymerase chain reaction testing may be performed on biopsy specimens to detect the presence of viral genome remaining from an earlier bout of myocarditis. Finally, the biopsy can be analyzed by light and electron microscopy to look for metabolic causes of dilated cardiomyopathy. Skeletal muscle biopsy may also be helpful. Hemodynamic assessment during catheterization will assess the progression of the disease. The effect of drug therapy with afterload-reducing agents can be assessed in the catheterization laboratory prior to their clinical use.

Cardiopulmonary stress testing is a useful clinical tool in patients with cardiomyopathy for measuring the response to medical therapies as well as deciding on the appropriate timing of cardiac transplantation.

Treatment & Prognosis

Patients with dilated cardiomyopathy may require in-hospital management of CHF (see section on Congestive Heart Failure). As outpatients they are treated with digoxin, diuretics, afterload-reducing agents, and fluid restriction. Once stabilized on these agents, some can be treated with carvedilol. Anticoagulants such as warfarin (Coumadin) may be used to prevent thrombus formation secondary to stagnant blood flow within the dilated, poorly contractile cardiac chambers. If arrhythmias occur, they require treatment. Antiarrhythmic agents that do not suppress myocardial contractility, such as digoxin and amiodarone, are preferred. Internal defibrillators are used in some patients with refractory arrhythmias in the setting of dilated cardiomyopathy. Specific therapy directed at the cause can have a dramatic effect; for instance, in some of the mitochondrial metabolic disorders. Treatment of carnitine deficiency may result in improved cardiac function. Antiarrhythmic therapy in patients with arrhythmia-induced cardiomyopathy is often curative. Ultimately, if medical management is unsuccessful, cardiac transplantation is considered.

2. Hypertrophic Cardiomyopathy

The most common cause of hypertrophic cardiomyopathy (HCM) is familial hypertrophic cardiomyopathy, which affects 1 in 500 individuals. It most com-

monly presents in the older child, adolescent, or adult although it may be seen as early as the neonatal period. Other causes of HCM seen in the neonatal and childhood period include glycogen storage disease, mitochondrial disorders, and other metabolic disorders.

Familial Hypertrophic Cardiomyopathy

In the familial form, HCM is most commonly caused by a mutation in one of four genes that encode proteins of the cardiac sarcomere (the B-myosin heavy chain, cardiac troponin T, A-tropomyosin, and myosin-binding protein C genes).

Clinical Findings

Patients may be asymptomatic, despite having significant hypertrophy, or may present with symptoms of inadequate coronary perfusion such as angina, syncope, or exercise intolerance. Patients may experience sudden cardiac death, often precipitated by sporting activities. Cardiac examination will demonstrate a left precordial bulge with a diffuse point of maximal impulse. An LV heave may be present. A palpable or audible S_4 may be present. If outflow tract obstruction is present, a systolic ejection murmur will be audible. A murmur may not be audible at rest but is easily provoked with minimal exercise. Although the older patient with HCM typically has disease primarily in the LV, RVH, either alone or in association with LVH, may be seen in the neonate. Affected neonates may be cyanotic if RV outflow tract obstruction is significant.

A. ECHOCARDIOGRAPHY

The diagnosis of HCM is made in most cases by echocardiography, which demonstrates an asymmetrical septal hypertrophy. Younger patients may have concentric hypertrophy, making the diagnosis less obvious. Systolic anterior motion of the mitral valve leaflet may occur and may contribute to the degree of LV outflow tract obstruction. The mitral valve leaflet may become distorted with time, resulting in mitral insufficiency. LV outflow tract obstruction may be present at rest. Provokable outflow tract obstruction should be assessed with either amyl nitrate or monitored exercise. Systolic function is most often hypercontractile in the young child but may deteriorate over time, often in association with a change in morphology as hypertrophy develops into LV dilation. Diastolic function is often impaired. Patients are at risk for myocardial ischemia, possibly as a result of systolic compression of the intramyocardial septal perforators, myocardial bridging of epicardial coronary arteries, or an imbalance of coronary artery supply and demand due to the presence of massive myocardial hypertrophy.

B. ELECTROCARDIOGRAPHY

The ECG may be normal, but more typically will demonstrate deep Q waves in the inferolateral leads (II, III, aVf, V₅, and V₆) secondary to depolarization of the hypertrophied septum. ST segment abnormalities may be seen in the same leads. Age-dependent criteria for LVH will often be met. Criteria for left atrial enlargement may be present.

C. OTHER TESTING

Cardiopulmonary stress testing is a valuable tool in this patient population to ascertain the presence of provokable LV outflow tract obstruction, to assess for ischemia and arrhythmias, and to determine prognosis. A blunted blood pressure response and ventricular arrhythmias with exercise have both been associated with increased mortality in this patient group. Nuclear stress testing allows for assessment of myocardial perfusion defects.

D. CARDIAC CATHETERIZATION

Cardiac catheterization should be performed in patients with HCM who have recurrent angina, syncope, resuscitated sudden death, or a worrisome stress test. Hemodynamic findings may include an elevated left atrial pressure secondary to impaired diastolic filling. If midcavitary LV outflow tract obstruction is present, an associated pressure gradient will be evident. Provocation of LV outflow tract obstruction with either rapid atrial pacing or isoproterenol may be sought. Angiography demonstrates a “ballerina slipper” configuration of the LV secondary to the midcavitary LV obliteration during systole. Coronary angiography should be performed to evaluate possible associated myocardial bridging, which may be an important source of myocardial ischemia in these patients. Angiography will show systolic obliteration, typically of the middle left anterior descending coronary artery.

Treatment and Prognosis

The prognosis is variable and depends in part on the degree of hypertrophy, the degree of outflow tract obstruction, the particular genetic defect, and the presence of coronary compression. Patients are restricted from strenuous athletics. Patients with resting or latent LV outflow tract obstruction may be treated with either β -blockers or disopyramide with good, albeit temporary, relief of obstruction. Patients with a provokable LV outflow tract gradient above 60 mm Hg require additional treatment. Although dual-chamber pacing has been used in some children with good relief of obstruction, larger series demonstrate no significant improvement in obstruction. Surgical myectomy with resection of part of the hypertrophied septum has been used with

good results. Ethanol ablation is a technique being used with increasing frequency for the adult with HCM and LV outflow tract obstruction. This procedure, performed in the cardiac catheterization laboratory, involves the selective infiltration of ethanol in a coronary septal artery branch, thereby inducing a small myocardial infarction. This leads to a reduction in septal size and improvement of obstruction. The long-term effects of this procedure are unknown, and this procedure is not currently employed for pediatric patients. Surgical unroofing of a myocardial bridge may improve prognosis in those with myocardial ischemia secondary to epicardial coronary compression. Internal defibrillators are being placed in patients with documented ventricular arrhythmias, resuscitated sudden death, or a strong family history of HCM with associated sudden death.

Glycogen Storage Disease of the Heart

At least 10 types of glycogen storage disease are recognized. The type that primarily involves the heart is Pompe disease (GSD IIa). The deficient enzyme (acid maltase) is necessary for hydrolysis of the outer branches of glycogen, and its absence results in marked deposition of glycogen within the myocardium. Cardiac glycogenesis is a rare heritable (autosomal recessive) disorder.

Affected infants are well at birth, but onset occurs by the sixth month of life. These children have a history of retardation of growth and development, feeding problems, poor weight gain, and CHF. Physical examination reveals generalized muscular weakness, a large tongue, cardiomegaly, and no significant heart murmurs. Chest radiographs reveal marked cardiomegaly with or without pulmonary venous congestion. The ECG shows a short PR interval with LVH with ST depression and T wave inversion over the left precordial leads. Echocardiography shows severe concentric LVH.

Children with this disease usually die before age 1 year. Death may be sudden or the result of progressive CHF.

3. Restrictive Cardiomyopathy

Restrictive cardiomyopathy is a rare entity in the pediatric population, accounting for less than 5% of all cases of cardiomyopathy.

Clinical Findings

Patients present with signs of CHF as outlined previously. Physical examination is remarkable for a prominent S₄ and jugular venous distention.

A. ELECTROCARDIOGRAPHY

ECG demonstrates marked right and left atrial enlargement with normal ventricular voltages. ST/T wave abnormalities may be present.

B. ECHOCARDIOGRAPHY

The diagnosis may be confirmed echocardiographically, noting the presence of normal sized ventricles with massively dilated atrium. Due to infiltration of the ventricular myocardium, the LV becomes “restrictive,” and atrial emptying is impaired.

Course and Prognosis

The condition is usually idiopathic. Endocardial fibroelastosis, a histologic diagnosis, may be noted. The endocardium has marked milky white thickening, as do the subendocardial layers of the LV and left atrium. The mitral valve may be involved. Irrespective of cause, the prognosis is poor. Anticongestive therapy may be tried, but many patients will require cardiac transplantation.

MYOCARDITIS

The most common causes of myocarditis are adenovirus, coxsackie A and B, echovirus, and cytomegalovirus. In addition, the human immunodeficiency virus (HIV) causes myocarditis. Our ability to determine the cause of myocarditis has been enhanced greatly by the availability of polymerase chain reaction technology to replicate identifiable segments of viral genome from the myocardium of affected children.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical picture usually falls into two separate patterns: (1) Onset of CHF is sudden in a newborn who has been in relatively good health 12–24 hours previ-

ously. This is a malignant form of the disease and is thought to be secondary to overwhelming viremia and tissue invasion of multiple organ systems, including the heart. (2) In the older child, the onset of cardiac findings tends to be more gradual. There is often a history of an upper respiratory tract infection or gastroenteritis within the month prior to the development of cardiac findings. This is a more insidious form of the disease and may have a late postinfectious or autoimmune component. However, clinical presentation can be acute or chronic in all ages and in all types of myocarditis.

In the newborn infant, the signs of CHF are usually apparent. The skin is pale and gray, and peripheral pallor may be present. The pulses are rapid, weak, and thready. Edema of the face and extremities may be present. Significant cardiomegaly is present, and the left and right ventricular impulses are weak. On auscultation, the heart sounds may be muffled and distant. S₃ and S₄ are common, resulting in a gallop rhythm. Murmurs are usually absent, although a murmur of tricuspid or mitral insufficiency can occasionally be heard. Moist rales are usually present at both lung bases. The liver is enlarged and frequently tender.

B. IMAGING

Generalized cardiomegaly can be seen on radiograph. Moderate to marked pulmonary venous congestion is evident. Pneumonia is commonly present.

C. ELECTROCARDIOGRAPHY

The ECG is variable. Classically, there is evidence of low voltage of the QRS throughout all frontal and precordial leads and depression of the ST segment and inversion of the T waves in leads I, III, and aVF and in the left precordial leads during the acute stage. Dysrhythmias are common, and AV and intraventricular conduction disturbances may be present. With the more benign form, or during the recovery phase of the malignant form, high-voltage QRS complexes are commonly seen and are indicative of LVH.

D. ECHOCARDIOGRAPHY

Echocardiography demonstrates four-chamber dilation with poor ventricular function and AV valve regurgitation.

E. MYOCARDIAL BIOPSY

A tissue diagnosis obtained from either myocardium or skeletal muscle is usually indicated in pediatric cardiomyopathy/myocarditis. Primary processes (metabolic disorders such as mitochondrial oxidation chain defects and glycogen storage disease, and muscular dystrophies such as Duchenne or Becker) can be differentiated from inflammatory diseases of the myocardium (myocarditis).

Treatment

The use of digitalis in a rapidly deteriorating child with myocarditis is dangerous and should be undertaken with great caution as it may provoke ventricular dysrhythmias in this situation. The inpatient cardiac supports outlined previously are used in the treatment of these patients.

The administration of corticosteroids for myocarditis is controversial. If the patient's condition continues to deteriorate despite anticongestive measures, corticosteroids are commonly used, although conclusive data supporting their effectiveness in this condition are lacking. Other immunosuppressive agents, such as cyclosporine, are now being tried in viral myocarditis.

Subsequent to the successful use of intravenous immunoglobulin for children with Kawasaki disease, several trials have occurred using this product in presumed viral myocarditis. The therapeutic value of this treatment still remains unconfirmed in many practitioners' minds.

Prognosis

The prognosis for a patient with myocarditis is related to the age at onset and to the patient's response to therapy. If the patient is younger than age 6 months or older than age 3 years and responds poorly to therapy, the prognosis is poor. Many patients recover clinically but have persistent LV dysfunction with cardiomegaly. It is possible that subclinical myocarditis in childhood is the pathophysiologic basis for some of the idiopathic dilated cardiomyopathies occurring later in life. Children with myocarditis whose ventricular function fails to return to normal are potential candidates for cardiac transplantation.

INFECTIVE ENDOCARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Preexisting organic heart murmur.
- Persistent fever.

- Increasing symptoms of heart disease (ranging from easy fatigability to heart failure).
- Splenomegaly (70% of cases).
- Embolic phenomena (50% of cases).
- Leukocytosis, elevated erythrocyte sedimentation rate, hematuria, positive blood culture.

General Considerations

Bacterial or fungal infection of the endocardial surface of the heart or the intimal surface of certain arterial vessels (coarcted segment of aorta or ductus arteriosus) is a rare condition that usually occurs when a preexisting abnormality of the heart or great arteries is present. It may develop in a normal heart during the course of septicemia.

The frequency of infective endocarditis appears to be increasing owing to many factors, including (1) increased survival rates for children with congenital heart disease, (2) greater long-term use of central venous catheters, and (3) increased use of prosthetic material and valves. Pediatric patients without preexisting heart disease are also at increased risk for infective endocarditis owing to (1) increased survival rates for children with immune deficiencies, (2) greater long-term use of indwelling lines in critically ill newborns, and (3) increased incidence of intravenous drug abuse.

Patients at greatest risk include those with left-sided outflow obstruction or aorticopulmonary shunts and those with allograft, heterograft, or prosthetic cardiac valves. The actual cause of the episode of infective endocarditis can be identified approximately 30% of the time, and these include dental procedures, nonsterile surgical procedures, and cardiovascular surgery.

Organisms causing endocarditis include viridans streptococci (about 50% of cases), *Staphylococcus aureus* (about 30%), and fungal agents (about 10%).

Clinical Findings

A. HISTORY

Almost all patients with infective endocarditis have a history of heart disease. There may or may not be a history of infection or a surgical procedure (tooth extraction, tonsillectomy).

B. SYMPTOMS, SIGNS, AND LABORATORY FINDINGS

Findings include changing murmurs, fever, positive blood culture, weight loss, cardiomegaly, elevated sedimentation rate, splenomegaly, petechiae, embolism, and leukocytosis. Other findings are hematuria, signs of CHF, clubbing, joint pains, and hepatomegaly. Vegeta-

tions are large enough to be seen by echocardiography in 70% of children with endocarditis.

Prevention

Patients at risk for infective endocarditis should be given appropriate antibiotics before any type of dental work (tooth extraction, cleaning), before operations within the oropharynx, gastrointestinal tract, and genitourinary tract, and for body piercing and tattooing, which often are performed in less than sanitary conditions. Continuous antibiotic prophylaxis (as in the treatment of rheumatic fever) is not recommended in patients with congenital heart disease.

The following schedule is recommended: under 40 kg, 50 mg/kg of oral amoxicillin; over 40 kg, 2000 mg. This dose is to be given 1 hour prior to dental procedures. If the patient is allergic to amoxicillin, an alternative prophylactic antibiotic is used.

Treatment

In a patient with known heart disease, the presence of an otherwise unexplained fever should alert the physician to the possibility of infective endocarditis. A positive blood culture or other major findings of infective endocarditis confirm the diagnosis. If a positive blood culture is obtained and the organism is identified, specific treatment should be begun immediately. Even if blood cultures are negative after 48 hours, it is advisable to begin antibiotic therapy (if other evidence of infective endocarditis is present), because most positive cultures are obtained within the first 48 hours. If CHF occurs and progresses unremittingly in the face of adequate antibiotic therapy, surgical excision of the infected area and prosthetic valve replacement must be considered.

Course & Prognosis

The prognosis depends on how early in the course of the infectious process treatment is instituted. The prognosis is better in patients in whom the blood culture is positive. If CHF develops, the prognosis is poor. Embolization may occur during or after treatment from the vegetations themselves. Infective endocarditis is a serious condition and should be avoided if at all possible.

Friedel JM et al. Infective endocarditis after oral body piercing. *Cardiol Rev* 2003;11(5):252 [PMID: 12943601].

PERICARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Retrosternal pain made worse by deep inspiration and decreased by leaning forward.*
- *Fever.*
- *Shortness of breath and grunting respirations are common.*
- *Pericardial friction rub.*
- *Tachycardia.*
- *Hepatomegaly and distention of the jugular veins.*
- *ECG with elevated ST segment.*

General Considerations

Involvement of the pericardium rarely occurs as an isolated event. In most cases, pericardial disease occurs in association with a more generalized process. Common causes include rheumatic fever, viral pericarditis, purulent pericarditis, rheumatoid arthritis, uremia, and tuberculosis. Pericarditis after cardiac surgery (postpericardiotomy syndrome) is a common condition in pediatric cardiology, most commonly seen after surgical closure of an ASD.

In the pediatric age group, pericardial disease usually takes the form of acute pericarditis. In most cases, fluid effuses into the pericardial cavity. The consequences of such effusion depend on the amount, type, and speed of fluid accumulation. Under certain circumstances, serious compression of the heart occurs, which can lead to cardiac tamponade. Unless the pericardial fluid is evacuated in this situation, death may occur.

Clinical Findings

A. SYMPTOMS AND SIGNS

The symptoms depend to a great extent on the cause of the pericarditis. Pain is common. It is usually sharp and stabbing, located in the mid chest and in the shoulder and neck, made worse by deep inspiration, and considerably decreased by sitting up and leaning forward. Shortness of breath and grunting respirations are common findings in all patients.

The physical findings depend on whether a significant amount of effusion is present: (1) In the absence of significant accumulation of fluid, the pulses are normal.

The heart has a characteristic scratchy, high-pitched friction rub. The rub is often systolic and diastolic and can be located at any point between the apex and the left sternal border. The location and timing vary considerably from time to time. The heart sounds are usually normal, and the heart is not enlarged to percussion. (2) If considerable pericardial fluid has accumulated, the cardiovascular findings are different. The heart is enlarged to percussion, but on auscultation it is very quiet. Heart sounds are distant and muffled. A friction rub may not be present. In the absence of cardiac tamponade, the peripheral, venous, and arterial pulses are normal.

Cardiac tamponade is characterized by distention of the jugular veins, tachycardia, enlargement of the liver, peripheral edema, and pulses paradoxus in which the systolic pressure drops by more than 10 mm Hg during inspiration. This finding is best determined with the use of a manual blood pressure cuff. At this point, the patient is critically ill and has all the symptoms and signs suggestive of right-sided CHF.

Not all patients with marked cardiac compression demonstrate all of these findings. If the patient appears critically ill and pericarditis and effusion are evident, treatment should be instituted even though all the clinical signs of cardiac tamponade are not present.

B. IMAGING

In pericarditis without significant effusion, chest radiographic findings are normal. With pericardial effusion, the cardiac silhouette is enlarged, often in the shape of a water bottle.

C. ELECTROCARDIOGRAPHY

A number of ECG abnormalities occur in patients with pericarditis. Low voltage is commonly seen in patients with significant pericardial effusion. The ST segment is commonly elevated during the first week of involvement. The T wave is usually upright during this time. Following this, the ST segment is normal and the T wave becomes flattened.

D. ECHOCARDIOGRAPHY

Echocardiography is essential in the diagnosis and management of pericarditis. Serial echo studies allow the cardiologist a direct noninvasive estimate of the volume of fluid and its changes over time. In addition, echocardiography will demonstrate cardiac tamponade by compression of the atria by the pericardial effusion.

Treatment

Treatment depends on the cause of pericarditis. Cardiac tamponade resulting from any cause must be treated by evacuation of the fluid. If there are findings

of impending circulatory collapse, an immediate pericardiocentesis is performed. If pericardiocentesis is unsuccessful, a surgical pericardiectomy is required. Diuretics are to be avoided in the patient with cardiac tamponade because they reduce ventricular preload, which can exacerbate the degree of cardiac compression.

Prognosis

The prognosis depends to a great extent on the cause of the pericardial disease. Cardiac tamponade from any cause results in death unless the fluid is evacuated.

SPECIFIC DISEASES INVOLVING THE PERICARDIUM

Acute Rheumatic Fever

When pericarditis occurs during the course of acute rheumatic fever, it is almost always associated with involvement of the myocardium and the endocardium (pancarditis). Thus heart murmurs are almost always present. The pericarditis is usually of the serofibrinous variety and is usually not associated with a significant pericardial effusion. The treatment of the pericardial effusion is accomplished by the therapy for the acute rheumatic fever.

Viral Pericarditis

Viral pericarditis occurs in children and young adults. The most common cause is coxsackie virus B. Influenza virus has also been implicated. There is usually a history of a protracted upper respiratory tract infection. The pericardial effusion may last for several weeks. Cardiac tamponade is rare. Constrictive pericarditis can occur as a sequela of viral pericarditis.

Purulent Pericarditis

The most common causes of purulent pericarditis are pneumococci, streptococci, staphylococci, and *Haemophilus influenzae*. This disorder is always secondary to infection elsewhere, although occasionally the primary site is unknown. In addition to demonstrating signs of cardiac compression, patients are septic and run extremely high fevers. The purulent fluid accumulating within the pericardial sac is usually quite thick and filled with polymorphonuclear leukocytes. Although antibiotics will sterilize the pericardial fluid, pericardial tamponade commonly develops, and surgical excision of the pericardium is frequently necessary. Acutely, pericardiocentesis may be lifesaving if there are findings of tamponade on presentation. The wide use

of the *H influenzae* vaccine in recent years has significantly reduced the incidence of this condition.

Postpericardiotomy Syndrome

Postpericardiotomy syndrome is characterized by fever, chest pain, friction rub, and elevation of the ST segment noted on ECG 1–2 weeks after open-heart surgery. The syndrome appears to be an autoimmune disease with high titers of antiheart antibody and with detectable evidence of fresh or reactivated viral illness. The syndrome is often self-limited and responds well to short courses of aspirin or corticosteroid therapy. Rarely, it lasts for months to years and may require pericardiocentesis or pericardiectomy.

HYPERTENSION

Blood pressure should be determined at every pediatric visit beginning at age 3 years. Because this is now being done, systemic hypertension has become more widely recognized as a pediatric problem. Pediatric standards for blood pressure have been published. Blood pressures in children must be obtained when the child is relaxed, and an appropriate-size cuff must always be used. The widest cuff that fits between the axilla and the antecubital fossa is used in each case. Most children age 10–11 years need a standard adult-size cuff (bladder width of 12 cm), and many high school students need a large adult-size cuff (width of 16 cm) or leg cuff (width of 18 cm). The 95th percentile value for blood pressure (Table 19–19) is similar for both sexes and all three ethnic groups. Blood pressure varies more with altitude and body weight than with sex or ethnic origin. If the blood pressure taken in a quiet atmosphere and sitting position exceeds the 95th percentile for systolic, diastolic muffle, or diastolic disappearance pressures, it should be repeated several times over a 2- to 4-week interval. If it is elevated persistently, an evaluation for the cause of the hypertension should be undertaken. Although most hypertension in children is essential, there is a higher incidence of treatable conditions within pediatrics than in adult medicine, such as coarctation of the aorta, renal artery stenosis, chronic renal disease, and pheochromocytoma. Over-the-counter and recreational drug use may be important causative or contributing factors. Pediatricians must look for these conditions when a child presents with hypertension. If no secondary cause is found, and the hypertension is deemed essential, anti-

ATHEROSCLEROSIS AS A PEDIATRIC PROBLEM

Awareness of the importance of coronary artery risk factors in general—and atherosclerosis in particular—has risen dramatically in the general population since the mid 1970s. Although coronary artery disease is still the leading cause of death in the United States, the age-adjusted incidence of death from ischemic heart disease has been decreasing since that time as a result of an improved diet, decreased smoking, awareness and treatment of hypertension, and an increase in physical activity. During this period, a large number of serum samples from the pediatric population have been collected and analyzed for lipids, and epidemiologic studies have been performed to determine the relationship of lipid levels to coronary heart disease. The level of serum lipids in childhood usually remains the same

through adolescence. Biochemical abnormalities in the lipid profile appear early in childhood and correlate with higher risk for coronary artery disease in adulthood. High-density lipoprotein (HDL) has been identified as an antiatherogenic factor. The most common lipid profile referred to treatment centers has changed to a high triglyceride level, modest elevation of low-density lipoprotein (LDL), and low HDL level associated with obesity, insulin resistance, and prediabetes.

The concept of routine universal pediatric screening after age 3 years remains controversial. The National Cholesterol Education Program recommends selective screening in children with high-risk family members, defined as a parent with a total cholesterol over 240 mg/dL or a parent or grandparent with early-onset cardiovascular disease. When children have LDL levels greater than 130 mg/dL on two successive tests, dietary lifestyle counseling is appropriate. Dietary modification may decrease cholesterol levels by 5–20%. If the patient is unresponsive to diet change and at extreme risk (ie, a LDL level > 160 mg/dL, an HDL level < 35 mg/dL, and a history of cardiovascular disease in a first-degree relative at an age younger than 40 years), drug therapy may be indicated. Cholestyramine, a bile exchange resin, has had moderate success, but compliance is poor in children because of the drug's unpalatability. Niacin and the HMG-CoA reductase inhibitors are also used in the pediatric population and have had encouraging preliminary results.

PRIMARY PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Often subtle with symptoms of dyspnea, fatigue, chest pain, and syncope.
- Exclusion of all causes of secondary pulmonary hypertension.
- Rare, progressive, and often fatal disease without treatment.
- ECG with RVH.
- Loud pulmonary component of S₂.

General Considerations

Unexplained or primary pulmonary hypertension (PPH) in children is a rare disease with an estimated overall incidence of 1–2 persons per million worldwide. Pulmonary hypertension is defined as a mean pulmonary pressure that is greater than 25 mm Hg at rest or greater than 30 mm Hg during exercise. PPH is a diagnosis of exclusion of all other causes of pulmonary hypertension. Secondary pulmonary hypertension is most commonly associated with congenital heart disease, pulmonary parenchymal disease, causes of chronic hypoxia (upper airway obstruction), thrombosis, liver disease, and collagen vascular disease. The diagnosis of PPH is difficult to make in the early stages because of its subtle manifestations. Most patients with PPH are young adults, predominantly women; however, the sex incidence is equal in children. Familial PPH occurs in 6% of affected individuals. The locus for familial PPH is found on chromosome 2 (2q33) and is caused by abnormalities in the transforming growth factor beta family, specifically bone morphogenetic protein receptor II. Without treatment, the median survival is 2.5 years.

Clinical Findings

A. SYMPTOMS AND SIGNS

The clinical picture varies depending on the severity of the pulmonary hypertension. Initial symptoms may be brought on by strenuous exercise or competitive sports, and syncope may be the first symptom. Dyspnea on exertion is present in most patients; syncope occurs in approximately one third of patients. Palpitations or chest pain may occur with exercise. As the disease progresses, patients have signs of low cardiac output and right heart failure. Right heart failure may be manifested by an increase in hepatomegaly with peripheral edema and a gallop rhythm on examination. Murmurs of pulmonary regurgitation and tricuspid regurgitation are common. An S₃ is occasionally heard with advanced right heart failure.

B. IMAGING

The chest radiograph typically shows an enlarged heart with a prominent pulmonary artery and dilated proximal right and left pulmonary arteries. The peripheral pulmonary vascular markings may be normal or diminished.

C. ELECTROCARDIOGRAPHY

The ECG usually shows right atrial enlargement with RVH and right axis deviation.

D. ECHOCARDIOGRAPHY

The echocardiogram is an important diagnostic tool for excluding causes of congenital heart disease. It fre-

quently shows RVH and dilation. The tricuspid and pulmonary insufficiency jets may be used to estimate pulmonary artery systolic and diastolic pressures.

E. CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Cardiac catheterization has an increased risk in children with pulmonary hypertension and should be performed with great caution. The procedure is done first to rule out cardiac causes of pulmonary hypertension and then to define treatment strategies. Patients who have a pulmonary vascular bed that is reactive to short-acting vasodilator agents (nitric oxide, adenosine, prostacyclin) may receive treatment with calcium channel blockers. In contrast, patients who have a pulmonary vascular bed that does not improve with these short-acting agents often receive prostacyclin therapy. Angiography may show a marked decrease in the number of small pulmonary arteries with tortuous vessels.

Treatment

The goal of therapy is to reduce pulmonary artery pressure and increase cardiac output. The cardiac catheterization data are used to define the treatment plan. Patients who have shown a response to pulmonary vasodilators are given calcium channel blockers such as nifedipine or diltiazem. Patients who are unreactive to these vasodilators in the catheterization laboratory initially receive prostacyclin therapy. Patients with severe, unreactive pulmonary hypertension may be considered for lung transplantation. Common therapies include warfarin to prevent thromboembolic events. This approach is beneficial in adults. Digoxin and diuretics may be used if signs of right heart failure are present. Receptor antagonists to the potent vasoconstrictor peptide endothelin show great promise in the treatment of pulmonary hypertension.

Survival rates of greater than 90% have been reported using chronic oral calcium channel blockade in patients who responded acutely to vasodilator testing. In patients in whom calcium channel blockade fails, or in those who do not respond acutely to vasodilator therapy, intravenous prostacyclin has been used with a 5-year survival rate of greater than 80%.

CHEST PAIN

Overview

Chest pain is a common complaint of pediatric patients, accounting for 6 in 1000 visits to urban emergency rooms and urgent care clinics. Although children with chest pain are commonly referred for cardiac evaluation, chest pain in children is rarely due to cardiac pathology. Other possible causes of chest pain include musculoskeletal pain, esophagitis/gastritis, and functional pain.

Approach to the Work-up

A detailed history and physical exam should guide the pediatrician through an appropriate work-up of chest pain. (A known medical history of cardiac or respiratory disease will of course provide additional guidance.) Rarely is there a need for laboratory tests or further evaluation by a specialist. The duration, location, intensity, frequency, and radiation of the pain should be documented, and possible triggering events preceding the pain should be explored. For instance, chest pain following exertion may lead to a more elaborate evaluation for a cardiac disorder. Or the timing of the pain in relation to meals may suggest a gastrointestinal cause. The patient should also be asked about how pain relief is achieved. A social history to reveal psychosocial stressors and cigarette smoke exposure may assist in determining the cause. On physical exam, attention must be placed on the vital signs, general appearance of the child, the chest wall musculature, cardiac, pulmonary, and abdominal exam findings, and quality of peripheral pulses. Attempts should be made to reproduce the pain by direct palpation and through forced resistance applied to the patient's upper extremities. If the pain is reproduced, it is almost always musculoskeletal in origin.

Clinical Considerations

Cardiac disease is a rare cause of chest pain, but if misdiagnosed it may be life-threatening. Myocardial infarction rarely occurs in healthy children. Children with underlying illnesses such as diabetes mellitus, chronic anemia, or an anomalous left coronary artery may be at increased risk for ischemia. It is also important to ask the family specifically about a history of Kawasaki disease, treated or untreated. These children are at risk for cardiac sequelae including myocardial infarct secondary to thrombosis of their coronary aneurysms, cardiac arrhythmias, or sudden death. More than 50% of children and adolescents who exhibit sequelae from Kawasaki disease arrive at the emergency department with chest pain.

Other cardiac causes of chest pain include arrhythmias. The most common arrhythmia in children is supraventricular tachycardia (SVT), but atrial flutter and premature ventricular contractions (PVCs) may also be associated with chest pain in children. Other structural lesions that cause chest pain include aortic stenosis, pulmonary stenosis, and mitral valve prolapse. Structural cardiac lesions are usually detected prior to the child's emergency room visit. They are accompanied by significant findings on cardiac exam. Of children diagnosed with mitral valve prolapse, 31% will complain of chest pain, caused by papillary muscle ischemia. Other cardiac lesions that cause chest pain include dilated cardiomyopathy, hypertrophic obstructive cardiomyopathy, myocarditis, rheumatic fever, aortic dissection, and pericarditis. Pain from hypertrophic obstructive cardiomyopathy may be associated with exertion.

Noncardiac chest pain may be due to a respiratory illness—for example, reactive airway disease, pneumonia, pneumothorax, or pulmonary embolism. Gastrointestinal causes of chest pain include reflux, esophagitis, and foreign body. The most common cause of chest pain (30% of children) is inflammation of musculoskeletal structures of the chest wall. Costochondritis involves inflammation of the costochondral or costosternal junctions and is usually unilateral. Chest wall pain is more common in girls and is reproducible on examination.

After a complete history and physical are obtained, the information gathered can guide the examiner to the appropriate diagnosis or, if necessary, the appropriate laboratory tests to be ordered. In most cases, additional tests are not necessary. If a cardiac origin is suspected, a pediatric cardiologist should be consulted. Positive cardiac findings on initial evaluation should be followed with a combination of the following: an ECG, chest radiograph, echocardiogram, Holter monitor, and serum troponin and creatinine kinase assays.

CARDIAC TRANSPLANTATION

Cardiac transplantation has developed into an effective therapeutic modality for end-stage inflammatory cardiac diseases such as myocarditis and cardiomyopathies. In addition, transplantation has become a common final therapeutic pathway for many structural cardiac defects associated with cardiomyopathic changes. Cardiac damage from either long-standing congenital disease or surgery can also lead to transplantation. Approximately 300 pediatric cardiac transplant procedures are performed annually in the United States. The current estimated half-life for children undergoing cardiac

transplantation in the 1980s and early 1990s is approximately 15 years. This is a rapidly developing field, and the most recent data indicate an improved prognosis.

Cardiac transplantation is the paradigm of an inflammatory disease of the transplanted myocardium. Because the donor and the recipient are not matched for histocompatibility antigens, the potential for graft rejection by the host immune system is always present. Long-term immunosuppressive medications are required to control this inflammatory process. The mainstay for immunosuppressive agents in cardiac transplant recipients remains cyclosporin A. Cyclosporine is usually well tolerated but has been associated with the potential for renal dysfunction, hypertension, and probably an increased risk of malignancy. In addition, adolescent patients are affected by the visible side effects of hirsutism and gingival hyperplasia. In the current era, the therapeutic blood levels of cyclosporine have been reduced, and most of these side effects occur less frequently. Graft rejection can be triggered by lack of compliance, infection, and other issues, which are not well understood. Although the greatest risk of rejection is in the first 3 months after transplant, a low risk persists even years after the transplant procedure.

Unlike other inflammatory diseases of the myocardium, the process of graft rejection is fairly well understood. The T lymphocyte is the predominant effector cell, which receives antigen presentation, predominantly from tissue histiocytes and macrophages. These cells present antigens to the T-cell receptor in a cradle. Because the donor antigens are new to the host, a population of T lymphocytes can react to these antigens. This process is in contrast to the presentation of host antigens, which do not have T lymphocytes that are programmed to respond. The process of elimination of self-responding T lymphocytes takes place largely in the thymus in utero. However, a process of acquired tolerance, even to the foreign antigens of the donor, may also involve the thymus and peripheral sites. Because the default mechanism for the immune system is to not react to an antigen, with the passage of time and under the influence of immunosuppression, the host becomes less and less responsive to donor antigens posttransplant.

The population of pediatric patients with a heart transplant in the United States is approximately 3000 and growing; thus the major medical challenge is surveillance and treatment of graft rejection.

Clinical Findings

A. SYMPTOMS AND SIGNS

Transplant recipients undergoing the process of graft rejection are usually asymptomatic in the early stages. With progression they may develop tachycardia, tachy-

plea, elevated central venous pressure, and a gallop rhythm. These findings are similar to what would be expected with CHF. As low cardiac output progresses, nausea and vomiting may ensue, followed by altered mental status, and finally peripheral circulatory collapse.

B. IMAGING

Chest radiographs often show cardiac enlargement and increased pulmonary vascular markings.

C. ELECTROCARDIOGRAPHY

Abnormalities in conduction can be present, although the most typical finding is a decrease in QRS voltage. Arrhythmias, both atrial and ventricular, can be evidence of rejection.

D. ECHOCARDIOGRAPHY

Echocardiography is a sensitive surveillance tool for graft rejection. Changes in ventricular compliance and function are typical and become progressive with increasing duration of the rejection episode. Valvular insufficiency may also indicate rejection. A new pericardial effusion can also indicate inflammation due to the rejection process.

E. CARDIAC CATHETERIZATION AND ENDOMYOCARDIAL BIOPSY

The hemodynamic measurements can be relatively normal with mild rejection, but with progression the pulmonary capillary wedge pressure increases, indicating decreasing ventricular compliance. Often this is a global process, and the RV filling pressures or central venous pressure may also be elevated. The endomyocardial biopsy has remained the mainstay of tissue diagnosis for graft rejection. The appearance of infiltrating lymphocytes with myocellular damage is the hallmark of graft rejection. Occasionally patients may have only a sparse lymphocytic infiltration despite profound myocardial performance abnormalities. Presumably, the depression in the myocardial function in the absence of lymphocytes is related to inflammatory mediators such as tumor necrosis factor and the various interleukins.

Treatment

The treatment for graft rejection depends on reversing the immunologic inflammatory cascade. High-dose corticosteroids are the first line of treatment. These can stabilize or reverse most rejection episodes. Occasionally additional therapy in the form of antithymocyte biologic preparations such as antithymocyte globulin or OKT-3 (a murine monoclonal antibody to the CD3 T-lymphocyte epitope) is needed to reverse the rejection process. Most rejection episodes can be treated effectively if diagnosed promptly. A high index of suspicion

must be maintained whenever a patient has a history of cardiac transplantation. Usually graft function will return to the baseline state, although severe rejection episodes can result in graft loss and patient death even with optimal therapy.

Course & Prognosis

The clinical course of cardiac transplantation in pediatric patients is usually quite good. Despite the chronic immunosuppression, the risk of infection is low beyond the early posttransplant period. Most children seem to tolerate environmental pathogens quite readily. Overwhelming infection is uncommon. Noncompliance with lifetime immunosuppression, especially among adolescents, is of great concern. Several recent studies have identified noncompliance as the leading cause of late death after transplantation. Posttransplant lymphoproliferative disorder, a syndrome related to Epstein-Barr virus infection, can result in a Burkitt-like lymphoma that will usually respond to a reduction in immunosuppression. Most children are not physically limited, and they do not require restrictions related to the cardiovascular system. Because the heart is denervated, patients may exhibit a blunted response to exercise at the onset. The greatest concern over the long term following heart transplantation is related to a syndrome of accelerated coronary atherosclerosis. This premature form of atherosclerosis is unlike typical adult coronary disease in that it progresses quite rapidly. The insult to the coronary endothelium is immune-mediated and can cause coronary obliteration. If the process is recognized and treated, its late appearance may mimic the more typical adult atherosclerotic disease. This observation has led some researchers to suggest that adult atherosclerotic disease is largely an inflammatory process, perhaps initiated by environmental pathogens.

Overall, despite the concerns of immunosuppression and the risk of late rejection and graft atherosclerosis, the majority of pediatric patients enjoy physiologic rehabilitation following cardiac transplantation with a 60–70% 10-year survival. Newer, more specific, and more effective immunosuppressive agents are currently being tried in clinical studies or are being evaluated in preclinical studies, making the future almost certainly better for children after cardiac transplantation. Donor availability remains a major limitation to the expansion of indications for cardiac transplantation.

DISORDERS OF RATE & RHYTHM

The recognition and treatment of cardiac arrhythmias have improved markedly since the 1980s. Better monitoring has increased the awareness and detection of rhythm disturbances. There is also a true rise in the incidence of arrhythmias. More children are now surviving cardiac surgery and acute carditis and live chronically with altered hemodynamics, physiology, and structural changes. These changes over time will create altered conduction and new arrhythmias.

The advent of invasive electrophysiology with recordings from the endocardium has greatly improved our understanding of the conduction system. Now, with cardiac ablation techniques, we can offer these children a “cure” rather than lifelong antiarrhythmia treatment.

Sinus Arrhythmia

It is normal to have phasic variation in the heart rate (sinus arrhythmia). Typically, the sinus rate varies with the respiratory cycle, whereas P-QRS-T intervals remain normal. Marked sinus arrhythmia is defined as a greater than 100% variation in heart rate. It may occur in association with respiratory distress or increased intracranial pressure, or it may be present in normal children. It alone never requires treatment; however, it may be associated with sinus node dysfunction or autonomic nervous system dysfunction.

Sinus Bradycardia

Depending on the patient's age, sinus bradycardia is defined as either (1) a heart rate below the normal limit for age (neonates to 6 years, 60 beats/min; 7–11 years, 45 beats/min; older than 12 years, 40 beats/min) or (2) a heart rate inappropriately slow for the functional status of the patient (chronotropic incompetence). In critically ill patients, common causes of sinus bradycardia include hypoxia, central nervous system damage, and iatrogenic medication side effects. Only symptomatic bradycardia (syncope, low cardiac output, or ex-

ercise intolerance) requires treatment (atropine or cardiac pacing).

Sinus Tachycardia

The heart rate normally accelerates in response to stress (eg, fever, hypovolemia, anemia, CHF). Although sinus tachycardia in the normal heart is well tolerated, symptomatic tachycardia with decreased cardiac output is more ominous and warrants evaluation for associated structural heart disease or true tachyarrhythmias. Treatment may be indicated for correction of the underlying cause of sinus tachycardia (eg, transfusion for anemia, correction of hypovolemia or fever).

PREMATURE ATRIAL CONTRACTIONS

Premature atrial contractions are triggered by an ectopic focus in the atrium. They are one of the most common premature beats occurring in the pediatric population, particularly during the fetal and newborn periods. They may be conducted (followed by a QRS) or nonconducted (not followed by a QRS as the beat has occurred so early that the AV node is still refractory) (Figure 19–4). A less-than-compensatory pause usually occurs until the next normal sinus beat. Depending on the ectopic focus of the premature contraction, the frontal plane vector of the P wave may be normal (+30–90 degrees) or abnormal. As an isolated finding, premature atrial contractions are benign and require no treatment. They may need to be suppressed with antiarrhythmic agents when they trigger tachyarrhythmias or produce bradycardia secondary to non-conduction.

PREMATURE JUNCTIONAL CONTRACTIONS

Premature junctional contractions arise within the AV node or the bundle of His. Most often, they induce a normal QRS complex with no preceding P wave. When conducted aberrantly to the ventricles, they cannot be distinguished from PVCs except by invasive electrophysiologic study. Premature junctional contractions are usually benign and require no specific therapy.

PREMATURE VENTRICULAR CONTRACTIONS

PVCs may originate in either ventricle and are characterized by an abnormal QRS of over 80 ms duration in newborns and 120 ms in adolescents and adults (Figure 19–5). PVCs originating from a single ectopic focus all have the same configuration; those of multifocal origin show varying configurations. The consecutive occur-

Figure 19-4. Lead II rhythm strip with premature atrial contractions. Beats 1, 3, 7, and 8 are conducted to the ventricles, whereas beats 2, 4, 5, and 6 are not.

Figure 19-5. Lead V₅ rhythm strip with unifocal premature ventricular contractions in a bigeminy pattern. The arrow shows a ventricular couplet.

rence of two PVCs is referred to as a ventricular couplet and of three or more as ventricular tachycardia.

Most unifocal PVCs in otherwise normal patients are benign. The significance of the PVCs can be confirmed by having the patient exercise. As the heart rate increases, benign premature contractions usually disappear. If exercise results in an increase or coupling of contractions, underlying disease may be present. Multifocal PVCs are always abnormal and may be more dangerous. They may be associated with drug overdose (tricyclic antidepressants, digoxin toxicity), electrolyte imbalance, myocarditis, or hypoxia. Treatment is directed at correcting the underlying disorder.

SINUS NODE DYSFUNCTION

Sinus node dysfunction, or sick sinus syndrome, is a clinical syndrome of inappropriate sinus nodal function and rate. The abnormality may be a true anatomic defect of the sinus node or its surrounding tissue, or it may be an abnormality of autonomic input. It is defined as one or more of the following:

1. Sinus bradycardia
2. Marked sinus arrhythmia
3. Chronotropic incompetence
4. Sinus pause or arrest
5. Sinoatrial exit block
6. Combined bradyarrhythmias and tachyarrhythmias
7. Sinus node reentry
8. Atrial muscle reentry tachycardia.

It is usually associated with postoperative repair of congenital heart disease (most commonly the Mustard or Senning repair for complete transposition of the great arteries or the Fontan procedure), but it is also seen in unoperated congenital heart disease, in acquired heart diseases, and in normal hearts. In some cases the disorder is inherited. Symptoms usually manifest between ages 2 and 17 years and consist of episodes of syncope, presyncope, or disorientation. Some patients may experience palpitations, pallor, or exercise intolerance.

The evaluation of sinus node dysfunction involves both surface ECG and invasive electrophysiologic testing. Exercise testing, and ambulatory monitoring help define any arrhythmias and correlate rhythm changes with symptoms.

Treatment for sinus node dysfunction is indicated only in symptomatic patients. Asymptomatic patients can just be observed for the onset of exercise intolerance or syncope because there is little chance of sudden death prior to the onset of symptoms. Bradyarrhyth-

mias are treated with vagolytic (atropine) or adrenergic (aminophylline) agents or permanent cardiac pacemakers. Antiarrhythmic treatment of tachyarrhythmias often produces or enhances bradycardia, thus requiring permanent cardiac pacing. In selected cases, a pacemaker is inserted prophylactically prior to the initiation of antiarrhythmic medications.

The prognosis is excellent when appropriate treatment is provided, with total morbidity and mortality rates nearly equal to those of the underlying heart disease. However, in severe cases, if left untreated, sinus node dysfunction may become chronic and may even lead to sudden death.

Miller MS et al: Neonatal bradycardia. *Prog Pediatr Cardiol* 2000;11:19 [PMID: 10822186].

SUPRAVENTRICULAR TACHYCARDIA

SVT, also known as paroxysmal SVT or paroxysmal atrial tachycardia, is defined as an abnormal arrhythmia mechanism arising above or within the bundle of His. The mode of presentation depends on the tachycardia rate, the presence of underlying cardiac structural or functional abnormalities, coexisting illness and the patient's age. Tachycardia may be poorly tolerated in a child who has preexisting CHF or an underlying systemic disease such as anemia or sepsis, or it may go unnoticed in an otherwise healthy child. Incessant tachycardia in an otherwise healthy individual, albeit slow (120–150 beats/min), may cause myocardial dysfunction and CHF if left untreated. The mechanisms of tachycardia can be divided into three groups: reentry, enhanced automaticity, and triggered dysrhythmias.

Reentry is conduction through two or more pathways, creating a sustained repetitive circular loop. The circuit can be confined to the atrium (intraatrial reentry, a form of atrial flutter) (Figure 19–6). It may be confined within the AV node (AV nodal reentrant tachycardia), or it may encompass an accessory connection between atria and ventricle (atrioventricular tachycardia). The arrhythmia circuit includes conduction through the normal pathway (ie, the AV node) as well as the accessory AV connection. If during tachycardia the electrical impulse travels antegrade (from atria to ventricle) through the AV node and retrograde (from ventricle to atria) back up the accessory pathway, orthodromic reciprocating tachycardia is present. If during tachycardia the electrical impulse travels antegrade through the accessory pathway and retrograde up through the AV node, then antidromic reciprocating tachycardia is present. WPW syndrome is a subclass of reentrant tachycardia in which, during sinus rhythm, the impulse travels antegrade down the accessory connection, bypassing the AV node and creating ventricu-

Figure 19–6. Leads aVF (F) and V₁, showing atrial flutter with “sawtooth” atrial flutter waves.

lar preexcitation (early eccentric activation of the ventricle with a short PR interval and slurred upstroke of the QRS, a delta wave) (Figure 19–7). Reentrant tachycardia represents approximately 80% of pediatric arrhythmias, has a wide range of rates, and may or may not demonstrate P waves. Reentrant tachycardia initiates and terminates abruptly. Most patients with WPW have otherwise structurally normal hearts. WPW however has been noted to occur with increased frequency in association with the following congenital cardiac lesions: tricuspid atresia, Ebstein anomaly of the tricuspid valve, HCM, and ccTGA.

Enhanced automaticity (also known as automatic or ectopic tachycardia) is created when a focus of cardiac tissue develops an abnormally fast spontaneous rate of depolarization. These arrhythmias represent approximately 20% of childhood arrhythmias and are usually under autonomic influence. ECG demonstrates a normal QRS complex preceded by an abnormal P wave (Figure 19–8). Junctional ectopic tachycardia does not have a P wave preceding the QRS waves and may be associated with AV dissociation or 1:1 retrograde conduction. Ectopic tachycardias demonstrate a gradual onset and offset and may be paroxysmal or incessant. When

they are incessant, they are usually associated with CHF and a clinical picture of dilated cardiomyopathy.

Triggered dysrhythmia is extremely rare. It is caused by enhanced afterdepolarizations of the action potential that reach the takeoff potential. These tachycardias are usually associated with diseased atrial myocardium, are triggered by premature atrial contractions or sinus tachycardia, initiate and terminate abruptly, and mimic intraatrial reentry (atrial flutter). However, they can be distinguished from atrial flutter: they terminate with the administration of adenosine, while atrial flutter does not (see section on Atrial Flutter & Fibrillation).

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical presentation varies with the patient’s age. Infants tend to turn pale and mottled with onset of tachycardia and may become irritable. With long duration of tachycardia, symptoms of CHF develop. Heart rates can be from 240 to 300 beats/min. Older children may complain of dizziness, palpitations, fatigue, and chest pain. Heart rates usually range from 240 beats/min in

Figure 19–7. Leads I and II with spontaneous intermittent ventricular preexcitation (Wolff–Parkinson–White syndrome).

Figure 19-8. Lead II rhythm strip of ectopic atrial tachycardia. The tracing demonstrates a variable rate with a maximum of 260 beats/min, an abnormal P wave, and a gradual termination.

the younger child to 150–180 beats/min in the teenager. CHF is less common in children than in infants. Tachycardia may be associated with either congenital heart defects, as mentioned earlier, or acquired conditions such as cardiomyopathies and myocarditis.

B. IMAGING

Findings on chest radiograph are normal during the early course of tachycardia. If CHF is present, the heart is enlarged and pulmonary venous congestion is evident.

C. ELECTROCARDIOGRAPHY

ECG is the most important tool in the diagnosis of SVT.

1. The heart rate is rapid and out of proportion to the patient's physical status (ie, a rate of 140 beats/min with an abnormal P wave while quiet and asleep).
2. The rhythm is extremely regular. There is little variation in the rate throughout the entire tracing.
3. P waves may or may not be present. If they are present, the PR interval and appearance do not vary. P waves may be difficult to find because they are superimposed on the preceding T wave. Furthermore, if the abnormal focus is located within the AV node, the P waves will not be seen.

4. The QRS complex is usually the same as during normal sinus rhythm. However, the QRS complex is occasionally widened (SVT with aberrant ventricular conduction), in which case the condition may be difficult to differentiate from ventricular tachycardia.

Treatment

A. ACUTE TREATMENT

During initial episodes of SVT, patients require close monitoring. Correction of acidosis and electrolyte abnormalities is also indicated.

1. Vagal maneuvers—The “diving reflex,” produced by placing an ice bag on the nasal bridge for 20 seconds (for infants) or by immersing the face in ice water (for children or adolescents), will increase parasympathetic tone and terminate some tachycardias. The Valsalva maneuver, which can be performed by older compliant children, may also terminate SVT.

2. Adenosine—Adenosine transiently blocks AV conduction and terminates tachycardias that incorporate the AV node.

Adenosine does not convert tachycardias whose mechanism is confined to the atria (atrial ectopic tachycardia, intraatrial reentry). However, it serves as a diagnostic tool in these arrhythmias by demonstrating con-

tinuation of the atrial tachycardia during AV block, implying that AV node conduction is not a crucial element of the tachycardia circuit. The dose is 50–250 µg/kg by rapid intravenous bolus. It is antagonized by aminophylline and should be used with caution in patients with sinus node dysfunction or asthma.

3. Transesophageal atrial pacing—Atrial overdrive pacing and termination can be performed from a bipolar electrode-tipped catheter positioned in the esophagus adjacent to the left atrium. Overdrive pacing at rates approximately 30% faster than the tachycardia rate will interrupt the tachycardia circuit and restore sinus rhythm.

4. Direct current cardioversion—Direct current (DC) cardioversion (0.5–2 synchronized J/kg) should be used immediately when a patient presents in cardiovascular collapse.

B. CHRONIC TREATMENT

1. Digitalis—Digoxin is still frequently used for long-term treatment and maintenance of sinus rhythm. The doses used are the same as those for CHF. Conversion should be accomplished within 8–12 hours. In some patients digoxin can accelerate conduction over an accessory pathway, and in those children digitalis products are contraindicated. Patients with an accessory pathway (eg, those with WPW syndrome) often have primary atrial tachycardias (atrial flutter or fibrillation, atrial ectopic tachycardias), and with enhanced conduction in the accessory pathway these primary atrial tachycardias can transmit to the ventricles, causing ventricular fibrillation. Therefore, an evaluation of the effect of digoxin on the accessory pathway should be performed in the electrophysiology lab before chronic digoxin use in patients with WPW syndrome.

2. Beta-adrenergic blocking agents—Propranolol decreases sinus heart rate and AV nodal conduction. It is effective in the treatment of both reentrant and ectopic arrhythmias in doses ranging from 1 to 4 mg/kg/d. Long-acting β-blockers, such as atenolol and nadolol, are used because they have fewer central nervous system side effects than propranolol and may be given only once or twice a day.

3. Calcium channel antagonists—Verapamil and other calcium channel blockers markedly prolong conduction through the AV node and are effective in interrupting and preventing reentrant tachycardias that incorporate the AV node. They are ineffective in terminating atrial tachycardias but may be useful in controlling the ventricular response by producing AV blockade. Verapamil comes in short- and long-acting preparations; the dose is 3–5 mg/kg/d. It may cause myocardial dysfunction and is contraindicated in infants.

4. Other drugs—Recently introduced antiarrhythmic medications (eg, flecainide, propafenone, sotalol, and amiodarone) have increased pharmacologic actions and are extremely effective. However, these drugs also have serious side effects, including proarrhythmia (production of arrhythmias) and sudden death, and should be used only under the direction of a pediatric cardiologist.

5. Radiofrequency ablation—This is a nonsurgical transvascular catheter technique that will desiccate an arrhythmia focus or accessory pathway and permanently “cure” an arrhythmia. The immediate success rate is approximately 90%, with a rate of recurrence of 10%. The risk of developing complete heart block is approximately 2–10% when applying burns in the vicinity of the AV node/His bundle. The procedure can be performed in infants or adults. In children younger than age 4 years, the risks are higher, and the procedure should be reserved for those whose arrhythmias are refractory to medical management. In well-tolerated SVTs that respond to vagal maneuvers, no further treatment is necessary. However, the high success rate, low complication and recurrence rates, and the elimination of the need for chronic antiarrhythmic medications have made radiofrequency ablation the primary treatment option in most pediatric cardiovascular centers.

Prognosis

SVT has an excellent prognosis. When it occurs in early infancy, 90% will respond to initial treatment. Approximately 30% will recur at an average age of 8 years.

Moak JP: Supraventricular tachycardia in the neonate and infant. *Prog Pediatr Cardiol* 2000;11(1):25 [PMID: 10822187].

ATRIAL FLUTTER & FIBRILLATION

Atrial flutter and fibrillation are rare in children and are most often associated with organic heart disease—particularly postoperative congenital heart disease and sinus node dysfunction. Atrial flutter can occur in infancy and can mimic SVT. The atrial rate is usually greater than 240 beats/min and often more than 300 beats/min. The ventricular rate depends on the rate of AV conduction and is usually slower than the atrial rate.

Treatment & Prognosis

Transesophageal atrial pacing is the treatment of choice to terminate atrial flutter. When it is not successful, antiarrhythmic medications (eg, digoxin, sotalol, and amiodarone) may succeed; however, DC cardioversion is frequently necessary.

The prognosis in neonates without structural heart disease is excellent, and after conversion these patients may need no further treatment.

POSTOPERATIVE INCISIONAL INTRAATRIAL REENTRY

Improved surgical survival for patients with congenital heart disease has created a new, increasingly prevalent, chronic arrhythmia: incisional intraatrial reentry, or postoperative atrial flutter. In these tachycardias, electrically isolated corridors of atrial myocardium (eg, the tricuspid valve–inferior vena cava isthmus, or the region between an atrial incision and the crista terminalis) act as pathways for sustained reentrant circuits of electrical activity. These tachycardias are chronic, medically refractory, and clinically incapacitating. Electromagnetic mapping permits precise localization of these corridors. Long linear radiofrequency or surgical lesions are then used to interrupt the reentrant circuits.

Van Hare GF: Intra-atrial reentry tachycardia in pediatric patients. *Prog Pediatr Cardiol* 2001;13(1):41 [PMID: 11413057].

VENTRICULAR TACHYCARDIA

Ventricular tachycardia is uncommon in childhood (Figure 19–9). It is usually associated with underlying abnormalities of the myocardium (myocarditis, cardiomyopathy, myocardial tumors, postoperative congenital heart disease) or toxicity (hypoxia, electrolyte imbalance, drug toxicity). Sustained tachycardia is generally an unstable situation and, if left untreated, will usually degenerate into ventricular fibrillation.

Accelerated idioventricular rhythm is a sustained ventricular tachycardia occurring in neonates with normal hearts. The rate is within 10% of the preceding sinus rate, and it is a self-limiting arrhythmia that requires no treatment.

Acute termination of ventricular tachycardia involves restoration of the normal myocardium when possible (correct electrolyte imbalance, drug toxicity, and so on) and DC cardioversion (1–4 J/kg), cardioversion with lidocaine (1 mg/kg), or both. Chronic suppression of ventricular arrhythmias with antiarrhythmic drugs has many side effects (including proarrhythmia and death), and it must be initiated in the hospital under the direction of a pediatric cardiologist.

LONG QT SYNDROME

The congenital long QT syndromes (types 1–6) in children are arrhythmic disorders in which ventricular re-

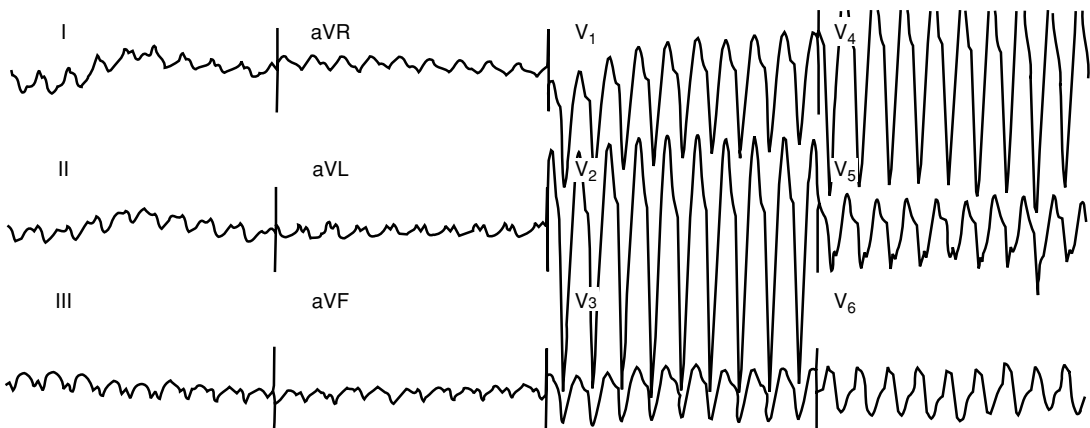

Figure 19–9. Twelve-lead ECG from a child with imipramine toxicity and ventricular tachycardia.

polarization is irregular and prolonged (QTc > 0.44 seconds, or 0.46 seconds in postpubertal females). Some myocardial ion channelopathies predispose patients to “torsade de pointes” (multifocal ventricular tachycardia) and manifest as syncope, seizures, or sudden death in response to exercise. If untreated, they account for a very high mortality rate (5%/year). They are inherited genetically in an autosomal dominant or recessive pattern (the latter being associated with congenital deafness, the Jervell–Lange–Nielsen syndrome). Or they may arise spontaneously. Treatment with β -blockade and exercise limitation is only partially successful. In recurrent, medically refractory cases, implantable cardioverter defibrillators are necessary to prevent sudden death. Congenital long QT syndrome has now been demonstrated to be one of the causes of SIDS. The *SCN5A* gene has been isolated from a child who died from SIDS.

Acquired long QT syndrome—resulting from altered ventricular repolarization secondary to myocardial toxins, ischemia, or inflammation—also predisposes a patient to ventricular arrhythmias. Numerous medications as outlined previously can also cause QT prolongation. ECGs are recommended before therapy (for a baseline measurement) and after steady state is achieved. Another drug capable of prolonging the QT interval, cisapride (used for gastroesophageal reflux), has now been removed from the US market.

SUDDEN DEATH

Hypertrophic cardiomyopathy (the most common cause of sudden death in young athletes) and other cardiomyopathies (dilated cardiomyopathies, restrictive cardiomyopathy, or arrhythmogenic RV dysplasia) may

be hereditary and should be looked for in patients with resuscitated cardiac arrest or family members of those who have died suddenly. Congenital structural anomalies of the coronary arteries are the second most common cause of sudden death in young athletes. These anomalies are not hereditary. The coronary arteries need to be evaluated in survivors of sudden death events. Arrhythmias in patients with postoperative congenital heart disease are important causes of morbidity and mortality and may present as sudden death events. All survivors of cardiac arrest require thorough evaluation for arrhythmias, including invasive electrophysiology. Episodes of seizures, syncope, and presyncope in congenital heart disease patients should be evaluated for the possibilities of arrhythmias, and they may also require thorough electrophysiologic evaluation and treatment.

When a child dies suddenly and unexpectedly, or is resuscitated from cardiac arrest that had no apparent cause, it is necessary to conduct a detailed family history looking for seizures, syncope, or early sudden death. Family members should be examined with an arrhythmia screen, physical examination, ECG, and echocardiography to detect arrhythmias or cardiomyopathies.

HEART BLOCK

1. First-Degree Heart Block

First-degree heart block is an ECG diagnosis of prolongation of the PR interval. The block does not in itself cause problems, but it is frequently associated with congenital heart defects such as AV septal defects, ccTGA, and with diseases such as rheumatic carditis. The PR interval may also be prolonged as a result of digoxin therapy.

2. Second-Degree Heart Block

Mobitz type I (Wenckebach) heart block is recognized by progressive prolongation of the PR interval until there is no QRS following a P wave (Figure 19–10). Mobitz type I heart block occurs in normal hearts at rest and is usually benign. In Mobitz type II heart block, there is no progressive lengthening of the PR interval before the dropped beat (Figure 19–11). Mobitz type II heart block is frequently associated with organic heart disease, and a complete evaluation is necessary.

Lead I

Figure 19–10. Lead I rhythm strip with Mobitz type I (Wenckebach) second-degree heart block. There is progressive lengthening of the PR interval prior to the nonconducted P wave (arrows).

3. Complete Heart Block

In complete heart block, the atria and ventricles beat independently. Ventricular rates can range from 40 to 80 beats/min, whereas atrial rates are faster (Figure 19–12).

Congenital complete heart block, the most common form of complete heart block, has a very high association with maternal systemic lupus erythematosus. Serologic screening should be performed in the mother of an infant with complete heart block even if she has no symptoms of collagen vascular disease. Congenital complete heart block is also associated with congenitally corrected transposition of the great vessels and AV septal defect. Acquired complete heart block may be secondary to acute myocarditis, drug toxicity, electrolyte imbalance, hypoxia, and cardiac surgery.

Clinical Findings

Prenatal bradycardia is frequently noted in infants with congenital complete heart block, and emergent delivery is required if hydrops fetalis develops. Postnatal adaptation largely depends on the heart rate; infants with heart rates lower than 55 beats/min are at significantly greater risk for low cardiac output, CHF, and death. Wide QRS complexes and a rapid atrial rate are also poor prognostic signs. Most patients have an innocent flow murmur from increased stroke volume. In symptomatic patients, the heart can be quite enlarged, and pulmonary edema may be present. In older patients, syncope can be the presenting symptom, or heart block may be found unexpectedly on routine physical examination. Complete cardiac evaluation, including echocardiography and Holter monitoring, is necessary

Lead III

Figure 19–11. Lead III rhythm strip with Mobitz type II second-degree heart block. There is a consistent PR interval with occasional loss of AV conduction (arrow).

Figure 19-12. Twelve-lead ECG and lead II rhythm strip of complete heart block. The atrial rate is 150 beats/min, and the ventricular rate is 60 beats/min.

to assess the patient for ventricular dysfunction and to relate any symptoms to concurrent arrhythmias.

Treatment

In patients thought to be at risk for syncope, CHF, or sudden death, the treatment of choice for complete heart block is insertion of a permanent pacemaker. Until permanent pacing can be instituted, patients can be assisted temporarily by infusions of isoproterenol or by temporary transcutaneous pacemakers.

Moak JP et al: Congenital heart block: Development of late-onset cardiomyopathy, a previously underappreciated sequela. *J Am Coll Cardiol* 2001;37(1):238 [PMID: 11153745].

SYNCOPE (Fainting)

Syncope is a sudden transient loss of consciousness that resolves spontaneously. The common form of syncope (simple fainting) occurs in 15% of children and is a disorder of control of heart rate and blood pressure by the autonomic nervous system that causes hypotension or bradycardia. It is often associated with rapid rising and postural hypotension, prolonged standing, or hypovolemia. Patients exhibit vagal symptoms such as pallor,

nausea, or diaphoresis. Syncope, also known as autonomic dysfunction, can be evaluated with head-up tilt table testing. The patient is placed supine on a tilt table, and then—under constant heart rate and blood pressure monitoring—is tilted to the upright position. If symptoms develop, they can be classified as vasodepressor (hypotension), cardioinhibitory (bradycardia), or mixed.

Syncope is usually self-limited (lasting approximately 6 months to 2 years) and can be controlled with dietary salt and volume loading to prevent hypovolemia. In refractory cases, medications to manipulate the autonomic nervous system have been useful. Flurocortisone (0.1 mg/kg/d) is a mineralocorticoid that causes renal salt resorption and thus increases intravascular volume. Beta-blockade (atenolol, 0.5 to 2.0 mg/kg/d) can inhibit the catecholamine surge and help prevent the rebound bradycardia and hypotension. Vagolytic agents (disopyramide 2.5 mg/kg qid) help control hypervagotonia, and the selective serotonin reuptake inhibitors have also been effective in alleviating symptoms. Syncope that occurs during exercise or stress or is associated with a positive family history is a warning sign that a serious underlying dysrhythmia may be present, calling for further investigation.

Judith M. Sondheimer, MD

EVALUATION OF THE CHILD WITH VOMITING

Assessment of the child with recurrent episodes of vomiting should start with a complete history, physical examination, and description of the vomitus (Table 20–1). Emesis of gastric contents is characteristic of gastric outlet obstruction, central nervous system masses or infection, peptic disease, urinary tract infection, otitis or sinusitis, metabolic diseases (especially those causing acidosis), rumination, and psychogenic vomiting. Gastroesophageal (GE) reflux should be suspected in a healthy child with effortless postprandial spitting. An upper gastrointestinal (GI) series is essential to rule out anatomic causes in young infants. A urinalysis and culture will rule out urinary tract infection or urinary obstruction, which may cause vomiting, especially in young infants. Serum electrolytes should be measured as abnormalities of sodium, potassium, magnesium and calcium may also cause vomiting by interfering with normal motor functions of the GI tract. Increased intracranial pressure may cause vomiting. The decision to obtain radiographs and scans of the central nervous system, chest, or sinuses is based on a specific indication from the history or physical examination.

The child who vomits bile-stained material may have small intestinal obstruction and should be examined immediately. Bile staining may be gold or green in color. The history and physical examination are the essential starting points and should include duration of vomiting, the presence of blood in the vomitus, the presence of abdominal pain or distention, the character of the stools, and the presence of fever. Pain localized to the right lower quadrant suggests appendicitis. Midline or diffuse abdominal pain suggests pancreatitis or generalized peritonitis. Abdominal distention suggests intestinal obstruction. Viral and bacterial gastroenteritis are associated with diarrhea and may produce generalized ileus with bilious vomiting. Gallbladder disease is uncommon in childhood but should be suspected in children with a family or personal history of hemolytic disorders, hypercholesterolemia, or primary medical conditions promoting gallstones. The presence of mucus and blood in the stool should arouse suspicion of intestinal intussusception or bacterial or toxic colitis. Three-way radiographs of the abdomen are a first diag-

nostic step in localizing the site of intestinal obstruction.

The evaluation of bloody vomitus should start with confirmation that the material vomited is indeed blood. Numerous causes must be considered, including swallowed maternal blood in newborns, oropharyngeal lesions, nosebleed, peptic disease, bleeding disorders, foreign bodies, and esophageal varices. Mallory–Weiss tear of the mucosa of the GE junction is common after prolonged vomiting. Careful assessment of the cardiovascular stability of the child is essential before extensive evaluation is initiated. Passage of a nasogastric tube will help determine whether bleeding is ongoing. The hematocrit should be measured. If further diagnostic investigation is desired, the most productive test is upper intestinal endoscopy.

GASTROESOPHAGEAL REFLUX

Postprandial regurgitation is the most common symptom of GE reflux in young infants. Regurgitation ranges from effortless spitting to forceful vomiting. Although usually a harmless condition of young infants, severe GE reflux may cause failure to thrive, esophagitis with hematemesis, occult blood loss, anemia, esophageal stricture, and inflammatory esophageal polyps. Aspiration pneumonia, chronic cough, wheezing, and asthma-like attacks are reported. Dysphagia, colic after feedings, and neck contortions (Sandifer syndrome) may occur. Ruminative behavior is sometimes a symptom. Apneic spells in young infants, especially occurring with position change after feeding, may be caused by GE reflux. GE reflux is common in neurologically impaired children. The underlying cause of GE reflux is unknown, but the facilitating mechanism appears to be spontaneous relaxation of the lower esophageal sphincter rather than a chronically weak or immature sphincter.

GE reflux is a clinical diagnosis in thriving infants younger than age 6 months. An upper GI series is important to rule out anatomic causes of vomiting, but is not an accurate test for GE reflux because of the 30% false-positive rate. Prolonged monitoring of esophageal pH is a more sensitive test if the symptoms are not typical. Esophageal intraluminal impedance monitoring is a pH-independent means to detect fluid movement in

Table 20–1. Causes of vomiting and regurgitation.

GASTROINTESTINAL TRACT DISORDERS	
Esophagus	Intestine and colon
Achalasia	Atresia and stenosis
Gastroesophageal reflux (chalasia)	Meconium ileus
Hiatal hernia	Malrotation, volvulus
Esophagitis	Duplication
Atresia with or without fistula	Intussusception
Congenital vascular or mucosal rings, webs	Foreign body
Stenosis	Polyposis
Duplication and diverticulum	Soy or cow's milk protein intolerance
Foreign body	Gluten enteropathy
Periesophageal mass	Food allergy
Stomach	Hirschsprung disease
Hypertrophic pyloric stenosis	Chronic intestinal pseudo-obstruction
Pylorospasm	Appendicitis
Diaphragmatic hernia	Inflammatory bowel disease
Peptic disease and gastritis	Gastroenteritis, infections
Antral web	Other abdominal organs
Duodenum	Hepatitis
Annular pancreas	Gallstones
Duodenitis and ulcer	Pancreatitis
Malrotation	Peritonitis
Mesenteric bands	
Superior mesenteric artery syndrome	
EXTRAGASTROINTESTINAL TRACT DISORDERS	
Sepsis	Adrenal insufficiency
Pneumonia	Renal tubular acidosis
Otitis media	Inborn errors
Urinary tract infection	Urea cycle disorders
Meningitis	Phenylketonuria
Subdural effusion	Maple syrup urine disease
Hydrocephalus	Organic acidemia
Brain tumor	Galactosemia
Reye syndrome	Fructose intolerance
Rumination	Tyrosinosis
Intoxications	Scleroderma
Alcohol	Epidermolysis bullosa
Aspirin	
Acetaminophen	

the esophagus. It may be a more accurate method to detect and describe pathologic reflux once standards have been clarified in children. Esophageal and gastric scintiscanning is sometimes helpful in identifying pulmonary aspiration. Esophagoscopy is not diagnostic, but esophagitis can be identified.

Treatment & Prognosis

In 85% of infants with GE reflux, the condition is self-limited, disappearing between ages 6 and 12 months, coincident with assumption of erect posture and initiation of solid feedings. Regurgitation may be reduced by offering small feedings at frequent intervals or by thickening feedings with rice cereal (2–3 tsp/oz of formula). Prethickened antireflux formulas are available. Histamine (H₂)-receptor antagonists (ranitidine, 5 mg/kg/d in two doses) and proton pump inhibitors (eg, omeprazole, 0.5–1 mg/kg/d in one dose) are effective in controlling esophagitis and often reduce pain secondary to reflux. Prokinetic agents such as metoclopramide (0.1 mg/kg before meals) hasten gastric emptying and improve esophageal motor function, but studies have not supported their efficacy in controlling symptoms.

Antireflux surgery is indicated if reflux causes (1) persistent vomiting with failure to thrive, (2) esophagitis or esophageal stricture, and (3) apneic spells or chronic pulmonary disease unresponsive to 2–3 months of medical therapy. Children older than age 18 months, children with large hiatal hernias, and neurologically handicapped children respond less well to medical therapy.

Rudolph CD et al: Guidelines for evaluation and treatment of gastroesophageal reflux in infants and children: Recommendations of the North American Society for Pediatric Gastroenterology and Nutrition. *J Pediatr Gastroenterol Nutr* 2001;23(Suppl):1.

ACHALASIA OF THE ESOPHAGUS

Esophageal achalasia is characterized by failure of relaxation of the lower esophageal sphincter in response to swallowing and abnormal, nonperistaltic motor activity in the esophageal body.

Clinical Findings

A. SYMPTOMS AND SIGNS

Achalasia is uncommon in children younger than age 5 years. Typical symptoms include retrosternal pain and episodes of food “sticking” in the throat or upper chest. Patients eat slowly and often drink large amounts of fluid with meals. Dysphagia is relieved by repeated forceful swallowing or by vomiting. Familial cases have been described in patients with Allgrove syndrome

(alacrima, adrenal insufficiency, and achalasia) and in patients with familial dysautonomia. Chronic cough, wheezing, recurrent pneumonitis, anemia, and weight loss may occur.

B. IMAGING AND MANOMETRIC STUDIES

The barium esophagogram shows a dilated esophagus with a short, tapered “beak” at the distal end. In infants, esophageal dilation may not be present. Cinefluoroscopy may show very disordered esophageal peristalsis. Esophageal manometry may show high resting pressure in the lower esophageal sphincter, failure of the sphincter to relax with swallowing, and abnormal or absent esophageal peristalsis. The cause is unknown. Decrease in neuronal nitric oxide synthetase (nNOS) in the area of the lower esophageal sphincter causes a local deficiency of nitric oxide, preventing normal sphincter relaxation. It is unclear whether the lack of nNOS is secondary or primary to achalasia. In acquired achalasia associated with Chagas’ disease, nNOS is also reduced, and ganglion cells may be decreased or absent in the muscular esophagus near the lower esophageal sphincter.

Differential Diagnosis

Congenital esophageal stricture, esophageal webs, peptic stricture secondary to chronic reflux, and esophageal masses may mimic esophageal achalasia. Intestinal pseudo-obstruction, multiple endocrine neoplasia IIb, systemic amyloidosis, and postvagotomy syndrome also cause esophageal dysmotility and symptoms similar to achalasia.

Treatment & Prognosis

Pneumatic dilation of the lower esophageal sphincter is of value in most cases and can be repeated if symptoms recur. Botulinum toxin injected into the lower esophageal sphincter may be effective temporarily. More definitive results can be achieved by surgically splitting the lower esophageal sphincter muscle (Heller myotomy), a procedure that can be performed laparoscopically or thoracoscopically. Because of the shorter duration of esophageal obstruction in children, the prognosis for return of some normal esophageal motor function after surgery is better in pediatric patients than in adults.

Hussain SZ et al: A review of achalasia in 33 children. *Dig Dis Sci* 2002;47:2538 [PMID: 12452392].

CAUSTIC BURNS OF THE ESOPHAGUS

Ingestion of caustic solids or liquids (pH > 12.0) may produce esophageal lesions ranging from superficial in-

flammation to coagulative necrosis with ulceration, perforation, and mediastinitis (or peritonitis if the stomach is involved). The severity of the oral or laryngeal lesions after ingestion does not correlate well with the degree of esophageal injury. Esophageal or laryngeal obstruction secondary to edema and exudate formation occurs within 24 hours. Pain may be severe. Strictures of the esophagus may develop quickly, or gradually over several months. Esophageal strictures develop in areas of anatomic narrowing such as the thoracic inlet, the GE junction, and at the point where the left bronchus crosses the esophagus. Stricture occurs only with full-thickness esophageal necrosis. Short circumferential strictures may occur, or the entire esophagus may become twisted and narrowed. Shortening of the esophagus may lead to hiatal hernia.

The lips, mouth, and airway should be carefully examined in any child with suspected alkali ingestion. Drooling is common. Oral lesions are especially common with solid agents. Vomiting should not be induced. Give intravenous corticosteroids (eg, methylprednisolone, 1–2 mg/kg/d) immediately to reduce oral cavity swelling and laryngeal edema. Intravenous fluids may be necessary if dysphagia is present. Esophagoscopy should be done within 24–48 hours after ingestion.

Treatment may be stopped if only first-degree burns are present. Corticosteroids may be beneficial in first- and second-degree burns, but are not likely to prevent stricture formation from third-degree burns. Repeated esophageal dilations may be necessary as a stricture develops but are not performed acutely. When radiographs show erosion into the mediastinum or peritoneum, antibiotics are mandatory. Intraluminal esophageal stenting may be beneficial during early management. Surgical replacement of the esophagus with a segment of colon or with a gastric tube may be necessary if dilation fails to control stricture.

Although other ingestants (eg, bleach, detergents, acids) may cause esophageal irritation, it is rare for any but the strongest acids and detergents to produce full-thickness necrosis and stricture.

Del Rosario JF, Orenstein SR: Common pediatric esophageal disorders. *Gastroenterologist* 1998;6:104.

HIATAL HERNIA

Hiatal hernias are classified as (1) paraesophageal, in which the esophagus and GE junction are normally placed with the gastric cardia herniated beside the esophagus through the diaphragmatic hiatus; or (2) sliding, in which the GE junction and a portion of the proximal stomach are herniated through the esophageal hiatus. Paraesophageal hernia is rare in childhood

and presents with pain, esophageal obstruction, or respiratory compromise. The most common situation in which a paraesophageal hernia occurs is in patients with previous fundoplication. Sliding hernia is common in children. GE reflux may accompany sliding hiatal hernia, although many cause no symptoms. Surgical correction of paraesophageal or hiatal hernia is indicated if symptoms persist in spite of medical treatment.

PYLORIC STENOSIS

The cause of postnatal pyloric circular muscle hypertrophy leading to gastric outlet obstruction is unknown. The incidence is 1–8:1000 births, with a 4:1 male predominance. A positive family history is present in 13% of patients. Recent studies suggest that erythromycin therapy may be associated with development of pyloric stenosis in infants younger than 30 days.

Clinical Findings

A. SYMPTOMS AND SIGNS

Vomiting usually begins between ages 2 and 4 weeks and rapidly becomes projectile after every feeding; vomiting starts at birth in about 10% of cases. Onset of symptoms may be delayed in premature infants. The vomitus is rarely bilious but may be blood-streaked. The infant is hungry and nurses avidly. Constipation, dehydration, weight loss, fretfulness, and finally apathy occur. The upper abdomen may be distended after feeding, and prominent gastric peristaltic waves from left to right may be seen. An olive-sized mass can be felt on deep palpation in the right upper abdomen, especially after the child has vomited.

B. LABORATORY FINDINGS

Hypochloremic alkalosis with potassium depletion occurs. Hemoconcentration is reflected by elevated hemoglobin and hematocrit values. Elevated unconjugated bilirubin occurs in 2–5% of cases.

C. IMAGING

An upper GI series reveals gastric retention of contrast and an elongated narrowed pyloric channel with a double tract of barium. Many normal infants have some delay in gastric emptying during upper GI series due to pylorospasm. This by itself is insufficient to make a diagnosis of pyloric stenosis. The enlarged pyloric muscle causes characteristic semilunar impressions on the gastric antrum. Ultrasonography shows a hypoechoic ring with a hyperdense center. Thickness of circular muscle is greater than 4 mm in pyloric stenosis.

Treatment & Prognosis

Pyloromyotomy is the treatment of choice and consists of incision down to the mucosa along the pyloric length. The procedure can be performed laparoscopically. To prevent complications during surgery, it is imperative first to resolve hydration and electrolyte abnormalities even if it takes 24–48 hours.

The outlook is excellent following surgery. Patients often vomit postoperatively as a consequence of gastritis, esophagitis, or associated GE reflux. The postoperative barium radiograph remains abnormal despite relief of symptoms.

Mahon BE et al: Maternal and infant use of erythromycin and other macrolide antibiotics as risk factors for infantile hypertrophic pyloric stenosis. *J Pediatr* 2001;139:380.

PEPTIC DISEASE

Peptic ulcers occur at any age but are more common between ages 12 and 18 years. Boys are affected more frequently than girls. Most ulcers in childhood are secondary to underlying illness, toxin, or a drug causing breakdown in normal mucosal defense, permitting acid peptic digestion of gastric or duodenal mucosa. Causes include (1) reduced mucosal protective mechanisms (aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs], hypoxia); (2) reduced metabolic activity of the mucosal cell, which allows for diffusion of hydrogen ions into the mucosa (hypoxia, hypotension); (3) increased secretion of acid or pepsin (increased parietal cell mass, increased postprandial secretion of gastrin, increased vagal tone); (4) reflux of bile from duodenum to stomach; and (5) decreased neutralizing activity in duodenal secretions.

A close association exists between *Helicobacter pylori* infection of the gastric antrum and nodular antral gastritis, duodenal ulcer, and gastric ulcer. There is no evidence that *H pylori* infection causes recurrent abdominal pain of childhood or dyspepsia without gastritis. *H pylori* antibody positivity is found in 10–20% of healthy North American children. It tends to increase with age. The prevalence is higher in areas with poor sanitation and contaminated water supply and is higher in families with an antibody-positive member. Diagnosis of *H pylori* infection is made by seeing organisms in gastric antral tissue, testing antral tissue for bacterial urease activity, or using the urease breath test. Serum antibody positivity does not prove active *H pylori* infection.

Clinical Findings

A. SYMPTOMS AND SIGNS

In children younger than age 6 years, vomiting and upper GI bleeding are the most common manifestations of peptic ulcer disease. Older children are more likely to complain of abdominal pain. Acute *H pylori* infection with gastritis is characterized by vomiting and often by hematemesis. Large ulcers in the pyloric channel may cause gastric outlet obstruction. Acute illnesses responsible for secondary ulcers include central nervous system disease, burns, sepsis, and multiorgan system failure. Chronic conditions such as pulmonary insufficiency, Crohn disease, hepatic cirrhosis, and rheumatoid arthritis are associated with peptic disease. Upper GI bleeding requiring transfusion is more commonly seen in secondary ulcers, particularly following ingestion of aspirin, alcohol, and NSAIDs, than in primary ulcer disease. Ulcers may occur throughout the upper GI tract secondary to NSAIDs. The use of specific cyclooxygenase-2 (COX-2) inhibitors (celecoxib [Celebrex], rofecoxib [Vioxx]) instead of the standard NSAIDs and aspirin—which inhibit both COX-1 and COX-2 enzymes—may result in a decrease in NSAID-associated complications. COX-1 regulates the production of thromboxane from arachidonic acid and thus decreases platelet aggregation with a resultant increase in bleeding tendency. COX-2, an inducible enzyme present in many tissues, regulates prostaglandin synthesis. COX-2 inhibition has a purer anti-inflammatory and analgesic effect with a reduced tendency to produce GI complications.

B. IMAGING AND ENDOSCOPY

An upper GI radiograph may show an ulcer crater. Soft signs of peptic disease, such as duodenal spasticity and irregularity, which are suggestive of ulcer in adults, are often seen in healthy children and are not reliable indicators of peptic disease. Upper intestinal endoscopy is the most accurate diagnostic test for peptic disease. It also allows for identification of other causes of peptic symptoms such as esophagitis, eosinophilic enteropathy, and celiac disease.

Treatment

Acid suppression or neutralization is the mainstay of peptic ulcer therapy. Liquid antacids are usually unacceptable to children in the volumes needed to neutralize gastric acid. H₂-receptor antagonists and proton pump inhibitors are more effective and usually produce endoscopic healing in 4–8 weeks. Bland “ulcer diets” are not indicated in children. Foods that cause pain should be avoided. Caffeine should be avoided because it increases

gastric acid secretion. Aspirin and NSAIDs should not be used.

Treatment of the peptic disease associated with *H pylori* infection requires eradication of the organism. The optimal therapeutic regimen is still undetermined. The combination of amoxicillin, metronidazole, and bismuth subsalicylate for 10–14 days and omeprazole and amoxicillin, are both effective. Clarithromycin for 7 days with a proton pump inhibitor for 6 weeks is also effective.

CONGENITAL DIAPHRAGMATIC HERNIA

Diaphragmatic hernia may be secondary to a posterolateral defect in the diaphragm (foramen of Bochdalek) or, in about 5% of cases, to a retrosternal defect (foramen of Morgagni). It represents failure of division of the thoracic and abdominal cavities at the 8th to 10th week of fetal life. All degrees of protrusion of the abdominal viscera through the diaphragmatic opening may occur. Eighty percent of posterolateral defects involve the left diaphragm. In eventration of the diaphragm, a leaf of the diaphragm with hypoplastic muscular elements balloons into the chest and leads to similar but milder symptoms.

Mild to severe respiratory distress is usually present at birth. The abdomen may be scaphoid because of displacement of the viscera. Breath sounds in the affected hemithorax are absent, with displacement of the point of maximal cardiac impulse. Thirty percent of newborn infants with diaphragmatic hernia die, mostly from pulmonary insufficiency. The lung on the affected side and also on the contralateral side may be hypoplastic, with decreased generations of airways, lymphatics, and pulmonary vessels. Pulmonary hypertension is present. Other complications include mediastinal shift with vascular kinking, pulmonary infection, prematurity, cardiac anomalies, and intestinal malrotation. Extracorporeal membrane oxygenation may decrease the early

postoperative mortality rate in patients with poor lung compliance. Inhaled nitric oxide reduces pulmonary vascular hypertension, and it was hoped that its use might improve the outcome in patients with diaphragmatic hernia. Results in controlled trials have thus far been disappointing. Occasionally, a diaphragmatic hernia is first identified in an older infant or child by an incidental radiograph or routine physical examination. These children usually have a more favorable prognosis than diaphragmatic hernias identified at birth.

CONGENITAL DUODENAL OBSTRUCTION

Extrinsic duodenal obstruction is usually due to congenital peritoneal bands associated with intestinal malrotation, annular pancreas, or duodenal duplication. Intrinsic obstruction is a result of stenosis, mucosal diaphragm (so-called wind sock deformity), or duodenal atresia. The duodenal lumen may be obliterated by a membrane or completely interrupted with a fibrous cord between the two segments. Atresia is more often distal than proximal to the ampulla of Vater.

Clinical Findings

A. ATRESIA

A history of polyhydramnios is common. Vomiting (usually bile-stained) and epigastric distention begin within a few hours of birth. Meconium may be passed normally. Duodenal atresia is commonly associated with other congenital anomalies (30%), including esophageal atresia, other intestinal atresias, and cardiac and renal anomalies. Prematurity (25–50%) and Down syndrome (20–30%) are associated conditions. Abdominal radiographs show gaseous distention of the stomach and proximal duodenum (the “double-bubble” radiologic sign). With protracted vomiting, less air may be in the stomach. Absence of gas distal to the obstruction suggests atresia or an extrinsic obstruction severe enough to completely occlude the lumen, whereas air scattered over the lower abdomen may indicate a partial duodenal obstruction. A barium enema may be helpful in determining the presence of malrotation or atresia lower in the GI tract.

B. DUODENAL STENOSIS

Obvious symptoms of duodenal obstruction may be delayed for weeks or years. Although the stenotic area is usually beyond the ampulla of Vater, the vomitus does not always contain bile.

Treatment & Prognosis

Duodenoduodenostomy is performed to bypass stenosis or atresia. Thorough exploration is necessary to ensure

that no additional anomalies are present lower in the GI tract. The mortality rate is significantly increased in infants with prematurity, Down syndrome, and associated congenital anomalies. Duodenal dilation and hypomotility resulting from antenatal obstruction may cause functional obstructive symptoms even after surgical treatment.

CONGENITAL INTESTINAL ATRESIAS & STENOSES

Excluding anal anomalies, intestinal atresia and stenosis account for one third of all cases of neonatal intestinal obstruction. Antenatal ultrasound can identify intestinal atresia in utero, and polyhydramnios occurs in most affected pregnancies. Prematurity and other congenital anomalies may be present. The localization and relative incidence of atresias and stenoses are listed in Table 20–2.

Failure to pass meconium, bile-stained vomiting, and abdominal distention usually begin in the first 48 hours of life. Atresias, stenoses, and obstructing membranes may affect multiple sites. The small intestine may be shortened significantly. Radiographic features include dilated loops of small bowel and absence of colonic gas. Barium enema reveals narrow-caliber microcolon if the atresia is in the lower small bowel. In over 10% of cases of intestinal atresia, the mesentery is absent, and the superior mesenteric artery cannot be identified beyond the origin of the right colic and ileocolic arteries. The ileum coils around one of these two arteries, giving rise to the so-called Christmas tree de-

Table 20–2. Localization and relative frequency of congenital gastrointestinal atresias and stenoses.

	Area Involved	Type of Lesion	Relative Frequency
Pylorus		Atresia; web or diaphragm	1%
Duodenum	80% are distal to the ampulla of Vater	Atresia, stenosis; web or diaphragm	45%
Jejunioileal	Proximal jejunum and distal ileum	Atresia (multiple in 6–29%); stenosis	50%
Colon	Left colon and rectum	Atresia (usually associated with atresias of the small bowel)	5–9%

formity. The tenuous blood supply often compromises surgical anastomoses. The differential diagnosis includes Hirschsprung disease, paralytic ileus secondary to sepsis, gastroenteritis or pneumonia, midgut volvulus, and meconium ileus. Surgery is mandatory. Postoperative complications include short bowel syndrome and hypomotility secondary to antenatal obstruction and proximal bowel dilation.

ANNULAR PANCREAS

Annular pancreas results when rotation and fusion of the dorsal and ventral pancreatic anlagen is incomplete. The condition presents with symptoms of partial or complete duodenal obstruction. Down syndrome and congenital anomalies of the GI tract occur frequently. Polyhydramnios is common. Clinical manifestations can develop late in childhood when the obstruction is less than complete. Treatment consists of duodenoduodenostomy or duodenojejunostomy without operative dissection or division of the pancreatic annulus.

INTESTINAL MALROTATION WITH OR WITHOUT VOLVULUS

The midgut, which extends from the duodenojejunal junction to the mid transverse colon, is supplied by the superior mesenteric artery, which runs in the root of the mesentery. During gestation, the midgut elongates into the umbilical sac, returning to the intra-abdominal position during the tenth week of gestation. The root of the mesentery rotates in a counterclockwise direction during retraction. This causes the colon to cross the abdominal cavity ventrally; the cecum to move from the left to the right lower quadrant, and the duodenum to cross dorsally and become partly retroperitoneal. When this rotation is incomplete, the dorsal fixation of the mesentery is defective and shortened, so that the bowel from the ligament of Treitz to the mid transverse colon may twist, causing a volvulus around the narrow mesenteric root and occluding the superior mesenteric artery.

Clinical Findings

A. SYMPTOMS AND SIGNS

Malrotation accounts for 10% of neonatal intestinal obstructions. Most infants present with recurrent bile-stained vomiting or acute small-bowel obstruction in the first 3 weeks of life. Intrauterine volvulus has been reported. The neonate may present with ascites. Later in life signs of intermittent intestinal obstruction, malabsorption, protein-losing enteropathy, or diarrhea may be present. Associated congenital anomalies, especially cardiac manifestations, occur in over 25% of symptomatic patients.

B. IMAGING

An upper GI series shows the duodenojejunal junction on the right side of the spine along with the jejunal loops. The diagnosis of malrotation can be further confirmed by barium enema, which may demonstrate a mobile cecum located in the midline, right upper quadrant, or left abdomen.

Treatment & Prognosis

The surgical treatment of malrotation is the Ladd procedure, in which the duodenum is mobilized and the short mesenteric root is extended. Midgut volvulus is a surgical emergency. Bowel necrosis results from occlusion of the superior mesenteric artery. When necrosis is extensive, it is recommended that a first operation include only reduction of the volvulus with lysis of mesenteric bands. Resection of necrotic bowel should be delayed if possible until a second-look operation 24–48 hours later can be undertaken in the hope that more bowel can be salvaged. The prognosis is guarded if perforation, peritonitis, or extensive intestinal necrosis is present. Treatment of malrotation discovered in children older than age 12 months is uncertain. Because volvulus can occur at any age, surgical repair is usually recommended, even in asymptomatic children. Laparoscopic repair of malrotation is possible but may be technically difficult and is never performed in the presence of volvulus.

Complications

If bowel necrosis is extensive, the infant with malrotation and volvulus may be left with an intestine of insufficient length to support normal absorption and growth—the so-called short bowel syndrome. Estimates of the small-bowel length of a newborn range from 150 to 300 cm. The commonly accepted definition of neonatal short bowel syndrome is less than 50% of the small intestinal length remaining after resection. In these patients, it is almost certain that intravenous nutrition will be required for months to years to support growth. The most common causes of short bowel syndrome in the newborn vary with the patient referral patterns of the institution, but include necrotizing enterocolitis (45%), intestinal atresias (23%), gastroschisis (15%), volvulus (15%), and, less commonly, entities such as congenital short bowel and extensive Hirschsprung disease. Although the remaining intestine does not experience a compensatory increase in length, if nutrition can be maintained, the enterocytes will proliferate on lengthened villi, and over time, the intestine will elongate in proportion to the child's increasing height and eventually may be sufficient for the patient's nutritional needs. Achieving independence from intra-

venous nutrition becomes less likely when the remaining intestine measures less than 30 cm. The presence of an intact colon is a factor improving the chances of independence from intravenous nutrition. Liver failure, a consequence of intravenous nutrition and recurrent infection, among other causes, is the most common cause of death in patients with short bowel syndrome. The mortality rate among all infants with short bowel syndrome is about 10–15%.

MECKEL DIVERTICULUM & OMPHALOMESENTERIC DUCT REMNANTS

1. Meckel Diverticulum

Meckel diverticulum is the most common of the omphalomesenteric duct remnants. It is usually found on the antimesenteric border of the mid to distal ileum. It is present in 1.5% of the population but rarely causes symptoms. In addition to the ileal mucosa, diverticula may contain gastric, pancreatic, jejunal, or colonic mucosa. Familial cases have been reported. Complications occur three times more frequently in males than in females and in 50–60% of cases within the first 2 years of life. Acid secreted by heterotopic gastric tissue causes ulceration and bleeding from adjacent ileal mucosa.

Clinical Findings

A. SYMPTOMS AND SIGNS

In 40–60% of symptomatic patients, painless passage of maroon or melanotic blood per rectum occurs. Acute bleeding may cause shock. Occult bleeding is less common. Intestinal obstruction occurs in 25% of symptomatic patients as a result of ileocolonic intussusception. Intestinal volvulus may occur around a fibrous remnant of the vitelline duct extending from the tip of the diverticulum to the abdominal wall. In some patients, entrapment of a bowel loop under a band running between the diverticulum and the base of the mesentery occurs. The diverticulum may be trapped in an inguinal hernia (Littre hernia). Diverticulitis occurs in 10–20% of symptomatic patients and is clinically indistinguishable from acute appendicitis. Perforation and general-

ized peritonitis may occur. Chronic recurrent abdominal pain may rarely be the only symptom.

B. IMAGING

Diagnosis of Meckel diverticulum is seldom made on barium radiograph. Radionuclide imaging uses ^{99m}Tc pertechnetate, which is taken up by the heterotopic gastric mucosa in the diverticulum. Stimulation of ^{99m}Tc pertechnetate uptake and retention of radionuclide by the heterotopic gastric mucosa by pentagastrin or cimetidine can reduce the number of false-negative results. Angiography or tagged red cell scan may be useful when bleeding is brisk.

Treatment & Prognosis

Treatment is surgical. At laparoscopy or laparotomy, the ileum proximal and distal to the diverticulum may reveal ulcerations and heterotopic tissue adjacent to the neck of the diverticulum. The prognosis for Meckel diverticulum is good. Marked hemorrhage may occur but is rarely exsanguinating.

2. Other Remnants of the Omphalomesenteric Duct

Fecal discharge from the umbilicus is evidence of a patent omphalomesenteric duct. The duct may be completely closed, causing a fibrous cord joining ileum and umbilicus and potentially the origin of a volvulus. A mucoid umbilical discharge may be indicative of a mucocele, which can protrude through the umbilicus and be mistaken for an umbilical granuloma because it is firm and bright red. In all cases, surgical excision of the omphalomesenteric remnant is indicated.

DUPLICATIONS OF THE GASTROINTESTINAL TRACT

Duplications are congenital anomalies of the GI tract. They are fluid-filled, spherical, or tubular structures found anywhere along the GI tract, most commonly in the ileum. Duplications usually contain fluid and sometimes blood if necrosis has taken place. Most duplications do not communicate with the intestinal lumen but are attached to the mesenteric side of the gut and share a common muscular coat. The epithelial lining of the duplication is usually of the same type as that from which it originates. Some duplications (neuroenteric cysts) are attached to the spinal cord and are associated with hemivertebrae and anterior or posterior spina bifida.

Symptoms of vomiting, abdominal distention, colicky pain, rectal bleeding, partial or total intestinal obstruction, or an abdominal mass may start in infancy.

Diarrhea and malabsorption may result from bacterial overgrowth in communicating duplications. Physical examination reveals a rounded, smooth, movable mass, and radiographic films of the abdomen show a noncalcified mass displacing the intestines or stomach. Scanning with ^{99m}Tc pertechnetate is useful in duplications containing gastric mucosa. Involvement of the terminal small bowel can give rise to an intussusception. Prompt surgical treatment is indicated.

CONGENITAL AGANGLIONIC MEGACOLON (HIRSCHSPRUNG DISEASE)

Hirschsprung disease results from an absence of ganglion cells in the mucosal and muscular layers of the colon. Neural crest cells fail to migrate to the mesodermal layers, possibly mediated by abnormalities in end-organ cell surface receptors or local deficiency of nitric oxide synthesis. The rectum alone (30%) or the rectosigmoid (44%) is usually affected. The entire colon is aganglionic in 8% of patients. Segmental aganglionosis is very rare and may be an acquired lesion. The aganglionic segment is of normal caliber or slightly narrowed, with dilation of the normal colon proximal to the aganglionic segment. The mucosa of the dilated colonic segment may become thin and inflamed (enterocolitis), resulting in diarrhea, bleeding, and protein loss.

A familial pattern has been described, particularly in total colonic aganglionosis. The disease is four times more common in boys than in girls, and 10–15% of patients have Down syndrome. Mutations in the *ret* proto-oncogene are recognized in a significant proportion of familial and sporadic cases.

Clinical Findings

A. SYMPTOMS AND SIGNS

Failure of the newborn to pass meconium—followed by vomiting, abdominal distention, and reluctance to feed—suggests the diagnosis of Hirschsprung disease. Infants of diabetic mothers may demonstrate symptoms of apparent intestinal obstruction and failure to pass meconium at birth. In this setting, small left colon syndrome should be suspected. Meglumine diatrizoate (Gastrografin) enema is both diagnostic and therapeutic as it reveals a meconium plug in the left colon, which is often passed during the diagnostic radiograph. The left colon is narrow but usually functional. In a small proportion of these patients, Hirschsprung disease may later be found. In some patients with Hirschsprung disease, symptoms of distention and vomiting appear later. Bouts of enterocolitis manifested

by fever, explosive diarrhea, and prostration are reported in about 50% of newborns with this disease. These episodes may lead to acute inflammatory and ischemic changes in the colon, with perforation (especially cecal) and sepsis. In later infancy, alternating constipation and diarrhea predominate. The older child is more likely to present with constipation. The stools are foul-smelling and ribbon-like, the abdomen enlarged, and the veins prominent; peristaltic patterns are readily visible, and fecal masses are palpable. Intermittent bouts of intestinal obstruction due to fecal impaction, hypochromic anemia, hypoproteinemia, and failure to thrive are common. Encopresis occurs rarely.

On digital examination, the anal canal and rectum are devoid of fecal material despite fecal impaction obvious on abdominal examination or radiograph. If the aganglionic segment is short, there may be a gush of flatus and stool as the finger is withdrawn.

B. LABORATORY FINDINGS

Ganglion cells are absent in both the submucosal and muscular layers of the involved bowel. Special stains may show nerve trunk hypertrophy and increased acetylcholinesterase activity. Ganglionated bowel above the aganglionic segment may be characterized by abnormal location and proliferation of ganglion cells. This finding—intestinal neuronal dysplasia—is sometimes associated with motor dysfunction that may result in poor motor function of the unresected intestine. A family history of Hirschsprung disease may be present in 5% of patients.

C. IMAGING

Radiographic examination of the abdomen may reveal dilated proximal colon and absence of gas in the pelvic colon. A barium enema using a catheter with the tip inserted barely beyond the anal sphincter usually demonstrates the narrowed segment distally with a sharp transition to proximal dilated colon. A transition zone may not be seen in neonates since the normal proximal bowel has not had time to become dilated. Retention of barium for 24–48 hours is not diagnostic of Hirschsprung disease, because it also occurs in retentive constipation. Retention of barium for 24 hours is a more reliable sign in neonates.

D. SPECIAL EXAMINATIONS

Failure of reflex relaxation of the internal anal sphincter muscle after balloon distention of the rectum occurs in all patients with Hirschsprung disease, regardless of the length of the aganglionic segment. In occasional patients, a nonrelaxing internal anal sphincter is the only abnormality. This condition is often called “ultrashort segment Hirschsprung disease.”

Differential Diagnosis

Hirschsprung disease accounts for 15–20% of cases of neonatal intestinal obstruction. In childhood, this disease must be differentiated from retentive constipation. In older infants and children it can be confused with celiac disease because of the striking abdominal distention and failure to thrive.

Treatment

Treatment is surgical. Initially, diverting colostomy (or ileostomy) is performed proximal to the aganglionic segment. Resection of the aganglionic segment may be postponed until the infant is at least age 6 months. At the time of definitive surgery, the transition zone between ganglionated and nonganglionated bowel is identified. Aganglionic bowel is resected, and a pull-through of ganglionated bowel to the preanal rectal remnant is made. Several surgical techniques, including laparoscopic pull-through, are in use. In children with ultrashort segment disease, an internal anal sphincter myotomy or botulinum toxin injection of the internal anal sphincter may suffice to control symptoms.

Prognosis

Complications following surgery include chronic constipation, fecal incontinence, anastomotic breakdown, or anastomotic stricture. Postoperative obstruction may result from inadvertent retention of a distal aganglionic colon segment or postoperative destruction of ganglion cells secondary to vascular impairment. Neuronal dysplasia of the remaining bowel may result in a pseudo-obstruction syndrome. Enterocolitis occurs postoperatively in 15% of patients.

Kubota M et al: External anal sphincter dysfunction and postoperative bowel habits in patients with Hirschsprung's disease. *J Pediatr Surg* 1997;32:22.

Wartiovaara K et al: Hirschsprung's disease genes and the development of the enteric nervous system. *Ann Med* 1998;30:66.

CHYLOUS ASCITES

In the neonate, chylous ascites may be due to congenital infection or developmental abnormality of the lymphatic system (intestinal lymphangiectasia). If the thoracic duct is involved, chylothorax may be present. Later in life, chylous ascites may result from congenital lymphangiectasia, retroperitoneal or lymphatic tumors, peritoneal bands, abdominal trauma, or infection, or it may occur after cardiac or abdominal surgery. It may be associated with intestinal malrotation.

Clinical Findings

A. SYMPTOMS AND SIGNS

In both congenital and acquired lymphatic obstruction, chylous ascites, diarrhea, and failure to thrive are noted. The abdomen is distended, with a fluid wave and shifting dullness. Unilateral or generalized peripheral edema may be present.

B. LABORATORY FINDINGS

Laboratory findings include hypoalbuminemia, hypogammaglobulinemia, and lymphopenia. Ascitic fluid contains lymphocytes and has the biochemical composition of chyle if the patient has just been fed; otherwise, it is indistinguishable from ascites secondary to cirrhosis.

Differential Diagnosis

Chylous ascites must be differentiated from ascites due to liver failure and, in the older child, from constrictive pericarditis and neoplastic, infectious, or inflammatory diseases causing lymphatic obstruction.

Complications & Sequelae

Chylous ascites from intestinal lymphatic obstruction is associated with fat malabsorption protein loss. Chronic intestinal loss of albumin and γ -globulin may lead to edema and increase the risk of infection. Rapidly accumulating chylous ascites may cause respiratory complications. The primary infections and malignancies causing chylous ascites may be life-threatening.

Treatment & Prognosis

Little can be done to correct congenital abnormalities due to hypoplasia, aplasia, or ectasia of the lymphatics. Treatment is supportive, consisting mainly of a very high protein diet and careful attention to infections. Shunting of peritoneal fluid into the venous system is sometimes effective. A fat-free diet supplemented with medium-chain triglycerides decreases the formation of chylous ascitic fluid. Total parenteral nutrition may be necessary. In the neonate, congenital chylous ascites may spontaneously disappear following one or more paracenteses and a medium-chain triglyceride diet.

Chye JK et al: Neonatal chylosis ascites: Report of 3 cases and review of the literature. *Pediatr Surg Int* 1997;12:296.

CONGENITAL ANORECTAL ANOMALIES

Anorectal anomalies occur once in every 3000–4000 births, and most types are more common

in males. Inspection of the perianal area is an essential part of the newborn physical examination.

Classification & Presentation

A. ANTERIOR DISPLACEMENT OF THE ANUS

This anomaly is more common in girls than boys. It may be associated with a posterior rectal shelf and usually is characterized by constipation and straining with stool. The diagnosis of an anteriorly displaced anus depends on finding the anus located close to the base of the scrotum or vaginal fourchette. If the center of the anus is located less than 33% of the total distance from vaginal fourchette (or base of scrotum) to coccyx, there is a high likelihood of difficulty with defecation.

B. ANAL STENOSIS

In anal stenosis, the anal aperture may be very small and filled with a dot of meconium. Defecation is difficult, and there may be ribbon-like stools, passage of blood and mucus per rectum, fecal impaction, and abdominal distention. This malformation accounts for about 10% of cases of anorectal anomalies. This anomaly may not be apparent at birth and may be discovered on rectal examination of the infant who is straining at stool.

C. IMPERFORATE ANAL MEMBRANE

The infant with an imperforate anal membrane fails to pass meconium, and a greenish bulging membrane is seen in the anal aperture. After excision, bowel and sphincter function are normal.

D. ANAL AGENESIS

In the child with anal agenesis, an anal dimple is present, and stimulation of the perianal area leads to puckering, indicating that the external sphincter is present. If no associated rectoperineal fistula is present, intestinal obstruction occurs. Fistulas may also be vulvar in the female and urethral in the male.

E. ANORECTAL AGENESIS

Anorectal agenesis accounts for 75% of total anorectal anomalies. Fistulas are almost invariably present. In the female, they may be vaginal or may enter a urogenital sinus, which is a common passageway for the urethra and vagina. In the male, fistulas are rectovesical or rectourethral. Associated major congenital malformations are common. Sacral defects and absence of internal and external anal sphincters are common.

Radiologic Findings

Careful radiologic evaluation is indicated immediately so that the anal anomaly and the extent of associated

anomalies of the bowel and the urogenital tract can be identified.

Treatment & Prognosis

Dilation of the anus should be undertaken in cases of anal stenosis. Treatment for imperforate anal membrane consists of excision of the membrane and dilation. Diverting colostomy is necessary in anorectal agenesis. In patients with anal agenesis and a visible perineal fistula of sufficient size to pass meconium, surgery can be deferred. Males without a visible fistula may have a urethral fistula, and diverting colostomy is recommended.

Of the patients with low imperforate anus, 80–90% are continent after surgery; of those with high imperforate anus, only 30% achieve continence. Gracilis muscle transplants may improve continence. Levatorplasty may also be used as a secondary operation following surgery for anorectal agenesis. Antegrade continence enema procedures may allow for continence in children without anal sphincter function by facilitating irrigation of the colon via a cecostomy or appendicostomy.

Endo M et al: Analysis of 1992 patients with anorectal malformations over the past two decades in Japan. *J Pediatr Surg* 1999;34:435.

ACUTE ABDOMEN

Entities causing acute abdomen are shown in Table 20–3. Some of the specific entities are discussed in subsequent sections. Reaching a speedy and accurate diagnosis in the patient with an acute abdomen is critical and requires skill in physical diagnosis, intimate acquaintance with the characteristic symptoms of a large number of conditions, and the judicious selection of laboratory and radiologic tests.

Gauderer MW: Acute abdomen. When to operate immediately and when to observe. *Semin Pediatr Surg* 1997;6:74.

PERITONITIS

Primary bacterial peritonitis accounts for less than 2% of pediatric cases of peritonitis. The most common organisms responsible are *Escherichia coli*, other enteric organisms, hemolytic streptococci, and pneumococci. Primary peritonitis occurs in patients with splenectomy, splenic dysfunction, or ascites (nephrotic syndrome, advanced liver disease, kwashiorkor). It occurs also in infants with pyelonephritis or pneumonia. Secondary peritonitis is associated with peritoneal dialysis, penetrating abdominal trauma, or a ruptured viscus. The organisms associated with secondary peritonitis vary depending on the cause. In association with peri-

toneal dialysis, organisms not commonly pathogenic such as *Staphylococcus epidermidis* and *Candida* may be the cause of secondary peritonitis. Multiple enteric organisms may be isolated after penetrating abdominal injury or bowel perforation. Intra-abdominal abscesses may form in pelvic, subhepatic, or subphrenic areas, but such localization of infection is less common in young infants than in adults.

Symptoms include severe abdominal pain, fever, nausea, and vomiting. Respirations are shallow. The abdomen is tender, rigid, and distended, with involuntary guarding. Bowel sounds may be absent. Diarrhea is fairly common in primary peritonitis and less so in secondary peritonitis.

The leukocyte count is high initially (> 20,000/ μ L), with a predominance of immature forms, and later may fall to neutropenic levels, especially in primary peritonitis. Bacterial peritonitis should be suspected if paracentesis fluid contains more than 500 leukocytes/ μ L or more than 32 mg/dL of lactate; if it has a pH less than 7.34; or if the pH is over 0.1 pH unit less than arterial blood pH. Diagnosis is made by Gram stain and culture, preferably of 5–10 mL of fluid for optimal yield. The blood culture is often positive in primary peritonitis.

Antibiotic treatment and supportive therapy for dehydration, shock, and acidosis are indicated. Surgical treatment of the underlying cause of secondary peritonitis is critical. Removal of infected peritoneal dialysis catheters in patients with secondary peritonitis is sometimes necessary and almost always required if *Candida* infection is present.

ACUTE APPENDICITIS

Acute appendicitis is the most common indication for emergency abdominal surgery in childhood. The frequency increases with age and peaks between 15 and 30 years. Obstruction of the appendix by fecaliths (25%) or parasites is a predisposing factor.

The incidence of perforation is high (40%) in infants and children. To avoid delay in diagnosis, it is important to maintain close communication with parents, perform a thorough physical examination and sequential examinations of the abdomen at frequent intervals over several hours, and interpret correctly the evolving symptoms and signs.

Clinical Findings

A. SYMPTOMS AND SIGNS

The typical child with appendicitis has fever and periumbilical abdominal pain, which then localizes to the right lower quadrant, accompanied by signs of peritoneal irritation. Anorexia, vomiting, constipation, and diarrhea also occur. The clinical picture is often atypical and includes generalized pain and tenderness around the umbilicus without leukocytosis. Rectal examination should always be done and may reveal localized mass or tenderness. Because many conditions give rise to symptoms mimicking appendicitis and because physical findings are often inconclusive, it is important to perform repeated examinations of the abdomen over several hours. In children younger than age 2 years, the

pain of appendicitis is poorly localized, and perforation before surgery is common.

B. LABORATORY FINDINGS

White blood cell counts are seldom higher than 15,000/ μ L. Pyuria, fecal leukocytes, and guaiac-positive stool are occasionally found.

C. IMAGING

A radiopaque fecalith is reportedly present in two thirds of cases of ruptured appendix. A positive diagnosis of nonperforated appendicitis cannot be made by barium enema. In experienced hands, ultrasonography of the acutely inflamed appendix shows a noncompressible, thickened appendix in 93% of cases. A localized fluid collection adjacent to or surrounding the appendix may also be seen. Abdominal computed tomography scan after instillation of rectal contrast with thin cuts in the area of the appendix may be diagnostic. Indium-labeled white blood cell scan may localize to an inflamed appendix. Enlarged mesenteric lymph nodes are a nondiagnostic finding.

Differential Diagnosis

The presence of intrathoracic infection (eg, pneumonia) or urinary tract infection should be kept in mind, along with other medical and surgical conditions leading to acute abdomen (see Table 20–3).

Treatment & Prognosis

Exploratory laparotomy or laparoscopy is indicated whenever the diagnosis of appendicitis cannot be ruled out after a period of close observation. Postoperative antibiotic therapy is reserved for patients with gangrenous or perforated appendix. A single intraoperative dose of cefoxitin or cefotetan is recommended for all patients to prevent postoperative complications. The mortality rate is less than 1% during childhood despite the high incidence of perforation. In uncomplicated nonruptured appendicitis, laparoscopic approach is associated with a shortened hospital stay.

Mason JD: The evaluation of acute abdominal pain in children. *Emerg Med Clin North Am* 1996;14:629.

INTUSSUSCEPTION

Intussusception is the most frequent cause of intestinal obstruction in the first 2 years of life. It is three times more common in males than in females. In most cases (85%) the cause is not apparent, although polyps, Meckel diverticulum, Hensch-Schönlein purpura, lymphoma, lipoma, parasites, foreign bodies, and viral enteritis with hypertrophy of Peyer patches are predisposing factors. Intussusception of the small intestine

occurs in patients with celiac disease and cystic fibrosis—related to the bulk of stool in the terminal ileum. Hensch-Schönlein purpura may also cause isolated small-bowel intussusception. In children older than age 6 years, lymphoma is the most common cause. Intermittent small-bowel intussusception is a rare cause of recurrent abdominal pain.

The usual ileocolic intussusception starts just proximal to the ileocecal valve and extends for varying distances into the colon. Swelling, hemorrhage, incarceration, and necrosis of the intussuscepted bowel may occur. Intestinal perforation and peritonitis occur as a result of impairment of venous return.

Clinical Findings

Characteristically, a thriving infant age 3–12 months develops recurring paroxysms of abdominal pain with screaming and drawing up of the knees. Vomiting and diarrhea occur soon afterward (90% of cases), and bloody bowel movements with mucus appear within the next 12 hours (50%). The child is characteristically lethargic between paroxysms. Prostration and fever supervene. The abdomen is tender and becomes distended. On palpation, a sausage-shaped mass may be found, usually in the upper mid abdomen. An intussusception can persist for several days if obstruction is not complete, and patients may present with separate attacks of enterocolitis. In older children, sudden attacks of abdominal pain may be related to chronic recurrent intussusception with spontaneous reduction. In July 1999, the American Academy of Pediatrics recommended suspending oral rotavirus immunization in the United States because of an increased occurrence of intussusception among young infants in the weeks following oral immunization.

Treatment

A. CONSERVATIVE MEASURES

Barium enema and air enema are both diagnostic and therapeutic. Reduction by barium enema should not be attempted if signs of strangulated bowel, perforation, or severe toxicity are present. Air insufflation of the colon under fluoroscopic guidance is a safe alternative to barium enema with excellent diagnostic sensitivity and specificity without the risk of contaminating the abdominal cavity with barium. Great care must be taken in performing either air or barium enema because ischemic damage to the colon secondary to vascular compromise increases the risk of perforation.

B. SURGICAL MEASURES

In extremely ill patients and in patients who have evidence of bowel perforation or in whom hydrostatic or

pneumatic reduction has been unsuccessful (25%), surgery is required. Surgery has the advantage of identifying any lead point such as a Meckel diverticulum. Surgical reduction of intussusception is associated with a lower recurrence rate than pneumatic reduction.

Prognosis

The prognosis relates directly to the duration of the intussusception before reduction. The mortality rate with treatment is 1–2%. The patient should be observed carefully after hydrostatic or pneumatic reduction because intussusception recurs within 24 hours in 3–4% of patients.

Eshel G et al: Intussusception: A nine year survey. *J Pediatr Gastroenterol Nutr* 1997;24:253.

FOREIGN BODIES IN THE ALIMENTARY TRACT

Most foreign bodies pass through the GI tract without difficulty, although objects longer than 5 cm may have difficulty negotiating the ligament of Treitz. Ingested foreign bodies tend to lodge in areas of natural constriction—valleculae, thoracic inlet, GE junction, pylorus, ligament of Treitz, and ileocecal junction. Foreign bodies lodged in the esophagus for more than 24 hours require removal. Smooth foreign bodies in the stomach, such as buttons or coins, may be watched without attempting removal for up to several months if the child is free of symptoms. Straight pins, screws, and nails generally pass without incident. Removal of open safety pins or wooden toothpicks is recommended. Disk-shaped batteries lodged in the esophagus should be removed immediately. Disk-shaped batteries in the stomach will generally pass uneventfully. The use of balanced electrolyte lavage solutions containing polyethylene glycol may help the passage of small, smooth foreign bodies lodged in the stomach or intestine. Lavage is especially useful in hastening the passage of disk-shaped batteries or ingested tablets that may be toxic. Failure of a smooth foreign body to exit the stomach suggests the possibility of gastric outlet obstruction.

Esophagogastroscopy will permit the removal of most foreign bodies lodged in the esophagus and stomach. A Foley catheter may be used to dislodge smooth, round esophageal foreign bodies in healthy children with no previous esophageal disease. The catheter is introduced into the esophagus, and the balloon at the distal end is inflated below the foreign body. Careful withdrawal of the catheter under fluoroscopic observation will bring the foreign body into the mouth, where it

can be extracted. Only an experienced radiologist should attempt this maneuver.

ANAL FISSURE

Anal fissure is a slit-like tear in the squamous epithelium of the anus, usually secondary to the passage of large, hard fecal masses. Anal stenosis, anal crypt abscess, and trauma can be contributory factors. Sexual abuse must be considered in children with large, irregular, or multiple anal fissures. Anal fissures may be the presenting sign of Crohn disease in older children.

The infant or child with anal fissure typically cries with defecation and will try to hold back stools. Sparse, bright red bleeding is seen on the outside of the stool or on the toilet tissue following defecation. The fissure can often be seen if the patient is examined in a knee-chest position with the buttocks spread apart. When a fissure cannot be identified, it is essential to rule out other causes of rectal bleeding such as juvenile polyp, perianal inflammation (due to group A streptococcal infection), or inflammatory bowel disease. Anal fissures should be treated promptly to break the constipation → fissure → retention → constipation cycle. A stool softener should be given. Anal dilation relieves sphincter spasm. Warm sitz baths after defecation may be helpful. In rare cases, silver nitrate cauterization or surgery is indicated. Anal surgery should be avoided in patients with Crohn disease because of the high risk of recurrence and progression after surgery.

INGUINAL HERNIA

A peritoneal sac precedes the testicle as it descends from the genital ridge to the scrotum. The lower portion of this sac envelops the testis to form the tunica vaginalis, and the remainder normally atrophies by the time of birth. In some cases, peritoneal fluid may become trapped in the tunica vaginalis of the testis (noncommunicating hydrocele). If the processus vaginalis remains open, peritoneal fluid or an abdominal structure may be forced into it (indirect inguinal hernia).

Most inguinal hernias are of the indirect type and occur more frequently (9:1) in boys than in girls. Hernias may be present at birth or may appear at any age thereafter. The incidence in premature male infants is close to 5%. Inguinal hernia is reported in 30% of male infants weighing 1000 g or less.

Clinical Findings

No symptoms are associated with an empty processus vaginalis. In most cases, a hernia is a painless inguinal swelling of variable size. The mother of the infant with an inguinal hernia may be the only person to see the

mass, as it may retract when the infant is active, cold, frightened, or agitated from the physical examination. There may be a history of inguinal fullness associated with coughing or long periods of standing, or there may be a firm, globular, and tender swelling, sometimes associated with vomiting and abdominal distention. In some instances, a herniated loop of intestine may become partially obstructed, leading to pain and partial intestinal obstruction. Rarely, bowel becomes trapped in the hernia sac, and complete intestinal obstruction occurs. Gangrene of the hernia contents or testis may occur. In girls, the ovary may prolapse into the hernia sac. Inspection of the two inguinal areas may reveal a characteristic bulging or mass. Infants should be observed for evidence of swelling after crying, and older children after bearing down. A suggestive history is often the only criterion for diagnosis, along with the "silk glove" feel of the rubbing together of the two walls of the empty hernia sac.

Differential Diagnosis

Inguinal lymph nodes may be mistaken for a hernia. Nodes are usually multiple with more discrete borders. A hydrocele of the cord should transilluminate. An undescended testis is usually mobile in the canal and is associated with absence of the gonad in the scrotum.

Treatment

Manual reduction of incarcerated inguinal hernias can be attempted after the sedated infant is placed in the Trendelenburg position with an ice bag on the affected side. Manual reduction is contraindicated if incarceration has been present for more than 12 hours or if bloody stools are noted. Surgery is usually indicated if a hernia has ever incarcerated. Hydroceles frequently resolve by age 2 years. Controversy remains about exploration of the opposite side. Exploration of the unaffected groin can document the patency of the processus vaginalis, but patency does not always mean that herniation will occur, especially in patients older than age 1 year, in whom the risk of contralateral hernia is about 10%. Incarceration of an inguinal hernia is more likely to occur in boys and in children younger than 10 months of age.

Gahukamble DB, Khamage AS: Early vs delayed repair of reduced incarcerated inguinal hernias in the pediatric population. *J Pediatr Surg* 1996;31:1218 [PMID: 8887087].

Nicholls E: Inguinal scrotal problems in children. *Practitioner* 2003;247:226.

UMBILICAL HERNIA

Umbilical hernias are more common in premature than in full-term infants and more common in black than in

white infants. Small bowel may incarcerate in small-diameter umbilical hernias. Most umbilical hernias regress spontaneously if the fascial defect has a diameter of less than 1 cm. Large defects and smaller hernias persisting after age 4 years should be treated surgically. Reducing the hernia and strapping the skin over the abdominal wall defect does not accelerate the healing process.

TUMORS OF THE GASTROINTESTINAL TRACT

1. Juvenile Polyps

Juvenile polyps are usually pedunculated and solitary. The head of the polyp is composed of hyperplastic glandular and vascular elements, often with cystic transformation. Juvenile polyps are benign, and 80% occur in the rectosigmoid. Their incidence is highest between ages 3 and 5 years, and they are rare before age 1 year and, because of autoamputation, after age 15 years. They are more frequent in boys. The painless passage of small amounts of bright red blood on a normal or constipated stool is the most frequent manifestation. Abdominal pain is rare, but a juvenile polyp can be the lead point for an intussusception. Low-lying polyps may prolapse during defecation.

Rarely, many juvenile polyps may be present in the colon, causing anemia, diarrhea, and protein loss. A few cases of generalized juvenile polyposis involving the stomach, small bowel, and colon have been reported. These cases are associated with a slightly increased risk of cancer.

Colonoscopy is both diagnostic and therapeutic when polyps are suspected. After removal of the polyp by electrocautery, nothing further should be done if histologic findings confirm the diagnosis. There is a slight risk of developing further juvenile polyps.

Other polyposis syndromes are summarized in Table 20-4.

2. Cancers of the Esophagus, Small Intestine, & Colon

Esophageal cancer is rare in childhood. Cysts, leiomyomas, and hamartomas predominate. Caustic injury of the esophagus increases the risk of squamous cell carcinoma as a very long term complication. Chronic peptic esophagitis is associated with Barrett esophagus, a precancerous lesion. Simple GE reflux in infancy without esophagitis is not a risk for cancer of the esophagus.

The most common gastric or small-bowel cancer in children is lymphoma or lymphosarcoma. Intermitting abdominal pain, abdominal mass, intussusception, or a celiac-like picture may be present. Carcinoid tumors are

Table 20–4. Gastrointestinal polyposis syndromes.

	Location	Number	Histology	Extraintestinal Findings	Malignant Potential	Recommended Therapy
Juvenile polyps	Colon	Single (70%) Several (30%)	Hyperplastic, hamartomatous	None	None	Remove polyp for continuous bleeding or prolapse.
Familial juvenile polyposis coli ^a	Colon	More than ten	Hyperplastic with focal adenomatous change	None	10–25%; higher if familial	Remove all polyps. Consider colectomy if very numerous or adenomatous.

^bAutosomal recessive.

usually benign and most often an incidental finding in the appendix following appendectomy. Metastasis is rare. The carcinoid syndrome (flushing, sweating, hypertension, diarrhea and vomiting), associated with serotonin secretion, only occurs with metastatic carcinoid tumors.

Adenocarcinoma of the colon is rare in pediatric patients. The transverse colon and rectosigmoid are the two most commonly affected sites. The low 5-year survival rate relates to the nonspecificity of presenting complaints and the large percentage of undifferentiated types. Children with a family history of colon cancer, chronic ulcerative colitis, or familial polyposis syndromes are at greater risk.

3. Mesenteric Cysts

These rare tumors may be small or large and single or multiloculated. Invariably thin-walled, they contain serous, chylous, or hemorrhagic fluid. They are commonly located in the mesentery of the small intestine but may also be seen in the mesocolon. Most mesenteric cysts cause no symptoms. Traction on the mesentery may lead to colicky abdominal pain, which can be mild and recurrent but may appear acutely with vomiting. Volvulus may occur around a cyst, and hemorrhage into a cyst may be mild or hemodynamically significant. A rounded mass can occasionally be palpated or seen on radiograph to displace adjacent intestine. Abdominal ultrasonography is usually diagnostic. Surgical removal is indicated.

4. Intestinal Hemangioma

Hemangiomas of the bowel may cause acute or chronic blood loss. They may also cause intestinal obstruction via intussusception, local stricture, or intramural hematoma formation. Thrombocytopenia and consumptive coagulopathy are occasional complications. Some lesions are telangiectasias (Rendu–Osler–Weber syndrome), and others are capillary hemangiomas. The largest group are cavernous hemangiomas, which are composed of large, thin-walled vessels arising from the submucosal vascular plexus. They may protrude into the lumen as polypoid lesions or may invade the intestine from mucosa to serosa.

ACUTE INFECTIOUS DIARRHEA (Gastroenteritis)

Viruses are the most common cause of acute gastroenteritis in developing and developed countries. Bacterial and parasitic enteric infections are discussed in Chapters 38 and 39. Of the viral agents causing enteric infection, rotavirus, a 67-nm double-stranded RNA virus

with at least eight serotypic variants, is the most common. As with most viral pathogens, rotavirus affects the small intestine, causing voluminous watery diarrhea without leukocytes or blood. In the United States, rotavirus affects mainly infants between ages 3 and 15 months. Peak incidence in the United States is in the winter months. Sporadic cases occur at other times. The virus is transmitted via the fecal–oral route and survives for hours on hands and for days on environmental fomites.

Diagnosis & Treatment of Rotavirus Infections

The incubation period for rotavirus is 24–48 hours. Vomiting is the first symptom in 80–90% of patients, followed within 24 hours by low-grade fever and voluminous watery diarrhea. Diarrhea usually lasts 4–8 days but may last longer in young infants or immunocompromised patients. The white blood cell count is rarely elevated. The stool sodium level is usually less than 40 mEq/L. Thus, as patients become dehydrated from unreplaced fecal water loss, they may become hypernatremic. The stool does not contain blood or white cells. Metabolic acidosis results from bicarbonate loss in the stool, ketosis from poor intake, and lactic acidemia from hypotension and hypoperfusion.

Replacement of fluid and electrolyte deficits and ongoing losses is critical, especially in small infants. (Oral and intravenous therapy are discussed in Chapter 42.) The use of oral rehydration fluid is appropriate in most cases. The use of clear liquids or hypocaloric (dilute formula) diets for more than 48 hours is not advisable in uncomplicated viral gastroenteritis because starvation depresses digestive function and prolongs diarrhea.

Intestinal lactase levels are reduced during rotavirus infection. Brief use of a lactose-free diet is associated with a shorter period of diarrhea but is not critical to successful recovery in most healthy infants. Reduced fat intake during recovery may reduce nausea and vomiting.

Antidiarrheal medications are ineffective (kaolin–pectin combinations) or even dangerous (loperamide, tincture of opium, diphenoxylate with atropine). Bismuth subsalicylate preparations may reduce stool volume but are not critical to recovery. Oral immunoglobulin or specific antiviral agents have occasionally been useful in limiting duration of disease in immunocompromised patients.

Specific identification of rotavirus is not required in every case, especially in outbreaks. Rotavirus antigens can be identified in stool. False positives (which may actually be nonpathogenic rotavirus) are seen in neonates. Some immunity is imparted by the first episode of rotavirus infection. Serum antibodies are

present, but their role in prevention of subsequent attacks is unclear. Repeat infections occur but are usually less severe. Prevention of rotavirus is mainly by good hygiene and prevention of fecal–oral contamination. In July 1999, the American Academy of Pediatrics recommended suspending the use of oral rotavirus vaccine in the United States despite an approximately 75% protection rate of vaccinated infants because of its association with intussusception in the first 3 weeks following vaccine administration.

Diagnosis & Treatment of Other Viral Infections

Other viral pathogens in stool have been identified by electron microscopy, special viral cultures, or enzyme-linked immunoassays in infants with diarrhea. Depending on the geographic location, enteric adenoviruses (serotypes 40 and 41) or caliciviruses are the next most common viral pathogens in infants. The symptoms of enteric adenovirus infection are similar to those produced from rotavirus, but infection is not seasonal and duration of illness may be longer. The Norwalk agent, a calicivirus, is a small RNA virus that causes chiefly vomiting but also some diarrhea in older children and adults, usually in common source outbreaks (perhaps water-borne). The duration of symptoms is short, usually 24–48 hours. Other potentially pathogenic viruses include astroviruses, corona-like viruses, and other small round viruses. Cytomegalovirus rarely causes diarrhea in immunocompetent children but may cause erosive colitis or enteritis in immunocompromised hosts. Cytomegalovirus enteritis is particularly common after bone marrow transplantation and in late stages of HIV infection.

Cairo JP et al: Etiology of outpatient pediatric nondysenteric diarrhea: A multicenter study in the United States. *Pediatr Infect Dis J* 1999;18:94.

CHRONIC DIARRHEA

It is difficult to define chronic diarrhea because normal bowel habits vary greatly. Some infants normally have 5–8 soft small stools daily. A gradual or sudden increase in the number and volume of stools (> 15 g/kg/d) combined with an increase in fluidity should raise a suspicion that an organic cause of chronic diarrhea is present.

Diarrhea may result from any of the following pathogenetic mechanisms: (1) interruption of normal cell transport processes for water, electrolytes, or nutrients; (2) decrease in the surface area available for absorption, which may be due to shortening of the bowel or mucosal disease; (3) increase in intestinal motility;

(4) increase in unabsorbable osmotically active molecules in the intestinal lumen; (5) increase in intestinal permeability, leading to increased loss of water and electrolytes; and (6) stimulation of enterocyte secretion by toxins or cytokines.

Noninfectious Causes of Diarrhea

A. ANTIBIOTIC THERAPY

Diarrhea is reported in up to 60% of children receiving antibiotics. Eradication of normal gut flora and overgrowth of other organisms may cause diarrhea. Most antibiotic-associated diarrhea is watery in nature, is not associated with systemic symptoms, and decreases when antibiotic therapy is stopped. Pseudomembranous colitis, caused by the toxins produced by *Clostridium difficile*, occurs in 0.2–10% of patients taking antibiotics, especially clindamycin, cephalosporins, and amoxicillin. Patients develop fever, tenesmus, and abdominal pain with diarrhea, which contains leukocytes and sometimes gross blood up to 8 weeks after antibiotic exposure. Treatment with oral metronidazole (30 mg/kg/d) or oral vancomycin (30–50 mg/kg/d) for 7 days is recommended. Vancomycin is many times more expensive than metronidazole and no more efficacious. Relapse occurs after treatment in 10–50% of patients because of exsporation of residual spores in the colon. Retreatment with the same antibiotic regimen is usually effective, but multiple relapses are possible.

B. EXTRAINTestinal INFECTIONS

Infections of the urinary tract and upper respiratory tract (especially otitis media) are at times associated with diarrhea. The mechanism remains obscure. Antibiotic treatment of the primary infection, toxins released by infecting organisms, and local irritation of the rectum (in patients with bladder infection) may play a role.

C. MALNUTRITION

Malnutrition is associated with an increased frequency of enteral infections. Decreased bile acid synthesis, pancreatic enzyme output, and disaccharidase activity; altered motility; and changes in the intestinal flora all may cause diarrhea. Severely malnourished children are at higher risk of enteric infections because of depressed immune functions, both cellular and humoral.

D. DIET

Overfeeding may cause diarrhea, especially in young infants. Relative deficiency of pancreatic amylase in young infants may produce diarrhea after starchy foods. Fruit juices, especially those high in fructose or sorbitol, produce osmotic diarrhea because these osmotically active sugars are poorly absorbed by the immature gut.

Intestinal irritants (spices and foods high in fiber) and histamine-containing or histamine-releasing foods (eg, citrus fruits, tomatoes, certain cheeses, red wines, and scombroid fish) also cause diarrhea.

E. ALLERGIC DIARRHEA

Diarrhea caused by allergy to dietary proteins is a frequently entertained but rarely authenticated diagnostic entity. Protein allergy is more common in infants younger than age 12 months, who may experience mild to severe colitis. A personal or family history of atopy is common in infants with enteric protein allergy. Older children may develop a celiac-like syndrome with flattening of small-bowel villi, steatorrhea, hypoproteinaemia, occult blood loss, and chronic diarrhea. Skin testing is not reliable. Double-blind oral challenge with the suspected food under careful observation is necessary to confirm intestinal protein allergy. Mild diarrhea with blood and mucus may occur in thriving young infants receiving either breast milk or formula. In the breast-fed infant, maternal avoidance of milk protein may be effective in reducing the signs of colitis. Feeding a protein hydrolysate formula may also reduce symptoms. Because allergic colitis in young infants is self-limited, the condition does not absolutely require treatment if the infant is thriving and the colitic symptoms are not severe. Colonoscopy is not required for diagnosis, but rectal biopsies usually show mild lymphonodular hyperplasia, mucosal edema, and slight eosinophilia. In infants, the condition usually disappears after 12 months. Allergies to fish, peanuts, and eggs are more likely to be lifelong. Multiple food allergy (more than three) is rare.

Khan S, Orenstein S: Eosinophilic gastroenteritis: Epidemiology, diagnosis and management. *Paed Drugs* 2002;4:563.

F. CHRONIC NONSPECIFIC DIARRHEA

Chronic nonspecific diarrhea is the most common cause of loose stools in thriving children. The typical patient is a healthy child age 6–20 months who was a colicky baby and who has three to six loose mucoid stools per day during the waking hours. The diarrhea worsens with a low-residue, low-fat, or high-carbohydrate diet and during periods of stress and infection. It clears spontaneously at about age 3½ years (usually coincident with toilet training). No organic disease is discoverable. Possible causes include abnormalities of bile acid absorption in the terminal ileum, incomplete carbohydrate absorption (excessive fruit juice ingestion seems to worsen the condition or in some cases appears to be the primary cause), and abnormal motor function. A high familial incidence of functional bowel disease is observed. Stool tests for blood, white cells, fat, parasites, and bacterial pathogens are negative.

The following measures are helpful: institution of a slightly high-fat (about 40% of total calories), low-carbohydrate, high-fiber diet; avoidance of between-meal snacks; and avoidance of chilled fluids, especially fruit juices. It may be helpful to give loperamide, 0.1–0.2 mg/kg/d in two or three divided doses; cholestyramine, 2–4 g in divided doses; or psyllium agents, 1–2 tsp twice daily.

G. SECRETORY DIARRHEA

Certain malignancies of childhood, including neuroblastoma, ganglioneuroma, metastatic carcinoid, and GI neuroendocrine tumors such as pancreatic VIPoma or gastrinoma, may secrete substances such as gastrin and vasoactive intestinal polypeptide that promote small-intestine secretion of water and electrolytes. These children present with large volume, watery diarrhea that does not cease when they discontinue oral feedings. Fat malabsorption is not characteristic. The serum potassium level is often low because of losses in diarrhea. The hallmark of the diarrhea is that, unlike osmotic and infectious viral diarrheas, the sodium content of the stool water is high, usually between 90 and 140 mEq/L of stool. Other specific signs and symptoms are associated with specific tumors. Neuroblastoma and ganglioneuroma lead to elevations in urinary homovanillic acid and vanillylmandelic acid. Metastatic carcinoid is associated with characteristic flushing and sweating. Gastrinoma may be associated with multiple duodenal ulcers (Zollinger–Ellison syndrome). In all secretory diarrheas, a careful radiologic search for a tumor mass is indicated. Bacterial overgrowth of the small bowel in patients with short bowel, cancer chemotherapy, or anatomic abnormalities may lead to the production of enterotoxins, which can promote a secretory diarrhea without the presence of tumor. Cholera is the best known bacterial secretory diarrhea. Its enterotoxin stimulates cyclic adenosine monophosphate in the enterocyte, which promotes salt and water secretion.

THE MALABSORPTION SYNDROMES

Malabsorption of ingested food has many causes (Table 20–5). Shortening of the small bowel (usually via surgical resection) and mucosal damage (celiac disease) both reduce surface area. Impaired motility of the small intestine may interfere with normal propulsive movements and mixing of food with pancreatic and biliary secretions. Anaerobic bacteria proliferate under these conditions and impair fat absorption by deconjugation of bile acids (intestinal pseudo-obstruction, postoperative blind loop syndrome). Impaired intestinal lymphatic (congenital lymphangiectasis) or venous drainage also causes malabsorption. Diseases reducing pancreatic exocrine function (cystic fibrosis, Shwach-

man syndrome) or the production and flow of biliary secretions cause nutrient malabsorption. Malabsorption of specific nutrients may be genetically determined (disaccharidase deficiency, glucose–galactose malabsorption, and abetalipoproteinemia).

Clinical Findings

GI symptoms such as diarrhea, vomiting, anorexia, abdominal pain, failure to thrive, and abdominal distension are common. Observation of the stools for abnormal color, consistency, bulkiness, odor, mucus, and blood is important. Microscopic examination of stools for neutral fat and fatty acids is helpful because most malabsorption syndromes involve some fat malabsorption. Pancreatic insufficiency is associated with neutral fat in the stool. Fatty acids are the major fatty material found in the stool of patients with mucosal disease (celiac disease) and liver disease.

Quantitative assessment of fat absorption requires measurement of fat excreted in the feces as a proportion of fat intake for a defined period. Excretion of 5% of ingested fat is normal for a child older than age 1 year; 10–15% is normal in a younger infant. Prothrombin time and serum carotene, vitamin E, and vitamin D levels may be depressed by long-standing fat malabsorption. Accurate assessment of protein absorption is difficult and requires isotopic labeling of amino acids. Loss of serum proteins across the intestinal mucosa can be estimated by measurement of fecal α_1 -antitrypsin. Malabsorption of complex carbohydrate is rarely measured. Disaccharide or monosaccharide malabsorption is estimated by reduction in stool pH, increased breath hydrogen after ingestion of carbohydrate, or decreased intestinal mucosal disaccharidase activity.

Other tests that may suggest a specific cause of malabsorption in a child include sweat chloride concentration (cystic fibrosis), intestinal mucosal biopsy (eg, celiac disease, intestinal lymphangiectasia, giardiasis, inflammatory bowel disease), liver and gallbladder function tests, and pancreatic secretion of enzymes after stimulation with secretin and cholecystokinin. Some of the most common disorders associated with malabsorption in pediatric patients are detailed in the following sections.

1. Protein-Losing Enteropathies

Loss of plasma proteins into the GI tract occurs in association with inflammatory conditions of the intestine, intestinal graft-versus-host disease, acute and chronic intestinal infections, venous or lymphatic obstruction or malformations, and malignant infiltration of the intestine or its lymphatics and vasculature.

Clinical Findings

Signs and symptoms are mainly those related to hypoproteinemia, and in some instances to malabsorption. Edema, ascites, poor weight gain, and, depending on the underlying condition, signs of specific vitamin and mineral deficiencies may all be present. Serum albumin and globulins may be decreased. Fecal α_1 -antitrypsin, a marker for protein loss, is elevated (> 3 mg/g dry weight stool; slightly higher in breast-fed infants). Disorders associated with protein-losing enteropathy are listed in Table 20–6.

Differential Diagnosis

Hypoalbuminemia may be due to an increased catabolic rate or may be associated with poor protein intake, impaired hepatic protein synthesis, or congenital malformations of lymphatics outside the GI tract. Proteinuria associated with nephritis and nephrotic syndrome may also cause hypoalbuminemia.

Table 20–6. Disorders associated with protein-losing enteropathy.

Vascular obstruction

- Congestive heart failure
- Constrictive pericarditis
- Atrial septal defect
- Primary myocardial disease
- Increased right atrial pressure^a

Stomach

- Giant hypertrophic gastritis (Ménétrier disease), often secondary to cytomegalovirus infection
- Polyps
- Gastritis secondary to *Helicobacter pylori* infection

Small intestine

- Celiac disease
- Intestinal lymphangiectasia
- Blind loop syndrome
- Abetalipoproteinemia
- Chronic mucosal ischemia (eg, from chronic volvulus or radiation enteritis)
- Allergic enteropathy
- Malrotation
- Inflammatory bowel disease

Colon

- Ulcerative colitis
 - Hirschsprung disease
 - Pseudomembranous colitis
 - Polyposis syndromes
 - Villous adenoma
 - Solitary rectal ulcer
-

^aChildren who undergo Fontan procedure for tricuspid atresia are especially prone.

Treatment

Albumin infusions, diuretics, and a high-protein/low-fat diet may control symptoms. Treatment must be directed toward identifying and treating the underlying cause of GI protein loss if possible.

2. Celiac Disease (Gluten Enteropathy)

Celiac disease results from intestinal sensitivity to the gliadin fraction of gluteins from wheat, rye, barley, and (possibly) oats. Most pediatric cases present during the second year of life, but the age at onset and the severity are both variable. Up-to-date estimates of disease frequency are being revised with the widespread use of sensitive screening tests such as the tissue transglutaminase and endomysial antibodies. Screening with antigliadin antibodies is no longer recommended because of the high frequency of false-positive tests. It is estimated that the frequency of celiac disease in the United States is around 1:300, a figure approaching the high incidence reported in the past from European countries. It is thought that intestinal damage and villous atrophy result from a cell-mediated immune response initiated by exposure to a polypeptide fragment of gliadin, the alcohol-soluble fraction of gluten. Ten percent of first-degree relatives may be affected. The inheritance is probably polygenic, but it might result from a single gene in combination with an environmental precipitant such as intestinal viral infection. The increased incidence of celiac disease in children with type I diabetes mellitus, IgA deficiency, and Down syndrome is consistent with possible immunologic factors in the development of celiac disease. Individuals with HLA-DR4 and perhaps DR3 tissue type are at higher risk.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Diarrhea—Affected children present with digestive disturbances starting at age 6–12 months—the age at which grains are first fed. Initially, the diarrhea may be intermittent; subsequently it is continuous, with bulky, pale, frothy, greasy, foul-smelling stools. During celiac crises, dehydration, shock, and acidosis occur. In cases in which anorexia is severe (about 10%), diarrhea may be absent.

2. Constipation, vomiting, and abdominal pain—This triad of symptoms may occasionally dominate the clinical picture and suggest a diagnosis of intestinal obstruction. Constipation generally results from a combination of anorexia, dehydration, muscle weakness, and bulky stools.

3. Failure to thrive—The onset of diarrhea is usually accompanied by loss of appetite, failure to gain weight, and irritability. Weight loss is most marked in the limbs and buttocks. The abdomen becomes distended secondary to gas and fluid in the intestinal tract. Short stature and delayed puberty are characteristic in older children and may be the only symptoms.

4. Anemia and vitamin deficiencies—Anemia usually responds to iron supplementation and is rarely megaloblastic. Anemia is more likely to be the presenting problem of adult patients with celiac disease. Deficiencies in fat-soluble vitamins are common. Rickets can be seen when growth has not been completely halted by the disease. Osteomalacia is more common, however, and pathologic fractures may occur. Hypoproteinemias secondary to vitamin K malabsorption can cause easy bleeding.

5. Silent celiac disease—Serologic screening among pediatric patients with nonspecific GI complaints, growth failure, conditions linked to celiac disease (type I diabetes, thyroid disease, vitiligo, IgA deficiency, Down syndrome), and family members of celiac patients is widespread. The therapy for a symptom-free child with positive serology is unclear. Intestinal biopsy specimens from children with positive serology are very often abnormal and consistent with celiac disease. In these patients, the prudent response is to recommend a gluten-free diet. In patients with positive serology but normal intestinal biopsies, careful follow-up without diet therapy is the most appropriate current recommendation.

B. LABORATORY FINDINGS

1. Fat content of stools—A 3-day collection of stools usually reveals excessive fecal fat excretion. A normal child will excrete 5–10% of ingested fats. The patient with untreated celiac disease will excrete more than 15% of daily fat intake. Anorexia may be so severe that steatorrhea may not be present in 10–25% of patients until normal intake is established.

2. Impaired carbohydrate absorption—A low oral glucose tolerance curve is seen. Absorption of D-xylose is impaired, with blood levels lower than 20 mg/dL 60 minutes after ingestion.

3. Hypoproteinemia—Hypoalbuminemia can be severe enough to lead to edema. There is evidence of increased protein loss in the gut lumen and poor hepatic synthesis secondary to malnutrition.

C. IMAGING

A small-bowel series shows a malabsorptive pattern characterized by segmentation, clumping of the barium column, and hypersecretion. These changes are nonspe-

cific and can be found in patients with other malabsorption states (see Table 20–5).

D. BIOPSY FINDINGS

Intestinal biopsy is the most reliable test for celiac disease. Under the dissecting microscope, the jejunal mucosa lacks the slender, finger-like projections that characterize normal villi. Under the light microscope, the florid celiac mucosa has shortened or absent villi, lengthened crypts of Lieberkühn, intense plasma cell infiltration of the lamina propria, and numerous intraepithelial lymphocytes.

E. SEROLOGIC TESTS

The false-positive rate for the IgG anti gliadin antibody is 10% among healthy individuals. The false-positive rate for IgA anti gliadin antibodies is lower. Endomysial or tissue transglutaminase antibody assays have greater than 95% sensitivity and slightly less specificity for the diagnosis. Because both of these antibodies are of the IgA class, screening for them in a patient who is IgA-deficient may yield a falsely negative result. The best available serologic screening test, therefore, is a quantitative IgA level with a transglutaminase antibody assay.

Differential Diagnosis

The differential diagnosis includes disorders that cause malabsorption. Strict adherence to two diagnostic criteria is essential—the characteristic small-bowel microscopic changes and clinical improvement on a gluten-free diet. Repeated mucosal biopsies to prove histologic recovery on gluten-free diet and relapse on gluten challenge are not critical to the diagnosis in typical patients.

Treatment

A. DIET

Treatment consists of dietary gluten restriction for life. All sources of wheat, rye, and barley must be eliminated during the initial treatment. Some patients may be able to tolerate oats in the diet, but this should be tested only after recovery has occurred. Lactose is poorly tolerated in the acute stage because extensive mucosal damage causes secondary disaccharidase deficiency. Normal amounts of fat are advisable. Supplemental calories, vitamins, and minerals are indicated in the acute phase. Clinical improvement is usually evident within a week, and histologic repair is complete after 3–12 months. Tissue transglutaminase titers may decrease on a gluten-free diet, but usually do not disappear.

B. CORTICOSTEROIDS

Corticosteroids can hasten clinical improvement but are indicated only in very ill patients with signs and symp-

toms of celiac crisis (profound anorexia, malnutrition, diarrhea, edema, abdominal distention, and hypokalemia).

Prognosis

Clinical and histologic recovery is the rule but may be slow. Malignant lymphoma of the small bowel occurs with increased frequency in adults with long-standing disease. Dietary treatment seems to decrease the risk of this complication.

Cerf-Bensussan N: Coeliac disease: An update on facts and questions based on the 10th international symposium on coeliac disease. *J Pediatr Gastroenterol Nutr* 2003;37:412.

Fasano A et al: The prevalence of celiac disease in at risk and not at risk groups in the United States: A multicenter study. *Arch Int Med* 2003;163:286.

3. Disaccharidase Deficiency

Starches and the disaccharides sucrose and lactose are quantitatively the most important dietary carbohydrates. The dietary disaccharides and oligosaccharide products of pancreatic amylase action on starch require hydrolysis by intestinal brush border disaccharidases before significant absorption can take place. Disaccharidase levels are higher in the jejunum and in the proximal ileum than in the distal ileum and duodenum.

In primary disaccharidase deficiency, a single enzyme is affected, disaccharide intolerance is likely to persist, intestinal histologic findings are normal, and a family history is common.

Because disaccharidases are located on the luminal surface of intestinal enterocytes, they are susceptible to mucosal damage. Many conditions cause secondary disaccharidase deficiency, with lactase usually most severely depressed. Histologic examination reveals changes compatible with the underlying disorder.

Clinical Findings

A. PRIMARY (CONGENITAL)

1. Lactase deficiency—Congenital lactase deficiency is rare. The ingestion of lactose results in diarrhea, gassy distention, and abdominal pain. The stools are frothy, with a pH below 4.5, owing to the presence of organic acids. Vomiting is common. Severe malnutrition may occur. Reducing substances are present in the stools. The blood glucose fails to rise more than 10 mg/dL after ingestion of 1 g/kg of lactose. A rise in breath hydrogen after oral administration of lactose (from hydrogen produced by normal colon flora during fermentation of unabsorbed carbohydrate) is also diagnostic.

Patients respond to a reduction of dietary lactose. Tolerance for dietary starch and sucrose is normal. Lac-

tase extracted from *Aspergillus* and *Kluyvera* species (Lactaid) can be added to milk products or taken with meals to enhance lactose hydrolysis. Although all human racial groups are lactase-sufficient at birth, genetically determined lactase deficiency may develop after age 3 to 5 years in some groups. Certain racial groups are more likely to develop lactase deficiency. In Asians, genetic lactase deficiency develops in virtually 100% of individuals. In Africans, the incidence in most tribes is over 80%. In African Americans, the incidence is about 70%, and among European Americans, the incidence is between 30 and 60%.

2. Sucrase and isomaltase deficiency—This is a combined defect that is inherited as an autosomal recessive trait. Ten percent of Alaskan natives are affected. The condition is rare in other groups. Abdominal distention, failure to thrive, and chronic diarrhea may be the presenting symptoms. Distaste for and avoidance of sucrose occurs even in young infants.

Because sucrose is not a reducing sugar, tests for reducing substances in the stool may be negative unless the sucrose in the stool is hydrolyzed by colon bacteria. A sucrose tolerance test (1 g/kg) is likely to be abnormal. Breath hydrogen will be elevated after ingestion of sucrose. Treatment of primary sucrase–isomaltase deficiency requires elimination of most sucrose. A preparation of yeast sucrase taken with meals is also effective.

B. SECONDARY (ACQUIRED)

1. Secondary lactase deficiency—The most common mechanism by which secondary lactase deficiency occurs is small intestinal injury due to viral infection. This condition is usually self-limited, lasting days or, at most, weeks after recovery from infection. Celiac disease, giardiasis, malnutrition, abetalipoproteinemia, immunoglobulin deficiencies, and intestinal mucosal injury secondary to radiation and cancer chemotherapy all can decrease intestinal lactase activity.

2. Secondary sucrase deficiency—Intestinal mucosal damage tends to lower the levels of all disaccharidases. Signs of sucrose intolerance are usually masked by the more striking symptoms of lactose intolerance. Infectious diarrhea is the most common cause of secondary sucrose intolerance.

Prognosis

Primary disaccharidase deficiency is a lifelong defect. However, in both lactase and sucrase deficiencies, tolerance for the disaccharide may increase with age. The prognosis in the secondary or acquired forms of disaccharidase deficiency depends on the underlying illness.

Baudon JJ et al: Sucrase-isomaltase deficiency: Changing pattern over 2 decades. *J Pediatr Gastroenterol Nutr* 1996;22:284 [PMID: 8708882].

Treem WR et al: Saccharosidase therapy for congenital sucrase isomaltase deficiency. *J Pediatr Gastroenterol Nutr* 1999;28:137.

4. Glucose–Galactose Malabsorption

Glucose–galactose malabsorption is a rare disorder in which the sodium–glucose transport protein is defective. The gene has been localized to the long arm of chromosome 22. Transport of glucose in the intestinal epithelium and renal tubular epithelium is severely impaired. Diarrhea begins with the first feedings, accompanied by reducing sugar in the stool and acidosis. Small-bowel histologic findings are normal. Glycosuria and aminoaciduria may occur. The glucose tolerance test is flat. Fructose is well tolerated. The diarrhea subsides promptly on withdrawal of glucose and galactose from the diet. The acquired form of glucose–galactose malabsorption occurs mainly in infants younger than age 6 months, usually following acute viral or bacterial enteritis.

In the congenital disease, exclusion of glucose and galactose from the diet is mandatory. A satisfactory formula is one with a carbohydrate-free base plus added fructose. The prognosis is good if the disease is diagnosed early, because tolerance for glucose and galactose improves with age. In secondary monosaccharide intolerance, prolonged parenteral nutrition may be required until intestinal transport mechanisms for monosaccharides return.

Wright EM: Glucose–galactose malabsorption. *Am J Physiol* 1998;275:G879.

5. Intestinal Lymphangiectasia

This form of protein-losing enteropathy results from a congenital ectasia of the bowel lymphatic system, often associated with abnormalities of the lymphatics in the extremities. Obstruction of lymphatic drainage of the intestine leads to rupture of the intestinal lacteals with leakage of lymph into the lumen of the bowel. Fat loss may be significant and lead to steatorrhea. Chronic loss of lymphocytes and immunoglobulins increases the susceptibility to infections.

Clinical Findings

Peripheral edema, diarrhea, abdominal distention, lymphedematous extremities, chylous effusions, and repeated infections are common. Laboratory findings are low serum albumin, decreased immunoglobulin levels, lymphocytopenia, and anemia. Fecal fat loss is in-

creased. Serum calcium and magnesium are frequently depressed as these cations are lost in complex with unabsorbed fatty acids. Lymphocytes may be seen in large numbers on a stool smear. Fecal α_1 -antitrypsin is elevated. Radiographic studies reveal an edematous small-bowel mucosal pattern, and biopsy reveals dilated lacteals in the villi and lamina propria. If only the lymphatics of the deeper layers of bowel or intestinal mesenterics are involved, laparotomy may be necessary to establish the diagnosis.

Differential Diagnosis

Other causes of protein-losing enteropathy must be considered, although an associated lymphedematous extremity strongly favors this diagnosis.

Treatment & Prognosis

A very high protein diet (up to 6–7 g/kg/d may be needed) enriched with medium-chain triglycerides as a fat source may allow for adequate nutrition and growth in patients with intestinal mucosal lymphangiectasia. Vitamin and calcium supplements should be given. Antibiotics are used for specific infections. Total parenteral nutrition is helpful on a temporary basis. Surgery is needed when the lesion is localized to a small area of the bowel or in cases of constrictive pericarditis or obstructing tumors. Intravenous albumin and immune globulin may also be used to control symptoms. The prognosis is not favorable, although remission may occur with age. Malignant degeneration of the abnormal lymphatics may occur, and intestinal lymphoma of the B-cell type may be a long-term complication of intestinal lymphangiectasia.

6. Cow's Milk Protein Intolerance

Milk protein intolerance is more common in males than females and in young infants with a family history of atopy. The estimated prevalence is 0.5–1%. Colic, vomiting, and diarrhea are the major symptoms. Stools often contain blood and mucus. Sigmoidoscopic examination reveals a superficial colitis, often with edema, a mild eosinophilic infiltrate, and lymphonodular hyperplasia. Pneumatosis intestinalis may be present on radiograph. Viral gastroenteritis sometimes precedes the onset of symptoms. Less commonly, milk protein may induce eosinophilic gastroenteritis with protein-losing enteropathy, hypoalbuminemia, and hypogammaglobulinemia. A celiac-like syndrome with villous atrophy, malabsorption, hypoalbuminemia, occult blood in the stool, and anemia can occur in older children. IgE-mediated anaphylactic shock is a rare but potentially life-threatening manifestation of milk protein sensitivity in

infancy. If the symptoms suggest an anaphylactic response to milk or any other protein, food challenge should be performed only in a setting in which resuscitation can be carried out.

Infants who are solely breast-fed can also develop blood-streaked stools and a sigmoidoscopic picture similar to that of formula-fed infants with milk protein sensitivity. Tiny amounts of intact allergen passed in breast milk may be the cause, but other environmental allergens may play a role. Elimination of whole milk from the mother's diet sometimes resolves bloody diarrhea. A switch to a protein hydrolysate formula almost always results in improvement. Because the blood loss and diarrhea in these breast-fed infants are rarely severe, it is not essential that breast feeding be stopped. If symptoms are severe or prolonged, however, a trial of semielemental formula is recommended. The colitic pattern of milk protein sensitivity and colitis in breast-fed infants usually clears spontaneously by age 6–12 months.

Early reports that patients with milk protein allergy have a 30% incidence of sensitivity to soy protein, with similar symptoms, have not been uniformly confirmed.

7. Immunologic Deficiency States with Diarrhea or Malabsorption

Diarrhea is common in immune deficiency states, but the cause is often obscure. Between 50% and 60% of patients with idiopathic acquired hypogammaglobulinemia have steatorrhea and intestinal villous atrophy. Lymphonodular hyperplasia is a common feature in this group of patients. Patients with congenital or Bruton-type agammaglobulinemia usually have diarrhea and abnormal intestinal morphology. Patients with isolated IgA deficiency may also present with chronic diarrhea, a celiac-like picture, lymphoid nodular hyperplasia, and giardiasis. Patients with isolated cellular immunity defects, combined cellular and humoral immune incompetence, and HIV infection may have severe chronic diarrhea leading to malnutrition. The cause of diarrhea may be common bacterial, viral, fungal, or parasitic pathogens, organisms usually considered nonpathogenic (*Blastocystis hominis*, *Candida*); or unusual organisms (cytomegalovirus, *Cryptosporidium*, *Isospora belli*, *Mycobacterium* species, microsporidia, and algal organisms such as cyanobacteria). Often the cause is not found. The incidence of disaccharidase deficiency is high. Chronic granulomatous disease may be associated with intestinal symptoms suggestive of chronic inflammatory bowel disease. A rectal biopsy may reveal the presence of typical macrophages.

Treatment must be directed toward correction of the immunologic defect. Specific treatments are available or are being developed for many of the unusual

pathogens causing diarrhea in the immunocompromised host. Thus a vigorous diagnostic search for specific pathogens is warranted in these individuals.

8. Pancreatic Insufficiency

The most common cause of pancreatic exocrine insufficiency in childhood is cystic fibrosis. Decreased secretion of pancreatic digestive enzymes is caused by obstruction of the exocrine ducts by thick secretions, which destroys the pancreatic acinar cells. This destruction of acinar cells may occur antenatally. Some genotypes of cystic fibrosis have partially or completely preserved pancreatic exocrine function. Other conditions associated with exocrine pancreatic insufficiency are discussed in Chapter 21.

9. Other Genetic Disorders Causing Malabsorption

A. A- β -LIPOPROTEINEMIA

A- β -lipoproteinemia is an autosomal recessive condition in which the secretion of triglyceride-rich lipoproteins from the small intestine (chylomicrons) and liver (very low density lipoproteins) is abnormal. Profound steatosis of the intestinal enterocytes (and hepatocytes) and severe fat malabsorption occur. Deficiencies of fat-soluble vitamins occur over time, with neurologic complications of vitamin E deficiency and atypical retinitis pigmentosa. The serum cholesterol level is very low, and the red cell membrane lipids are abnormal, causing acanthosis of the red blood cells, which sometimes is the key to diagnosing this rare condition.

B. ACRODERMATITIS ENTEROPATHICA

Acrodermatitis enteropathica is an autosomal recessive condition in which the intestine has a selective inability to absorb zinc. The condition usually becomes clinically obvious at the time of weaning and is characterized by rash on the extremities, rashes around the body orifices, eczema, profound failure to thrive, steatorrhea, diarrhea, and immune deficiency. Zinc supplementation by mouth results in rapid improvement.

CONSTIPATION

Constipation is passage of bulky or hard stool at infrequent intervals. Retention of feces in the rectum results in encopresis (involuntary fecal leakage) in 60% of affected children. Organic causes of constipation are listed in Table 20-7. Most constipation in childhood is not organic but a result of voluntary or involuntary retentive behavior.

Clinical Findings

Normal infants younger than age 3 months often grunt, strain, and turn red in the face while passing normal stools. This pattern may be viewed erroneously as constipation. Failure to appreciate this normal developmental pattern may lead to the unwise use of laxatives or enemas. Infants and children may gradually develop the ability to ignore the sensation of rectal fullness and retain stool. Many factors promote and reinforce this behavior, which results in impaction of the rectum and overflow incontinence or encopresis: painful defecation; skeletal muscle weakness; psychological issues, especially those relating to control and authority; modesty and distaste for school bathrooms; medications; and others listed in Table 20-7. The dilated rectum becomes less sensitive to dilation, thus perpetuating the problem, regardless of the original cause. As many as 1-2% of healthy primary school children have retentive constipation. The ratio of males to females is 4:1 in some studies.

Differential Diagnosis

Features distinguishing retentive constipation from Hirschsprung disease are summarized in Table 20-8.

Treatment of Retentive Constipation

Increased intake of fluids and high-residue foods such as bran, whole wheat, fruits, and vegetables may be sufficient therapy in mild constipation. It should be noted that the most likely response to increased fluid intake in normally hydrated children is increased urination with little effect on defecation. The use of a barley malt extract (Maltsupex), 1-2 tsp added to feedings two or three times daily, is helpful in small infants. Polyethylene glycol solution is also a safe softener. Stool softeners such as dioctyl sodium sulfosuccinate, 5-10 mg/kg/d, prevent excessive drying of the stool but are less effective in children with voluntary stool retention. Cathartics such as standardized extract of senna fruit (eg, Senokot syrup), 1-2 tsp twice daily depending on age, can be used for short periods.

If encopresis is present, treatment should start with relieving fecal impaction. An effective stool softener should be given as a maintenance medication in doses sufficient to induce two or three loose bowel movements per day. Such medications include mineral oil (2-3 mL/kg/d), a nonabsorbable osmotic agent such as polyethylene glycol (Miralax, 1 gm/kg/d), and milk of magnesia (1-2 mL/kg/d). After several weeks to months of regular loose stools, the stool softener can be tapered and stopped. Mineral oil should not be given to non-ambulatory infants, physically handicapped or bed-

Table 20–7. Causes of constipation.

Functional or retentive causes	Abnormalities of myenteric ganglion cells
Dietary causes	Hirschsprung disease
Undernutrition, dehydration	Waardenburg syndrome
Excessive milk intake	Multiple endocrine neoplasia IIa
Lack of bulk	Hypo- and hyperganglionosis
Cathartic abuse	von Recklinghausen disease
Drugs	Multiple endocrine neoplasia IIb
Narcotics	Intestinal neuronal dysplasia
Antihistamines	Chronic intestinal pseudo-obstruction
Some antidepressants	Spinal cord defects
Vincristine	Metabolic and endocrine disorders
Structural defects of gastrointestinal tract	Hypothyroidism
Anus and rectum	Hyperparathyroidism
Fissure, hemorrhoids, abscess	Renal tubular acidosis
Anterior ectopic anus	Diabetes insipidus (dehydration)
Anal and rectal stenosis	Vitamin D intoxication (hypercalcemia)
Presacral teratoma	Idiopathic hypercalcemia
Small bowel and colon	Skeletal muscle weakness or incoordination
Tumor, stricture	Cerebral palsy
Chronic volvulus	Muscular dystrophy/myotonia
Intussusception	
Smooth muscle diseases	
Scleroderma and dermatomyositis	
Systemic lupus erythematosus	
Chronic intestinal pseudo-obstruction

Table 20–8. Differentiation of retentive constipation and Hirschsprung disease.

	Retentive Constipation	Hirschsprung Disease
Onset	2–3 years	At birth
Abdominal distention	Rare	Present
Nutrition and growth	Normal	Poor
Soiling and retentive behavior	Intermittent or constant	Rare
Rectal examination	Ampulla full	Ampulla may be empty
Rectal biopsy	Ganglion cells present	Ganglion cells absent
Rectal manometry	Normal rectoanal reflex	Nonrelaxation of internal anal sphincter after rectal distention
Barium enema	Distended rectum	Narrow distal segment with proximal megacolon

bound children, or those with GE reflux. Aspiration of mineral oil may cause lipid pneumonia. Stool softeners help extinguish the tendency to retention and the establishment of a regular bowel habit by making defecation quick, easy, and painless. Recurrence of encopresis should be treated promptly with a short course of stimulant laxatives or an enema. A multiple vitamin is recommended while mineral oil is administered. Psychiatric consultation may be indicated for patients with resistant symptoms or severe emotional disturbances.

GASTROINTESTINAL BLEEDING

Vomiting blood and passing blood per rectum are alarming symptoms. The history is the key to identifying the bleeding source. The following questions should be answered:

1. Is it really blood, and is it coming from the GI tract? A number of substances simulate hematochezia or melena (Table 20–9). The presence of blood should be confirmed chemically. Genitourinary problems, coughing, tonsillitis, lost teeth, or epistaxis may cause what appears to be

GI bleeding. An adolescent female may be experiencing menarche.

- How much blood is there and what is its color and character? Table 20–10 lists the sites of GI bleeding predicted by the appearance of the blood in the stools. Table 20–11 lists causes of rectal bleeding.
- Is the child acutely or chronically ill? The physical examination should be thorough. Physical signs of portal hypertension, intestinal obstruction, or coagulopathy are particularly important. The nasal passages should be inspected for signs of recent epistaxis, the vagina for menstrual blood, and the anus for fissures and hemorrhoids.

A systolic blood pressure below 100 mm Hg and a pulse rate above 100 beats/min in an older child suggest at least a 20% reduction of blood volume. A pulse rate increase of 20 beats/min or a drop in systolic blood pressure greater than

10 mm Hg when the patient sits up is also a sensitive index of significant volume depletion.

- Is the child still bleeding? Serial determinations of vital signs and hematocrit are essential to assess ongoing bleeding. Detection of blood in the gastric aspirate confirms a bleeding site proximal to the ligament of Treitz. However, its absence does not rule out the duodenum as the source. Testing the stool for occult blood will help in monitoring ongoing loss of blood.

Treatment

If a hemorrhagic diathesis is detected, vitamin K should be given intravenously. In severe bleeding, the need for volume replacement is monitored by measurement of central venous pressure. In less severe cases, vital signs, serial hematocrits, and gastric aspirates are sufficient.

If blood is recovered from the gastric aspirate, gastric lavage with saline should be performed until only a blood-tinged return is obtained. Upper intestinal endoscopy is then done to identify the bleeding site. Endoscopy is superior to barium contrast study for lesions such as esophageal varices, stress ulcers, and gastritis. Colonoscopy may identify the source of bright red rectal bleeding but should be performed as an emergency only if the extent of bleeding warrants immediate inves-

Table 20–10. Identification of sites of gastrointestinal bleeding.

Symptom or Sign	Location of Bleeding Lesion
Effortless bright red blood from the mouth	Nasopharyngeal or oral lesions; tonsillitis; esophageal varices; lacerations of esophageal or gastric mucosa (Mallory–Weiss syndrome)
Vomiting of bright red blood or of “coffee grounds”	Lesion proximal to ligament of Treitz
Melanotic stool	Lesion proximal to ligament of Treitz, upper small bowel. Blood loss in excess of 50–100 mL/24 h
Bright red or dark red blood in stools	Lesion in the ileum or colon. (Massive upper gastrointestinal bleeding may also be associated with bright red blood in stool.)
Streak of blood on outside of a stool	Lesion in the rectal ampulla or anal canal

Table 20–11. Differential diagnosis of gastrointestinal bleeding in children by symptoms and age at presentation.

	Infant	Child (2–12 years)	Adolescent (> 12 years)
Hematemesis	Swallowed maternal blood Peptic esophagitis Mallory–Weiss tear Gastritis Gastric ulcer Duodenal ulcer Gastric, duodenal ulcer	Epistaxis Peptic esophagitis Caustic ingestion Mallory–Weiss tear Esophageal varices Gastritis Gastric ulcer Duodenal ulcer Hereditary hemorrhagic telangiectasia Hemobilia Henoch–Schönlein purpura	Esophageal ulcer Peptic esophagitis Mallory–Weiss tear Esophageal varices Gastric ulcer Gastritis Duodenal ulcer Hereditary hemorrhagic telangiectasia Hemobilia Henoch–Schönlein purpura
Painless melena	Duodenal ulcer Duodenal duplication Ileal duplication Meckel diverticulum Gastric heterotopia ^a	Duodenal ulcer Duodenal duplication Ileal duplication Meckel diverticulum Gastric heterotopia ^a	Duodenal ulcer Leiomyoma (sarcoma)
Melena with pain, obstruction, peritonitis, perforation	Necrotizing enterocolitis Intussusception ^b Volvulus	Duodenal ulcer Hemobilia ^c Intussusception ^b Volvulus Ileal ulcer (isolated)	Duodenal ulcer Hemobilia ^c Crohn disease (ileal ulcer)
Hematochezia with diarrhea, crampy abdominal pain	Infectious colitis Pseudomembranous colitis Eosinophilic colitis Hirschsprung enterocolitis	Infectious colitis Pseudomembranous colitis Granulomatous (Crohn) colitis Hemolytic–uremic syndrome Henoch–Schönlein purpura Lymphonodular hyperplasia	Infectious colitis Pseudomembranous colitis Granulomatous (Crohn) colitis Hemolytic–uremic syndrome Henoch–Schönlein purpura
Hematochezia without diarrhea or abdominal pain	Anal fissure Eosinophilic colitis Rectal gastric mucosa heterotopia Colonic hemangiomas	Anal fissure Solitary rectal ulcer Juvenile polyp Lymphonodular hyperplasia	Anal fissure Hemorrhoid Solitary rectal ulcer Colonic arteriovenous malformation

^aEctopic gastric tissue in jejunum or ileum without Meckel diverticulum.

^bClassically, “currant jelly” stool.

^cHemobilia often accompanied by vomiting, right upper quadrant pain.

tigation and if plain abdominal radiographs show no signs of intestinal obstruction. Colonoscopy on an unprepped colon is often inadequate for making a diagnosis.

Small- or large-bowel lesions that bleed briskly (> 0.5 mL/min) may be localized by angiography or radionuclide scanning following injection of labeled red cells.

Persistent vascular bleeding (varices, vascular anomalies) may be relieved temporarily using intravenous vasopressin, 20 units/1.73 m² over a 20-minute period, or

intravenous octreotide, 25–30 μg/m²/h (preferable because of fewer adverse effects). Sustained infusion of octreotide may be used for up to 48 hours if needed. Bleeding from esophageal varices may be stopped by temporary compression with a Sengstaken–Blakemore tube. Sclerotherapy or banding of bleeding varices is the treatment of choice.

If gastric decompression, acid suppressive therapy, and transfusion are ineffective in stopping ulcer bleeding, laser therapy, local injection of epinephrine, electrocautery, or emergency surgery may be necessary.

Fox VL: Gastrointestinal bleeding in infants and children. *Gastrointest Clin North Am* 2000;29:37.

RECURRENT ABDOMINAL PAIN

About 10% of healthy school children between ages 5 and 15 years will at some time experience recurrent episodes of abdominal pain severe enough to interfere with normal activities. An organic cause can be found in fewer than 10% of patients.

Clinical Findings

A. SYMPTOMS AND SIGNS

Attacks of abdominal pain are characteristically of variable duration and intensity. It is not rare for the child or parent to report that the pain is constant, all day every day. Although the pain is usually located in the periumbilical area, location far from the umbilicus does not rule out recurrent abdominal pain. Pain may occur both day and night. Weight loss is rare. Pain may be associated with dramatic reactions—frantic crying, clutching the abdomen, doubling over. Parents may be alarmed, and children are often taken to emergency departments, where the evaluation is negative for an abdominal crisis. School attendance may suffer, and enjoyable family events may be disrupted. The pain may be associated with pallor, nausea, vomiting, and slight temperature elevation.

The pain usually bears little relationship to bowel habits and physical activity. However, some patients have a constellation of symptoms strongly suggesting irritable bowel syndrome—bloating, postprandial pain, lower abdominal discomfort, and erratic stool habits with a sensation of obstipation or incomplete evacuation of stool. A precipitating or stressful situation in the child's life at the time the pains began can sometimes be elicited. School phobia may be a precipitant. A history of functional GI complaints is often found in family members.

A thorough physical examination is essential and usually normal. Complaints of abdominal tenderness elicited during palpation sometimes seem out of proportion to visible signs of distress.

B. LABORATORY FINDINGS

Complete blood count, sedimentation rate, urinalysis, and stool test for occult blood usually suffice. In the adolescent female patient, ultrasound of the abdomen may be helpful to detect gallbladder or ovarian pathology. If the pain is atypical, further testing suggested by symptoms and family history should be done.

Differential Diagnosis

Abdominal pain secondary to disorders of the urinary tract and extra-abdominal sources are listed in Table

20–3. Pinworms, mesenteric lymphadenitis, and chronic appendicitis are improbable causes of recurrent abdominal pain. Lactose intolerance usually causes abdominal distention, gas, and diarrhea with milk ingestion. At times, however, abdominal discomfort may be the only symptom. Abdominal migraine and abdominal epilepsy are rare conditions with an episodic character often associated with vomiting. The incidence of peptic gastritis, esophagitis, duodenitis, and ulcer disease is probably underappreciated. Upper intestinal endoscopy may be useful.

Treatment & Prognosis

Treatment consists of reassurance based on a thorough physical appraisal and a sympathetic, age-appropriate explanation of the nature of functional pain. The concept of “visceral hyperalgesia” or increased pain signaling from physiologic stimuli such as gas, acid secretion, or stool is one that parents can understand and helps them to respond appropriately to the child's complaints. Reassurance without education is rarely helpful. Regular activity should be resumed, especially school attendance. Therapy for emotional problems is sometimes required, but drugs should be avoided. In older patients, and in those with what appears to be visceral hyperalgesia, amitriptyline in low doses may occasionally be helpful. Antispasmodic medications are rarely helpful and should be reserved for patients with more typical irritable bowel complaints.

INFLAMMATORY BOWEL DISEASE

Crohn disease and ulcerative colitis are the two major idiopathic inflammatory bowel diseases of children. They share many features resulting from bowel inflammation, such as diarrhea, pain, fever, and blood loss, but they differ in important aspects, such as distribution of disease, histologic findings, incidence and type of extraintestinal symptoms, response to medications and surgery, and prognosis. A comparison of these two conditions is shown in Table 20–12. The cause is unknown but is probably a result of inappropriate activation of the mucosal immune system fueled by the presence of normal luminal flora. The aberrant response appears to be facilitated by defects in the barrier function of the intestinal epithelium as well. The single

Table 20–12. Features of Crohn’s disease and ulcerative colitis.

	Crohn’s Disease	Ulcerative Colitis
Age at onset	10–20 years	10–20 years
Incidence	4–6 per 100,000	3–15 per 100,000
Area of bowel affected	Oropharynx, esophagus, and stomach, rare; small bowel only, 25–30%; colon and anus only, 25%; ileocolitis, 40%; diffuse disease, 5%	Total colon, 90%; proctitis, 10%
Distribution	Segmental; disease-free skip areas common	Continuous; distal to proximal
Pathology	Full-thickness, acute, and chronic inflammation; noncaseating granulomas (50%), extraintestinal fistulas, abscesses, stricture, and fibrosis may be present	Superficial, acute inflammation of mucosa with microscopic crypt abscess
Radiographic findings	Segmental lesions; thickened, circular folds, cobblestone appearance of bowel wall secondary to longitudinal ulcers and transverse fissures; fixation and separation of loops; narrowed lumen; “string sign”; fistulas	Superficial colitis; loss of haustra; shortened colon and pseudopolyps (islands of normal tissue surrounded by denuded mucosa) are late findings
Intestinal symptoms	Abdominal pain, diarrhea (usually loose with blood if colon involved), perianal disease, enteroenteric or enterocutaneous fistula, abscess, anorexia	Abdominal pain, bloody diarrhea, urgency, and tenesmus
Extraintestinal symptoms		
Arthritis/arthralgia	15%	9%
Fever	40–50%	40–50%
Stomatitis	9%	2%
Weight loss	90% (mean 5.7 kg)	68% (mean 4.1 kg)
Delayed growth and sexual development	30%	5–10%
Uveitis, conjunctivitis	15% (in Crohn colitis)	4%
Sclerosing cholangitis	—	4%
Renal stones	6% (oxalate)	6% (urate)
Pyoderma gangrenosum	1–3%	5%
Erythema nodosum	8–15%	4%
Laboratory findings	High erythrocyte sedimentation rate; microcytic anemia; low serum iron and total iron-binding capacity; increased fecal protein loss; low serum albumin; antineutrophil cytoplasmic antibodies present in 10–20%; <i>Saccharomyces cerevisiae</i> antibodies positive in 60%.	High erythrocyte sedimentation rate; microcytic anemia, high white blood cell count with left shift; antineutrophil cytoplasmic antibodies present in 80%

Reproduced, with permission, from Kirschner BS: Inflammatory bowel disease in children. *Pediatr Clin North Am* 1988;35:189.

greatest risk factor for inflammatory bowel disease is a positive family history (found in 15–30% of inflammatory bowel disease patients). Monozygotic twins have a 37% concordance for Crohn disease and a 10% concordance for ulcerative colitis. Recent genetic studies have identified an inflammatory bowel disease susceptibility gene on chromosome 16 (*CARD15*), the product of which is involved in the activation of the nuclear factor NFκB and also in the responsiveness to bacterial lipopolysaccharides. More genetic loci are being identified, giving some hope that basic immune mechanisms of Crohn disease and perhaps ulcerative colitis will be soon discovered. There is no indication that emotional factors are a primary cause of these diseases.

Diagnostic Testing

A. CROHN DISEASE

Because Crohn disease can occur at any location in the GI tract from the mouth to the anus, a complete evaluation is required. Upper and lower endoscopy allows investigation of mouth, esophagus, duodenum, colon, and terminal ileum. Biopsy specimens from all these areas may reveal the typical histologic findings. Barium radiograph of the small intestine is still the best way to look for small-bowel disease, but capsule video endoscopy may soon be a more uniformly available means to study the small intestine. Computed tomographic scan and magnetic resonance imaging of the small bowel can show mucosal and mural edema but are not specific enough to confirm a diagnosis. Serum antibodies to *Saccharomyces cerevisiae* are present in 40–60% of patients with Crohn disease. This may be helpful for screening if positive, but it is not sensitive or specific enough to be diagnostic. Fecal calprotectin is a neutrophil-associated protein, which, when elevated in stool, suggests the presence of an inflammatory process. It may be more useful for monitoring therapy in established Crohn disease than for diagnosis.

B. ULCERATIVE COLITIS

Colonoscopy with mucosal biopsy is the best diagnostic test for ulcerative colitis. Nearly pathognomonic signs may be seen on barium enema, but the test is being replaced in most instances by colonoscopy. The perinuclear neutrophil cytoplasmic antigen is positive in 60–70% of patients with ulcerative colitis. Fecal calprotectin is high in patients with active disease.

C. INDETERMINATE COLITIS

This poorly defined entity is a diagnostic challenge and is generally a diagnosis of exclusion in patients in whom colonoscopic biopsy specimens do not seem typical of ulcerative colitis or Crohn disease. More experience is needed to determine whether this is indeed a separate

disease. These patients may have superficial Crohn colitis or may have ulcerative colitis with relative rectal sparing. The same group of medications are used for its treatment.

Differential Diagnosis

A. CROHN DISEASE

When extraintestinal symptoms predominate, Crohn disease can be mistaken for rheumatoid arthritis, systemic lupus erythematosus, or hypopituitarism. Frequently, the acute onset of ileocolitis is mistaken for acute appendicitis. Symptoms sometimes suggest celiac disease, peptic ulcer, intestinal obstruction, intestinal lymphoma, anorexia nervosa, or growth failure from endocrine causes.

B. ULCERATIVE COLITIS

In the acute stage, bacterial pathogens and toxins causing colitis must be ruled out. These include *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, *Entamoeba histolytica*, enteroinvasive *Escherichia coli* (*E coli* 0157), *Aeromonas hydrophila*, and *Clostridium difficile*. Mild ulcerative colitis sometimes mimics irritable bowel symptoms. Crohn disease of the colon is an important differential possibility.

Complications (See Table 20–12.)

A. CROHN DISEASE

Intestinal obstruction, fistula, and abscess formation are common. Perforation and hemorrhage are rare. Malnutrition is caused by anorexia and compounded by malabsorption, protein-losing enteropathy, disaccharidase deficiency, and diarrhea induced by bile salts. Systemic complications include perianal disease, pyoderma gangrenosum, arthritis, amyloidosis, and growth retardation. The risk of colon cancer is increased in patients with Crohn colitis, although not to the extent seen in ulcerative colitis.

B. ULCERATIVE COLITIS

Arthritis, uveitis, pyoderma gangrenosum, and malnutrition all occur. Growth failure and delayed puberty are less common than in Crohn disease. Liver disease (chronic active hepatitis, sclerosing cholangitis) is more common. In patients with pancolitis, carcinoma of the colon occurs with an incidence of 1–2% per year after the first 10 years of disease. Cancer risk is a function of disease duration and not age at onset. The mortality rate from colon cancer is high because the usual signs (occult blood in stool, pain, and abnormal radiologic findings) are not specific and may be ignored in a patient with colitis. Routine cancer screening via colonoscopy, with multiple biopsies and evaluation of

specimens by histology for metaplasia and by flow cytometry for aneuploidy, is recommended in pediatric patients after 10 years of pancolitis. Dysplasia that persists in absence of inflammation is an indication for colectomy, as is aneuploidy in multiple biopsies.

Treatment

A. MEDICAL TREATMENT

Medical treatment for Crohn disease and ulcerative colitis is similar and includes anti-inflammatory, antidiarrheal, and antibiotic medication. No medical therapy has proved uniformly effective.

1. Diet—A high-protein, high-carbohydrate diet with normal amounts of fat is recommended. Decreased amounts of fiber may help decrease symptoms in those with colitis or with partial intestinal obstruction. Lactose is poorly tolerated when disease is active. The main concern should be ensuring adequate caloric intake. Restrictive or bland diets are counterproductive because they usually result in poor intake. Vitamin and iron supplements are recommended. Zinc levels are often low in patients with Crohn disease and should be supplemented. Supplemental calories in the form of liquid diets are well tolerated. Total parenteral nutrition for periods of 4–6 weeks may induce remission of symptoms and stimulate linear growth and sexual development. Enteral administration of low-residue or elemental liquid diets is widely used outside of the United States to induce remission in patients with Crohn disease. It is less effective in ulcerative colitis. Home programs of both enteral and parenteral nutritional support have been especially effective in patients with intractable symptoms or growth failure.

2. Nonabsorbable salicylate derivatives—Sulfasalazine is effective in mild cases of ulcerative colitis and perhaps in cases of Crohn disease of the colon. It prevents relapse of ulcerative colitis once remission is induced. The drug is not absorbed in the small intestine. It is hydrolyzed by colon flora into sulfapyridine and 5-aminosalicylate. The sulfonamide moiety is probably inactive but is responsible for the allergic side effects of the drug. The salicylate moiety probably has local anti-inflammatory activity in the colon. Side effects are common, including skin rash, nausea, headache, and abdominal pain. More rarely, serum sickness, hemolytic anemia, aplastic anemia, and pancreatitis occur. Response to therapy may be slow. Sulfasalazine inhibits folic acid absorption, and supplemental folic acid is required.

The recommended dosage is 2–3 g/d in three divided doses for children over age 10 years or 50 mg/kg/d for younger children. Half of this dosage is used as a maintenance medication for well-controlled ulcerative coli-

tis. Salicylate polymers for both oral and rectal use (ol-salazine, mesalamine) are available. A variety of pH-sensitive tablet coatings and microencapsulation allow release of these products at specific locations in the GI tract, thereby improving their efficacy. They are no more effective than sulfasalazine but can be tolerated by sulfonamide-sensitive patients and have fewer side effects.

3. Corticosteroids—With more severe inflammatory bowel disease, corticosteroids are used. Methylprednisolone, 2 mg/kg/d, or hydrocortisone, 10 mg/kg/d, may be given intravenously when disease is severe. Prednisone, 1–2 mg/kg/d orally in two or three divided doses, is given for 6–8 weeks, followed by a gradual tapering. Alternate-day steroids are associated with fewer side effects as the dosage of drug is tapered. There is no evidence that corticosteroids prevent relapses. Prednisone is often given in conjunction with sulfasalazine. The patient's varicella immunity should be confirmed by history or antibody screen and the parents counseled appropriately as to risk and therapy after varicella exposure. Serum titers against *E histolytica* and stool examination for amebic parasites must be checked before starting therapy with corticosteroids, because amebic colitis may become generalized with steroid therapy. Hydrocortisone in the form of enema or foam can be instilled into the rectum in patients with tenesmus or ulcerative proctitis. Budesonide, which has "one pass metabolism" in the liver, is available in both oral and rectal preparations. These preparations are most useful for treatment of rectal disease (enemas and suppositories) and right-sided colon disease (oral) and in appropriate doses have fewer corticoid side effects.

4. Azathioprine—Azathioprine (Imuran), 1–2 mg/kg/d orally, or 6-mercaptopurine can be used when a high maintenance dose of corticosteroids is necessary to keep the inflammatory bowel disease under control (especially in Crohn disease). The optimal dose of 6-mercaptopurine depends on the patient's ability to metabolize the compound. Positive results of this therapy may be delayed weeks to months. Side effects include pancreatitis, hepatotoxicity, and bone marrow suppression. Metabolites of azathioprine should be monitored to avoid over- and underdosing in patients with variable metabolizing capacity. Genetic testing is available to identify individuals with diminished ability to metabolize azathioprine.

5. Metronidazole—This drug is used in treating Crohn disease in patients with perianal disease. Disease tends to recur when the drug is discontinued. It may also be effective in treating Crohn disease of the colon. The dosage of metronidazole is 15–30 mg/kg/d in three divided doses. Peripheral neuropathy may be a side ef-

fect with prolonged use. Ciprofloxacin may have similar therapeutic effects.

6. Cyclosporine—This powerful immunosuppressant is effective in severe, steroid-resistant ulcerative colitis, but because of side effects and rapid relapse after discontinuation, it is usually used to buy time in severely affected patients for whom surgical treatment is planned but who are too ill to tolerate surgery immediately.

7. Methotrexate—There has been recent encouraging experience with both oral and subcutaneous methotrexate in treating Crohn disease. Liver toxicity is a risk with prolonged use.

8. Anticytokines—Tumor necrosis factor alpha (TNF- α) is a proinflammatory cytokine produced in monocytes, macrophages, and activated T cells, which among other functions stimulates the production of proinflammatory cytokines such as interleukins IL-1, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor. TNF- α levels are increased in intestinal mucosa of Crohn disease patients. Administration of a chimeric human-mouse antibody to TNF- α (infliximab) has been effective in the treatment of Crohn disease, especially in patients with resistant perianal disease. Relapse is common within 3 months of first treatment, and most patients require repeated intravenous infusions of the medication at intervals ranging from 4 to 12 weeks in order to remain in remission. Anaphylactic reactions to this medication have been reported, and infusions should be carried out in a setting where emergency resuscitation is available. Humanizing the antibody and the concomitant use of azathioprine seem to decrease the incidence of severe allergic reactions. Treatment with the anti-inflammatory cytokine IL-10 is in the developmental stage for patients with Crohn disease. Anticytokine therapy is less effective in ulcerative colitis.

9. Thalidomide—Thalidomide has been used in patients with inflammatory bowel disease, especially those with oral and vaginal ulcers secondary to Crohn disease. The mechanism of its therapeutic action may be via its prevention of TNF secretion or its antiangiogenic activity. This medication must be used under strict supervision in postpubescent female patients because of the risk of teratogenesis.

B. SURGICAL TREATMENT

1. Crohn disease—Crohn disease is not cured by surgery. However, 70% of patients eventually require surgery to relieve obstruction, drain abscess, relieve intractable symptoms, or encourage growth and sexual maturation. Newer treatment may decrease this figure. The relapse rate 6 years after surgery is 60%. Recurrence usually occurs at the site of anastomosis, most

likely within 2 years. The rate of recurrence may be less in disease limited to the colon. Surgery performed to correct growth retardation must be performed before puberty.

2. Ulcerative colitis—Surgery is curative and is recommended for those with uncontrolled hemorrhage, toxic megacolon, unrelenting pain and diarrhea, growth failure, high-grade mucosal dysplasia, or malignant tumors. There are now several surgical approaches (ileoanal anastomosis, Koch-type continent ileostomy) that allow a near-normal lifestyle after colectomy. Liver disease associated with ulcerative colitis (sclerosing cholangitis) is not improved by colectomy.

Prognosis

A. CROHN DISEASE

Although the mortality rate is low (2% in the first 7 years), morbidity is high. The disease is progressive in most cases. Over 50% of patients experience symptoms that affect the quality of life. About 20% have severe disabling disease, and 20% have so few symptoms that they describe themselves as healthy.

B. ULCERATIVE COLITIS

The prognosis is good. About 5% of patients present with toxic megacolon—massive colonic dilation secondary to full-thickness enterocolitis accompanied by shock and fever—and require immediate colectomy. Seventy-five percent have a relapsing and remitting course. Between 25% and 40% require colectomy—especially those with pancolitis, anemia, and hypoalbuminemia at the time of presentation.

LIVER

PROLONGED NEONATAL CHOLESTATIC JAUNDICE

The main clinical features of disorders causing prolonged neonatal cholestasis are (1) elevated serum conjugated bilirubin fraction (> 2 mg/dL or $> 20\%$ of total bilirubin), (2) elevated serum bile acids (> 10 μ mol/L), (3) variably acholic stools, (4) dark urine, and (5) hepatomegaly.

Prolonged neonatal cholestasis (conditions with decreased bile flow) has intrahepatic and extrahepatic causes. Specific clinical clues (Table 21–1) distinguish these two major categories of jaundice in 85% of cases. Histologic examination of tissue obtained by percutaneous liver biopsy increases the accuracy of differentiation to 95% (Table 21–2).

INTRAHEPATIC CHOLESTASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Elevated total and conjugated bilirubin.
- Hepatomegaly and dark urine.
- Patency of extrahepatic biliary tree.

General Considerations

Intrahepatic cholestasis is characterized by hepatocyte dysfunction and patency of the extrahepatic biliary system. A specific cause can be identified in about 25% of cases. Patency of the extrahepatic biliary tract is suggested by pigmented stools and lack of bile duct proliferation on liver biopsy. It can be confirmed least invasively by hepatobiliary scintigraphy using technetium-99m (^{99m}Tc)-diethyliminodiacetic acid (diethyl-IDA [DIDA]). Radioactivity in the bowel within 4–24 hours is evidence of bile duct patency. Finding

bilirubin in duodenal aspirates also confirms patency. Patency can also be determined by cholangiography carried out intraoperatively, percutaneously by transhepatic cholecystography, or endoscopic retrograde cholangiopancreatography (ERCP) using a pediatric-size side-viewing endoscope.

1. Perinatal or Neonatal Hepatitis Resulting from Infection

This diagnosis is considered in infants with jaundice, hepatomegaly, vomiting, lethargy, fever, and petechiae. It is important to identify perinatally acquired viral, bacterial, or protozoal infections (Table 21–3). Infection may occur transplacentally, by ascent through the cervix into amniotic fluid, from swallowed contaminated fluids (maternal blood, urine) during delivery, from blood transfusions administered in the early neonatal period, or from breast milk or environmental sources. Infectious agents associated with neonatal intrahepatic cholestasis include herpes simplex virus (HSV), varicella virus, enteroviruses (coxsackievirus and echovirus), cytomegalovirus (CMV), rubella virus, adenovirus, parvovirus, human herpesvirus (HHV) type 6, hepatitis B virus (HBV), human immunodeficiency virus (HIV), *Treponema pallidum*, and *Toxoplasma gondii*. Although hepatitis C may be transmitted vertically, it rarely causes neonatal cholestasis. The degree of liver cell injury caused by these agents is variable, ranging from massive hepatic necrosis (herpes simplex, enteroviruses) to focal necrosis and mild inflammation (CMV, HBV). Serum bilirubin, bile acids, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase are elevated. The infant is jaundiced and generally appears ill.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical symptoms usually appear in the first 2 weeks of life but may appear as late as age 2–3 months. Jaundice may be noted in the first 24 hours or may develop later. Loss of appetite, poor sucking reflex, lethargy, and vomiting are frequent. Stools may be normal to pale in color but are seldom acholic. Dark urine stains the diaper. Hepatomegaly is present, and the liver has a uni-

Table 21–1. Characteristic clinical features of intrahepatic and extrahepatic neonatal cholestasis.

Intrahepatic	Extrahepatic
Preterm infant, small for gestational age, appears ill; hepatosplenomegaly, other organ or system involvement; incomplete cholestasis (stools with some color); associated cause identified (infections, metabolic, familial, etc)	Full-term infant, seems well; hepatomegaly (firm to hard); complete cholestasis (acholic stools); polysplenia syndrome, equal right and left hepatic lobes

form firm consistency. Splenomegaly is variably present. Macular, papular, vesicular, or petechial rashes may occur. In less severe cases, failure to thrive may be the major complaint. Unusual presentations include liver failure, hypoproteinemia, anasarca (nonhemolytic hydrops), and hemorrhagic disease of the newborn.

B. DIAGNOSTIC STUDIES

Neutropenia, thrombocytopenia, and signs of mild hemolysis are common. Mixed hyperbilirubinemia, elevated aminotransferases with near-normal alkaline phosphatase, prolongation of clotting studies, mild acidosis, and elevated cord serum IgM suggest congenital infection. Nasopharyngeal washings and urine, stool, and cerebrospinal fluid (CSF) should be cultured for virus. Specific IgM antibody and nucleic acid tests may be useful, as are long-bone radiographs to determine the presence of “celery stalking” in the metaphyseal regions of the humeri, femurs, and tibias. When indicated, computed tomography (CT) and magnetic reso-

Table 21–2. Characteristic histologic features of intrahepatic and extrahepatic neonatal cholestasis.

	Intrahepatic	Extrahepatic
Giant cells	+++	+
Lobules	Disarray	Normal
Portal reaction	Inflammation/ minimal fibrosis	Fibrosis
Neoductular proliferation	Rare	Marked
Other	Steatosis, extramedullary hematopoiesis	Portal bile duct plugging, bile lakes

nance imaging scans can identify intracranial calcifications (especially CMV and toxoplasmosis). Hepatobiliary scintigraphy shows decreased hepatic clearance of the circulating isotope with excretion into the gut. Careful ophthalmologic examination may be useful for diagnosis of HSV, CMV, toxoplasmosis, and rubella.

A percutaneous liver biopsy is useful in distinguishing intrahepatic from extrahepatic cholestasis, but may not identify a specific infectious agent (see Table 21–2). However, typical inclusions of CMV in hepatocytes or bile duct epithelial cells, the presence of intranuclear acidophilic inclusions of herpes simplex, or positive immunohistochemical stains for several viruses can be diagnostic. Variable degrees of lobular disarray characterized by focal necrosis, multinucleated giant-cell transformation, and ballooned pale hepatocytes with loss of cord-like arrangement of liver cells are usual. Intrahepatocytic and canalicular cholestasis may be prominent. Portal changes are not striking, but modest neoductular proliferation and mild fibrosis may occur. Viral cultures or polymerase chain reaction (PCR) testing of biopsy material may be helpful.

Differential Diagnosis

Great care must be taken to distinguish infectious causes of intrahepatic cholestasis from genetic or metabolic disorders because the clinical presentations are similar. Galactosemia, congenital fructose intolerance, and tyrosinemia must be investigated promptly, because specific dietary therapy is available. α_1 -Antitrypsin deficiency, cystic fibrosis, and neonatal iron storage disease must also be considered. Specific physical features may be helpful when considering Alagille or Zellweger syndrome. Idiopathic neonatal hepatitis may be indistinguishable from infectious causes.

Patients with intrahepatic cholestasis frequently appear ill, whereas infants with extrahepatic cholestasis do not appear ill, have stools that are usually completely acholic, and have an enlarged, firm liver. Histologic findings are shown in Table 21–2.

Treatment

Most forms of viral neonatal hepatitis are treated symptomatically. However, infections with HSV, varicella, CMV, parvovirus, adenovirus, and toxoplasmosis have specific treatments. Fluids and adequate calories are encouraged. Intravenous dextrose is needed if feedings are not well tolerated. The consequences of cholestasis are treated as indicated (Table 21–4). Vitamin K orally or by injection and vitamins D and E orally should be provided. Cholagogues (cholestyramine or ursodeoxycholic acid [UDCA]) are used if cholestasis persists. Corticosteroids are contraindicated. Penicillin for sus-

Table 21–3. Infectious causes of neonatal hepatitis.

Infectious Agent	Diagnostic Tests	Specimens	Treatment
Cytomegalovirus	Culture and PCR, liver histology, IgM/ ^a IgG	Urine, blood, liver	?Ganciclovir (Foscarnet) ^b
Herpes simplex	PCR and culture, liver histology, Ag (skin)	Liver, blood, eye, throat, rectal, CSF, skin	Acyclovir
Rubella	Culture, IgM/ ^a IgG	Liver, blood, urine	Supportive
Varicella	Culture, PCR, Ag (skin)	Skin, blood, CSF, liver	Acyclovir (Foscarnet) ^b
Parvovirus	Serum IgM/ ^a IgG, PCR	Blood	Supportive, ? IVIG
Enteroviruses	Culture and PCR	Blood, urine, CSF, throat, rectal, liver	Pleconaril (investigative)
Adenovirus	Culture and PCR	Nasal/throat, rectal, blood, liver, urine	Cidofovir, ?IVIG
Hepatitis B virus (HBV)	HBsAg, HBcAg IgM	Serum	Supportive for acute infection
Hepatitis C virus (HCV)	HCV PCR, HCV-IgG	Serum	Supportive for acute infection
<i>Treponema pallidum</i>	Serology; dark-field exam	Serum, CSF	Penicillin
<i>Toxoplasma gondii</i>	IgM/ ^a IgG, PCR, culture	Serum, liver	Pyrimethamine and sulfadiazine with folinic acid
<i>Mycobacterium tuberculosis</i>	PPD, chest radiograph, liver tissue histologic stains and culture, gastric aspirate stain and culture	Serum, liver, gastric aspirate	INH, pyrazinamide, rifampin and streptomycin

^aIgG = positive indicates maternal infection and transfer of antibody transplacentally; negative indicates unlikelihood of infection in mother and infant.

IVIG = intravenous gamma globulin, PCR = polymerase chain reactin test for viral DNA or RNA, Ag = viral antigen testing, INH = isoniazid, CSF = cerebrospinal fluid, HBsAg = hepatitis B surface antigen, HBC = hepatitis B core antigen, PPD = purified protein derivative.

^bUse for resistant viruses.

pected syphilis or antibiotics for bacterial hepatitis need to be administered promptly.

Prognosis

Multiple organ involvement is commonly associated with neonatal infectious hepatitis and has a poor outcome. Death from hepatic or cardiac failure, intractable acidosis, or intracranial hemorrhage may occur, especially in herpesvirus or enterovirus infection and occasionally in CMV or rubella infection. HBV may rarely cause fulminant neonatal viral hepatitis; most infected infants become asymptomatic carriers of hepatitis B. Persistent liver disease results in mild chronic hepatitis, portal fibrosis, or cirrhosis. Chronic cholestasis, although rare following infections, may lead to dental enamel hypoplasia, failure to thrive, biliary rickets, severe pruritus, and xanthoma.

Specific Infectious Agents

A. NEONATAL HEPATITIS B VIRUS DISEASE

Infection with HBV may occur at any time during perinatal life, but the risk is higher when acute maternal disease occurs during the last trimester of pregnancy. However, most cases of neonatal disease are acquired from mothers who are asymptomatic carriers of hepatitis B. Although HBV has been found in most body fluids, including breast milk, neonatal transmission occurs occasionally transplacentally and primarily from exposure to maternal blood at delivery. In chronic hepatitis B surface antigen (HBsAg) carrier mothers, fetal and infant acquisition risk is greatest if the mother (1) is also hepatitis B envelope antigen (HBeAg)-positive and hepatitis B envelope antibody (HBeAb)-negative, (2) has detectable levels of serum-specific hepatitis B DNA polymerase, or (3) has high serum levels of hepatitis B core antibody (HBcAb). These findings are

Table 21-4. Treatment of complications of chronic cholestatic liver disease.

Indication	Treatment	Dose	Toxicity
Intrahepatic cholestasis	Phenobarbital	3–10 mg/kg/d	Drowsiness, irritability, interference with vitamin D metabolism
	Cholestyramine/colestipol hydrochloride	250–500 mg/kg/d	Constipation, acidosis, binding of drugs, increased steatorrhea
	Ursodeoxycholic acid	15–20 mg/kg/d	Transient increase in pruritus
Pruritus	Phenobarbital or cholestyramine/colestipol (or both)	Same as above	
	Antihistamines: diphenhydramine hydrochloride hydroxyzine	5–10 mg/kg/d 2–5 mg/kg/d	Drowsiness
	Ultraviolet light B	Exposure as needed	Skin burn
	Carbamazepine	20–40 mg/kg/d	Hepatotoxicity, marrow suppression, fluid retention
	Rifampin	10 mg/kg/d	Hepatotoxicity, marrow suppression
	Ursodeoxycholic acid	15–20 mg/kg/d	Transient increase in pruritus
Steatorrhea	Formula containing medium-chain triglycerides (eg, Pregestimil)	120–150 calories/kg/d for infants	Expensive
	Oil supplement containing medium-chain triglycerides	1–2 mL/kg/d	Diarrhea, aspiration
Malabsorption of fat-soluble vitamins	Vitamin A	10,000–25,000 units/d	Hepatitis, pseudotumor cerebri, bone lesions
	Vitamin D	800–5000 units/d	Hypercalcemia, hypercalciuria
	25-Hydroxycholecalciferol (vitamin D)	3–5 µg/kg/d	Hypercalcemia, hypercalciuria
	1,25-Dihydroxycholecalciferol (vitamin D)	0.05–0.2 µg/kg/d	Hypercalcemia, hypercalciuria
	Vitamin E (oral)	25–200 IU/kg/d	Potential of vitamin K deficiency
	Vitamin E (oral, TPGS ^a)	15–25 IU/kg/d	Potential of vitamin K deficiency
	Vitamin E (intramuscular)	1–2 mg/kg/d	Muscle calcifications
	Vitamin K (oral)	2.5 mg twice per week to 5 mg/d	
Malabsorption of other nutrients	Vitamin K (intramuscular)	2–5 mg each 4 wk	
	Multiple vitamin	1–2 times the standard dose	
	Calcium	25–100 mg/kg/d	Hypercalcemia, hypercalciuria
	Phosphorus	25–50 mg/kg/d	Gastrointestinal intolerance
	Zinc	1 mg/kg/d	Interference with copper and iron absorption

^aD- α -Tocopheryl polyethylene glycol-1000 succinate.

markers for circulating infectious virus; however, hepatitis B can be transmitted even if HBsAg is the only marker present.

Neonatal liver disease resulting from HBV is extremely variable. The infant has a 70–90% chance of acquiring HBV at birth from an HBsAg-positive mother if nothing is done to prevent infection. Most infected infants become prolonged asymptomatic carriers of HBV. Fulminant hepatic necrosis has rarely been reported. In such cases, progressive jaundice, stupor, shrinking liver size, and coagulation abnormalities dominate the clinical picture. Respiratory, circulatory, and renal failure usually follow. Histologically, the liver shows massive hepatocyte necrosis, collapse of the reticulum framework, minimal inflammation, and occasional pseudoacinar structures. Survival is rare but is associated with reasonable repair of liver architecture.

In less severe cases, focal hepatocyte necrosis occurs with a mild portal inflammatory response. Cholestasis is intracellular and canalicular. Chronic active hepatitis may be present for many years, with serologic evidence of persisting antigenemia (HBsAg) and mildly elevated serum aminotransferases. Chronic active hepatitis may rarely progress to cirrhosis within 1–2 years. Most infected infants have only mild evidence, if any, of liver injury.

To prevent perinatal transmission, all infants of mothers who are HBsAg-positive (regardless of HBeAg status) should receive hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine within the first 24 hours after birth and vaccine again at ages 1 and 6 months (see Chapter 9). This prevents HBV infection in 85–95% of infants. HBIG can provide some protection when given as late as 72 hours after birth. If not given at birth it can be administered as late as 7 days postpartum as long as the infant has received vaccine.

B. NEONATAL BACTERIAL HEPATITIS

Most bacterial liver infections in newborns are acquired by transplacental invasion from amnionitis with ascending spread from maternal vaginal or cervical infection. Onset is abrupt, usually within 48–72 hours after delivery, with signs of sepsis and often shock. Jaundice appears early and is of the mixed type. The liver enlarges rapidly, and the histologic picture is that of diffuse hepatitis with or without microabscess. The most common organisms involved are *Escherichia coli*, *Listeria monocytogenes*, and group B streptococci. Isolated neonatal liver abscess caused by *E coli* or *Staphylococcus aureus* is often associated with omphalitis or umbilical vein catheterization. Bacterial hepatitis and neonatal liver abscesses require specific antibiotics in large doses and, rarely, surgical or radiologic interventional drainage. Deaths are common, but survivors show no long-term consequences of liver disease.

C. NEONATAL JAUNDICE WITH URINARY TRACT INFECTION

Jaundice in affected infants—usually males—typically appears between the second and fourth weeks of life. This disorder causes lethargy, fever, poor appetite, jaundice, and hepatomegaly. Except for mixed hyperbilirubinemia, other liver function tests (LFTs) are mildly abnormal. Leukocytosis is present, and infection is confirmed by culture. The mechanism for the liver impairment is the toxic action of bacterial products (endotoxins) and inflammatory cytokines.

Treatment of the infection leads to prompt resolution of the cholestasis without hepatic sequelae. Metabolic liver diseases, such as galactosemia and tyrosinemia, may present with gram-negative bacterial urinary tract infection and must be considered.

2. Intrahepatic Cholestasis Resulting from Inborn Errors of Metabolism, Familial & “Toxic” Causes

These cholestatic syndromes caused by specific enzyme deficiencies, other genetic disorders, or certain precipitants associated with neonatal liver disease feature intrahepatic cholestasis (ie, jaundice, hepatomegaly, and normal to completely acholic stools). Some of the specific clinical conditions have characteristic clinical signs.

Enzyme Deficiencies & Other Inherited Disorders

Early specific diagnosis is important because dietary or pharmacologic treatment may be available (Table 21–5). Reversal of liver disease and clinical symptoms is prompt and permanent in several disorders as long as the diet is maintained. As with other inborn errors of metabolism, parents of the affected infant should be offered genetic counseling. For some disorders, prenatal genetic diagnosis is available.

Cholestasis caused by metabolic diseases such as galactosemia, fructose intolerance, and tyrosinemia may be accompanied by vomiting, lethargy, poor feeding, and irritability. Hepatomegaly is a constant finding. The infants often appear septic; gram-negative bacteria can be cultured from blood in 25–50% of cases, espe-

Table 21–5. Metabolic and genetic causes of neonatal cholestasis.

Disease	Inborn Error	Hepatic Pathology	Diagnostic Studies
Galactosemia	Galactose-1-phosphate uridylyltransferase	Cholestasis, steatosis, necrosis, pseudoacini, fibrosis	Galactose-1-phosphate uridylyltransferase assay of red blood cells
Fructose intolerance	Fructose-1-phosphate aldolase	Steatosis, necrosis, pseudoacini, fibrosis	Liver fructose-1-phosphate aldolase assay or leukocyte DNA analysis
Tyrosinemia	Fumarylacetoacetase	Necrosis, steatosis, pseudoacini, portal fibrosis	Urinary succinylacetone, fumarylacetoacetase assay of red blood cells
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator gene	Cholestasis, neoductular proliferation, excess bile duct mucus, portal fibrosis	Sweat test and leukocyte DNA analysis
Hypopituitarism	Deficient production of pituitary hormones	Cholestasis, giant cells	Thyroxine, TSH, cortisol levels
α_1 -Antitrypsin deficiency	Abnormal α_1 -antitrypsin molecule (Pi ZZ phenotype)	Giant cells, cholestasis, steatosis, neoductular proliferation, fibrosis, PAS-diastase-resistant cytoplasmic granules	Serum α_1 -antitrypsin phenotype
Gaucher disease	β -Glucosidase	Cholestasis, cytoplasmic inclusions in Kupffer's cells (foam cells)	β -Glucosidase assay in leukocytes
Niemann–Pick disease	Lysosomal sphingomyelinase	Cholestasis, cytoplasmic inclusions in Kupffer's cells	Sphingomyelinase assay of leukocytes or liver or fibroblasts (type C); leukocyte DNA analysis
Glycogen storage disease type IV	Branching enzyme	Fibrosis, cirrhosis, PAS-diastase-resistant cytoplasmic inclusions	Branching enzyme analysis of leukocytes or liver
Neonatal hemochromatosis	Unknown	Giant cells, portal fibrosis, hemosiderosis, cirrhosis	Histology, iron stains
Peroxisomal disorders (eg, Zellweger's syndrome)	Deficient peroxisomal enzymes or assembly	Cholestasis, necrosis, fibrosis, cirrhosis, hemosiderosis	Plasma very long chain fatty acids, qualitative bile acids, plasmalogen, pipercolic acid, liver electron microscopy
Abnormalities in bile acid metabolism	Several enzyme deficiencies defined	Cholestasis, necrosis, giant cells	Urine, serum, duodenal fluid analyzed for bile acids by fast atom bombardment-mass spectroscopy
Byler's disease (familial progressive intrahepatic cholestasis)	<i>FIC-1</i> and <i>BSEP</i> genes	Cholestasis, necrosis, giant cells, fibrosis	Histology, family history, normal cholesterol, low or normal γ -glutamyl transpeptidase, DNA analysis
<i>MDR</i> ₃ deficiency	<i>MDR</i> ₃ gene	Cholestasis, bile duct proliferation, portal fibrosis	Bile phospholipid level, DNA analysis
Alagille's syndrome (syndromic paucity of interlobular bile ducts)	<i>Jagged 1</i> gene mutations	Cholestasis, paucity of interlobular bile ducts, increased copper levels	Three or more clinical features, liver histology, DNA analysis

TSH = thyroid-stimulating hormone, PAS = periodic acid-Schiff.

cially in patients with galactosemia. Neonatal screening for galactosemia usually detects the disorder before cholestasis develops. Other inherited conditions associated with neonatal intrahepatic cholestasis are outlined in Table 21–5. Treatment of these disorders is discussed in Chapter 32.

“Toxic” Causes of Neonatal Cholestasis

A. NEONATAL ISCHEMIC–HYPOXIC CONDITIONS

Perinatal events that result in hypoperfusion of the gastrointestinal system are sometimes followed in 1–2 weeks by cholestasis. This occurs in premature infants with respiratory distress, severe hypoxia, hypoglycemia, shock, and acidosis. When these perinatal conditions develop in association with gastrointestinal lesions such as ruptured omphalocele, gastroschisis, or necrotizing enterocolitis, a subsequent cholestatic picture is common (25–50% of cases). Liver function studies reveal mixed hyperbilirubinemia, elevated alkaline phosphatase and γ -glutamyl transpeptidase (GGT) values, and variable elevation of the aminotransferases. Stools are seldom persistently acholic.

Choleretics (cholestyramine or UDCA), introduction of enteral feedings as soon as possible, and nutritional support are the mainstays of treatment until the cholestasis resolves (see Table 21–4). In some cases, this resolution may take 3–6 months. As long as no severe intestinal problem is present (eg, short gut syndrome), complete resolution of the hepatic abnormalities is the rule. But portal fibrosis with periportal scarring is occasionally found on follow-up biopsy.

B. PROLONGED PARENTERAL NUTRITION

Cholestasis may develop after 1–2 weeks in premature newborns receiving total parenteral nutrition (TPN). Even full-term infants with significant intestinal disease, resections, or dysmotility may develop TPN-related cholestasis. Contributing factors may include toxicity of intravenous amino acids, diminished stimulation of bile flow from prolonged absence of feedings, translocation of intestinal bacteria and their cell wall products, missing nutrients or antioxidants, photooxidation of amino acids, infusion of lipid hydroperoxides, and the “physiologic cholestatic” propensity of the premature infant. Histology of the liver may resemble that of extrahepatic biliary obstruction. Early introduction of feedings has reduced the frequency of this disorder. The prognosis is generally good. Occasional cases of cirrhosis, liver failure, and hepatoma may develop, particularly in infants with intestinal resections or anomalies.

C. INSPISSATED BILE SYNDROME

This syndrome is the result of accumulation of bile in canaliculi and in the small- and medium-size bile ducts

in hemolytic disease of the newborn (Rh, ABO) and in some infants receiving TPN. The same mechanisms may cause intrinsic obstruction of the common duct. An ischemia–reperfusion injury may also contribute to cholestasis in Rh incompatibility. In extreme hemolysis, the cholestasis may be seemingly complete, with acholic stools. Levels of bilirubin may reach 40 mg/dL, primarily conjugated. If inspissation of bile occurs within the extrahepatic biliary tree, differentiation from biliary atresia may be difficult. A trial of choleretics is indicated. Once stools show a return to normal color or ^{99m}Tc -DIDA scanning shows biliary excretion into the duodenum, patency of the extrahepatic biliary tree is ensured. Although most cases improve slowly over 2–6 months, persistence of complete cholestasis for more than 2 weeks requires further studies (ultrasonography, DIDA scanning, liver biopsy) with possible cholangiographic or magnetic resonance imaging of the extrahepatic biliary tree. Irrigation of the common bile duct is sometimes necessary to dislodge the obstructing inspissated biliary material.

3. Idiopathic Neonatal Hepatitis (Giant-Cell Hepatitis)

This type of cholestatic jaundice of unknown cause presents with features of cholestasis and a typical liver biopsy appearance; it accounts for 25–50% of cases of neonatal intrahepatic cholestasis. The degree of cholestasis is variable, and the disorder may be indistinguishable from extrahepatic causes in 10% of cases. Viral infections, α_1 -antitrypsin deficiency, Alagille syndrome, Niemann–Pick type C disease (NPC), progressive familial intrahepatic cholestasis (PFIC), and bile acid synthesis defects may present in a similar clinical and histologic manner. However, in PFIC and bile acid synthesis defects the γ -glutamyl transpeptidase levels are normal or low. Electron microscopy of the liver biopsy may help distinguish NPC and PFIC.

Intrauterine growth retardation, prematurity, poor feeding, emesis, poor growth, and partially or intermittently acholic stools are characteristic of intrahepatic cholestasis. Patients with neonatal lupus erythematosus may present with giant-cell hepatitis; however, thrombocytopenia, skin rash, or congenital heart block is usually also present.

In cases of suspected idiopathic neonatal hepatitis (absence of infectious, metabolic, and toxic causes), patency of the biliary tree should be verified to exclude extrahepatic surgical disorders. DIDA scanning and ultrasonography may be helpful in this regard. Some clinicians have used the enteral string test during DIDA scanning to confirm bile duct patency. Liver biopsy findings are usually diagnostic after age 6–8 weeks (see Table 21–2) but may be misleading before age 6 weeks. Failure to detect patency of the biliary tree, nondiagnostic liver biopsy findings, or persisting complete cholestasis (acholic stools) are indications for minilaparotomy and intraoperative cholangiography performed by an experienced surgeon, ERCP, percutaneous cholecystography, or magnetic resonance cholangiopancreatography (MRCP). Occasionally, a small but patent (hypoplastic) extrahepatic biliary tree is demonstrated and is probably the result rather than the cause of diminished bile flow; surgical reconstruction of hypoplastic biliary trees should not be attempted.

Once a patent extrahepatic tree is confirmed, therapy should include choleric agents, a special formula with medium-chain triglycerides (Pregestimil, Alimentum), and supplemental fat-soluble vitamins in water-miscible form (see Table 21–4). This therapy is continued as long as significant cholestasis remains (conjugated bilirubin > 1 mg/dL). Fat-soluble vitamin levels should be monitored while supplements are given and at least once after their discontinuation.

Eighty percent of patients recover without significant hepatic fibrosis. However, in 20% of cases with this presentation, the patient has PFIC and is likely to progress to cirrhosis. In general, failure to resolve the cholestatic picture by age 6–12 months is associated with progressive liver disease and evolving cirrhosis. This may occur with either normal or diminished numbers of interlobular bile ducts (paucity of interlobular ducts). Liver transplantation has been successful when signs of hepatic decompensation are noted (rising bilirubin, coagulopathy, intractable ascites).

4. Paucity of Interlobular Bile Ducts

Forms of intrahepatic cholestasis caused by decreased numbers of interlobular bile ducts (< 0.5 bile ducts per portal tract) may be classified according to whether they are associated with other malformations. The gene (*Jagged 1*) for the syndromic form, Alagille syndrome (arteriohepatic dysplasia), is located on chromosome 20p and codes for a ligand of the notch receptor, although the pathogenesis is not understood. Alagille syndrome is sometimes recognized by identification of the characteristic facies, which becomes more obvious with age. The forehead is prominent, as is the nasal bridge. The eyes are set deep and sometimes widely apart (hypertelorism). The chin is small and slightly pointed and projects forward. The ears are prominent. The stool color varies with the severity of cholestasis. Pruritus begins by age 3–6 months. Firm, smooth hepatomegaly may be present. Cardiac murmurs are present in 95% of patients, and butterfly vertebrae (incomplete fusion of the vertebral body or anterior arch) are present in 50%. Xanthomas develop later in the disease. Occasionally, early cholestasis is mild and not recognized.

Direct hyperbilirubinemia may be mild to severe (2–15 mg/dL). Serum alkaline phosphatase, GGT, and cholesterol are markedly elevated, especially early in life. Serum bile acids are always elevated. Aminotransferases are mildly increased, but clotting factors and other liver proteins are usually normal.

The cardiovascular abnormalities include peripheral and valvular pulmonary stenoses (most common), atrial septal defect, coarctation of the aorta, and tetralogy of Fallot. Up to 15% of patients develop intracranial hemorrhage early in childhood.

Eye abnormalities (posterior embryotoxon) and renal abnormalities (dysplastic kidneys, renal tubular ectasia, single kidney, hematuria) can also be present. Growth retardation with normal to increased levels of growth hormone is common. Although variable, the intelligence quotient is frequently low. Hypogonadism with micropenis may be present. A weak, high-pitched voice may develop. Neurologic disorders resulting from vitamin E deficiency (areflexia, ataxia, ophthalmoplegia) eventually develop in many children.

In the nonsyndromic form, paucity of interlobular bile ducts occurs in the absence of the extrahepatic malformations. Paucity of interlobular bile ducts may also occur in α_1 -antitrypsin deficiency, Zellweger syndrome, in association with lymphedema (Aagaenae's syndrome), PFIC, cystic fibrosis, CMV or rubella infection, and in-born errors of bile acid metabolism.

High doses (250 mg/kg/d) of cholestyramine may control pruritus, lower cholesterol, and clear xanthomas. Ursodeoxycholic therapy (15–25 mg/kg/d) appears to be more effective and less toxic than cholestyramine. Nutritional therapy to prevent wasting and deficiencies of fat-soluble vitamins is of particular importance because of the severity of cholestasis (see Table 21–4).

Prognosis is more favorable in the syndromic than in the nonsyndromic varieties. In the former, only 30–40% of patients have severe complications of disease, whereas over 70% of patients with nonsyndromic varieties progress to cirrhosis. Many of this latter group may have PFIC. In Alagille syndrome, cholestasis may improve by age 2–4 years, with minimal residual hepatic fibrosis. Survival into adulthood despite raised serum bile acids, aminotransferases, and alkaline phosphatase occurs in about 50% of cases. Several patients have developed hepatocellular carcinoma. Hypogonadism has been noted; however, fertility is not obviously affected. Cardiovascular anomalies may shorten life expectancy. Some patients have persistent, severe cholestasis, rendering their quality of life poor; liver transplantation has been performed under these circumstances.

PROGRESSIVE FAMILIAL INTRAHEPATIC CHOLESTASIS (Byler Disease)

PFIC is a group of disorders presenting as pruritus, diarrhea, jaundice, and failure to thrive in the first 6–12 months of life. PFIC type I (Byler disease), caused by mutations in the *FIC1* gene, is associated with low to normal serum levels of GGT and cholesterol and elevated levels of bilirubin, aminotransferases, and bile acids. Diarrhea is common. Liver biopsy results are similar to those found with giant-cell hepatitis but sometimes with a paucity of interlobular bile ducts and centrilobular fibrosis that progresses to cirrhosis. Electron microscopy shows diagnostic granular “Byler bile” in canaliculi.

Treatment includes administration of UDCA, partial biliary diversion if the condition is unresponsive to UDCA, and liver transplantation. PFIC type II is

caused by mutations in the bile salt export pump (*BSEP*) gene, which codes for an adenosine triphosphate (ATP)-dependent canalicular bile salt transport protein. Clinically and biochemically, patients are similar to PFIC type I patients, as are their liver histology and treatment options. PFIC type III is caused by mutations in the *MDR3* (multiple drug resistance protein type 3) gene, which encodes a canalicular protein that pumps phospholipid into bile. Serum GGT and bile acid levels are elevated, bile duct proliferation and portal tract fibrosis are seen in liver biopsies, and bile phospholipid levels are low. Treatment is similar to that for other forms of PFIC. Bile acid synthesis defects are clinically similar to those in PFIC I and PFIC II, with low serum levels of GGT and cholesterol; however, the serum level of total bile acids is low and urine bile acid analysis may identify a defect.

EXTRAHEPATIC NEONATAL CHOLESTASIS

Extrahepatic neonatal cholestasis is characterized by complete and persistent cholestasis (acholic stools) in the first 3 months of life; lack of patency of the extrahepatic biliary tree proved by intraoperative, percutaneous, or endoscopic cholangiography; firm to hard hepatomegaly; and typical features on histologic examination of liver biopsy tissue (see Table 21–2). Causes include biliary atresia, choledochal cyst, spontaneous perforation of the extrahepatic ducts, and intrinsic obstruction of the common duct.

1. Biliary Atresia

Biliary atresia is the progressive fibroinflammatory obliteration of the lumen of all, or part of, the extrahepatic biliary tree presenting within the first 3 months of life. In European Americans, biliary atresia occurs in 1:10,000–1:15,000 births, and the incidence in both sexes is equal. In Asian Americans, the incidence is higher, and the disorder is twice as common in girls. The abnormality found most commonly is complete atresia of all extrahepatic biliary structures. There appear to be at least two types of biliary atresia: the perinatal form (80% of cases) and the fetal-embryonic form (20% of cases). In the perinatal form, meconium and first-passed stools are usually normal in color, suggesting

early patency of the ducts. Evidence obtained from surgically removed remnants of the extrahepatic biliary tree suggests an inflammatory or sclerosing cholangiopathy. Although an infectious cause seems reasonable, no agent has been consistently found in such cases. A role for reovirus type 3 and rotavirus group C has been suggested. Certain histocompatibility locus antigen (HLA) types may predispose to biliary atresia. In the fetal-embryonic type, the bile duct presumably developed abnormally and is associated with other nonhepatic congenital anomalies. The strongest association of biliary atresia is with the polysplenia syndrome (situs inversus, preduodenal portal vein, interruption of the inferior vena cava, polysplenia, midline liver).

Jaundice may be noted in the newborn period but is more often delayed until age 2–3 weeks. The urine stains the diaper; and the stools are often pale yellow, buff-colored, gray, or acholic. Seepage of bilirubin products across the intestinal mucosa may give some yellow coloration to the stools. Hepatomegaly is common, and the liver may feel firm to hard; splenomegaly develops later. Pruritus, digital clubbing, xanthomas, and a rachitic rosary may be noted in older patients. By age 2–6 months, the growth curves reveal poor weight gain. Late in the course, ascites and bleeding complications occur.

No single laboratory test will consistently differentiate biliary atresia from other causes of complete obstructive jaundice. A study of hepatic 2,6-dimethyliminodiacetic acid (HIDA) excretion performed early in the course of disease and after pretreatment with phenobarbital (3–5 mg/kg/d for 5–7 days) helps to distinguish intrahepatic from extrahepatic causes of cholestasis, though it is not diagnostic. MRCP shows promise as an imaging study to define biliary atresia. Although biliary atresia is suggested by persistent elevation of serum γ -glutamyl transpeptidase or alkaline phosphatase levels, high cholesterol levels, and prolonged prothrombin times, these findings have also been reported in severe neonatal hepatitis, α_1 -antitrypsin deficiency, and bile duct paucity. Furthermore, these tests will not differentiate the location of the obstruction within the extrahepatic system. Generally, the aminotransferases are elevated only modestly in biliary atresia. Serum proteins and blood clotting factors are not affected early in the disease. Routine chest radiograph may reveal abnormalities suggestive of polysplenia syndrome. Ultrasonography of the biliary system should be performed to ascertain the presence of choledochal cyst and intra-abdominal anomalies. Liver biopsy specimens can differentiate intrahepatic causes of cholestasis from biliary atresia in over 90% of cases (see Table 21–2).

The major diagnostic dilemma is distinguishing between this entity and neonatal hepatitis, bile duct paucity, metabolic liver disease (particularly α_1 -anti-

trypsin deficiency), choledochal cyst, or intrinsic bile duct obstruction (stones, bile plugs). Although spontaneous perforation of extrahepatic bile ducts leads to jaundice and acholic stools, the infants are usually quite ill with chemical peritonitis from biliary ascites, and hepatomegaly is not found.

If the diagnosis of biliary atresia cannot be excluded by the diagnostic evaluation before age 60 days, surgical exploration is necessary. Laparotomy must include liver biopsy and an operative cholangiogram if a gallbladder is present. The presence of yellow bile in the gallbladder implies patency of the proximal extrahepatic duct system. Radiographic visualization of cholangiographic contrast in the duodenum excludes obstruction to the distal extrahepatic ducts.

In the absence of surgical correction, the following eventually develop: failure to thrive, marked pruritus, portal hypertension, hypersplenism, bleeding diathesis, rickets, ascites, and cyanosis. Bronchitis and pneumonia are common. Eventually, hepatic failure and death occur, almost always by age 18–24 months.

Except for the occasional example of correctable biliary atresia, in which choledochojejunostomy is feasible, the standard procedure is hepatopertoenterostomy (Kasai procedure). Occasionally, portocholecystostomy (gallbladder Kasai procedure) may be performed if the gallbladder is present and the passage from it to the duodenum is patent. These procedures are best done in specialized centers where experienced surgical, pediatric, and nursing personnel are available. Surgery should be performed as early as possible (before 60 days of life); the Kasai procedure should generally not be undertaken in infants older than age 4 months, because the likelihood of bile drainage at this age is very low. Orthotopic liver transplantation is now indicated for patients who do not undergo the Kasai procedure, who fail to drain bile after the Kasai procedure, or who progress to end-stage biliary cirrhosis despite surgical treatment. The 5-year survival rate following transplantation is 70–85%.

Whether or not the Kasai procedure is performed, supportive medical treatment measures consist of vitamin and caloric support (vitamins A, D, K, and E and formulas containing medium-chain triglycerides [Pregestimil or Alimentum]) (see Table 21–4). Bacterial infections (eg, ascending cholangitis) should be treated promptly with broad-spectrum antibiotics, and signs of bleeding tendency should be corrected with intramuscular vitamin K. Ascites can be managed initially with reduced sodium intake and spironolactone. Cholergics and bile acid-binding products (cholestyramine, aluminum hydroxide gel) are of little use. The value of UDCA remains to be determined.

When bile flow is sustained, the 10-year survival rate is 25–35%. Death is usually caused by liver failure, sep-

sis, acidosis, or respiratory failure secondary to intractable ascites. Esophageal variceal hemorrhage develops in 40% of patients. Surprisingly, terminal hemorrhage is unusual. Liver transplantation has dramatically changed the outlook for these patients.

2. Choledochal Cyst

Choledochal cysts cause 2–5% of cases of extrahepatic neonatal cholestasis; the incidence is fourfold higher in girls and higher in patients of Asian descent. In most cases, the clinical manifestations, basic laboratory findings, and histopathologic features on liver biopsy are indistinguishable from those associated with biliary atresia. Neonatal symptomatic cysts are usually associated with atresia of the distal common duct—accounting for the diagnostic dilemma—and may simply be part of the spectrum of biliary atresia. However, a palpable subhepatic mass and a positive ultrasound scan promptly resolve the diagnostic question. Discovery of such a mass eliminates the need for other studies. Immediate operation is indicated once abnormalities in clotting factors have been corrected and bacterial cholangitis, if present, has been treated with intravenous antibiotics. In older children, choledochal cyst presents as recurrent episodes of obstructive jaundice, pancreatitis, or right upper quadrant abdominal pain and vomiting, or as a right abdominal mass.

Excision of the cyst and choledocho–Roux-en-Y jejunal anastomosis are recommended. In some cases, because of technical problems, only the mucosa of the cyst can be removed with jejunal anastomosis to the proximal bile duct. Anastomosis of cyst to jejunum or duodenum is not recommended.

The prognosis depends on the presence or absence of associated evidence of atresia and the appearance of the intrahepatic ducts. If atresia is found, the prognosis is similar to that described in the preceding section. If an isolated extrahepatic cyst is encountered, the outcome is generally excellent, with resolution of the jaundice and return to normal liver architecture. However, bouts of ascending cholangitis, particularly if intrahepatic cysts are present, or obstruction of the anastomotic site may occur. The risk of biliary carcinoma developing within the cyst is about 5–15% at adulthood; therefore, cystectomy or excision of cyst mucosa should be undertaken whenever possible.

3. Spontaneous Perforation of the Extrahepatic Bile Ducts

The sudden appearance of obstructive jaundice, acholic stools, and abdominal enlargement with ascites in a sick newborn is suggestive of this condition. The liver is usually normal in size, and a yellow-green discoloration can often be discerned under the umbilicus or in the scrotum. In 24% of cases, stones or sludge obstructs the common bile duct. DIDA scan or ERCP shows leakage from the biliary tree, and ultrasonography confirms ascites or fluid around the bile duct.

Treatment is surgical. Simple drainage, without attempts at oversewing the perforation, is sufficient in primary perforations. A diversion anastomosis is constructed in cases associated with choledochal cyst or stenosis. The prognosis is generally good.

OTHER NEONATAL HYPERBILIRUBINEMIC CONDITIONS (Noncholestatic Nonhemolytic)

This group of disorders associated with hyperbilirubinemia is of two types: (1) unconjugated hyperbilirubinemia, consisting of breast milk jaundice,

Lucey–Driscoll syndrome, congenital hypothyroidism, upper intestinal obstruction, Gilbert disease, Crigler–Najjar syndrome, and drug-induced hyperbilirubinemia; and (2) conjugated noncholestatic hyperbilirubinemia, consisting of Dubin–Johnson syndrome and Rotor syndrome.

1. Unconjugated Hyperbilirubinemia

Breast Milk Jaundice

Persistent elevation of the indirect bilirubin fraction may occur in up to 36% of breast-fed infants. Enhanced β -glucuronidase activity in breast milk as the cause for increased absorption of unconjugated bilirubin is controversial. The increased enterohepatic shunting of unconjugated bilirubin exceeds the normal conjugating capacity in the liver of these infants. The mutation for Gilbert syndrome predisposes to breast milk jaundice and to more prolonged jaundice.

Hyperbilirubinemia does not usually exceed 20 mg/dL, with most cases in the range of 10–15 mg/dL. In patients whose bilirubin levels are above 4–5 mg/dL, the jaundice is noticeable by the fifth to seventh day of breast-feeding. It may accentuate the underlying physiologic jaundice—especially early, when total fluid intake may be less than optimal. Except for jaundice, the physical examination is usually normal; urine does not stain the diaper, and the stools are golden yellow.

The jaundice peaks by the third week of life and clears before age 3 months in almost all infants, even when breast-feedings are continued. All infants who remain jaundiced past age 2 weeks should have measurements of conjugated bilirubin to exclude hepatobiliary disease.

Kernicterus has never been reported in association with this condition. In special situations, breast-feeding may be discontinued temporarily and replaced by formula feedings for 2–3 days until serum bilirubin decreases by 2–8 mg/dL. Cow's milk formulas inhibit the intestinal reabsorption of unconjugated bilirubin. When breast-feeding is reinstated, the serum bilirubin may increase slightly but not to the previous level. Phototherapy is not indicated in the healthy full-term infant with this condition.

Monaghan G et al: Gilbert's syndrome is a contributory factor in prolonged unconjugated hyperbilirubinemia of the newborn. *J Pediatr* 1999;134:441 [PMID: 10190918].

Congenital Hypothyroidism

Although the differential diagnosis of indirect hyperbilirubinemia should always include congenital hypothyroidism, the diagnosis may be obvious from other clinical and physical clues or from the newborn screening results. The jaundice clears quickly with replacement thyroid hormone therapy, although the mechanism is unclear.

Labrone P et al: Bilirubin uridine diphosphate glucuronosyltransferase hepatic activity in jaundice associated with congenital hypothyroidism. *J Pediatr Gastroenterol Nutr* 1992;14:79 [PMID: 1573516].

Upper Intestinal Obstruction

The association of indirect hyperbilirubinemia with high intestinal obstruction (eg, duodenal atresia, annular pancreas, pyloric stenosis) in the newborn has been observed repeatedly; the mechanism is unknown. Diminished levels of hepatic glucuronyl transferase have been found on liver biopsy in pyloric stenosis, and genetic studies suggest that this indirect hyperbilirubinemia is an early sign of Gilbert syndrome.

Treatment is that of the underlying obstructive condition (usually surgical). Jaundice disappears once adequate nutrition is achieved.

Trioche P et al: Jaundice with hypertrophic pyloric stenosis is an early manifestation of Gilbert's syndrome. *Arch Dis Child* 1999;81:301 [PMID: 10490432].

Gilbert Syndrome

Gilbert syndrome is a common form (3–7% of the population) of familial hyperbilirubinemia associated with a partial reduction of hepatic bilirubin uridine diphosphate (UDP) glucuronyl transferase activity and perhaps an abnormality in the function or amount of one or more hepatocyte membrane protein carriers. Accelerated jaundice of the newborn, breast milk jaundice, and jaundice with intestinal obstruction may be present in affected infants. During puberty and beyond, mild fluctuating jaundice, especially with illness, and vague constitutional symptoms are common. Shortened red blood cell survival time in some patients is thought to be caused by reduced activity of enzymes involved in heme biosynthesis (protoporphyrinogen oxidase). Subsidence of hyperbilirubinemia has been achieved in patients by administration of phenobarbital (5–8 mg/kg/d), although this therapy is not justified.

The disease is inherited as an autosomal recessive abnormality of the promoter region of UDP-glucuronyl transferase-1; however, another factor is necessary for disease expression. The homozygous (16%) and het-

eryzous states (40%) are common. Males are affected more often than females (4:1). Serum unconjugated bilirubin is generally less than 3–6 mg/dL, although rare cases may exceed 8 mg/dL. The findings on liver biopsy and most other LFTs are normal except for prolonged indocyanine green and bromosulfophthalein (BSP) retention. An increase of 1.4 mg/dL or more in the level of unconjugated bilirubin after a 2-day fast (300 kcal/d) is consistent with the diagnosis of Gilbert syndrome. Genetic testing is available but rarely needed. No treatment is necessary.

Vajro P et al: Unusual presentation of Gilbert's syndrome in pediatric recipients of liver transplantation. *J Pediatr Gastroenterol Nutr* 2000;31:238 [PMID: 10997365].

Crigler–Najjar Syndrome

Infants with type I Crigler–Najjar syndrome usually develop rapid severe elevation of unconjugated bilirubin (> 30–40 mg/dL) with neurologic consequences (kernicterus). Consanguinity is often present. Prompt recognition of this entity and treatment with exchange transfusions are required, followed by phototherapy. Some patients have no neurologic signs until adolescence or early adulthood, at which time deterioration may occur suddenly. For diagnosis of this condition it is useful to obtain a duodenal bile specimen, which characteristically will be colorless and contain a predominance of unconjugated bilirubin, small amounts of monoconjugates, and only traces of diconjugated bilirubin. Phenobarbital administration in these patients does not significantly alter these findings, nor does it lower serum bilirubin levels. The glucuronyl transferase deficiency is inherited in an autosomal recessive pattern. A combination of phototherapy and cholestyramine may keep bilirubin levels below 25 mg/dL. The use of tin protoporphyrin or tin mesoporphyrin remains experimental. Liver transplantation is curative and may prevent kernicterus if performed early. An auxiliary orthotopic transplantation also relieves the jaundice while the patient retains native liver. Hepatocyte transplantation is experimental.

A milder form (type II) with both autosomal dominant and recessive inheritance is rarely associated with neurologic complications. Hyperbilirubinemia is less severe, and the bile is pigmented and contains bilirubin mono- and diglucuronide. Patients with this form respond to phenobarbital with lowering of serum bilirubin levels. An increased proportion of monoconjugated

and diconjugated bilirubin in the bile follows phenobarbital treatment.

Liver biopsy findings and LFTs are consistently normal in both types.

Drug-Induced Hyperbilirubinemia

Vitamin K₃ (menadiol) may elevate indirect bilirubin levels by causing hemolysis. Vitamin K₁ (phytonadione) can be used safely in neonates. Rifampin and antiretroviral protease inhibitors may cause unconjugated hyperbilirubinemia. Other drugs (eg, ceftriaxone, sulfonamides) may displace bilirubin from albumin, potentially increasing the risk of kernicterus—especially in the sick premature infant.

2. Conjugated Noncholestatic Hyperbilirubinemia (Dubin–Johnson Syndrome & Rotor Syndrome)

These diagnoses are suspected when persistent or recurrent conjugated hyperbilirubinemia and jaundice occur and liver function tests are normal. The basic defect in Dubin–Johnson syndrome affects the multiple organic anion transport protein (MRP₂) of the bile canalculus, causing impaired hepatocyte excretion of conjugated bilirubin into bile. A variable degree of impairment in uptake and conjugation complicates the clinical picture. Transmission is autosomal recessive, so a positive family history is occasionally obtained. In Rotor syndrome, the defect lies in hepatic uptake and storage of bilirubin. Bile acids are metabolized normally, so that cholestasis does not occur. Bilirubin values range from 2 to 5 mg/dL, and other LFTs are normal.

In Rotor syndrome, the liver is normal; in Dubin–Johnson syndrome, it is darkly pigmented on gross inspection and may be enlarged. Microscopic examination reveals numerous dark-brown pigment granules consisting of polymers of epinephrine metabolites, especially in the centrilobular regions. However, the amount of pigment varies within families, and some jaundiced family members may have no demonstrable pigmentation in the liver. Otherwise, the liver is histologically normal. Oral cholecystography fails to visual-

ize the gallbladder in Dubin–Johnson syndrome but is normal in Rotor syndrome. Differences in the excretion patterns of BSP, in results of DIDA cholescintigraphy, in urinary coproporphyrin I and III levels, and in the serum pattern of monoglucuronide and diglucuronide conjugates of bilirubin can help distinguish between these two conditions.

The prognosis is excellent, and no treatment is needed.

HEPATITIS A

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Gastrointestinal upset (anorexia, vomiting, diarrhea).*
- *Jaundice.*
- *Liver tenderness and enlargement.*

- *Abnormal LFTs.*
- *Local epidemic of the hepatitis A infection.*
- *Positive Anti-HAV IgM antibody.*

General Considerations

Hepatitis A virus (HAV) infection occurs in both epidemic and sporadic fashion (Table 21–6). Transmission by the fecal–oral route explains epidemic outbreaks from contaminated food or water supplies, including by food handlers. Viral particles 27 nm in diameter have been found in stools during the acute phase of hepatitis A infection and are similar in appearance to the enteroviruses. Sporadic cases usually result from contact with an affected individual. Transmission through blood products obtained during the viremic phase is a rare event, although it has occurred in a newborn nursery. The overt form of the disease is easily recognized by the clinical manifestations. However, two thirds of children are asymptomatic, and two thirds of symptomatic children are anicteric. Lifelong immunity to HAV follows infection. In developing countries, most children are exposed to HAV by age 10 years, while only 20% are exposed by age 20 years in developed countries.

Table 21–6. Hepatitis viruses.

	HAV	HBV	HCV	HDV	HEV
Type of virus	Enterovirus (RNA)	Hepadnavirus (DNA)	Flavivirus (RNA)	Incomplete (RNA)	Calicivirus (RNA)
Transmission routes	Fecal–oral	Parenteral, sexual, vertical	Parenteral, sexual, vertical	Parenteral, sexual	Fecal–oral
Incubation period (days)	15–40	50–150	30–150	20–90	14–65
Diagnostic test	Anti-HAV IgM	HBsAg, anti-HBc IgM	Anti-HCV, PCR–RNA test	Anti-HDV	Anti-HEV
Mortality rate (acute)	0.1–0.2%	0.5–2%	1–2%	2–20%	1–2% (in pregnant women, 20%)
Carrier state	No	Yes	Yes	Yes	No
Vaccine available	Yes	Yes	No	Yes (HBV)	No
Treatment	None	Interferon- α or lamivudine	Interferon- α plus ribavirin Pegylated interferon (adults)	Treatment for HBV	None

PCR = polymerase chain reaction; HAV = hepatitis A virus; HBsAg = hepatitis B surface antigen; HBc = hepatitis B core; HDV = hepatitis D (delta) virus; HBV = hepatitis B virus.

Antibody to HAV appears within 1–4 weeks of clinical symptoms. Although the great majority of children with infectious hepatitis are asymptomatic or have mild disease and recover completely, some will develop fulminant hepatitis.

HEPATITIS VIRUS ABBREVIATIONS

HAV	Hepatitis A virus
Anti-HAV IgM	IgM antibody to HAV
HBV	Hepatitis B virus
HBsAg	HBV surface antigen
HBcAg	HBV core antigen
HBeAg	HBV envelope antigen
Anti-HBs	Antibody to HBsAg
Anti-HBc	Antibody to HBcAg
Anti-HBc IgM	IgM antibody to HBcAg
Anti-HBe	Antibody to HBeAg
HCV	Hepatitis C virus
Anti-HCV	Antibody to HCV
HDV	Hepatitis D (delta) virus
Anti-HDV	Antibody to HDV
HEV	Hepatitis E virus
Anti-HEV	Antibody to HEV
NANBC	Non-A, non-B, non-C hepatitis virus

Clinical Findings

A. HISTORY

Features of the patient's history elicit direct exposure to a previously jaundiced individual, consumption of seafood or contaminated water, or recent travel to an area of endemic infection. Following an incubation period of 15–40 days, the initial nonspecific symptoms usually precede the development of jaundice by 5–10 days.

B. SYMPTOMS AND SIGNS

Fever, anorexia, vomiting, headache, and abdominal pain are the usual symptoms. Darkening of the urine precedes jaundice, which peaks in 1–2 weeks and then begins to subside. The stools may become light or clay-colored during this time. Clinical improvement can occur as jaundice develops. Tender hepatomegaly and jaundice are typically present; splenomegaly is variable.

C. LABORATORY FINDINGS

Aminotransferases and conjugated and unconjugated bilirubin levels are elevated. The leukocyte count is normal to low; the sedimentation rate is elevated. Serum proteins are generally normal, but an elevation of the γ -globulin fraction (> 2.5 g/dL) can occur and indicates a worse prognosis. Hypoalbuminemia, hypo-

glycemia, and marked prolongation of prothrombin time are serious prognostic findings. Diagnosis is made by serology. A positive anti-HAV IgM indicates acute disease, whereas IgG anti-HAV persists after recovery.

Percutaneous liver biopsy is rarely indicated but may be performed safely in most children provided that the partial thromboplastin time and platelet count are normal and the prothrombin time is prolonged less than 4–5 seconds. The presence of ascites may increase the risk of percutaneous liver biopsy. "Balloon cells" and acidophilic bodies are characteristic histologic findings. Liver cell necrosis may be diffuse or focal, with accompanying infiltration of inflammatory cells containing polymorphonuclear leukocytes, lymphocytes, macrophages, and plasma cells, particularly in portal areas. Some bile duct proliferation may be seen in the perilobular portal areas alongside areas of bile stasis. Regenerative liver cells and proliferation of reticuloendothelial cells are present. Occasionally massive hepatocyte necrosis occurs, portending a bad prognosis.

Differential Diagnosis

Before jaundice appears, the symptoms are those of a nonspecific viral enteritis. Other diseases with somewhat similar onset include pancreatitis, infectious mononucleosis, leptospirosis, drug-induced hepatitis, Wilson disease, autoimmune hepatitis, and, most often, other hepatitis viruses. Acquired CMV disease may also mimic HAV, although lymphadenopathy is usually present in the former.

Prevention

Some attempt at isolation of the patient during initial phases of illness is indicated, although most patients with hepatitis A are noninfectious by the time the disease becomes overt. Stool, diapers, and other fecally stained clothing should be handled with care for 1 week after the appearance of jaundice.

Passive-active immunization of exposed susceptible persons can be achieved by giving standard immune globulin, 0.02–0.04 mL/kg intramuscularly. Illness is prevented in 80–90% of individuals if immune globulin is given within 1–2 weeks of exposure. Individuals traveling to endemic disease areas should receive HAV vaccine or 0.02–0.06 mL/kg of immune globulin as prophylaxis if there is insufficient time (< 2 weeks) for the initial dose of vaccine. All children older than age 2 years with chronic liver diseases should receive two doses of HAV vaccine 6 months apart. It is currently recommended that universal childhood immunization for HAV be implemented in states in the United States with 20 or more cases per 100,000 population per year, and in local areas with a high prevalence.

Treatment

There are no specific measures. Sedatives and corticosteroids should be avoided. At the start of the illness, a light diet is preferable. During the icteric phase, lower-fat foods may diminish gastrointestinal symptoms but do not affect overall outcome. Drugs and elective surgery should be avoided.

Prognosis

Ninety-nine percent of children recover without sequelae. In rare cases of fulminant hepatitis, the patient may die in 5 days or may survive as long as 1–2 months without liver transplantation. The prognosis is poor if the signs and symptoms of hepatic coma develop, with deepening of jaundice and development of ascites; orthotopic liver transplantation is indicated under these circumstances. Incomplete resolution leads to prolonged hepatitis or chronic cholestatic hepatitis but not to cirrhosis. Rare cases of aplastic anemia following acute infectious hepatitis have been reported. A benign relapse of symptoms may occur in 10–15% of cases after 6–10 weeks of apparent resolution.

HEPATITIS B

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Gastrointestinal upset, anorexia, vomiting, diarrhea.*
- *Jaundice, tender hepatomegaly, abnormal LFTs.*
- *Serologic evidence of hepatitis B disease: HBsAg, HBeAg, anti-HBc IgM.*
- *History of parenteral, sexual, or household exposure or maternal HBsAg carriage.*

General Considerations

In contrast to hepatitis A, hepatitis B virus (HBV) infection has a longer incubation period of 21–135 days

(see Table 21–5). The disease is caused by a DNA virus that is usually acquired perinatally from a carrier mother, or later in life from blood products, shared needles, needle sticks, skin piercing, or tattoos; or through sexual transmission. Transmission via blood products has been almost eliminated by anti-HBc antibody donor-screening protocols. The complete HBV particle is composed of a core (28-nm particle) that is found in the nucleus of infected liver cells and a double outer shell (surface antigen). The surface antigen in blood is termed HBsAg. The antibody to it is anti-HBs. The core antigen is termed HBcAg and its antibody is anti-HBc. A specific anti-HBc IgM antibody occurs during primary viral replication.

Another important antigen–antibody system associated with HBV disease is the “e” (envelope) antigen system. HBeAg, a truncated soluble form of HBcAg, appears in the serum of infected patients early and correlates with active virus replication. Persistence of HBeAg is a marker of infectivity, whereas the appearance of anti-HBe generally implies termination of viral replication. However, HBV mutant viruses (precore mutant) may replicate with negative HBeAg tests for and positive tests for anti-HBe antibody. Other serologic markers indicating viral replication include the presence of DNA polymerase and circulating HBV DNA.

Clinical Findings

A. SYMPTOMS AND SIGNS

The symptoms are nonspecific, consisting only of slight fever (which may be absent) and mild gastrointestinal upset. Visible jaundice is usually the first significant finding. It is accompanied by darkening of the urine and pale or clay-colored stools. Hepatomegaly is present. Occasionally a symptom complex (caused by antigen–antibody complexes) of macular rash, urticarial lesions, and arthritis antedates the appearance of icterus. Occasionally, HBV infection presents as a glomerulonephritis or nephrotic syndrome. When acquired vertically at birth, chronic disease is frequently completely asymptomatic despite ongoing liver injury.

B. LABORATORY FINDINGS

To diagnose acute HBV infection, the HBsAg and anti-HBc IgM are the only tests needed. To document recovery, immunity, or response to the HBV vaccine, the anti-HBs is useful. If HBsAg persists after 8 weeks in acute infections, it may signify a chronic infection, although chronic infection is defined as lasting 6 months or more. Vertical transmission to newborns is documented by positive HBsAg.

LFT results are similar to those discussed earlier for hepatitis A. Liver histology is similar for HAV and

HBV disease, although specific stains may detect HBcAg or HBsAg in the liver.

Renal involvement may be suspected on the basis of urinary findings suggesting glomerulonephritis or nephrotic syndrome.

Differential Diagnosis

The differentiation between HAV and HBV disease is made easier by a history of parenteral exposure, an HBsAg-positive parent, or an unusually long period of incubation. HBV and hepatitis C virus (HCV) infection or EBV infection are differentiated serologically. The history may suggest a drug-induced hepatitis, especially if a serum sickness prodrome is reported. Autoimmune hepatitis, Wilson disease, hemochromatosis, non-alcoholic steatohepatitis, and α_1 -antitrypsin deficiency should also be considered.

Non-A non-B non-C (NANBNC) hepatitis is diagnosed when test results for the serologic markers of HAV, HBV, HCV and EBV are negative; drug-induced hepatitis if there is a history of drug exposure; autoimmune hepatitis if autoimmune markers are present; Wilson disease if ceruloplasmin levels are abnormal; hemochromatosis if transferrin saturation is high; α_1 -antitrypsin deficiency if serum concentration is decreased, and steatohepatitis if liver biopsy findings are suggestive.

Prevention

Control of hepatitis B in the population is based on screening of blood donors and pregnant women, use of properly sterilized needles and surgical equipment, avoidance of sexual contact with carriers, and vaccination of all infants and adolescents, as well as household contacts, sexual partners, medical personnel, and those at high risk. Universal immunization of all infants born in the United States and of adolescents is now recommended, as it is in most other countries. When acquired vertically at birth, chronic disease is frequently asymptomatic despite ongoing liver injury or a benign carrier state. The vaccine is highly effective for preexposure prophylaxis (see Chapter 9). Postexposure administration of HBIG (0.06 mL/kg intramuscularly, given as soon as possible after exposure, up to 7 days) and initiation of vaccination are also effective.

Treatment

Supportive measures such as bed rest and a nutritious diet are used during the active stage of disease. Corticosteroids are contraindicated. No other treatment is needed for acute HBV infection. For patients with progressive disease (chronic active hepatitis), there are two treatment options. Treatment with α -interferon (5–6 million

units/m² body surface area injected subcutaneously three times a week for 4–6 months) inhibits viral replication in 30–40% of patients, normalizes the ALT level, and leads to the disappearance of HBeAg and the appearance of anti-HBe. Side effects are common. Younger children may respond better than older children. Orally administered lamivudine therapy (3 mg/kg/day up to 100 mg per day for 12 months) leads to a successful response in 25% of treated children, with minimal side effects. However, resistant organisms can emerge. Asymptomatic HBsAg carriers (normal serum ALT, no hepatomegaly) do not respond to either therapy. Liver transplantation is successful in acute fulminant hepatitis B; however, reinfection is common following liver transplantation for chronic hepatitis B. Chronic HBIG therapy or lamivudine therapy reduces recurrence after transplantation.

Prognosis

The prognosis is good, although fulminant hepatitis or chronic hepatitis and cirrhosis may supervene in up to 10% of patients. The course of the disease is variable, but jaundice seldom persists for more than 2 weeks. HBsAg disappears in 95% of cases at the time of clinical recovery. Persistent asymptomatic antigenemia may occur, particularly in children with vertical transmission, Down syndrome, or leukemia and in those undergoing chronic hemodialysis. Persistence of neonatally acquired HBsAg occurs in 70–90% of infants without immunoprophylaxis or vaccination, and the presence of e antigen in the HBsAg carrier indicates ongoing viral replication. If HBV infection is acquired later in childhood, HBV is cleared and recovery occurs in 90–95% of patients. Chronic hepatitis B disease predisposes the patient to development of hepatocellular carcinoma. Once chronic HBV infection is established, surveillance for development of hepatocellular carcinoma with hepatic ultrasonography and serum α -fetoprotein is performed annually. Routine HBV vaccination of newborns in endemic countries has reduced the incidence of hepatocellular carcinoma in children.

HEPATITIS C

General Considerations

Hepatitis C virus (HCV) virus is the most common cause of most non-B chronic hepatitis (90% of post-transfusion hepatitis cases) (see Table 21–6). Risk factors include illicit use of intravenous drugs (40%), occupational or sexual exposure (10%), and transfusions (10%); 30% of cases have no known risk factors. In children, most cases are associated with blood or blood product transfusions, transmission from an infected mother, or other household transmission. In the past, children with hemophilia or on chronic hemodialysis were at significant risk. The risk from transfused blood products has diminished greatly (from 1–2:100 to 1:100,000 units of blood) since the advent of blood testing for ALT and anti-HCV. HCV infection has been caused by contaminated immune serum globulin preparations. Vertical transmission from HCV-infected mothers occurs more commonly with mothers who are HIV-positive (10–20%) compared with those who are HIV-negative (5–6%). About 0.4% of adolescents and 1.5% of adults in the United States are infected. Infected infants have elevated ALT levels, but do not appear ill; long-term outcome is unknown. Transmission of the virus from breast milk is probably rare. HCV rarely causes fulminant hepatitis in children or adults in Western countries, but different serotypes do so in Asia.

HCV is a single-stranded RNA virus in the flavivirus family. At least seven genotypes of HCV exist. Several well-defined HCV antigens are the basis for serologic antibody tests. The third-generation enzyme-linked immunosorbent assay (ELISA) test for anti-HCV is highly accurate. Anti-HCV is generally present when symptoms occur; however, test results may be negative in the first few months of infection. HCV RNA, which can be detected in serum by PCR and branched-DNA test, indicates active infection.

Clinical Findings

A. SYMPTOMS AND SIGNS

The incubation period is 1–5 months, with insidious onset of symptoms. Many childhood cases, especially those acquired vertically, are asymptomatic despite development of chronic hepatitis. Flu-like prodromal symptoms and jaundice occur in less than 25% of cases. Hepatosplenomegaly may or may not be evident in chronic hepatitis. Ascites, clubbing, palmar erythema, or spider angiomas indicate progression to cirrhosis.

B. LABORATORY FINDINGS

Fluctuating mild to moderate elevations of aminotransferases over long periods are characteristic of chronic

HCV infection. Diagnosis is established by the presence of anti-HCV (second-generation ELISA) confirmed by the radioimmunoblot assay (RIBA) or HCV RNA by PCR. Anti-HCV is acquired passively at birth from infected mothers and cannot be used to confirm disease in the neonate for the first 15 months. HCV RNA testing should be performed in suspicious cases. Results of this test may be negative in the first month of life, but become positive by 4 months.

Percutaneous liver biopsy should be considered in chronic cases. Histologic examination shows portal triaditis with chronic inflammatory cells, occasional lymphocyte nodules in portal tracts, mild macrovesicular steatosis, and variable bridging necrosis, fibrosis, and cirrhosis. Cirrhosis in adults generally requires 10–30 years of chronic HCV infection, but it has occasionally developed sooner in children.

Differential Diagnosis

HCV hepatitis should be distinguished from HAV, HBV, and NANBNC hepatitis by serologic testing. Other causes of cirrhosis in children should be considered in cases of chronic illness, such as Wilson disease or α_1 -antitrypsin deficiency. Chronic hepatitis may also be caused by drug reactions, autoimmune disease, or steatohepatitis.

Treatment

Treatment of acute HCV hepatitis is supportive. Indications for treatment of chronic infection will be determined by current clinical trials. Chronic infection responds to interferon- α (3 million units/m² three times a week for 6–12 months) in 30–50% of cases. Relapses are common and appear to depend on genotype of the virus. Overall only 10–20% are sustained responders, and the response is poorer with infections with genotype 1a or 1b. Combined interferon plus ribavirin is more successful in adults and is being tested in children. Long-acting (pegylated) interferon (with or without ribavirin) is effective in adults and is being tested in children. End-stage liver disease secondary to HCV responds well to liver transplantation, although reinfection is common and gradually progressive. There is no vaccine, and no benefit from using immune globulin in infants born to infected mothers. Elective C-section of HCV-infected pregnant women with a high titer of circulating virus may lessen the likelihood for transmission.

Prognosis

In adults, 70–80% of HCV cases develop chronic hepatitis, and cirrhosis develops in 20% of those with

chronic infection for 10–30 years. Alcohol intake increases this risk. HCV is now the leading indication for liver transplantation in adults. A strong association exists between chronic HCV disease and the development of hepatocellular carcinoma after as little as 15 years. The outcome in children is less well defined, although cirrhosis may develop rapidly or after decades. About 50% of children infected by transfusion in the first few years of life develop chronic infection. Infants infected at birth often have concomitant HIV infection; their outcome is unknown at present. In adults, chronic HCV infection has been associated with mixed cryoglobulinemia, polyarteritis nodosa, a sicca-like syndrome, and membranoproliferative glomerulonephritis.

HEPATITIS D (Delta Agent)

General Considerations

The hepatitis D virus (HDV) is a 35-nm defective virus that requires a coat of HBsAg to be infectious (see Table 21–6). HDV infection thus can occur only in the presence of HBV infection. In developing countries, transmission is by intimate contact; in Western countries, by parenteral exposure. HDV is rare in North America. HDV can infect simultaneously with HBV, causing acute hepatitis, or can superinfect a patient with chronic HBV infection, predisposing the individual to chronic hepatitis or fulminant hepatitis. In children, the association between chronic HDV coinfection with HBV and chronic hepatitis and cirrhosis is a strong. Vertical HDV transmission is rare. The diagnosis of HDV is made by anti-HDV IgM. Treatment is directed at therapy for HBV infection (eg, interferon- α) or for fulminant hepatic failure.

Kelly D, Skidmore S: Hepatitis C-Z: Recent advances. *Arch Dis Child* 2002;86(5):339 [PMID: 11970925].

HEPATITIS E

General Considerations

Hepatitis E virus (HEV) infection is a cause of enterically transmitted, epidemic non-A, non-B hepatitis (see Table 21–6). It is rare in the United States. HEV is a calicivirus-like agent that is transmitted via the fecal–oral route. It occurs predominantly in developing countries in association with water-borne epidemics, and has only a 3% secondary attack rate in household contacts. Areas reporting epidemics include southeast Asia, China, the Indian subcontinent, the Middle East, northern and western Africa, Mexico, and Central America. Its clinical manifestations are similar to those of HAV infection except that symptomatic disease is rare in children, more common in adolescents and adults, and is associated with a high mortality (10–20%) in pregnant women, particularly in the third trimester. Diagnosis is established by detecting anti-HEV antibody. The outcome in nonpregnant individuals is benign, with no chronic hepatitis or chronic carrier state reported. There is no effective treatment.

OTHER HEPATITIS VIRUSES

The recently discovered hepatitis G virus (HGV), also called the GB virus, is relatively common and parenterally and vertically transmitted, but it has not been shown to produce acute or chronic liver disease. Coinfection appears to improve the prognosis of HIV disease. TT virus is also commonly transmitted, but is not a significant cause of hepatitis.

Other undiscovered NANBNC viruses probably cause the majority of cases of fulminant hepatitis in children. Infection with these uncharacterized agents is associated with the development of aplastic anemia in a small proportion of patients recovering from hepatitis and in 15–20% of those undergoing liver transplantation for fulminant hepatitis. Parvovirus has been associ-

ated with fulminant hepatitis; the prognosis is relatively good in children.

Infectious mononucleosis (Epstein–Barr virus) is commonly associated with acute hepatitis. CMV, adenovirus, and leptospirosis are other infectious causes of acute hepatitis.

FULMINANT HEPATIC FAILURE (Acute Massive Hepatic Necrosis, Acute Liver Failure)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute hepatitis with deepening jaundice.
- Extreme elevation of AST and ALT.
- Prolonged prothrombin time.
- Encephalopathy and cerebral edema.
- Asterixis and fetor hepaticus.

General Considerations

Fulminant hepatic failure is defined as acute liver dysfunction resulting in hepatic coma and coagulopathy within 6 weeks after onset. Mortality is 60–80% in children (without liver transplantation). An unusually virulent infectious agent or peculiar host susceptibility is postulated in many cases. In the first few weeks of life, fulminant hepatic failure can be caused by herpes simplex, enteroviruses, adenovirus, galactosemia, fructose intolerance, tyrosinemia, neonatal iron storage disease, respiratory chain and fatty acid oxidation defects, familial erythrophagocytic histiocytosis, bile acid synthesis defects, and peroxisomal diseases. In older infants and children, HBV, NANBNC hepatitis, parvovirus, and HEV are sometimes causative. HAV rarely is responsible. Patients with immunologic deficiency diseases and those receiving immunosuppressive drugs are vulnerable to herpes viruses. In children with HIV infection, nucleoside analogues have triggered lactic acidosis and liver failure. In older children, Wilson dis-

ease, acute fatty liver of pregnancy, Reye syndrome, autoimmune hepatitis, drugs (eg, acetaminophen, anesthetic agents) or toxins (eg, poisonous mushrooms, herbs), leukemia, and cardiac dysfunction must also be considered.

Clinical Findings

In some patients, the disease proceeds in a rapidly fulminant course with deepening jaundice, coagulopathy, hyperammonemia, ascites, a rapidly shrinking liver, and progressive coma. Terminally, AST and ALT, which were greatly elevated (2000–10,000 units/L), may improve at the time when the liver is getting smaller and undergoing massive necrosis and collapse. Some patients start with a course typical of benign hepatitis and then suddenly become severely ill during the second week of the disease. Fever, anorexia, vomiting, and abdominal pain may be noted, and worsening of LFTs parallels changes in sensorium or impending coma. Hyperreflexia and a positive extensor plantar response are seen. A characteristic breath odor (fetor hepaticus) is present. A generalized bleeding tendency occurs at this time. Impairment of renal function, manifested by either oliguria or anuria, is an ominous sign. The striking laboratory findings include elevated serum bilirubin levels (usually > 20 mg/dL), high AST and ALT (> 3000 units/L) that may decrease terminally, low serum albumin, hypoglycemia, and prolonged prothrombin time. Blood ammonia levels may be elevated, whereas blood urea nitrogen is often very low. Hyperpnea is frequent, and mixed respiratory alkalosis and metabolic acidosis are present.

Differential Diagnosis

Infectious, metabolic, and drug/toxin causes are most common. Patients with Reye syndrome or urea cycle defects are typically anicteric. Wilson disease, autoimmune hepatitis, acute leukemia, cardiomyopathy, and Budd–Chiari syndrome should be considered. Acetaminophen, herbal remedies and other toxins (eg, “Ecstasy”) need to be considered even if there is a negative history.

Complications

The development and depth of hepatic coma determine the prognosis. Patients in grade 3 or 4 coma (unresponsiveness to verbal stimuli, decorticate or decerebrate function) rarely survive without transplantation, and may have residual CNS deficits. Cerebral edema, which usually accompanies coma, is frequently the cause of death. Extreme prolongation of prothrombin time or international normalized ratio (INR) predicts poor recovery. Ac-

etaminophen overdose is the exception. Sepsis, hemorrhage, renal failure, or cardiorespiratory arrest is a common terminal event. The rare survivor without transplantation may have residual fibrosis or even cirrhosis.

Treatment

Many regimens have been tried, but controlled evaluation of therapy remains difficult. Exchange transfusion (with fresh heparinized blood) temporarily repairs both the chemical and hematologic abnormalities. Plasmapheresis with plasma exchange, total body washout, charcoal hemoperfusion, and hemodialysis using a special high-permeability membrane have been used in the treatment of fulminant hepatic failure. Removal of circulating toxins may be of greater benefit to extrahepatic organ function (brain) than to the liver itself. Reversal of hepatic encephalopathy may follow any of these therapeutic modalities, but without improving the final prognosis. Extracorporeal hepatic support devices are in development. Orthotopic liver transplantation is successful in 60–85% of cases; however, patients in grade 4 coma may not always recover cerebral function. Therefore, patients in hepatic failure should be transferred early to centers where liver transplantation can be performed. Criteria for deciding when to perform transplantation are not firmly established; however, serum bilirubin over 20 mg/dL, prothrombin time over 30 seconds, and factor V levels less than 20% indicate a poor prognosis. Living related donors may be required for transplantation in a timely fashion. The prognosis is better for acetaminophen ingestion, particularly when *N*-acetylcysteine treatment is given.

Corticosteroids may be harmful, unless autoimmune hepatitis is the cause. Sterilization of the colon with oral antibiotics such as metronidazole, neomycin, or gentamicin is recommended. An alternative is acidification of the colon with lactulose, 1–2 mL/kg three or four times daily, which reduces blood ammonia levels and traps ammonia in the colon. Some centers use *N*-acetylcysteine in all patients.

Close monitoring of fluid and electrolytes is mandatory and requires a central venous line. Ten percent dextrose solutions should be infused (6–8 mg/kg/min) to maintain normal blood glucose. Diuretics, sedatives, and tranquilizers are to be used sparingly. Early signs of cerebral edema are treated with infusions of mannitol (0.5–1 g/kg).

Comatose patients are intubated, given mechanical ventilatory support, and monitored for signs of infection. Coagulopathy is treated with fresh-frozen plasma, other clotting factor concentrates, platelet infusions, or exchange transfusion. Plasmapheresis and hemodialysis may help maintain a patient while awaiting liver transplantation. Epidural monitoring for increased intracra-

nial pressure in patients awaiting liver transplantation is advocated. Artificial hepatic support devices are being developed, although continuous venous–venous dialysis may be helpful. Prophylactic immune globulin, 0.02 mL/kg intramuscularly, should be given to close contacts of patients who have HAV infection.

Prognosis

The overall prognosis remains poor without liver transplantation. Exchange transfusions or other modes of heroic therapy do not improve survival figures. The presence of nests of liver cells seen on liver biopsy amounting to more than 25% of the total cells and rising levels of clotting factors V and VII coupled with rising levels of serum α -fetoprotein may signify a more favorable prognosis for survival. The survival rate in patients who undergo liver transplantation (60–85%) exceeds that of those who do not (20–40%).

AUTOIMMUNE HEPATITIS (LUPOID HEPATITIS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute or chronic hepatitis
- Hypergammaglobulinemia
- Positive ANA, ASMA, or anti-LKM

General Considerations

Autoimmune hepatitis (AIH) is most common in adolescent girls, although it occurs at all ages and in either sex. Chronic hepatitis may also follow HBV, HCV, and

HDV infections. Rarely, chronic hepatitis evolves from drug-induced hepatitis (eg, pemoline) or may develop in conjunction with such diseases as ulcerative colitis, Sjögren syndrome, or autoimmune hemolytic anemia. Wilson disease, α_1 -antitrypsin deficiency, and bile acid synthesis defects may also present as chronic hepatitis. A positive HBsAg test implicates HBV, and anti-HCV and anti-HDV suggest HCV and HDV, respectively. Positive antinuclear antibodies, smooth muscle antibodies (type I AIH) or liver–kidney microsomal (LKM) antibodies (type II AIH), elevated serum IgG, and systemic manifestations (eg, arthralgia, weight loss, acne, amenorrhea) are characteristic of AIH.

A genetic susceptibility to development of this entity is suggested by the increased incidence of the histocompatibility antigens HLA-A1 and HLA-B8. These histocompatibility antigens may be related to a defect in suppressor T-cell function noted in patients with chronic hepatitis. Increased autoimmune disease in families of patients and a high prevalence of seroimmunologic abnormalities in relatives have been noted. Occasionally patients have an “overlap syndrome” of AIH and primary sclerosing cholangitis.

Clinical Findings

Fever, malaise, recurrent or persistent jaundice, skin rash, arthritis, amenorrhea, gynecomastia, acne, pleurisy, pericarditis, or ulcerative colitis may be found in the history of these patients, or asymptomatic hepatomegaly or splenomegaly may be found on examination. Occasionally patients present in acute liver failure. Cutaneous signs of chronic liver disease may be noted (eg, spider angiomas, liver palms, digital clubbing). Hepatosplenomegaly is frequently present.

LFTs reveal moderate elevations of serum bilirubin, AST, ALT, and serum alkaline phosphatase. Serum albumin may be low. Serum IgG levels are strikingly elevated (in the range of 2–6 g/dL). Low levels of C3 complement have been reported. Three subtypes have been described based on autoantibodies present: type 1: anti-smooth muscle (antiactin), type 2: anti-LKM (anticytochrome P-450), and type 3: antisoluble liver antigen.

Histologic examination of liver biopsy specimens shows loss of the lobular limiting plate, and interface hepatitis (“piecemeal” necrosis). Portal fibrosis, an inflammatory reaction of lymphocytes and plasma cells in the portal areas and perivascularly, and some bile duct and Kupffer cell proliferation and pseudolobule formation may be present. Cirrhosis may exist at diagnosis in up to 50% of patients.

Differential Diagnosis

Laboratory and histologic findings differentiate other types of chronic hepatitis (eg, HBV, HCV, and HDV

infection; steatohepatitis; Wilson disease; α_1 -antitrypsin deficiency; primary sclerosing cholangitis). Primary sclerosing cholangitis occasionally presents in a manner similar to AIH, including the presence of autoantibodies. Wilson disease and α_1 -antitrypsin deficiency must be excluded if HBV and HCV studies are negative. Drug-induced (isoniazid, methyldopa, pemoline) chronic hepatitis should be ruled out. In acute, severe viral hepatitis, histologic examination may also show an “aggressive” lesion early in the disease (< 3 months).

Complications

Untreated disease that continues for months to years eventually results in postnecrotic cirrhosis, with complications of portal hypertension. Persistent malaise, fatigue, amenorrhea, and anorexia parallel disease activity. Bleeding from esophageal varices and development of ascites usually usher in hepatic failure.

Treatment

Corticosteroids (prednisone, 2 mg/kg/d) decrease the mortality rate during the early active phase of the disease. Azathioprine, 1–2 mg/kg/d, is of value in decreasing the side effects of long-term corticosteroid therapy but should not be used alone during the induction phase of treatment. Steroids are reduced over a 6- to 12-month period, and azathioprine is continued for 1–2 years if AST and ALT are normal. Liver biopsy is performed before stopping azathioprine therapy; if inflammation persists, then azathioprine is continued. Relapses are treated similarly. Many patients require chronic azathioprine therapy. UCDA, cyclosporine, tacrolimus, or methotrexate may be helpful in poorly responsive cases. Use of mycophenolate mofetil instead of azathioprine is under study. Liver transplantation is indicated when disease progresses to decompensated cirrhosis despite therapy or in unresponsive cases presenting in acute liver failure. Steroid therapy may be life-saving in those presenting in acute liver failure.

Prognosis

The overall prognosis for AIH is improved significantly with early therapy. Some studies report cures (normal histologic findings) in 15–20% of patients. Relapses (seen clinically and histologically) occur in 40–50% of patients after cessation of therapy; remissions follow repeat treatment. Survival for 10 years is common despite residual cirrhosis. Of children with AIH, 20–50% eventually require liver transplantation. Complications of portal hypertension (bleeding varices, ascites) require specific therapy. Liver transplantation is successful 70–90% of the time. Disease recurrence after trans-

plantation occurs 10–50% of the time and is treated similarly to pretransplant disease.

STEATOHEPATITIS

Patients with steatohepatitis present with asymptomatic soft hepatomegaly or mild to moderately elevated aminotransferases (2 to 10 times the upper limit of normal). ALT is frequently higher than AST. Alkaline phosphatase and GGT may be mildly elevated, but bilirubin is normal. Liver biopsy shows macrovesicular steatosis, mild portal inflammation, normal bile ducts, and variable degrees of portal fibrosis to cirrhosis. Ultrasonography or CT scanning indicates fat density in the liver. Most cases are associated with obesity or type II diabetes mellitus. One to three percent of adolescents may have steatohepatitis, based on the observation that 15–25% of American adolescents are overweight or obese and that roughly 10% of these will have steatohepatitis. Steatohepatitis is also associated with Wilson disease, hereditary fructose intolerance, tyrosinemia, HCV hepatitis, cystic fibrosis, fatty acid oxidation defects, kwashiorkor, Reye syndrome, respiratory chain defects, and toxic hepatopathy (ethanol and others). Treatment is weight reduction and exercise for obesity or treatment for the other causes. A pilot trial suggests that vitamin E may be of value. A similar entity, termed nonalcoholic steatohepatitis, occurs in adults. Cirrhosis and liver failure have been described in adults with this disease.

α_1 -ANTITRYPSIN DEFICIENCY LIVER DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Serum α_1 -antitrypsin level less than 50–80 mg/dL.
- Identification of a specific protease inhibitor (Pi) system phenotype (ZZ, SZ).
- Detection of diastase-resistant glycoprotein deposits in periportal hepatocytes.
- Histologic evidence of liver disease.
- Family history of early-onset pulmonary disease or liver disease.

General Considerations

The disease is caused by a deficiency in α_1 -antitrypsin, a protease inhibitor (Pi) system, predisposing patients to chronic liver disease and an early onset of pulmonary emphysema. It is most often associated with the Pi phenotype ZZ. The other phenotype associated with possible liver disease is SZ. Heterozygotes may have a slightly higher incidence of liver disease. The exact relationship between low levels of serum α_1 -antitrypsin and the development of liver disease is unclear. Emphysema develops because of a lack of inhibition of neutrophil elastase, which destroys pulmonary connective tissue. Although all patients with the ZZ genotype eventually have antitrypsin inclusions in hepatocytes, only about 10–20% develop significant liver disease. An associated abnormality in the microsomal disposal of accumulated aggregates may be necessary for the liver disease phenotype.

About 20% of affected individuals present with neonatal cholestasis. About 10% of individuals with α_1 -antitrypsin deficiency have or have had clinically significant liver injury by age 18 years. Very few children have significant pulmonary involvement. Most children are asymptomatic, with no laboratory or clinical evidence of liver disease.

Clinical Findings

A. SYMPTOMS AND SIGNS

α_1 -Antitrypsin deficiency should be considered in all infants with neonatal cholestasis. Serum GGT is usually elevated. Jaundice, acholic stools, and malabsorption suggest neonatal hepatitis but are not pathognomonic of any one cause. Infants are often small for gestational

age, and hepatosplenomegaly may be present. The family history may be positive for emphysema or cirrhosis.

In older children, hepatomegaly or physical findings suggestive of cirrhosis, especially in the face of a negative history of liver disease, should always lead one to consider α_1 -antitrypsin deficiency. Recurrent pulmonary disease (bronchitis, pneumonia) may be present in a few children.

B. LABORATORY FINDINGS

Levels of the α_1 -globulin fraction may be less than 0.2 mg/dL on serum protein electrophoresis. α_1 -Antitrypsin levels are low (< 50–80 mg/dL) in homozygotes (ZZ). Specific Pi phenotyping should be done to confirm the diagnosis. LFTs often reflect underlying hepatic pathologic changes. Hyperbilirubinemia (mixed) and elevated aminotransferases, alkaline phosphatase, and GGT are present early. Hyperbilirubinemia generally resolves, while aminotransferase elevation may persist. Signs of cirrhosis and portal hypertension may develop.

Liver biopsy after age 6 months shows diastase-resistant, periodic acid-Schiff staining intracellular granules, with hyaline masses, particularly in periportal zones. These may be absent prior to age 6 months.

Differential Diagnosis

In newborns, other specific causes of neonatal cholestasis need to be considered. In older children, other causes of insidious cirrhosis (eg, HBV or HCV infection, autoimmune hepatitis, Wilson disease, cystic fibrosis, hemochromatosis, glycogen storage disease) should be considered.

Complications

Of all infants with Pi ZZ α_1 -antitrypsin deficiency, only 20% develop liver disease in childhood. The complications of portal hypertension, cirrhosis, and chronic cholestasis predominate in affected children. Occasionally, children develop paucity of interlobular bile ducts.

Early-onset pulmonary emphysema occurs in young adults (age 30–40 years), particularly in smokers. An increased susceptibility to hepatocellular carcinoma has been noted in cirrhosis associated with α_1 -antitrypsin deficiency.

Treatment

There is no specific treatment for the liver disease of this disorder. Replacement of the protein by transfusion therapy is successful in preventing pulmonary disease in affected adults. The neonatal cholestatic condition is treated with cholagogues, medium-chain triglyceride-containing formula, and water-miscible vitamins (see

Table 21–4). UCDA may reduce AST, ALT, and GGT, but its effect on outcome is unknown. Portal hypertension, esophageal bleeding, ascites, and other complications are treated as described elsewhere. Hepatitis A and B vaccines should be given to children with α_1 -antitrypsin deficiency. Genetic counseling is indicated whenever the diagnosis is made. Diagnosis by prenatal screening is possible. Liver transplantation cures the deficiency. Cigarette smoke exposure should be eliminated to help prevent pulmonary manifestations.

Prognosis

Of those patients presenting with neonatal cholestasis, approximately 10–25% will need liver transplantation in the first 5 years of life, 15–25% during childhood or adolescence, and 50–75% will survive into adulthood with variable degrees of liver fibrosis. A correlation between histologic patterns and clinical course has been documented in the infantile form of the disease. Liver failure can be expected 5–15 years after development of cirrhosis. Recurrence or persistence of hyperbilirubinemia along with worsening coagulation studies indicates the need for evaluation for possible liver transplantation. Decompensated cirrhosis caused by this disease is an excellent indication for liver transplantation; the survival rate should reach 80–90%.

WILSON DISEASE (Hepatolenticular Degeneration)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute or chronic liver disease.
- Deteriorating neurologic status.
- Kayser–Fleischer rings.
- Elevated liver copper.

- *Abnormalities in levels of ceruloplasmin and serum and urine copper.*

General Considerations

Wilson disease is caused by a mutation in the gene on chromosome 13 coding for a specific P-type ATPase involved in copper transport. This results in impaired bile excretion of copper and incorporation of copper into ceruloplasmin by the liver. The accumulated hepatic copper causes oxidant (free-radical) damage to the liver. Subsequently, copper accumulates in the basal ganglia and other tissues. The disease should be considered in all children older than 4 years old with evidence of liver disease (especially with hemolysis) or with suggestive neurologic signs. A family history is often present, and 25% of patients are identified by screening asymptomatic homozygous family members. The disease is autosomal recessive and occurs in 1:30,000 live births in all populations.

Clinical Findings

A. SYMPTOMS AND SIGNS

Hepatic involvement may be fulminant, present as an acute hepatitis, may masquerade as chronic liver disease, or may progress insidiously to postnecrotic cirrhosis. Findings include jaundice; hepatomegaly early in childhood; splenomegaly; Kayser–Fleischer rings; and later onset of neurologic manifestations such as tremor, dysarthria, and drooling beginning after age 10 years. Deterioration in school performance is often the earliest neurologic expression of disease. Psychiatric symptoms may also occur. The Kayser–Fleischer rings can sometimes be detected by unaided visual inspection as a brown band at the junction of the iris and cornea, but slitlamp examination is always necessary. Absence of Kayser–Fleischer rings does not exclude this diagnosis.

B. LABORATORY FINDINGS

The laboratory diagnosis is sometimes difficult. Serum ceruloplasmin levels (measured by the oxidase method) are usually less than 20 mg/dL. (Normal values are 23–43 mg/dL.) Low values, however, occur normally in infants younger than age 3 months, and in at least 5–10% of homozygotes the levels may be within the lower end of the normal range (20–30 mg/dL), particularly if immunoassays are used for ceruloplasmin. Rare patients with higher ceruloplasmin levels have been reported. Serum copper levels are low, but the overlap with normal is too great for satisfactory discrimination. In acute fulminant Wilson disease, serum copper levels

are elevated markedly owing to hepatic necrosis and release of copper. The presence of anemia, hemolysis, very high serum bilirubin levels (> 20–30 mg/dL), and low alkaline phosphatase are characteristic of acute Wilson disease. Urine copper excretion in children older than age 3 years is normally less than 30 µg/d; in Wilson disease, it is greater than 150 µg/d. Finally, the tissue content of copper from a liver biopsy, normally less than 50 µg/g dry tissue, is greater than 250 µg/g in Wilson disease.

Glycosuria, aminoaciduria, and depressed serum uric acid levels have been reported. Hemolysis and gallstones may be present; bone lesions simulating those of osteochondritis dissecans have also been found.

The coarse nodular cirrhosis, steatosis, and glyco-genated nuclei seen on liver biopsy may distinguish Wilson disease from other types of cirrhosis. Early in the disease, vacuolation of liver cells, steatosis, and lipofuscin granules can be seen, as well as Mallory bodies. The presence of Mallory bodies in a child is strongly suggestive of Wilson disease. Stains for copper may sometimes be negative despite high copper content in the liver. Therefore, liver copper levels must be determined biochemically on biopsy specimens. Electron microscopy findings may be helpful.

Differential Diagnosis

During the icteric phase, acute viral hepatitis, α_1 -antitrypsin deficiency, autoimmune hepatitis, Indian childhood cirrhosis, and drug-induced hepatitis are the usual diagnostic possibilities. Later, other causes of cirrhosis and portal hypertension require consideration. Laboratory testing for serum ceruloplasmin, 24-hour urine copper excretion, liver copper concentration, and a slitlamp examination of the cornea will differentiate Wilson disease from the others. The radiocopper ceruloplasmin incorporation test is sometimes needed to differentiate Wilson disease with a normal ceruloplasmin level from other liver disease with increased liver and urine copper values. Urinary copper excretion during penicillamine challenge may help differentiate Wilson disease from other causes. Genetic testing may be necessary in confusing cases. Other copper storage diseases that occur in early childhood include Indian childhood cirrhosis, Tyrolean childhood cirrhosis, and idiopathic copper toxicosis. However, ceruloplasmin concentrations are normal in these conditions.

Complications

Progressive liver disease, postnecrotic cirrhosis, hepatic coma, and death are common in the untreated patient. The complications of portal hypertension (variceal hemorrhage, ascites) are poorly tolerated by these pa-

tients. Progressive degenerating central nervous system disease and terminal aspiration pneumonia are common in untreated older people. Acute hemolytic disease may result in renal impairment and profound jaundice as part of the presentation of fulminant hepatitis.

Treatment

Copper chelation with D-penicillamine or trientine hydrochloride, 1000–2000 mg/d orally, is the treatment of choice in all cases, whether or not the patient is symptomatic. It is best to begin with 250 mg/d and increase the dose weekly by 250 mg increments. The target dose is 20 mg/kg/d. Strict dietary restriction of copper intake is not practical. Supplementation with zinc acetate (25–50 mg orally, three times daily) may reduce copper absorption. Copper chelation is continued for life, although doses may be reduced transiently at the time of surgery or early in pregnancy. Vitamin B₆ (25 mg) is given daily while on penicillamine to prevent optic neuritis. In some countries, after a clinical response to penicillamine or trientine, zinc therapy is substituted and continued for life. Tetrathiomolybdate is being tested as an alternative therapy. Noncompliance with the drug regimen can lead to fulminant liver failure and death.

General treatment measures for acute hepatitis are as outlined for infectious hepatitis. Liver transplantation is indicated for all cases of acute fulminant disease, progressive hepatic decompensation despite several months of penicillamine, and severe progressive hepatic insufficiency in patients who unadvisedly discontinue penicillamine therapy.

Prognosis

The prognosis of untreated Wilson disease is poor. Without transplantation, all patients with the fulminant presentation succumb. Copper chelation reduces hepatic copper content, reverses many of the liver lesions, and can stabilize the clinical course of established cirrhosis. Neurologic symptoms generally respond to therapy. All siblings should be immediately screened and homozygotes given treatment with copper chelation or zinc acetate therapy, even if asymptomatic. Genetic testing (haplotype analysis or genotyping) is available at a few centers for family members.

REYE SYNDROME (Encephalopathy with Fatty Degeneration of the Viscera)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Prodromal upper respiratory tract infection, influenza A or B illness, or varicella.*
- *Vomiting.*
- *Lethargy, drowsiness progressing to semicoma.*
- *Elevated AST, hyperammonemia, normal or slightly elevated bilirubin, prolonged prothrombin time.*
- *Microvesicular steatosis of the liver, kidneys, brain.*
- *Absence of other metabolic diseases.*

General Considerations

The number of reported cases of Reye syndrome is decreasing, perhaps because of a decline in the use of salicylates among younger children, who seem to be at greater risk. Varicella, influenza A and B, echovirus 2, coxsackievirus A, and Epstein–Barr virus infection are associated. Salicylate use is associated with Reye syndrome. Many apparent cases are actually caused by defects in fatty acid oxidation and other newly discovered metabolic diseases.

The pathogenesis is thought to be damage to mitochondria caused by salicylate metabolites or some other toxin or chemical in the milieu of a viral infection or underlying polymorphism in mitochondrial function. Mitochondrial dysfunction leads to elevated short-chain fatty acids and hyperammonemia as well as directly to cerebral edema.

Clinical Findings

A. SYMPTOMS AND SIGNS

Varicella, influenza, or minor upper respiratory tract illness precedes the development of vomiting, irrational behavior, progressive stupor, and coma. Restlessness

and convulsions may also occur. Striking physical findings are hyperpnea, irregular respirations, and dilated, sluggishly reacting pupils. Jaundice is minimal or absent. The liver may be normal or enlarged. Splenomegaly is absent. A positive Babinski sign, hyperreflexia, and decorticate and decerebrate posturing are consistent with increased intracranial pressure.

B. LABORATORY FINDINGS

CSF is acellular, and CSF glucose may be low in younger patients who have hypoglycemia. CSF pressure is increased. Moderate to severe elevations of AST, ALT, and lactate dehydrogenase and normal serum bilirubin and alkaline phosphatase values are characteristic. The prothrombin time is usually prolonged, and the blood ammonia is elevated to varying degrees. A mixed respiratory alkalosis and metabolic acidosis is typical. Hyperaminoacidemia (glutamine, alanine, lysine) and hypocitrullinemia are present.

Histology of the liver shows diffuse microvesicular steatosis with minimal inflammatory changes. Glycogen is virtually absent from the hepatocytes in biopsy specimens taken before administration of hypertonic glucose. Mitochondria are large, pleomorphic, and have decreased matricial density on electron microscopy.

The kidney changes include swelling and fatty degeneration of the proximal lobules.

C. ELECTROENCEPHALOGRAPHY

The electroencephalogram shows diffuse slow wave activity.

Differential Diagnosis

Differentiation of Reye syndrome from encephalitis, acute toxic encephalopathy, hepatic coma, or fulminant hepatitis can be made on clinical and laboratory grounds. A negative history and urine screen for ingestion of poisons and drugs, absence of cells in the CSF, and absence of jaundice favor a diagnosis of Reye syndrome. The fatty acid oxidation defects (eg, medium-chain acyl-CoA dehydrogenase deficiency) and other metabolic disorders may resemble Reye syndrome; gas chromatographic analysis of urine and serum acyl-carnitine levels will help differentiate them. Liver biopsy and electron microscopy can be diagnostic and are indicated in atypical cases.

Treatment

Treatment in an intensive care unit is mainly supportive. If cerebral edema can be minimized, the liver makes a full recovery. Mechanical ventilation may become necessary if the patient reaches grade 3 coma (agitated delirium, combativeness). Intracranial pressure

should be monitored directly and kept below 15–20 mm Hg, and systemic blood pressure should be kept high enough to maintain cerebral perfusion pressure above 45–50 mm Hg. Hyperventilation, mannitol infusions (0.5–1 g/kg every 4 hours), barbiturates, or ventricular drainage is used to lower intracranial pressure. Maintenance fluids using 10% glucose should be given at a rate sufficient to produce a urine flow of 1–1.5 mL/kg/h. Vitamin K, 3–5 mg intramuscularly, should be administered. Hypothermia and pentobarbital coma have been used to decrease body (brain) metabolic needs during the period of uncontrolled intracranial pressure.

Prognosis

At least 70% of patients with Reye syndrome survive. The prognosis is related to the depth of coma and the peak ammonia level on admission. Because Reye syndrome is less common now, many patients are diagnosed only when in deep coma. All patients should be screened for fatty acid oxidation and other metabolic defects. Survivors should not be given aspirin.

CIRRHOSIS

Cirrhosis is a histologically defined condition of the liver characterized by diffuse hepatocyte injury and regeneration, an increase in connective tissue (bridging fibrosis), and disorganization of the lobular and vascular architecture (regenerative nodules). It may be micronodular or macronodular in appearance. It is the vasculature distortion that leads to increased resistance to blood flow, producing portal hypertension and its consequences.

Many liver diseases may progress to cirrhosis. In children, the two most common forms of cirrhosis are postnecrotic and biliary—with different causes, symptomatology, and treatment requirements. Both forms can eventually lead to liver failure and death.

In the pediatric population, postnecrotic cirrhosis is often a result of acute or chronic liver disease (eg, idiopathic neonatal giant-cell hepatitis; viral hepatitis [HBV, HCV, or NANBNC hepatitis]; autoimmune or

drug-induced hepatitis); or certain inborn errors of metabolism (see Table 21–5). Cirrhosis is an exceptional outcome of HAV infection and only follows massive hepatic necrosis. The evolution to cirrhosis may be insidious, with no recognized icteric phase, as in some cases of HBV or HCV infection, Wilson disease, hemochromatosis, or α_1 -antitrypsin deficiency. At the time of diagnosis of cirrhosis, the underlying liver disease may be active, with abnormal LFT results; or it may be quiescent, with normal LFTs. Most cases of biliary cirrhosis result from congenital abnormalities of the bile ducts (biliary atresia, choledochal cyst, common duct stenosis), tumors of the bile duct, Caroli disease, Byler disease, primary sclerosing cholangitis, paucity of the intrahepatic bile ducts, and cystic fibrosis.

Occasionally, cirrhosis may follow a hypersensitivity reaction to certain drugs such as phenytoin. Parasites (*Opisthorchis sinensis*, *Fasciola*, *Ascaris*) may be causative in children living in endemic areas.

Clinical Findings

A. SYMPTOMS AND SIGNS

General malaise, loss of appetite, failure to thrive, and nausea are frequent complaints, especially in anicteric varieties. Easy bruising may be reported. Jaundice may or may not be present. The first indication of underlying liver disease may be ascites, gastrointestinal hemorrhage, or hepatic encephalopathy. Variable hepatosplenomegaly, spider angiomas, warm skin, palmar erythema, or digital clubbing may be present. A small, shrunken liver may be detected by percussion over the right chest wall that reveals resonance rather than expected dullness. Most often, the liver is enlarged slightly, especially in the subxiphoid region, where it has a firm to hard quality and an irregular edge. Ascites may be detected as shifting dullness or a fluid wave. Gynecomastia may be noted in males. Digital clubbing occurs in 10–15% of cases. Pretibial edema often occurs, reflecting underlying hypoproteinemia. In adolescent girls, irregularities of menstruation and amenorrhea may be early complaints.

In biliary cirrhosis, patients often have jaundice, dark urine, pruritus, hepatomegaly, and sometimes xanthoma in addition to the previously mentioned clinical findings. Undernutrition and failure to thrive because of steatorrhea may be more apparent in this form of cirrhosis.

B. LABORATORY FINDINGS

Mild abnormalities of aminotransferases (AST, ALT) are often present, with a decreased level of albumin and a variable increase in the level of γ -globulins. Prothrombin time is prolonged and may be unresponsive to vita-

min K administration. Burr and target red cells may be noted on the peripheral blood smear. Anemia, thrombocytopenia, and leukopenia are present if hypersplenism exists. However, cirrhosis may be present despite normal blood tests.

In biliary cirrhosis, elevated conjugated bilirubin, bile acids, GGT, alkaline phosphatase, and cholesterol are common.

C. IMAGING

Hepatic ultrasound or CT examination may demonstrate abnormal hepatic texture and nodules. In biliary cirrhosis, abnormalities of the biliary tree may be apparent by ultrasonography, CT, hepatobiliary scintigraphy, or cholangiography.

D. PATHOLOGIC FINDINGS

Liver biopsy findings of regenerating nodules and surrounding fibrosis are hallmarks of cirrhosis. Pathologic features of biliary cirrhosis also include canalicular and hepatocyte cholestasis, as well as plugging of bile ducts. The interlobular bile ducts may be increased or decreased, depending on the cause and the stage of the disease process.

Complications & Treatment

Major complications of cirrhosis in childhood include progressive nutritional disturbances and hormonal disturbances and the evolution of portal hypertension and its complications. Hepatocellular carcinoma occurs with increased frequency in the cirrhotic liver, especially in patients with the chronic form of hereditary tyrosinemia or after long-standing HBV or HCV disease. At present, there is no proven medical treatment for cirrhosis, but whenever a treatable condition is identified (eg, Wilson disease, galactosemia, congenital fructose intolerance) or an offending agent eliminated (HBV, HCV, drugs, toxins), disease progression can be altered; occasionally regression of fibrosis has been noted. Immunosuppressive treatment in autoimmune hepatitis can halt the progression of cirrhosis. Surgical correction of biliary tree abnormalities can stabilize the disease process or lead to a reversal in some situations. Children with cirrhosis should receive the hepatitis A and B vaccines. Liver transplantation may be appropriate in patients with cirrhosis whose disease is continuing to progress or in whom the complications of cirrhosis are no longer manageable.

Prognosis

Postnecrotic cirrhosis has an unpredictable course. Without transplantation, affected patients may die from liver failure within 10–15 years. Patients with a

rising bilirubin or a vitamin K-resistant coagulopathy along with diuretic refractory ascites usually survive less than 1–2 years. The terminal event in some patients may be generalized hemorrhage, sepsis, or cardiorespiratory arrest. For patients with biliary cirrhosis, the prognosis is similar, except for those with surgically corrected lesions that result in regression or stabilization of the underlying liver condition. With liver transplantation, the long-term survival rate is 70–80%.

PORTAL HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Splenomegaly.
- Recurrent ascites.
- Variceal hemorrhage.
- Hypersplenism.

General Considerations

Portal hypertension is defined as an increase in the portal venous pressure to more than 5 mm Hg greater than the inferior vena caval pressure. Portal hypertension is most commonly a result of cirrhosis. However, portal hypertension without cirrhosis may be divided into prehepatic, suprahepatic, and intrahepatic causes. Although the specific lesions vary somewhat in their clinical signs and symptoms, the consequences of portal hypertension are common to all.

A. PREHEPATIC PORTAL HYPERTENSION

Prehepatic portal hypertension from acquired abnormalities of the portal and splenic veins accounts for 5–8% of cases of gastrointestinal bleeding in children. A history of neonatal omphalitis, sepsis, dehydration, or umbilical vein catheterization is present in 30–50% of patients. Less common causes in older children include local trauma, peritonitis (pyelophlebitis), hypercoagulable states, and pancreatitis. Symptoms may occur before age 1 year, but in most cases the diagnosis is not

made until age 3–5 years. Patients with a positive neonatal history tend to be symptomatic earlier.

A variety of portal or splenic vein malformations, some of which may be congenital, have been described, including defects in valves and atretic segments. Cavernous transformation is probably the result of attempted collateralization around the thrombosed portal vein rather than a congenital malformation. The site of the venous obstruction may be anywhere from the hilum of the liver to the hilum of the spleen.

B. SUPRAHEPATIC VEIN OCCLUSION OR THROMBOSIS (BUDD–CHIARI SYNDROME)

In most instances, no cause can be demonstrated. Suggested causes include endothelial injury to hepatic veins by bacterial endotoxins, which has been demonstrated experimentally. The occasional association of hepatic vein thrombosis in inflammatory bowel disease favors the presence of endogenous toxins traversing the liver. Allergic vasculitis leading to endophlebitis of the hepatic veins has been described occasionally. In addition, hepatic vein obstruction may be secondary to tumor, abdominal trauma, hyperthermia, or sepsis, or it may occur following the repair of an omphalocele or gastroschisis. Congenital vena caval bands, webs, a membrane, or strictures above the hepatic veins are sometimes causative. Hepatic vein thrombosis may be a complication of oral contraceptive medications. Underlying thrombotic conditions (deficiency of antithrombin III, protein C or protein S, factor V Leiden; antiphospholipid antibodies; or mutations of the prothrombin gene) should be evaluated.

C. INTRAHEPATIC PORTAL HYPERTENSION

1. Cirrhosis (see previous section).

2. Veno-occlusive disease (acute stage)—This now occurs most frequently in bone marrow transplant patients. It may also develop after chemotherapy for acute leukemia, particularly with thioguanine. Additional causes include the ingestion of pyrrolizidine alkaloids (“bush tea”) or other herbal teas and a familial form of the disease occurring in congenital immunodeficiency states.

The acute form of the disease generally occurs in the first month after bone marrow transplantation and is heralded by the triad of weight gain (ascites), tender hepatomegaly, and jaundice.

3. Congenital hepatic fibrosis—This is a rare autosomal recessive cause of intrahepatic presinusoidal portal hypertension (Table 21–7). Liver biopsy is generally diagnostic, demonstrating Meyenburg complexes. On angiography, the intrahepatic branches of the portal vein may be duplicated. Renal abnormalities (microcystic disease) are often associated with the hepatic lesion;

Table 21–7. Biliary tract diseases of childhood.

	Acute Hydrops Transient Dilatation of Gallbladder^{a,b}	Choledochal Cyst^c (See Figure 20–1.)	Acalculous Cholecystitis^d	Caroli Disease^e (Idiopathic Intrahepatic Bile Duct Dilatation)	Congenital Hepatic Fibrosis^f
Predisposing or associated conditions	Premature infants with prolonged fasting or systemic illness. Hepatitis. Abnormalities of cystic duct. Kawasaki disease. Bacterial sepsis, EBV.	Congenital lesion. Female sex. Asians. Rarely with Caroli disease or congenital hepatic fibrosis.	Systemic illness, sepsis (<i>Streptococcus</i> , <i>Salmonella</i> , <i>Klebsiella</i> , etc), HIV infection. Gallbladder stasis, obstruction of cystic duct (stones, nodes, tumor).	Congenital lesion. Also found in congenital hepatic fibrosis or with choledochal cyst. Female sex. Autosomal-recessive polycystic kidney disease.	Familial (autosomal-recessive) 25% with autosomal-recessive polycystic kidney disease. Choledochal cyst. Caroli's disease. Meckel–Gruber, Ivemark's, or Jeune's syndrome.
Symptoms	Absent in premature infants. Vomiting, abdominal pain in older children.	Abdominal pain, vomiting, jaundice.	Acute severe abdominal pain, vomiting, fever.	Recurrent abdominal pain, vomiting. Fever, jaundice when cholangitis occurs.	Hematemesis, melena from bleeding esophageal varices.
Signs	Right upper quadrant abdominal mass. Tenderness in some.	Icterus, acholic stools, dark urine in neonatal period. Right upper quadrant abdominal mass or tenderness in older children.	Tenderness in mid and right upper abdomen. Occasional palpable mass in right upper quadrant.	Icterus, hepatomegaly.	Hepatosplenomegaly.
Laboratory abnormalities	Most are normal. Increased WBC count in sepsis (may be decreased in premature infants). Abnormal LFTs in hepatitis.	Conjugated hyperbilirubinemia, elevated GGT, slightly increased AST. Elevated pancreatic serum amylase if ampulla hepatopancreatica is involved.	Elevated WBC count, normal or slight abnormality of LFTs.	Abnormal LFTs. Increased WBC count with cholangitis. Urine abnormalities if associated with congenital hepatic fibrosis.	Low platelet and WBC count (hypersplenism), slight elevation of AST, GGT. Inability to concentrate urine.
Diagnostic studies most useful	Gallbladder ultrasonography.	Gallbladder ultrasonography, hepatobiliary scintigraphy, ERCP, or MRCP.	Scintigraphy to confirm non-function of gallbladder. Ultrasonography or abdominal CT scan to rule out other neighboring disease.	Transhepatic cholangiography, ERCP, MRCP, scintigraphy, ultrasonography, intravenous pyelography.	Liver biopsy. Ultrasonography of the liver and kidneys. Upper endoscopy.
Treatment	Treatment of associated condition. Needle or tube cystostomy rarely required. Cholecystectomy seldom indicated.	Surgical resection and choledochojejunostomy	Broad-spectrum antibiotic coverage, then cholecystectomy or cholecystostomy drainage and definitive surgery 3–4 weeks later.	Antibiotics and surgical or endoscopic drainage for cholangitis. Liver transplantation for some. Lobectomy for localized disease.	Treatment of portal hypertension. Liver/kidney transplantation for some.

(continued)

Table 21–7. Biliary tract diseases of childhood. (continued)

	Acute Hydrops Transient Dilatation of Gallbladder^{a,b}	Choledochal Cyst^c (See Figure 20–1.)	Acalculous Cholecystitis^d	Caroli Disease^e (Idiopathic Intrahepatic Bile Duct Dilatation)	Congenital Hepatic Fibrosis^f
Complications	Perforation with bile peritonitis rare.	Progressive biliary cirrhosis. Increased incidence of cholangiocarcinoma. Cholangitis in some.	Perforation and bile peritonitis, sepsis, abscess or fistula formation. Pancreatitis.	Sepsis with episodes of cholangitis, biliary cirrhosis, portal hypertension. Intraductal stones. Cholangiocarcinoma.	Bleeding from varices. Splenic rupture, severe thrombocytopenia. Progressive renal failure.
Prognosis	Excellent with resolution of underlying condition. Consider cystic duct obstruction if disorder fails to resolve.	Depends on anatomic type of cyst, associated condition, and success of surgery. Liver transplantation required in some.	Good with early diagnosis and treatment.	Poor, with gradual deterioration of liver function. Multiple surgical drainage procedures expected. Liver transplantation should alter long-term prognosis.	Good in absence of serious renal involvement and with control of portal hypertension. Slightly increased risk of cholangiocarcinoma.

Ultrasonography = liver and biliary tract scanning; scintigraphy = hepatobiliary scan using radiolabeled ^{99m}technetium; AST = aspartate aminotransferase (SGOT); CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; GGT = γ -glutamyl transpeptidase; LFT = liver function tests; MRCP = magnetic resonance cholangiopancreatography; WBC = white blood count.

therefore, renal ultrasonography and urography should be routinely performed.

4. Other rare causes—Hepatoportal sclerosis (idiopathic portal hypertension, noncirrhotic portal fibrosis), noncirrhotic nodular transformation of the liver, and schistosomal hepatic fibrosis are also rare causes of intrahepatic presinusoidal portal hypertension.

Clinical Findings

A. SYMPTOMS AND SIGNS

For prehepatic portal hypertension, splenomegaly in an otherwise well child is the most constant physical sign. Recurrent episodes of abdominal distention resulting from ascites may also be noted. The usual presenting symptoms are hematemesis and melena.

The presence of prehepatic portal hypertension is suggested by the following: (1) an episode of severe infection in the newborn period or early infancy—especially omphalitis, sepsis, gastroenteritis, severe dehydration, or prolonged or difficult umbilical vein catheterizations; (2) no previous evidence of liver disease; (3) a history of well-being prior to onset or recognition of symptoms; and (4) normal liver size and tests with splenomegaly.

Most patients with suprahepatic portal hypertension present with abdominal pain, tender hepatomegaly of acute onset, and abdominal enlargement caused by ascites. Jaundice is present in only 25% of patients. Vomiting, hematemesis, and diarrhea are less common. Cutaneous signs of chronic liver disease are often absent, as the obstruction is usually acute. Distended superficial veins on the back and the anterior abdomen, along with dependent edema, are seen when inferior vena cava obstruction affects hepatic vein outflow. Absence of hepatojugular reflux (jugular distention when pressure is applied to the liver) is a helpful clinical sign.

The symptoms and signs of intrahepatic portal hypertension are generally those of cirrhosis (see section on Cirrhosis).

B. LABORATORY FINDINGS AND IMAGING

Most other common causes of splenomegaly or hepatosplenomegaly may be excluded by proper laboratory tests. Cultures, Epstein–Barr virus titers, hepatitis serologies, blood smear examination, bone marrow studies, and LFTs may be necessary. In prehepatic portal hypertension, LFTs are generally normal. In Budd–Chiari syndrome and veno-occlusive disease, mild to moderate hyperbilirubinemia with modest elevations of aminotransferases and prothrombin time are often present. Hypersplenism with mild leukopenia and thrombocytopenia is often present. Upper endoscopy may reveal varices in symptomatic patients. When pos-

sible, confirmation of a normal liver is best obtained by liver biopsy.

Doppler-assisted ultrasound scanning of the liver, portal vein, splenic vein, inferior vena cava, and hepatic veins may assist in defining the vascular anatomy. In prehepatic portal hypertension, abnormalities of the portal or splenic vein may be apparent, whereas the hepatic veins are normal. When noncirrhotic portal hypertension is suspected, angiography often is diagnostic. Selective arteriography of the superior mesenteric artery is recommended prior to surgical shunting to determine the patency of the superior mesenteric vein.

For suprahepatic portal hypertension, an inferior vena-cavogram using catheters from above or below the suspected obstruction may reveal an intrinsic filling defect, an infiltrating tumor, or extrinsic compression of the inferior vena cava by an adjacent lesion. A large caudate lobe of the liver suggests Budd–Chiari syndrome. Care must be taken in interpreting extrinsic pressure defects of the subdiaphragmatic inferior vena cava if ascites is significant.

Simultaneous wedged hepatic vein pressure and hepatic venography are useful to demonstrate obstruction to major hepatic vein ostia and smaller vessels. In the absence of obstruction, reflux across the sinusoids into the portal vein branches can be accomplished. Pressures should also be taken from the right heart and supradiaphragmatic portion of the inferior vena cava to eliminate constrictive pericarditis and pulmonary hypertension from the differential diagnosis.

Differential Diagnosis

All causes of splenomegaly must be included in the differential diagnosis. The most common ones are infections, immune thrombocytopenic purpura, blood dyscrasias, lipidosis, reticuloendotheliosis, cirrhosis of the liver, and cysts or hemangiomas of the spleen. When hematemesis or melena occurs, other causes of gastrointestinal bleeding are possible, such as gastric or duodenal ulcers, tumors, duplications, and inflammatory bowel disease.

Because ascites is almost always present in suprahepatic portal hypertension, cirrhosis resulting from any cause must be excluded. Other suprahepatic (cardiac, pulmonary) causes of portal hypertension must also be ruled out. Although ascites may occur in prehepatic portal hypertension, it is uncommon.

Complications

The major manifestation and complication of portal hypertension is bleeding esophageal varices. Fatal exsanguination is uncommon, but hypovolemic shock or resulting anemia may require prompt treatment. Hy-

persplenism with leukopenia and thrombocytopenia occurs but seldom causes major symptoms. Rupture of the enlarged spleen secondary to trauma is always a threat. Retroperitoneal edema has been reported (Clatworthy sign).

Without treatment, complete and persistent hepatic vein obstruction leads to liver failure, coma, and death. A nonportal type of cirrhosis may develop in the chronic form of hepatic veno-occlusive disease in which small- and medium-sized hepatic veins are affected. Death from renal failure may occur in rare cases of congenital hepatic fibrosis.

Treatment

Definitive treatment of noncirrhotic portal hypertension is generally lacking. In prehepatic portal hypertension, the experience with surgical portosystemic shunts is complicated by a lack of sustained patency in most children younger than age 10 years. Aggressive medical treatment of the complications of prehepatic portal hypertension is the preferred option. Some centers have reported good results with shunting procedures, and the mesorex shunt is preferred when possible. Venocclusive disease may be prevented somewhat by the prophylactic use of UCDA prior to conditioning for bone marrow transplantation. Withdrawal of the suspected offending agent, if possible, may increase the chance of recovery. For suprahepatic portal hypertension, efforts should be directed at determining the underlying cause and correction, if possible. Either surgical or angio-

graphic relief of obstruction should be attempted if a defined obstruction of the vessels is apparent. Liver transplantation should be considered early in the course if direct correction is not possible. In most cases, management of portal hypertension is directed at management of the complications (Table 21–8).

Prognosis

For prehepatic portal hypertension, the prognosis depends on the site of the block, the effectiveness of variceal eradication, the availability of suitable vessels for shunting procedures, and the experience of the surgeon. Each unsuccessful surgical procedure worsens the prognosis. In patients treated by medical means, bleeding episodes seem to diminish with adolescence.

The prognosis in patients treated by medical and supportive therapy may be better than in the surgically treated group, especially when surgery is performed at an early age. Portacaval encephalopathy is unusual after shunting except when protein intake is excessive, but neurologic outcome may be better in patients who receive a mesenterico-left portal bypass when compared with medical management alone.

The mortality rate of hepatic vein obstruction is very high (95%). In veno-occlusive disease, the prognosis is better, with complete recovery possible in 50% of acute forms and 5–10% of subacute forms.

Brown RS Jr, Lake JR: Transjugular intrahepatic portosystemic shunt as a form of treatment for portal hypertension: Indica-

Table 21–8. Treatment of complications of portal hypertension.

Complication	Diagnosis	Treatment
Bleeding esophageal varices	Endoscopic verification of variceal bleeding	Endosclerosis or variceal band ligation. Octreotide, 30 µg/m ² /h intravenous. Pediatric Sengstaken–Blakemore tube. Surgical variceal ligation, selective venous embolization, TIPS, OLT. Propranolol may be useful to prevent recurrent bleeding.
Ascites	Clinical examination (fluid wave, shifting dullness), abdominal ultrasonography	Sodium restriction (1–2 mEq/kg/d), spironolactone (3–5 mg/kg/d), furosemide (1–2 mg/kg/d), intravenous albumin (0.5–1 g/kg per dose), paracentesis, peritoneovenous (LeVeen) shunt, TIPS, surgical portosystemic shunt, OLT. ^a
Hepatic encephalopathy	Abnormal neurologic examination, elevated plasma ammonia	Protein restriction (0.5–1 g/kg/d), intravenous glucose (6–8 mg/kg/min), neomycin (2–4 g/m ² BSA PO in 4 doses), lactulose (1 mL/kg per dose [up to 30 mL] every 4–6 h PO), plasmapheresis, hemodialysis, OLT. ^a
Hypersplenism	Low WBC count, platelets, and/or hemoglobin. Splenomegaly.	No intervention, partial splenic embolization, TIPS, surgical portosystemic shunt, OLT. Splenectomy may worsen variceal bleeding.

^aIn order of sequential management.

TIPS = transjugular intrahepatic portosystemic shunt, OLT = orthotopic liver transplantation, BSA = body surface area, WBC = white blood cell.

BILIARY TRACT DISEASE

1. Cholelithiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Episodic right upper quadrant abdominal pain.
- Elevated bilirubin, alkaline phosphatase, and GGT
- Stones or sludge seen on abdominal ultrasound.

General Considerations

Gallstones may develop at all ages in the pediatric population and in utero. Gallstones may be divided into cholesterol stones, which contain more than 50% cholesterol, and pigment stones, black (sterile bile) and brown (infected bile). Pigment stones predominate in the first decade of life, while cholesterol stones account for up to 90% of gallstones in adolescence. For some

patients, gallbladder dysfunction is associated with biliary sludge formation, which may evolve into “sludge balls” or tumefaction bile and then into gallstones. The process is reversible in many patients.

Clinical Findings

A. HISTORY

Most symptomatic gallstones are associated with acute or recurrent episodes of moderate to severe, sharp right upper quadrant or epigastric pain. The pain may radiate substernally or to the right shoulder. On rare occasions, the presentation may include a history of jaundice, back pain, or generalized abdominal discomfort, when it is associated with pancreatitis, suggesting stone impaction in the common duct or ampulla hepatopancreatica. Nausea and vomiting may occur during attacks. Pain episodes often occur postprandially, especially after ingestion of fatty foods. The groups at risk for gallstones include patients with known or suspected hemolytic disease; females; teenagers with prior pregnancy; obese individuals; certain racial or ethnic groups, particularly Native Americans (Pima Indians) and Hispanics; infants and children with ileal disease (Crohn disease) or prior ileal resection; and patients with cystic fibrosis or Wilson disease. Infants on prolonged parenteral hyperalimentation are at particular risk for gallstone formation. Other, less certain risk factors include a positive family history, use of birth control pills, and diabetes mellitus.

B. SYMPTOMS AND SIGNS

During acute episodes of pain, tenderness is present in the right upper quadrant or epigastrium, with a positive inspiratory arrest (Murphy sign), usually without peritoneal signs. If present, scleral icterus is helpful. Evidence of underlying hemolytic disease in addition to icterus may include pallor (anemia), splenomegaly, tachycardia, and high-output cardiac murmur. Fever is unusual in uncomplicated cases.

C. LABORATORY FINDINGS

Laboratory tests are usually normal unless calculi have lodged in the extrahepatic biliary system, in which case the serum bilirubin and GGT (or alkaline phosphatase) may be elevated. Amylase and lipase levels may be increased if stone obstruction occurs at the ampulla hepatopancreatica.

D. IMAGING

Ultrasound evaluation is the best imaging technique, showing abnormal intraluminal contents (stones, sludge) as well as anatomic alterations of the gallbladder or dilation of the biliary ductal system. The presence of an anechoic acoustic shadow differentiates calculi from

intraluminal sludge or sludge balls. Ceftriaxone may cause similar findings. Plain abdominal radiographs will show calculi with a high calcium content in the region of the gallbladder in up to 15% of patients. Lack of visualization of the gallbladder with hepatobiliary scintigraphy suggests chronic cholecystitis. In selected cases, ERCP or MRCP may be helpful in defining subtle abnormalities of the bile ducts and locating intraductal stones.

Differential Diagnosis

Other abnormal conditions of the biliary system with similar presentation are summarized in Table 21–7. Liver disease (hepatitis, abscess, tumor) can cause similar symptoms or signs. Peptic disease, reflux esophagitis, paraesophageal hiatal hernia, cardiac disease, and pneumomediastinum must be considered when the pain is epigastric or substernal in location. Renal or pancreatic disease is a possible explanation if the pain is localized to the right flank or mid back. Subcapsular or supracapsular lesions of the liver (abscess, tumor, hematoma) or right lower lobe infiltrate may also be a cause of non-traumatic right shoulder pain.

Complications

Major problems are related to stone impaction in either the cystic or common duct and lead to stricture formation or perforation. Acute distention and subsequent perforation of the gallbladder may occur when gallstones cause obstruction of the cystic duct. Stones impacted at the level of the ampulla hepatopancreatica often cause gallstone pancreatitis.

Treatment

Symptomatic cholelithiasis is best treated by either open or laparoscopic cholecystectomy. Intraoperative cholangiography via the cystic duct is required so that the physician can be certain the ductal system is free of retained stones. Calculi in the extrahepatic bile ducts may be removed by ERCP, sphincterotomy, and balloon extraction.

Gallstones developing in premature infants on total parenteral nutrition can be followed by ultrasound examination. Most of the infants are asymptomatic, and the stones will resolve in 3–36 months. Gallstone dissolution using cholelitholytics (UCDA) or mechanical means (lithotripsy) has not been approved for use in children. Asymptomatic gallstones do not usually require treatment, as less than 20% will eventually cause problems.

Prognosis

The prognosis is excellent in uncomplicated cases that come to standard cholecystectomy.

2. Primary Sclerosing Cholangitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Pruritus and jaundice.*
- *Elevated GGT.*
- *Associated with inflammatory bowel disease.*
- *Abnormal ERCP or MRCP.*

General Considerations

Primary sclerosing cholangitis (PSC) is a progressive liver disease of unknown cause, characterized by chronic inflammation and fibrosis of the intra- or extrahepatic bile ducts (or both), with eventual obliteration of peripheral bile ducts, cholangiographic evidence of strictures, and dilation of all or parts of the biliary tree. PSC is more common in males with inflammatory bowel disease, particularly ulcerative colitis. It can also be seen with histiocytosis X, sicca syndromes, congenital and acquired immunodeficiency syndromes, and cystic fibrosis.

Clinical Findings

A. SYMPTOMS AND SIGNS

PSC often has an insidious onset. Clinical symptoms may include abdominal pain, fatigue, pruritus, and jaundice. Acholic stools and steatorrhea can occur. Physical findings include hepatomegaly, splenomegaly, and jaundice.

B. LABORATORY FINDINGS

The earliest finding may be asymptomatic elevation of the GGT. Subsequent laboratory abnormalities include

elevated levels of alkaline phosphatase and bile acids. Later, cholestatic jaundice and elevated AST and ALT may occur. Patients with associated inflammatory bowel disease often test positive for perinuclear antineutrophil cytoplasmic antibodies (pANCA). Other markers of autoimmune liver disease (antinuclear antibodies and antismooth muscle antibody) are often found but are not specific for PSC. Sclerosing cholangitis due to cryptosporidia is common in immunodeficiency syndromes.

C. RADIOLOGIC FINDINGS

Ultrasound may show dilated intrahepatic bile ducts behind strictures. ERCP or MRCP is the diagnostic study of choice, demonstrating irregularities of the biliary tree.

Differential Diagnosis

The differential diagnosis includes infectious hepatitis, secondary cholangitis, autoimmune hepatitis, metabolic liver disease, cystic fibrosis, choledochal cyst, or other anomalies of the biliary tree, including Caroli disease and congenital hepatic fibrosis.

Complications

Complications include secondary bacterial cholangitis, pancreatitis, biliary fibrosis, and cirrhosis. Progression to liver failure is common and the risk of cholangiocarcinoma is higher in PSC.

Treatment

No completely effective treatment is available. Patients with early disease may benefit from high-dose UCDA (20 mg/kg/d). Patients with autoimmune markers may benefit from treatment with corticosteroids and azathioprine. Antibiotic treatment of cholangitis and dilation and stenting of dominant bile duct strictures can reduce symptoms.

Prognosis

The majority of patients will eventually require liver transplantation; however, the course of the disease may be 10–20 years.

3. Other Biliary Tract Disorders

For a schematic representation of the various types of choledochal cysts, see Figure 21–1. For summary information on acute hydrops, choledochal cyst, acalculous cholecystitis, Caroli disease, and congenital hepatic fibrosis, see Table 21–7.

PYOGENIC & AMEBIC LIVER ABSCESS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and painful enlarged liver.
- Ultrasound of liver demonstrating an abscess.
- Positive serum ameba antigen titer or positive bacterial culture of abscess fluid.

TYPE	FINDINGS
I	Spherical dilatation of the common duct
II	Congenital diverticulum of the common bile duct
III	Intrahepatic diverticulum of the common bile duct (cholechocele)
IVa	Multiple intrahepatic communicating cysts (Caroli disease)
IVb	Mixed extrahepatic and intrahepatic fusiform or cystic dilation (possibly variants of Caroli disease, congenital hepatic fibrosis)

Figure 21–1. Classification of cystic dilation of the bile ducts. Types I, II, and III are extrahepatic choledochal cysts. Type IVa is solely intrahepatic, and type IVb is both intrahepatic and extrahepatic. GB = gallbladder; CBD = common bile duct.

General Considerations

Pyogenic liver abscesses are often caused by intestinal bacteria seeded via the portal vein from infected viscera and occasionally from ascending cholangitis or gangrenous cholecystitis. Blood cultures are positive in up to 60% of patients. The resulting lesion tends to be solitary and located in the right hepatic lobe. Bacterial seeding may also occur from infected burns, pyodermas, and osteomyelitis. Unusual causes include omphalitis, subacute infective endocarditis, pyelonephritis, Crohn disease, and perinephric abscess. In immunocompromised patients, *S aureus*, gram-negative organisms, and fungi may seed the liver from the arterial system. Multiple pyogenic liver abscesses are associated with severe sepsis. Children receiving anti-inflammatory and immunosuppressive agents and children with defects in white blood cell function (chronic granulomatous disease) are prone to pyogenic hepatic abscesses, especially those caused by *S aureus*.

Amebic liver abscess is rare in children. An increased risk is associated with travel through areas of endemic infection (Mexico, Southeast Asia). *Entamoeba histolytica* invasion occurs via the large bowel, although a history of diarrhea (colitis-like picture) is not always obtained.

Clinical Findings

With pyogenic liver abscess, nonspecific complaints of fever, chills, malaise, and abdominal pain are frequent. Weight loss is very common, especially in delayed diagnosis. A few patients have shaking chills and jaundice. The dominant complaint is a constant dull pain over an enlarged liver that is tender to palpation. An elevated hemidiaphragm with reduced or absent respiratory excursion may be demonstrated on physical examination and confirmed by fluoroscopy. Laboratory studies show leukocytosis and, at times, anemia. LFTs may be normal or reveal mild elevation of transaminases and alkaline phosphatase. Amebic liver abscesses are usually heralded by an acute illness with high fever, chills, and leukocytosis. Early in the course, liver tests may suggest mild hepatitis. An occasional prodrome may include cough, dyspnea, and shoulder pain as rupture of the abscess into the right chest occurs. Consolidation of the right lower lobe is common (10–30% of patients).

Ultrasound liver scan is the most useful diagnostic aid in evaluating pyogenic and amebic abscesses, detecting lesions as small as 1–2 cm. Nuclear scanning with gallium or technetium sulfur colloid or CT imaging may be useful in differentiating tumor or hydatid cyst.

The distinction between pyogenic and amebic abscesses is best made by indirect hemagglutination test (which is positive in more than 95% of patients with

amebic liver disease) and the prompt response of the latter to antiamebic therapy (metronidazole). Examination of material obtained by needle aspiration of the abscess using ultrasound guidance is often diagnostic.

Differential Diagnosis

Hepatitis, hepatoma, hydatid cyst, gallbladder disease, or biliary tract infections can mimic liver abscess. Subphrenic abscesses, empyema, and pneumonia may give a similar picture. Inflammatory disease of the intestines or of the biliary system may be complicated by liver abscess.

Complications

Spontaneous rupture of the abscess may occur with extension of infection into the subphrenic space, thorax, peritoneal cavity, and, occasionally, the pericardium. Bronchopleural fistula with large sputum production and hemoptysis can develop in severe cases. Simultaneously, the amebic liver abscess may be secondarily infected with bacteria (in 10–20% of patients). Metastatic hematogenous spread to the lungs and the brain has been reported.

Treatment

Ultrasound- or CT-guided percutaneous needle aspiration for aerobic and anaerobic culture with simultaneous placement of a catheter for drainage, combined with appropriate antibiotic therapy, is the treatment of choice for solitary pyogenic liver abscess. Multiple liver abscesses may also be treated successfully by this method. Surgical intervention may be indicated if rupture occurs outside the capsule of the liver or if enterohepatic fistulae are suspected.

Amebic abscesses in uncomplicated cases should be treated promptly with oral metronidazole, 35–50 mg/kg/d, in three divided doses for 10 days. Intravenous metronidazole can be used for patients unable to take oral medication. Failure to improve after 72 hours of drug therapy suggests superimposed bacterial infection or an incorrect diagnosis. At this point, needle aspiration or surgical drainage is indicated. Once oral feedings can be tolerated, a 20-day course of iodoquinol (30 mg/kg/d in three doses) is started as a luminal amebicide. Resolution of the abscess cavity occurs over 3–6 months.

Prognosis

An unrecognized and untreated pyogenic liver abscess is universally fatal. With drainage and antibiotics, the cure rate is about 90%. Most amebic abscesses are cured with conservative medical management; the mor-

tality rate is less than 3%. If extrahepatic complications occur (empyema, bronchopleural fistula, pericardial complications), 10–15% of patients will succumb.

HEPATOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Abdominal enlargement and pain, weight loss, anemia.*
- *Hepatomegaly with or without a definable mass.*
- *Mass lesion on imaging studies.*
- *Laparotomy and tissue biopsy.*

General Considerations

Primary epithelial neoplasms of the liver represent 0.2–5.8% of all malignant conditions in children. After Wilms' tumor and neuroblastoma, hepatomas are the third most common intra-abdominal cancer. The incidence is higher in Southeast Asia, where childhood cirrhosis is more common. There are two basic morphologic types with certain clinical and prognostic differences. Hepatoblastoma predominates in male infants and children and accounts for 79% of liver cancer in children, with most cases appearing before age 5 years. There is an increased risk of hepatoblastoma in Beckwith–Wiedemann syndrome, hemihypertrophy, familial adenomatous polyposis coli, and in premature or low-birth-weight infants. Most lesions are found in the right lobe of the liver. Pathologic differentiation from hepatocarcinoma may be difficult. Hepatocarcinoma, the other major malignant tumor of the liver, occurs more frequently after age 3 years. This type of neoplasm carries a poorer prognosis than hepatoblastoma and causes more abdominal discomfort. Patients with chronic HBV or HCV infection, cirrhosis, glycogen storage disease type I, tyrosinemia, or α_1 -antitrypsin deficiency have an increased risk for hepatocellular carcinoma. The late development of hepatoma in

patients receiving androgens for treatment of Fanconi syndrome and aplastic anemia must also be kept in mind. The use of anabolic steroids by body-conscious adolescents poses a risk of hepatic neoplasia. An interesting aspect of primary epithelial neoplasms of the liver has been the increased incidence of associated anomalies and endocrine abnormalities. Virilization has been reported as a consequence of gonadotropin activity of the tumor. Feminization with bilateral gynecomastia may occur in association with high estradiol levels in the blood, the latter a consequence of increased aromatization of circulating androgens by the liver. Leydig cell hyperplasia without spermatogenesis is found on testicular biopsy. Hemihypertrophy, congenital absence of the kidney, macroglossia, and Meckel diverticulum have been found in association with hepatocarcinoma.

Clinical Findings

A noticeable increase in abdominal girth with or without pain is the most constant feature of the history. A parent may note a bulge in the upper abdomen or report feeling a hard mass. Constitutional symptoms (eg, anorexia, fatigue, fever, chills) may be present. Teenage boys may complain of gynecomastia.

A. SYMPTOMS AND SIGNS

Weight loss, pallor, and abdominal pain associated with a large abdomen are common. Physical examination reveals hepatomegaly with or without a definite tumor mass, usually to the right of the midline. In the absence of cirrhosis, signs of chronic liver disease are usually absent. However, evidence of virilization or feminization in prepubertal children may be noted.

B. LABORATORY FINDINGS

Normal LFTs are the rule. Anemia frequently occurs, especially in cases of hepatoblastoma. Cystathioninuria has been reported. α -Fetoprotein levels are often elevated, especially in hepatoblastoma. Estradiol levels are sometimes elevated. Final tissue diagnosis is best obtained at laparotomy, although ultrasound- or CT-guided needle biopsy of the liver mass can be used.

C. IMAGING

Ultrasonography, CT, and MRI are useful for diagnosis and for following tumor response to therapy. A scintigraphic study of bone and lung and selective angiography are generally part of the preoperative work-up to evaluate metastatic disease.

Differential Diagnosis

In the absence of a palpable mass, the differential diagnosis is that of hepatomegaly with or without anemia or

jaundice. Hematologic and nutritional conditions should be ruled out, as well as HBV and HCV infection, α_1 -antitrypsin deficiency disease, lipid storage diseases, histiocytosis X, glycogen storage disease, tyrosinemia, congenital hepatic fibrosis, cysts, adenoma, focal nodular hyperplasia, inflammatory pseudotumor, and hemangiomas. If fever is present, hepatic abscess (pyogenic or amebic) must be considered. Venous-occlusive disease and hepatic vein thrombosis are rare possibilities. Tumors in the left lobe may be mistaken for pancreatic pseudocysts.

Complications

Progressive enlargement of the tumor, abdominal discomfort, ascites, respiratory difficulty, and widespread metastases (especially to the lungs and the abdominal lymph nodes) are the rule. Rupture of the neoplastic liver and intraperitoneal hemorrhage have been reported. Progressive anemia and emaciation predispose the patient to an early septic death.

Treatment

An aggressive surgical approach has resulted in the only long-term survivals. Complete resection of the lesion offers the only chance for cure. It appears that every isolated lung metastasis should also be surgically resected. Radiotherapy and chemotherapy have been disappointing in the treatment of primary liver neoplasms, although new combinations of drugs are continually being evaluated. These modalities are also used for initial cytoreduction of tumors found to be unresectable at the time of primary surgery. Second-look celiotomy has, in some cases, allowed resection of the tumor, resulting in a reduced mortality rate. Liver transplantation has been disappointing but continues to be performed in selected patients. The survival rate may be better for those patients in whom the tumor is incidental to another disorder (tyrosinemia, biliary atresia, cirrhosis). In HBV-endemic areas, childhood HBV vaccination has reduced the incidence of hepatocellular carcinoma.

Prognosis

The survival rate if the tumor is completely removed is 90% for hepatoblastoma and 33% for hepatocellular carcinoma. Fibrolamellar oncocytic hepatocarcinoma has a more favorable prognosis. The overall survival and cure rate is less than 20%. If metastases are present, survival is reduced to 30% for hepatoblastoma.

LIVER TRANSPLANTATION

Orthotopic liver transplantation is no longer experimental. Children with end-stage liver disease, acute fulminant hepatic failure, or complications from metabolic liver disorders should be considered for liver transplantation. Recent advances in immunosuppression (eg, cyclosporine and tacrolimus, use of monoclonal antibodies against T cells, introduction of mycophenolate mofetil and sirolimus), better candidate selection, improvements in surgical techniques, and experience in postoperative management have contributed to improved results.

The major indications for childhood transplantation are

1. A failed Kasai operation or decompensated cirrhosis caused by biliary atresia
2. α_1 -Antitrypsin deficiency
3. Posthepatic (autoimmune chronic active hepatitis, hepatitis B or C disease) cirrhosis
4. Tyrosinemia
5. Crigler–Najjar syndrome type I
6. Wilson disease
7. Acute fulminant hepatic failure when recovery is unlikely
8. Primary sclerosing cholangitis
9. Hepatic-based malignancies
10. Cases in which the consequences of chronic cholestasis severely impair the patient's quality of life.

Children should be referred early for evaluation because the limiting factor for success is the small donor pool. Pared-down adult livers, organs from living related donors, and split adult donor livers are being used in children in many centers. Ten percent of recipients require retransplantation. In general, 75–85% of children survive at least 2–5 years after transplantation, with long-term survival expected to be comparable. Lifetime immunosuppression therapy using combina-

tions of cyclosporine, tacrolimus, prednisone, or azathioprine, with its incumbent risks, is necessary to prevent rejection. The overall quality of life for children with a transplanted liver appears to be excellent. The lifelong risk of Epstein–Barr virus-induced lymphoproliferative disease is approximately 5% and is related to age and EBV exposure status at time of transplant and intensity of immunosuppression. Various protocols are being tested for prevention and treatment of lymphoproliferative disease.

PANCREAS

ACUTE PANCREATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Epigastric abdominal pain radiating to the back.*
- *Nausea and vomiting.*
- *Elevated serum amylase and lipase.*
- *Evidence of pancreatic inflammation by CT or ultrasound.*

General Considerations

Most cases of acute pancreatitis are the result of drugs, viral infections, systemic diseases, abdominal trauma, or obstruction of pancreatic flow. More than 20% are idiopathic. Causes of pancreatic obstruction include

stones, choledochal cyst, tumors of the duodenum, pancreas divisum, and ascariasis. Acute pancreatitis has been seen following treatment with sulfasalazine, thiazides, valproic acid, azathioprine, mercaptopurine, asparaginase, antiretroviral drugs (especially ddI), high-dose corticosteroids, and other drugs. It may also occur in cystic fibrosis, systemic lupus erythematosus, α_1 -antitrypsin deficiency, diabetes mellitus, Crohn disease, glycogen storage disease type I, hyperlipidemia types I and V, hyperparathyroidism, Henoch–Schönlein purpura, Reye syndrome, organic acidopathies, Kawasaki disease, or chronic renal failure; during rapid refeeding in cases of malnutrition; and in familial cases. Alcohol-induced pancreatitis should be considered in the teenage patient.

Clinical Findings

A. SYMPTOMS AND SIGNS

An acute onset of persistent (hours to days), moderate to severe upper abdominal and midabdominal pain occasionally referred to the back, and vomiting, is the common presenting picture. The abdomen is tender but not rigid, and bowel sounds are diminished, suggesting peritoneal irritation. Abdominal distention is common in infants and younger children. Jaundice is unusual. Ascites may be noted, and a left-sided pleural effusion is present in some patients. Periumbilical and flank bruising indicate hemorrhagic pancreatitis.

B. LABORATORY FINDINGS

Leukocytosis and an elevated serum amylase (>3 times normal) should be expected early, except in infants younger than age 6 months who may have hypoamylasemia. Serum lipase is elevated and persists longer than serum amylase. The immunoreactive trypsinogen test may also be of value. Pancreatic amylase isoenzyme determination can help differentiate nonpancreatic causes (eg, salivary, intestinal, tubo-ovarian) of serum amylase elevation. Hyperglycemia (serum glucose > 300 mg/dL), hypocalcemia, falling hematocrit, rising blood urea nitrogen, hypoxemia, and acidosis may all occur in severe cases and imply a poor prognosis.

C. IMAGING

Plain radiographic films of the abdomen may show a localized ileus (sentinel loop). Ultrasonography shows decreased echodensity of the gland in comparison with the left lobe of the liver. Pseudocyst formation can also be seen early in the course. CT scanning is better for detecting pancreatic phlegmon, or abscess formation. ERCP or MRCP may be useful in confirming patency of the main pancreatic duct in cases of abdominal trauma; in recurrent acute pancreatitis; or in revealing stones, ductal strictures, and pancreas divisum.

Differential Diagnosis

Other causes of acute upper abdominal pain include lesions of the stomach, duodenum, liver, and biliary system; acute gastroenteritis or atypical appendicitis; pneumonia; volvulus; intussusception; and nonaccidental trauma.

Complications

Complications early in the disease include shock, fluid and electrolyte disturbances, ileus, acute respiratory distress syndrome, and hypocalcemic tetany. Hypervolemia is seen between the third and fifth days, at which time renal tubular necrosis may occur. The gastrointestinal, neurologic, musculoskeletal, hepatobiliary, dermatologic, and hematologic systems may also be involved.

Later, 5–20% of patients develop a pseudocyst heralded by recurrence of abdominal pain and rise in the serum amylase. Up to 60–70% of these pseudocysts will resolve spontaneously. Infection, hemorrhage, rupture, or fistulization may occur. Phlegmon formation is common and may extend from the gland into the retroperitoneum or into the lesser sac. Most regress, but some require drainage. Infection in this inflammatory mass is a constant threat. Pancreatic abscess formation is rare (3–5%) and develops 2–3 weeks after the initial insult. Fever, leukocytosis, and pain suggest this complication; diagnosis is made by ultrasound or CT scanning.

Chronic pancreatitis, exocrine or endocrine pancreatic insufficiency, and pancreatic lithiasis are rare sequelae of acute pancreatitis.

Treatment

Medical management includes rest, gastric suction, fluids, electrolyte replacement, and blood or colloid as needed. Pain should be controlled with opioids. Oxygen may be required if desaturation occurs. Acid suppression may be helpful. Nutrition is provided by the parenteral or enteral (jejunal) route. Broad-spectrum antibiotic coverage is useful only in necrotizing pancreatitis. Drugs known to produce acute pancreatitis should be discontinued.

Surgical treatment is reserved for traumatic disruption of the gland, intraductal stone, other anatomic obstructive lesions, and unresolved or infected pseudocysts or abscesses. Early endoscopic decompression of the biliary system reduces the morbidity associated with pancreatitis caused by obstruction of the common bile duct.

Prognosis

In the pediatric age group, the prognosis is surprisingly good with conservative management. The mortality

rate is 5–10% in patients treated by operation and 1% in those treated medically. The morbidity rate is high with surgery as a result of fistula formation.

Pietzak MM, Thomas DW: Pancreatitis in childhood. *Pediatr Rev* 2000;21:406 [PMID: 11121497].

CHRONIC PANCREATITIS

Chronic pancreatitis is differentiated from acute pancreatitis in that the pancreas remains structurally or functionally abnormal after an attack.

The causes are multiple and can be divided into toxic-metabolic (eg, alcohol, chronic renal failure, hypercalcemia), idiopathic, genetic, autoimmune, recurrent and severe acute pancreatitis, and obstructive pancreatitis (eg, pancreas divisum, choledochal cyst).

Clinical Findings

The diagnosis often is delayed by the nonspecific symptoms and the lack of persistent laboratory abnormalities.

A. SYMPTOMS AND SIGNS

There is usually a history of recurrent upper abdominal pain of variable severity but prolonged duration. Radiation of the pain into the back is a frequent complaint. Fever and vomiting are not common. Steatorrhea and symptoms of diabetes may develop later in the course, and malnutrition secondary to failure of pancreatic exocrine secretions may also occur.

B. LABORATORY FINDINGS

Serum amylase and lipase levels are usually elevated during early acute attacks but are often normal later. Pancreatic insufficiency and reduced volume and bicarbonate response may be found at pancreatic stimulation testing or by determination of fecal pancreatic elastase 1. Mutations of the cationic trypsinogen gene, the pancreatic secretory trypsin inhibitor, and the cystic fibrosis transmembrane conductance regulator gene (CFTR) are associated with recurrent acute and chronic pancreatitis. Elevated blood glucose and glycohemoglobin levels and glycosuria frequently occur in protracted disease. Sweat chloride should be checked for cystic fibrosis and serum calcium for hyperparathyroidism.

C. IMAGING

Radiographs of the abdomen may show pancreatic calcifications in up to 30% of patients. Ultrasound or CT examination demonstrates pancreatic enlargement, ductal dilation, and calculi in up to 80%. CT is the initial imaging procedure of choice. ERCP can show duc-

tal dilation, stones, strictures, or stenotic segments. The use of endoscopic ultrasound and MRCP in the diagnosis and staging of chronic pancreatitis is being evaluated.

Differential Diagnosis

Other causes of recurrent abdominal pain must be considered. Specific causes of pancreatitis such as hyperparathyroidism; systemic lupus erythematosus; infectious disease; and ductal obstruction by tumors, stones, or helminths must be excluded by appropriate tests.

Complications

Disabling abdominal pain, steatorrhea, nutritional deprivation, pancreatic pseudocysts, and diabetes are the most frequent long-term complications. Pancreatic carcinoma occurs more frequently in chronic pancreatitis, and in up to 40% of patients with hereditary pancreatitis by age 70.

Treatment

Medical management of acute attacks is indicated (see Acute Pancreatitis section). If ductal obstruction is strongly suspected, endoscopic therapy (balloon dilation, stenting, stone removal, sphincterotomy) should be pursued. Relapses seem to occur in most patients. Orally ingested non-enteric-coated pancreatic enzymes at mealtime may reduce pain episodes in some patients. Antioxidant therapy is being investigated. Pseudocysts may be marsupialized to the surface or drained into the stomach or into a loop of jejunum if they fail to regress spontaneously. Experience in pediatric patients indicates that lateral pancreaticojejunostomy can reduce pain in patients with a dilated pancreatic duct and may prevent or delay progression of functional pancreatic impairment.

Prognosis

In the absence of a correctable lesion, the prognosis is not good. Disabling episodes of pain, pancreatic insufficiency, diabetes, and pancreatic cancer may ensue. Narcotic addiction and suicide are risks in teenagers with disabling disease.

GASTROINTESTINAL & HEPATOBILIARY MANIFESTATIONS OF CYSTIC FIBROSIS

Cystic fibrosis is a disease with protean manifestations. Although pulmonary and pancreatic involvement dominate the clinical picture for most patients (see Chapter 18), a variety of other organs can be involved. Table 21-9 lists the important gastrointestinal, pancreatic, and hepatobiliary conditions that may affect cystic fibrosis patients along with their clinical findings, incidence, most useful diagnostic studies, and preferred treatment.

SYNDROMES WITH PANCREATIC EXOCRINE INSUFFICIENCY

Several syndromes are associated with exocrine pancreatic insufficiency. Clinically the patients present with a history of failure to thrive, diarrhea, fatty stools, and an absence of respiratory symptoms. Laboratory findings include a normal sweat chloride; low fecal pancreatic elastase 1; and low to absent pancreatic lipase, amylase, and trypsin levels on duodenal intubation. Each disorder has several associated clinical features that aid in the differential diagnosis. In Shwachman syndrome, pancreatic exocrine hypoplasia with widespread fatty replacement of the glandular acinar tissue is associated with neutropenia because of maturational arrest of the granulocyte series. Metaphyseal dysostosis and an elevated fetal hemoglobin are common, but immunoglobulin deficiency and hepatic dysfunction are also reported. CT examination of the pancreas demonstrates the widespread fatty replacement. Serum immunoreactive trypsinogen levels are extremely low.

Other associations of exocrine pancreatic insufficiency include (1) aplastic alae, aplasia cutis, deafness (Johanson-Blizzard syndrome); (2) sideroblastic anemia, developmental delay, seizures, and liver dysfunction (Pearson bone marrow pancreas syndrome);

Table 21–9. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis.

Organ	Condition	Symptoms	Age at Presentation	Incidence (%)	Diagnostic Evaluation	Management
Esophagus	Gastroesophageal reflux, esophagitis	Pyrosis, dysphagia, epigastric pain, hematemesis.	All ages	10–20	Endoscopy and biopsy, overnight pH study	H ₂ blockers, antacids, carafate, PPIs, surgical antireflux procedure.
	Varices	Hematemesis, melena.	Childhood and adolescents	3–10	Endoscopy	Endosclerosis, band ligation, drugs (see text), TIPS liver transplantation. (see Table 21–8)
Stomach	Gastritis	Upper abdominal pain, vomiting, hematemesis.	School age and older	10–25	Endoscopy and biopsy	H ₂ blockers, antacids, carafate, PPIs.
	Hiatal hernia	Reflux symptoms (see above), epigastric pain.	School age and older	3–5	Endoscopy; barium swallow	As above. Surgery in some.
Intestine	Meconium ileus	Abdominal distention, bilious emesis.	Neonate	10–15	Radiologic studies, plain abdominal films; contrast enema shows microcolon	Dislodgement of obstruction with Gastrografin enema. Surgery if unsuccessful or if case complicated by atresia, perforation, or volvulus.
	Distal intestinal obstruction syndrome	Abdominal pain, acute and recurrent; distention; occasional vomiting.	Any age, usually school age through adolescence	10–15	Palpable mass in right lower quadrant, radiologic studies	Gastrografin enema, intestinal lavage solution, diet, bulk laxatives, adjustment of pancreatic enzyme intake.
	Fibrosing colonopathy	As above. History of high enzyme dosage.	≥3 years	< 1	Barium enema or UGI/SBFT, abdominal ultrasound, or CT	Reduce pancreatic enzyme dose to < 2000 units of lipase/kg per dose if indicated. Surgical resection may be necessary.
	Intussusception	Acute, intermittent abdominal pain; distention; emesis.	Infants through adolescence	1–3	X-ray studies, barium enema	Reduction by barium or air enema or surgery if needed. Diet. Bulk laxatives. Adjustment of pancreatic enzyme intake.
	Rectal prolapse	Anal discomfort, rectal bleeding.	Infants and children to age 4–5 years	15–25	Visual mass protruding from anus	Manual reduction, adjustment of pancreatic enzyme dosage, reassurance as problem resolves by age 3–5 years.

Intestine (cont'd)	Carbohydrate intolerance	Abdominal pain, flatulence, continued diarrhea with adequate replacement therapy.	Any age	10–25	Intestinal mucosal biopsy and disaccharidase analysis. Breath hydrogen after lactose load.	Reduce lactose intake; reduction of gastric hyperacidity if mucosa shows partial villous atrophy. Beware concurrent celiac disease or <i>Giardia</i> infection.
Pancreas	Total exocrine insufficiency	Diarrhea, steatorrhea, malnutrition, failure to thrive. Specific fat-soluble vitamin deficiency states.	Neonate through infancy	85–90	72-h fecal fat evaluation, fecal pancreatic elastase	Pancreatic enzyme replacement, may need elemental formula, fat-soluble vitamin and vitamin E supplements.
	Pancreatic sufficiency (partial exocrine insufficiency)	Occasional diarrhea, mild growth delay.	Any age	10–15	72-hour fecal fat evaluation, direct pancreatic function tests	Pancreatic enzyme replacement in selected patients. Fat-soluble vitamin supplements as indicated by biochemical evaluation.
	Pancreatitis	Recurrent abdominal pain, vomiting.	Older children through adolescence. Primarily in patients with partial pancreatic sufficiency.	0.1	Increased serum lipase and amylase, pancreatic provocative test, endoscopic pancreatogram	Addition of pancreatic enzymes to feeds, endoscopic removal of sludge or stones if present, endoscopic papillectomy.
	Diabetes	Weight loss, polyuria, polydipsia.	Older children through adolescence	5–7	Glucose tolerance test and insulin levels	Diet, insulin.
Liver	Steatosis	Hepatomegaly.	Neonates and infants, but can be seen at all ages	20–60	Liver biopsy	Improved nutrition, replacement of pancreatic enzymes and vitamins.
	Focal biliary cirrhosis	Hepatomegaly.	Infants and older patients Prevalence increases with age.	10–70	Liver biopsy	As above. Taurine supplements (still experimental), ursodeoxycholic acid.
	Multilobular biliary cirrhosis	Hepatosplenomegaly, hematemesis from esophageal varices; hypersplenism, jaundice, ascites late in course.	School age through adolescence	5–15	Liver biopsy, endoscopy	Improved nutrition, ursodeoxycholic acid, endosclerosis or band ligation of varices, or partial splenic embolization, liver transplantation.

(continued)

Table 21–9. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis. (continued)

Organ	Condition	Symptoms	Age at Presentation	Incidence (%)	Diagnostic Evaluation	Management
Liver (cont'd)	Neonatal jaundice	Cholestatic jaundice hepatomegaly; often seen with meconium ileus.	Neonates	0.1–1	Sweat chloride test, liver bi- opsy	Nutritional support, special formula with medium-chain triglyceride-containing oil, pancreatic enzyme replace- ment, vitamin supplements.
Gallbladder	Microgallbladder	None.	Congenital—present at any age	30	Ultrasound or hepatobili- ary scintigraphy	None needed.
	Cholelithiasis	Recurrent abdominal pain, rarely jaundice.	School age through adoles- cence	1–10	Ultrasound	Surgery if symptomatic and low risk, trial of cholelitholy- tics in others.
Extrahepatic bile ducts	Intraluminal obstruction (sludge, stones, tumor)	Jaundice, hepatomegaly, ab- dominal pain.	Neonates, then older children through adolescence	Rare in neonates (< 0.1)	Ultrasound and hepatobiliary scintigraphy, endoscopic cholangiography	Surgery in neonates, endo- scopic intervention in older patients or surgery.
	Extraluminal obstruction (intrapancreatic compression, tumor)	As above.	Older children to adults	Rare (< 1)	As above	Surgical biliary drainage pro- cedure or biliary stent place- ment vs. balloon dilation endoscopically.

PPI = proton pump inhibitor; CT = computed tomography; TIPS = transjugular intrahepatic portosystemic shunt; UGI/SBFT = upper gastrointestinal/small bowel follow-through radiologic series.

(3) duodenal atresia or stenosis; (4) malnutrition; and (5) pancreatic hypoplasia or agenesis.

The complications and sequelae of deficient pancreatic enzyme secretion are malnutrition, diarrhea, and growth failure. The degree of steatorrhea may lessen with age. Intra-gastric lipolysis primarily caused by lingual lipase may compensate in patients with low or absent pancreatic function. In Shwachman syndrome, the major sequela is short stature. Increased numbers of infections may result from chronic neutropenia. Neutrophil mobility is also impaired in many patients. In addition, an increased incidence of leukemia has been noted in these patients.

Pancreatic enzyme and fat-soluble vitamin replacement are required therapy in most patients. The prognosis appears to be good for those able to survive the increased number of bacterial infections early in life and those patients without severe associated defects.

ISOLATED EXOCRINE PANCREATIC ENZYME DEFECT

Normal premature infants and most newborns produce little, if any, pancreatic amylase following meals or exogenous hormonal stimulation. This temporary physiologic insufficiency may persist for the first 3–6 months of life and be responsible for diarrhea when complex carbohydrates (cereals) are introduced into the diet.

Congenital pancreatic lipase deficiency and congenital colipase deficiency are extremely rare disorders, causing diarrhea and variable malnutrition with malabsorption of dietary fat and fat-soluble vitamins. The sweat chloride level is normal, and neutropenia is absent. Treatment is oral replacement of pancreatic enzymes and a low-fat diet or formula containing medium-chain triglycerides.

Table 21–10. Pancreatic tumors.

	Age	Major Findings	Diagnosis	Treatment	Associated Conditions
Insulinoma	Any age	Hypoglycemia, seizures; high serum insulin; abdominal pain and mass infrequent	Ultrasound, CT scan, MRI, EUS	Surgery	
Adenocarcinoma	Any age	Epigastric pain, mass weight loss, anemia, biliary obstruction	Ultrasound, CT scan, MRI, EUS	Surgery	Chronic pancreatitis
Gastrinoma	Older than age: 5–8 years	Male sex, gastric hypersecretion, peptic symptoms, multiple ulcers, gastrointestinal bleeding, anemia, diarrhea	Elevated fasting gastrin and postsecretin suppression test (> 300 pg/mL), CT scan, MRI, EUS laparotomy	H ₂ blockers, omeprazole, surgical resection, total gastrectomy	Zollinger–Ellison syndrome, multiple endocrine neoplasia syndrome type I, neurofibromatosis
VIPoma	Any age	Secretory diarrhea, hypokalemia, weight loss	Elevated vasoactive intestinal polypeptide (VIP) levels; sometimes, elevated serum gastrin and pancreatic polypeptide	Surgery, octreotide	
Glucagonoma	Older patients	Necrolytic rash, diarrhea, anemia, thrombotic events	Elevated glucagon, gastrin, VIP	Surgery	

CT = computed tomography, MRI = magnetic resonance imaging, EUS = endoscopic ultrasound.

Exocrine pancreatic insufficiency of proteolytic enzymes (eg, trypsinogen, trypsin, chymotrypsin) is caused by enterokinase deficiency, a duodenal mucosal enzyme required for activation of the pancreatic proenzymes. These patients present with malnutrition associated with hypoproteinemia and edema but are free of respiratory symptoms and have a normal sweat test. They respond to pancreatic enzyme replacement therapy and feeding formulas that contain a casein hydrolysate (eg, Nutramigen, Pregestimil).

PANCREATIC TUMORS

Pancreatic tumors, whether benign or malignant, are rare lesions. They most often arise from ductal or acinar epithelium (malignant adenocarcinoma) or from islet (endocrine) components within the gland, such as the benign insulinoma (adenoma) derived from β cells. Other pancreatic tumors also originate from these pluripotential endocrine cells (gastrinoma, VIPoma,

glucagonoma). These malignant lesions produce diverse symptoms, because they release biologically active polypeptides from this ectopic location. The clinical features of these tumors are summarized in Table 21–10. The differential diagnosis of these abdominal tumors includes Wilms' tumor, neuroblastoma, and malignant lymphoma. In older children, endoscopic ultrasonography can aid in localizing these tumors.

Gary M. Lum, MD

EVALUATION OF THE KIDNEY & URINARY TRACT

HISTORY

When renal disease is suspected, the history should include

1. Family history of cystic disease, hereditary nephritis, deafness, dialysis, or renal transplantation
2. Preceding acute or chronic illnesses (eg, UTI, pharyngitis, impetigo, endocarditis)
3. Rashes or joint pains
4. Growth delay or failure to thrive
5. Polyuria, polydipsia, enuresis, urinary frequency, or dysuria
6. Documentation of hematuria, proteinuria, or discolored urine
7. Pain (abdominal, costovertebral angle, or flank) or trauma
8. Sudden weight gain or edema
9. Drug or toxin exposure

For the newborn or small infant, the physician should obtain birth history and information regarding prenatal ultrasonographic studies, birth asphyxia, Apgar scores, oligohydramnios, dysmorphic features, abdominal masses, voiding patterns, anomalous development, and umbilical artery catheterization.

PHYSICAL EXAMINATION

Important aspects of the physical examination include the height, weight, skin lesions (café-au-lait or ash leaf spots), pallor, edema, or skeletal deformities. Anomalies of the ears, eyes, or external genitalia may be associated with renal disease. The blood pressure should be measured in a quiet setting. The cuff should cover two thirds of the child's upper arm, and peripheral pulses should be noted. An ultrasonic device is useful for measurements in infants. The abdomen should be palpated, with attention to the kidneys, abdominal masses, musculature, and the presence of ascites.

LABORATORY EVALUATION OF RENAL FUNCTION

Urinalysis

Commercially available dipsticks can be used to screen for the presence of red blood cells, hemoglobin, leukocytes, nitrites, and protein and to approximate pH. Positive results for blood should always be confirmed by microscopy, as should any suspicion of crystalluria. Significant proteinuria (> 150 mg/dL) detected by dipstick should be confirmed by quantitation either with a 24-hour collection or by the protein/creatinine ratio (see following section) of a random specimen.

Serum Analysis

The standard indicators of renal function are serum levels of urea nitrogen and creatinine; their ratio is normally about 10:1. This ratio may increase when renal perfusion or urine flow is decreased, as in urinary tract obstruction or dehydration. Because serum urea nitrogen levels are more affected by these and other factors (eg, nitrogen intake, catabolism, use of corticosteroids) than are creatinine levels, the most reliable single indicator of glomerular function is the serum level of creatinine. For example, serum creatinine increasing from 0.5 mg/dL to 1.0 mg/dL represents a 50% decrease in glomerular filtration rate. Small children should have serum creatinine levels well under 0.8 mg/dL, and only larger adolescents should have levels exceeding 1 mg/dL. Less precise but nonetheless important indicators of the possible presence of renal disease are abnormalities of serum electrolytes, pH, calcium, phosphorus, magnesium, albumin, or complement.

Measurement of Glomerular Filtration Rate

The endogenous creatinine clearance (C_{cr}) in milliliters per minute estimates the glomerular filtration rate (GFR). A 24-hour urine collection is usually obtained; however, in small children from whom collection is difficult, a 12-hour daytime specimen, collected when urine flow rate is greatest, is acceptable. The procedure for collecting a timed urine specimen should be explained carefully so that the parent or patient under-

stands fully the rationale of (1) first emptying the bladder (discarding that urine) and noting the time; and (2) putting all urine subsequently voided into the collection receptacle, including the last void, 12 or 24 hours later. Reliability of the 24-hour collection can be checked by measuring the total 24-hour creatinine excretion in the specimen. Total daily creatinine excretion (creatinine index) should be in the range of 14–20 mg/kg. Creatinine indices on either side of this range suggest collections that were either inadequate or excessive. Calculation by the following formula requires measurements of plasma creatinine (P_{Cr}) in mg/mL, urine creatinine (U_{Cr}) in mg/mL, and urine volume (V) expressed as mL/min:

$$C_{Cr} = \frac{U_{Cr} V}{P_{Cr}}$$

Creatinine is a reflection of body muscle mass. Because accepted ranges of normal creatinine clearance are based on adult parameters, correction for size is needed to determine normal ranges in children. Clearance is corrected to a standard body surface area of 1.73 m^2 in the formula:

$$\text{"Corrected" } C_{Cr} = \frac{\text{Patient's } C_{Cr} \times 1.73 \text{m}^2}{\text{Patient's body surface area}}$$

Although $80\text{--}125 \text{ mL/min}/1.73 \text{ m}^2$ is the normal range for creatinine clearance, estimates at the lower end of this range may indicate problems.

A simple and tested formula for quick approximation of creatinine clearance incorporates use of the plasma creatinine level and the child's length in centimeters:

$$C_{Cr} (\text{mL/min}/1.73\text{m}^2) = \frac{0.55 \times \text{Height in cm}}{P_{Cr} \text{ in mg/dL}}$$

Note: Because this formula takes into account the body surface area, further correction is not necessary. Use $0.45 \times$ length in centimeters for newborns and for infants younger than age 1 year. This method of calculation is not meant to detract from the importance of clearance determinations but is useful when a suspicious plasma creatinine needs to be checked.

Urine Concentrating Ability

Inability to concentrate urine is associated with polyuria, polydipsia, or enuresis and is often the first

sign of chronic renal failure. The first morning void should be concentrated. Evaluation of other abnormalities of urinary concentration or dilution is discussed later in the sections on specific disease entities, such as diabetes insipidus.

Microhematuria or Isolated Proteinuria

In children with asymptomatic hematuria or proteinuria, the search for renal origins will yield the most results. Isolated proteinuria may reflect urologic abnormalities, benign excretion, or glomerular alterations. The presence of red cell casts suggests glomerulonephritis (GN), but the absence of casts does not rule out this disease. Anatomic abnormalities such as cystic disease may be a source of hematuria.

Benign hematuria, including benign familial hematuria, is diagnosed by exclusion. In this group are children whose hematuria is caused by asymptomatic hypercalciuria. Figure 22–1 suggests an approach to the renal work-up of hematuria. GN is discussed in more detail later in this chapter.

The association of proteinuria with hematuria is characteristic of more significant glomerular disease. Quantitation of the proteinuria is customarily accomplished by a time collection (eg, over a 24-hour period). However, an assessment of the degree of proteinuria may be made with the performance of the urine protein/creatinine ratio in a random urine sample. A protein-to-creatinine ratio of more than 0.2 is abnormal. A timed urine collection is performed as described previously for creatinine clearance. In the evaluation of asymptomatic proteinuria, orthostatic or postural proteinuria should be ruled out. The protein present in urine voided on arising in the morning is compared with that in urine formed in the upright position during the rest of the day. This can be accomplished more simply by comparing the protein/creatinine ratios. If the quantitation is accomplished by separation of the "upright" and "supine" portions of a 24-hour collection, if the upright collection contains 80–100% of the entire 24-hour measured protein, and if there are no other markers of renal disease, the diagnosis of benign postural proteinuria is acceptable.

An approach to the work-up of isolated proteinuria is shown in Figure 22–2. Note that corticosteroid therapy is indicated in the algorithm because this may be initiated prior to referral. Other renal lesions with proteinuric manifestations are discussed later in this chapter.

Special Tests of Renal Function

Measurements of urinary sodium, creatinine, and osmolality are useful in differentiating prerenal causes of

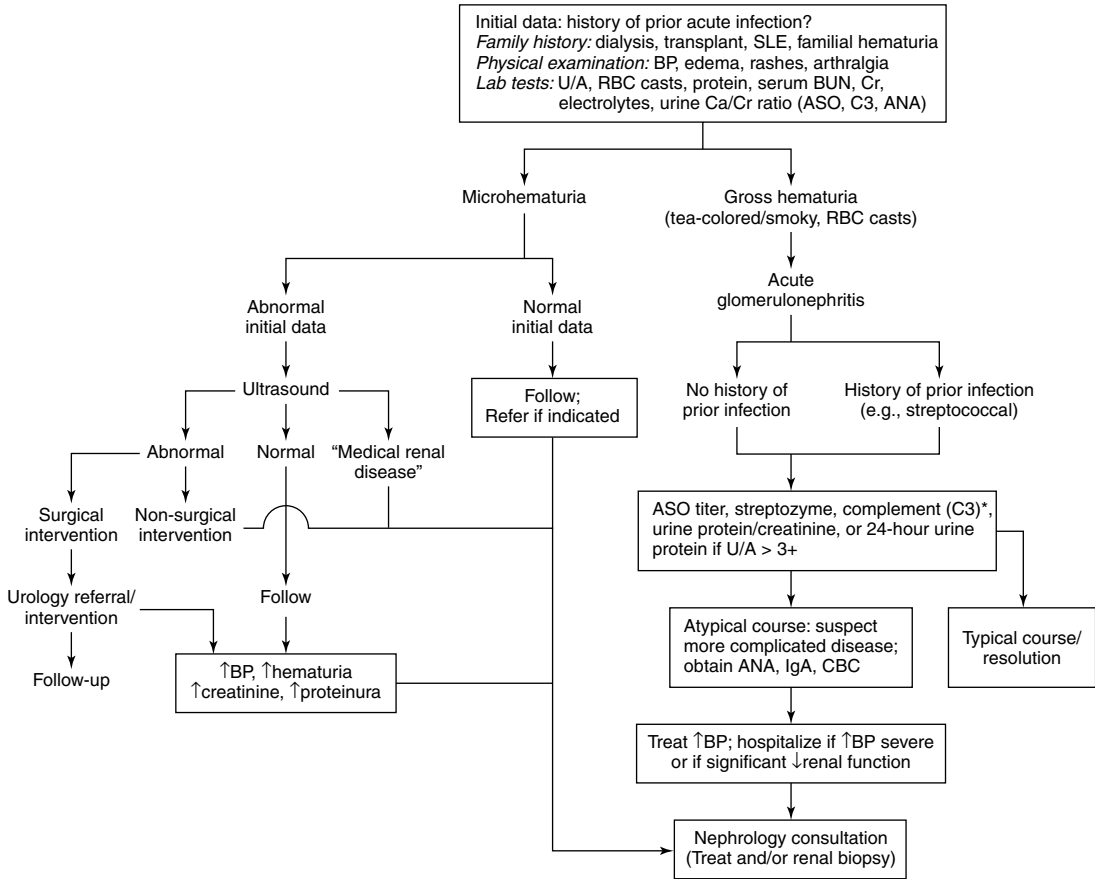

Figure 22–1. Approach to the renal work-up of hematuria. (Exclude UTI, lithiasis, trauma, bleeding disorders, sickle cell disease.) ANA = antinuclear antibody; ASO = antistreptolysin antibody; BP = blood pressure; BUN = blood urea nitrogen; C3 = complement; Ca = calcium; Cr = creatinine; GN = glomerulonephritis; IgA = immunoglobulin A; PSGN = poststreptococcal glomerulonephritis; RBC = red blood cell; SLE = systemic lupus erythematosus; U/A = urinalysis.

renal insufficiency from renal causes such as acute tubular necrosis. The physiologic response to decreased renal perfusion is decreased urinary output, increased urine osmolality, increased urinary solutes (eg, creatinine), and decreased urinary sodium (usually < 20 mEq/L). Prolonged underperfusion results in varying increases in the serum creatinine and blood urea nitrogen (BUN) concentrations, prompting the need to differentiate between this state and acute tubular necrosis (see Acute Renal Failure section).

The presence of certain substances in urine may suggest tubular dysfunction. For example, urine glucose should be less than 5 mg/dL. Hyperphosphaturia occurs with significant tubular abnormalities (eg, Fanconi syndrome). Measurement of the phosphate concentra-

tion of a 24-hour urine specimen and evaluation of tubular reabsorption of phosphorus (TRP) will help document renal tubular diseases as well as hyperparathyroid states. TRP (expressed as percentage of reabsorption) is calculated as follows:

$$TRP = 100 \left[1 - \frac{S_{Cr} \times U_{PO4}}{S_{PO4} \times U_{Cr}} \right]$$

where S_{Cr} = serum creatinine; U_{Cr} = urine creatinine; S_{PO4} = serum phosphate; and U_{PO4} = urine phosphate. All values for creatinine and phosphate are expressed in milligrams per deciliter for purposes of calculation. A

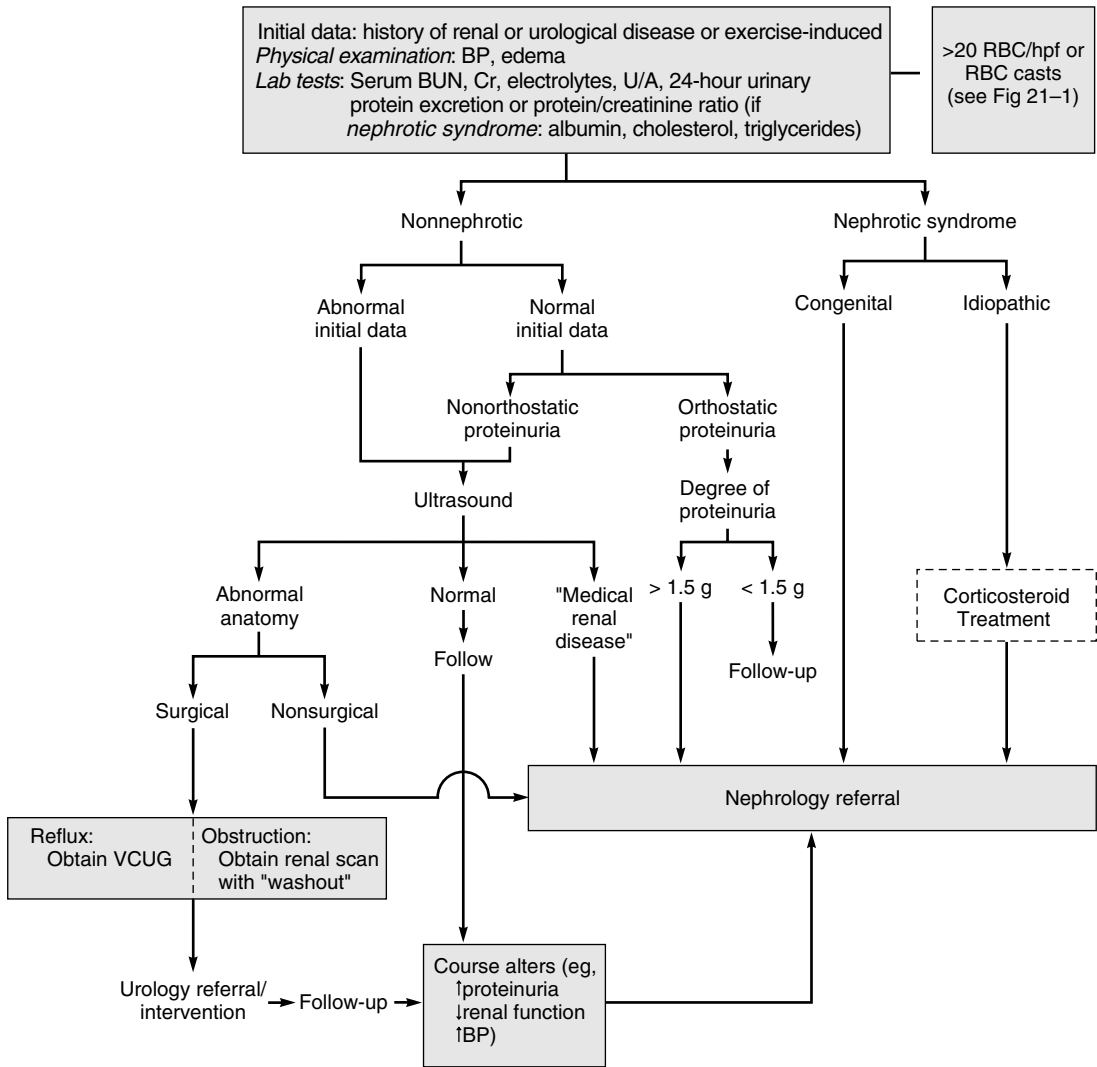

Figure 22-2. Approach to the work-up of isolated proteinuria. BP = blood pressure; Cr = creatinine; hpf = high-power field; RBC = red blood cell; U/A = urinalysis; VCUG = voiding cystourethrogram. *Complement is depressed in acute poststreptococcal glomerulonephritis, chronic glomerulonephritis, and lupus. Will normalize within a month in poststreptococcal glomerulonephritis.

TRP value of 80% or more is considered normal, although it depends somewhat on the value of S_{PO_4} .

The urinary excretion of amino acids in generalized tubular disease reflects a quantitative increase rather than a qualitative change. Diseases affecting proximal tubular reabsorption of bicarbonate—including isolated renal tubular acidosis, Fanconi syndrome (which occurs in diseases such as cystinosis), and chronic renal failure—are discussed later in the chapter.

LABORATORY EVALUATION OF IMMUNOLOGIC FUNCTION

Many parenchymal renal diseases are thought to have immune causation, although the mechanisms are largely unknown. Examples of mechanisms in the kidney include (1) deposition of circulating antigen-antibody complexes that are themselves injurious or incite injurious responses and (2) formation of antibody di-

rected against the glomerular basement membrane itself (rare in children).

Total serum complement and the C3 and C4 complement components should be measured when immune-mediated renal injury or chronic GN is suspected. Where clinically indicated, antinuclear antibodies, hepatitis B surface antigen, and rheumatoid factor should be obtained. In rare cases the presence of cold-precipitable proteins (cryoglobulins), C3 “nephritic” factor, or antiglomerular basement membrane (anti-GBM) antibody may be helpful in determining a specific diagnosis. At some point in the work-up, the diagnosis may be supported or confirmed by the description of renal histology.

RADIOGRAPHIC EVALUATION

Renal ultrasonography is a useful noninvasive tool in the evaluation of renal parenchymal disease, urinary tract abnormalities, or renal blood flow. Excretory urography is used to assess the anatomy and function of the kidney, collecting system, and bladder. Radioisotope studies provide valuable information concerning renal anatomy, blood flow, and integrity and function of the glomerular, tubular, and collecting systems.

Evaluation of the lower urinary tract (voiding cystourethrography or cystoscopy) is indicated when vesicoureteral reflux or bladder outlet obstruction is suspected. Cystoscopy is rarely useful in the evaluation of asymptomatic hematuria or proteinuria in children.

Renal arteriography or venography is indicated to define vascular abnormalities (eg, renal artery stenosis) prior to surgical intervention. Less invasive measures such as ultrasonography and Doppler studies can demonstrate renal blood flow or thromboses.

RENAL BIOPSY

Histologic information is valuable for diagnosis, treatment, and prognosis. Satisfactory evaluation of renal tissue requires examination by light, immunofluorescence, and electron microscopy.

When a biopsy is anticipated, a pediatric nephrologist should be consulted. In children, percutaneous renal biopsy with a biopsy needle is an acceptable low-risk procedure—avoiding the risks of general anesthesia—when performed by an experienced physician. A surgeon should perform the biopsy procedure if operative exposure of the kidney is necessary, if an increased risk factor (eg, bleeding disorder) is present, or if a “wedge” biopsy is preferred.

CONGENITAL ANOMALIES OF THE URINARY TRACT

RENAL PARENCHYMAL ANOMALIES

About 10% of children have congenital anomalies of the genitourinary tract, which range in severity from asymptomatic to lethal. Some asymptomatic abnormalities may have significant complications. For example, patients with “horseshoe” kidney (kidneys fused in their lower poles) have a higher incidence of renal calculi. Unilateral agenesis is usually accompanied by compensatory hypertrophy of the contralateral kidney and thus should be compatible with normal renal function. Supernumerary and ectopic kidneys are usually of no significance. Abnormal genitourinary development can result in varying degrees of renal maldevelopment and function, of which complete renal agenesis is the most severe. When the agenesis is bilateral, it causes early death. Severe oligohydramnios is present and can result in pulmonary hypoplasia and peculiar (Potter) facies.

Renal Dysgenesis

Renal dysgenesis represents a spectrum of anomalies. In simple hypoplasia, which may be unilateral or bilateral, the affected organs are smaller than normal. In the various forms of dysplasia, immature, undifferentiated renal tissue persists. In some of the dysplasias, the number of normal nephrons is insufficient to sustain life once the child reaches a critical body size. Such lack of renal tissue may not be readily discernible in the newborn period because the infant’s urine production, though poor in concentration, may be adequate in volume. Often, the search for renal insufficiency is initiated only when growth fails or chronic renal failure develops.

Other forms of renal dysplasia include oligomeganephronia (characterized by the presence of only a few large glomeruli) and the cystic dysplasias (characterized by the presence of renal cysts). This group includes microcystic disease (congenital nephrosis). A simple cyst within a kidney may be clinically unimportant because it does not predispose to progressive polycystic development. An entire kidney lost to multicystic development with concomitant hypertrophy and normal function of the contralateral side may also be of little clinical consequence. Nonetheless, even a simple cyst could pose problems if it becomes a site for lithiasis, infection, or hematuria.

Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) is increasingly diagnosed by prenatal ultrasound. In its most severe form the cystic kidneys are nonfunctional in utero, and, therefore, newborns can have Potter facies and other complications of oligohydramnios. In infancy and childhood, kidney enlargement by cysts may initially be recognized by abdominal palpation of the renal masses. Hypertension is an early problem. The rate of the progression of renal insufficiency varies, as does growth failure and other complications of chronic renal failure. Two genes (*ADPKD-1* and *ADPKD-2*) account for 80% and 10% of cases of the autosomal dominant polycystic kidney disease, respectively. Susceptibility of members in ADPKD families is detected by gene linkage studies. Renal ultrasound identifies cysts in about 80% of affected children by age 5 years. Children with this diagnosis need close monitoring for the development and treatment of hypertension, and their families should be offered genetic counseling. Management of end-stage renal failure is by dialysis or renal transplantation.

Gabow PA: Utility of ultrasonography in the diagnosis of autosomal dominant polycystic kidney disease in children. *J Am Soc Nephrol* 1997;8:105.

Murcia NS, Sweeney WE Jr, Avner ED: New insights into the molecular pathophysiology of polycystic kidney disease. *Kidney Int* 1999;55:1187.

Medullary Cystic Disease (Juvenile Nephronophthisis)

Medullary cystic disease is characterized by varying sizes of cysts in the renal medulla and is associated with tubular and interstitial nephritis. Children present with renal failure and signs of tubular dysfunction (decreased concentrating ability, Fanconi syndrome). This lesion should not be confused with medullary sponge kidney (renal tubular ectasia), a frequently asymptomatic disease occurring in adults.

DISTAL URINARY TRACT ANOMALIES

Obstruction at the ureteropelvic junction may be the result of intrinsic muscle abnormalities, aberrant vessels, or fibrous bands. The lesion can cause hydronephrosis and usually presents as an abdominal mass in the newborn. Obstruction can occur in other parts of the ureter, especially at its entrance into the bladder, with resulting proximal hydroureter and hydronephrosis. Whether intrinsic or extrinsic, urinary tract obstruction should be relieved surgically as soon as possible to minimize damage to the kidneys.

Severe bladder malformations such as exstrophy are clinically obvious and provide a surgical challenge. More subtle—but urgent in terms of diagnosis—is obstruction of urine flow from vestigial posterior urethral valves. This anomaly, which occurs almost exclusively in males, usually presents as anuria or a poor voiding stream in the newborn period, with severe obstruction of urine flow. Ascites may occur, and the kidneys and bladder may be easily palpable. Surgical drainage of urine is urgently required to prevent irreversible damage, if possible.

Complex Anomalies

Prune belly syndrome is an association of urinary tract anomalies with cryptorchidism and absent abdominal musculature. Although complex anomalies, especially renal dysplasia, usually cause early death or the need for dialysis or transplantation, some patients have lived into the third decade with varying degrees of renal insufficiency. Early urinary diversion is essential to sustain renal function. A renal biopsy at the time of this surgery may predict subsequent renal function.

Other complex malformations and external genital anomalies such as hypospadias are beyond the scope of this text. Overall, urologic abnormalities resulting in severe compromise and destruction of renal tissue provide therapeutic and management challenges aimed at preserving all remaining function and treating the complications of progressive chronic renal failure.

HEMATURIA & GLOMERULAR DISEASE

Children with painful hematuria should be investigated for urinary tract infection (UTI) or direct injury to the urinary tract. Dysuria commonly suggests cystitis or urethritis; back pain may support the presence of pyelonephritis; and colicky flank pain may mean the passage of a stone. Bright red blood or clots in the urine are associated with bleeding disorders, trauma, and arteriovenous malformations. Abdominal masses suggest the presence of urinary tract obstruction, cystic disease, or tumors involving the renal or perirenal structures.

Asymptomatic hematuria is a challenge because clinical and diagnostic data are required to decide whether to refer the child to a nephrologist. Figure 22–1 delineates the outpatient approach to renal hematuria. The concern regarding the differential diagnosis is the possible presence of glomerular disease.

GLOMERULONEPHRITIS

Poststreptococcal Glomerulonephritis

Acute poststreptococcal GN is the most common form of “postinfectious” GN. The epidemiologic relationship between certain strains of streptococci and GN is well recognized. Antigen–antibody complexes are formed in the bloodstream and deposited in the glomeruli. These deposited complexes may incite glomerular inflammation and activate the complement system.

The diagnosis of poststreptococcal disease is supported by a recent history (7–14 days previously) of group A β -hemolytic streptococcal infection. If a positive culture is not available, recent infection may be supported by an elevated antistreptolysin O titer or by high titers of other antistreptococcal antibodies. Other infections can cause similar glomerular injury; thus, “postinfection GN” may be a better term for this type of acute GN. In most cases recovery is expected and usually complete within weeks. In cases when the diagnosis is in some question, or in patients whose renal function progressively deteriorates, a renal biopsy should be performed.

The clinical presentation of GN is usually with gross hematuria (coffee-colored or tea-colored urine), with or without edema (eg, periorbital), which in mild cases occurs secondary to the alteration in glomerular function, resulting in sodium and water retention. Symptoms are usually nonspecific. In cases accompanied by hypertension (a common finding), headache may be present. Fever is uncommon. Severe glomerular injury (which usually occurs in severe, acute presentations of the more chronic or destructive forms of GN) may be accompanied by massive proteinuria (nephrotic syndrome), anasarca or ascites, and severe compromise of renal function.

Typical poststreptococcal GN has no specific treatment. Appropriate antibiotic therapy is indicated if an infection is still present. The disturbances in renal function and resulting hypertension may require close follow-up and management, with reduction in salt intake, treatment with diuretics, or antihypertensive drugs. In severe cases, with profound renal failure, hemodialysis or peritoneal dialysis may be necessary; corticosteroids may also be administered in an attempt to influence the course of the infection.

The acute abnormalities generally resolve in 2–3 weeks; serum complement (C3) may be normal as early as 3 days or as late as 30 days after onset. Although microscopic hematuria may persist for as long as a year, most children recover completely. Persistent deterioration in renal function, urinary abnormalities beyond 18 months, persistent hypocomplementemia, and nephrotic syndrome are ominous signs. If any one of these is present, a renal biopsy is indicated.

IgA Nephropathy

When asymptomatic gross hematuria appears to accompany a minor acute febrile illness or other stressful occurrence, the diagnosis of IgA nephropathy may be entertained. In contrast to postinfection GN, in IgA nephropathy there is no evidence of prior infection, complement is not depressed, and serum immunoglobulin A is elevated in 50% of all cases. Often there are no associated clinical factors. The gross hematuria resolves within days, and there are no serious sequelae in 85% of cases of IgA nephropathy. Treatment is not indicated, and the prognosis is good in most cases. Prognosis is guarded, however, if severe proteinuria, hypertension, or renal insufficiency is present or ensues. In such instances, treatment is usually attempted. Although no treatment is universally accepted, corticosteroids and other immunosuppressive drugs are used. Omega-3 fatty acids present in fish oils are thought to be helpful.

Henoch–Schönlein Purpura

The diagnosis of Henoch–Schönlein purpura rests on the presence of a typical maculopapular rash found primarily, but not exclusively, on the dorsal surfaces of lower extremities and buttocks. Most children have abdominal pain and bloody diarrhea. Joint pain is common, and, depending on the extent of renal involvement, hypertension may be present. Joint and abdominal pain responds to treatment with corticosteroids. Renal involvement ranges from mild GN with microhematuria to severe GN and varying degrees of renal insufficiency. GN with massive proteinuria and renal insufficiency carries the worst prognosis. Twenty percent of such cases result in end-stage renal failure. There is no universally accepted treatment, but corticosteroids are often administered.

Membranoproliferative Glomerulonephritis

The most common “chronic” form of GN occurring in children is membranoproliferative GN. The diagnosis is established from the histologic appearance of the glomeruli. The discussion of the various types of this form of GN is complex. Clinically, type II carries the worse prognosis, as end-stage renal failure develops in most cases. Type I more often responds to treatment with corticosteroids. C3 is depressed (in both types) and may be useful as a marker of response to treatment.

The various types of GN have similar manifestations. Table 22–1 lists the most commonly encountered entities in the differential diagnosis of GN in childhood and their clinical and histopathologic descriptions. Severe glomerular histopathologic and clinical entities, such as anti-GBM antibody disease (Good-

Table 22–1. Glomerular diseases encountered in childhood.

Entity	Clinical Course	Prognosis
Postinfection glomerulonephritis. Onset occurs 10–14 days after acute illness, commonly streptococcal. Characteristics include acute onset, tea-colored urine, mild to severe renal insufficiency, and edema.	Acute phase is usually over in 2 weeks. There is complete resolution in 95% of cases. Severity of renal failure and hypertension varies. Microhematuria may persist to 18 months. Hypocomplementemia resolves in 1–30 d.	Excellent. Chronic disease is rare. Severe proteinuria, atypical presentation or course, or persistent hypocomplementemia suggest another entity.
Membranoproliferative glomerulonephritis. Presentation ranges from mild microhematuria to acute GN syndrome. Diagnosis is made by renal biopsy. Etiology is unknown. Type I and type II are most common. Lesion is chronic.	Course can be mild to severe (rapid deterioration in renal function); may mimic postinfection GN. Proteinuria can be severe. Complement depression is intermittent to persistent. Hypertension is usually significant.	Type I may respond to corticosteroids. Type II (dense deposit disease) is less treatable; function decrease varies from immediate to as long as 15 y in 30–50% of untreated cases.
IgA nephropathy. Classic presentation consists of asymptomatic gross hematuria during acute unrelated illness, with microhematuria between episodes. There are occasional instances of acute GN syndrome. Etiology is unknown. Diagnosis is made by biopsy.	90% of cases resolve in 1–5 y. Gross hematuric episodes resolve with recovery from acute illness. Severity of renal insufficiency and hypertension varies. Proteinuria occurs in more severe, atypical cases.	Generally good. Small percentage develop chronic renal failure. Proteinuria in the nephrotic range is a poor sign. There is no universally accepted medication. (Corticosteroids may be useful in severe cases.)
Henoch–Schönlein purpura glomerulonephritis. Degree of renal involvement varies. Asymptomatic microhematuria is most common, but GN syndrome can occur. Renal biopsy is recommended in severe cases; it can provide prognostic information.	Presentation varies with severity of renal lesion. In rare cases, may progress rapidly to serious renal failure. Hypertension varies. Proteinuria in the nephrotic range and severe decline in function can occur.	Overall, prognosis is good. Patients presenting with greater than 50% reduction in function or proteinuria exceeding 1 g/24 h may develop chronic renal failure. Severity of renal biopsy picture can best guide approach in such cases. There is no universally accepted medication.
Glomerulonephritis of systemic lupus erythematosus (SLE). Microhematuria and proteinuria are rarely first signs of this systemic disease. Renal involvement varies. GN often causes the most concern.	Renal involvement is mild to severe. Clinical complexity depends on degree of renal insufficiency and other systems involved. Hypertension is significant. Manifestations of the severity of the renal lesion guide therapeutic intervention.	Renal involvement accounts for most significant morbidity in SLE. Control of hypertension affects renal prognosis. Medication is guided by symptoms, serology, and renal lesion. End-stage renal failure can occur.
Hereditary glomerulonephritis (eg, Alport syndrome). Transmission is autosomal-dominant/X-linked, with family history marked by end-stage renal failure, especially in young males. Deafness and eye abnormalities are associated.	There is no acute syndrome. Females are generally less affected but are carriers. Hypertension and increasing proteinuria occur with advancing renal failure. There is no known treatment.	Progressive proteinuria and hypertension occur early, with gradual decline in renal function in those most severely affected. Disease progresses to end-stage renal failure in most males.

pasture syndrome), Wegener granulomatosis, and idiopathic, rapidly progressive GN, may be considered in the differential diagnosis of acute GN. But these disorders are exceedingly rare in children.

ACUTE INTERSTITIAL NEPHRITIS

Acute interstitial nephritis is characterized by diffuse or focal inflammation and edema of the renal interstitium

and secondary involvement of the tubules. It seems to be related most often to drugs (eg, β -lactam-containing antibiotics, such as methicillin).

Fever, rigor, abdominal or flank pain, and rashes may occur in drug-associated cases. Urinalysis should reveal leukocyturia and hematuria. Hansel staining of the urinary sediment is helpful in demonstrating the presence of eosinophils. The inflammation can be severe enough to cause significant deterioration of renal

function. If the diagnosis is unclear from a history of drug or toxin exposure or the presence of eosinophils in the urine, a renal biopsy may be performed to demonstrate the characteristic tubular and interstitial inflammation. Immediate identification and removal of the causative agent is imperative and may be all that is necessary. Treatment with corticosteroids is helpful in cases with progressive renal insufficiency or nephrotic syndrome. Severe renal failure requires supportive dialysis.

PROTEINURIA & RENAL DISEASE

Urine is not normally completely protein-free, but the average excretion is well below 150 mg/24 h. Small increases in urinary protein can accompany febrile illnesses or exertion and in some cases are produced while in the upright posture (discussed earlier).

An algorithm for investigation of isolated proteinuria is presented in Figure 22–2. In idiopathic nephrotic syndrome without associated features of GN, treatment with corticosteroids may be initiated as described later in this chapter. Nephrologic advice or follow-up should be sought, especially in difficult or frequently relapsing cases.

CONGENITAL NEPHROSIS

Congenital nephrosis is a rare autosomal recessive disorder. The kidneys are pale and large and may show microcystic dilations (microcystic disease) of the proximal tubules and glomerular changes. The latter consist of proliferation, crescent formation, and thickening of capillary walls. The pathogenesis is not well understood.

Infants with congenital nephrosis commonly have low birth weight, a large placenta, wide cranial sutures, and delayed ossification. Mild edema may be seen after the first few weeks of life. Anasarca follows, and the abdomen can become greatly distended by ascites. Massive proteinuria associated with typical-appearing nephrotic syndrome and hyperlipidemia is the rule. Hematuria is common. If the patient lives long enough, progressive renal failure occurs. Most affected infants succumb to infections at the age of a few months.

Treatment prior to dialysis and transplantation has little to offer other than nutritional support and management of the chronic renal failure.

IDIOPATHIC NEPHROTIC SYNDROME OF CHILDHOOD (Nil Disease, Lipoid Nephrosis, Minimal Change Disease)

Nephrotic syndrome is characterized by proteinuria, hypoproteinemia, edema, and hyperlipidemia. It may

occur as a result of any form of glomerular disease and may rarely be associated with a variety of extrarenal conditions. In young children, the disease usually takes the form of idiopathic nephrotic syndrome of childhood (nil disease, lipoid nephrosis, minimal change disease), which has characteristic clinical and laboratory findings, but no well-understood cause.

Clinical Findings

Affected patients are generally younger than age 6 years at the time of their first episode. Often following an influenza-like syndrome, periorbital swelling and perhaps oliguria are noticed. Within a few days, increasing edema—even anasarca—becomes evident. Other than vague malaise and occasionally abdominal pain, complaints are few. With significant “third spacing” of plasma volume, however, some children may present with hypotension. With marked edema, dyspnea due to pleural effusions may also occur.

Despite heavy proteinuria, the urine sediment is usually normal, although microscopic hematuria (< 20 RBC/high-power field) may be present. Plasma albumin levels are low, and lipid levels are increased. When azotemia occurs, it is usually secondary to intravascular volume depletion rather than to impairment of function.

Glomerular morphology is unremarkable except for fusion of foot processes of the glomerular basement membrane. This finding, however, is nonspecific and is associated with many proteinuric states. Changes in the glomerular mesangium may be minimal, with unremarkable findings on immunofluorescence and electron microscopic examination.

Complications

Infections (eg, peritonitis) sometimes occur, and pneumococci are frequently the cause. Hypercoagulability may be present, and thromboembolic phenomena are commonly reported. Hypertension and varying degrees of renal insufficiency are often encountered. In cases of minimal-change disease (no significant glomerular lesions are demonstrated), hypertension can still be noted and renal insufficiency is primarily due to decreased renal perfusion.

Treatment & Prognosis

As soon as the diagnosis of idiopathic nephrotic syndrome is made, corticosteroid treatment should be started. Prednisone, 2 mg/kg/d (maximum, 60 mg/d), is given as a single daily dose until the urine protein falls to trace or negative levels for a maximum of 8 weeks. The same dose is then administered on an al-

ternate-day schedule for 6 weeks; thereafter, the dose is tapered gradually and discontinued over the ensuing 2 months. If remission is achieved, only to be followed by relapse, the treatment course may be repeated. If at any time the nephrosis becomes refractory to treatment or if three relapses occur within 1 year, renal biopsy may be considered. A renal biopsy is also often considered when there is little or no response to treatment. One should take into account that the histologic findings may not alter the treatment plan, which is more often influenced by the need to eliminate the nephrotic syndrome regardless of underlying renal histology.

Unless the edema is symptomatic (eg, respiratory compromise due to ascites), diuretics should be used with extreme care; patients may have decreased circulating volume and are also at risk for intravenous thrombosis. However, careful restoration of compromised circulating volume with intravenous albumin infusion and administration of diuretics is helpful in mobilizing edema. Infections (eg, acute peritonitis) should be treated promptly to reduce morbidity. Immunization with pneumococcal vaccine is advised.

The initial response to corticosteroids is a guide to prognosis. A prompt remission lasting for over 1 year is almost always permanent. Failure to respond or early relapse usually heralds a prolonged series of relapses. This not only may indicate the presence of more serious nephropathy, but it presents a challenge in choosing future therapy. Chlorambucil or cyclophosphamide drug therapy is predictably successful only in children who respond to corticosteroids. Patients who do not respond to corticosteroids or who relapse frequently should be referred to a pediatric nephrologist. Intravenous solumedrol in more refractory cases has been shown to be helpful. In some cases, when the continued usage of corticosteroids alone is unsuccessful and raises concerns of toxicity, concomitant treatment with either cyclosporin A or tacrolimus appears to be helpful.

Chesney RW: The idiopathic nephrotic syndrome. *Curr Opin Pediatr* 1999;11:158.

FOCAL GLOMERULAR SCLEROSIS

Focal glomerular sclerosis is one cause of corticosteroid-resistant or frequent relapsing nephrotic syndrome. The cause is unknown. The diagnosis is made by renal biopsy, which shows normal-appearing glomeruli as well as some partially or completely sclerosed glomeruli. The lesion has serious prognostic implications because as many as 15–20% of cases can progress to end-stage renal failure. The clinical response to corticosteroid treatment is variable. In difficult cases, cyclosporin A or tacrolimus has been used in addition to corticosteroids.

MESANGIAL NEPHROPATHY (Mesangial Glomerulonephritis)

Mesangial nephropathy is another form of corticosteroid-resistant nephrotic syndrome. The renal biopsy shows a distinct increase in the mesangial matrix of the glomeruli. Very often the expanded mesangium contains deposits of IgM demonstrable on immunofluorescent staining. The cause is unknown. Corticosteroid therapy may induce remission, but relapses are common. Choices for treating this type of nephrotic syndrome are the same as noted earlier.

MEMBRANOUS NEPHROPATHY (Membranous Glomerulonephritis)

Although largely idiopathic in nature, membranous nephropathy can be found in association with diseases such as hepatitis B antigenemia, systemic lupus erythematosus, congenital and secondary syphilis, and renal vein thrombosis; with immunologic disorders such as autoimmune thyroiditis; and with administration of drugs such as penicillamine. The pathogenesis is unknown, but the glomerular lesion is thought to be the result of prolonged deposition of circulating antigen–antibody complexes.

The onset of membranous nephropathy may be insidious or may resemble that of idiopathic nephrotic syndrome of childhood (see preceding section). It occurs more often in older children and adults. The proteinuria of membranous nephropathy responds little if at all to corticosteroid therapy. Low-dose corticosteroid therapy, however, has been shown to reduce or delay development of chronic renal insufficiency. The diagnosis is made by renal biopsy.

■ DISEASES OF THE RENAL VESSELS

RENAL VEIN THROMBOSIS

In the newborn period, renal vein thrombosis may complicate sepsis or dehydration. It may be observed in an infant of a diabetic mother, or it may be the result of umbilical vein catheterization. It may result from any condition that produces a hypercoagulable state (eg, clotting factor deficiency, systemic lupus erythematosus, or thrombocytosis). Renal vein thrombosis is less common in older children and adolescents; it may develop following trauma or without any apparent predisposing factors. Nephrotic syndrome may either cause or result from renal vein thrombosis. Spontaneous renal

vein thrombosis has been associated with membranous glomerulonephropathy.

Clinical Findings

Renal vein thrombosis in newborns is generally characterized by the sudden development of an abdominal mass. If the thrombosis is bilateral, oliguria may be present; urine output may be normal with a unilateral thrombus. In older children, flank pain, sometimes with a palpable mass, is a common presentation.

No single laboratory test is diagnostic of renal vein thrombosis. Hematuria usually is present. Proteinuria is less constant. In the newborn, thrombocytopenia may be found; this is rare in older children. The diagnosis is made by ultrasonography and Doppler flow studies.

Treatment

Anticoagulation with heparin is the treatment of choice both in newborns and in older children. In the newborn, a course of heparin combined with treatment of the underlying problem is usually all that is required. Management in other cases is less straightforward. The tendency for recurrence and embolization has led some to recommend long-term anticoagulation. If an underlying membranous GN is suspected, biopsy should be performed.

Course & Prognosis

The mortality rate in newborns from renal vein thrombosis depends on the underlying cause. With unilateral thromboses, the prognosis for adequate renal function is good. Renal vein thrombosis may rarely recur in the same kidney or occur in the other kidney years after the original episode of thrombus formation. Extension into the vena cava, with pulmonary emboli, is possible.

RENAL ARTERIAL DISEASE

Arterial disease (eg, fibromuscular hyperplasia and congenital stenosis) is a rare cause of hypertension in children. Although there are few clinical clues to underlying arterial lesions, arterial lesions should be suspected in children whose hypertension is severe, with onset at or before age 10 years, or associated with delayed visualization with nuclear medicine scan. The diagnosis is established by renal arteriography with selective renal vein renin measurements. Some of these lesions may be approached by transluminal angioplasty or surgery (see Renal Hypertension section), but repair may be technically impossible in many small children. Although thrombosis of renal arteries is rare, it should be considered in a patient experiencing acute onset of hypertension and hematuria in an appropriate setting (eg, in as-

sociation with hyperviscosity or umbilical artery catheterization). Early diagnosis and treatment (eg, heparin) provides the best chance of reestablishing renal blood flow.

HEMOLYTIC–UREMIC SYNDROME

Hemolytic–uremic syndrome is the most common glomerular vascular cause of acute renal failure in childhood. It is usually the result of infection with Shiga-toxin-producing (also called verotoxin-producing) strains of *Shigella* or *Escherichia coli*. There are many serotypes, but the most common pathogen in the United States is *E coli* 0157:H7. Bloody diarrhea is the usual presenting complaint, followed by hemolysis and renal failure. Circulating verotoxin causes endothelial damage, which leads to platelet deposition, microvascular occlusion with subsequent hemolysis, and thrombocytopenia. Ingestion of undercooked ground beef or unpasteurized foods is a common cause. Such microvascular endothelial activation may also be triggered by some drugs (eg, cyclosporin A); by viruses (human immunodeficiency virus [HIV]); and by pneumococcal infections, in which bacterial neuraminidase exposes the Thomsen–Friedenrich antigen on red cells, platelets, and endothelial cells, thereby causing platelet aggregation, endothelial damage, and hemolysis. Rare cases are caused by predisposing genetic factors (eg, congenitally depressed C3 complement and factor H deficiency).

Clinical Findings

The epidemic form begins with a prodrome of abdominal pain, diarrhea, and vomiting. Oliguria, pallor, and bleeding manifestations, principally gastrointestinal, occur next. Hypertension and seizures develop in some children—especially those who develop severe renal failure and fluid overload. There may also be significant direct involvement of the central nervous system (CNS).

Anemia is profound, and red blood cell fragments are seen on blood smears. A high reticulocyte count confirms the hemolytic nature of the anemia, but may not be noted in the presence of renal failure. Thrombocytopenia is profound, but other coagulation abnormalities are less consistent. Serum fibrin split products are often present, but fulminant disseminated intravascular coagulation is rare. Hematuria and proteinuria are often present. The serum complement level is normal except in those cases related to congenital predisposition.

Complications

These usually result from renal failure. Neurologic problems, particularly seizures, may result from elec-

trolyte abnormalities such as hyponatremia, hypertension, or from CNS vascular disease. Severe bleeding, transfusion requirements, and hospital-acquired infections must be anticipated.

Treatment

Meticulous attention to fluid and electrolyte status is crucial. The use of antimotility agents and antibiotics is believed to worsen the disease. Antibiotics may up-regulate and cause the release of large amounts of bacterial Shiga toxin. Early dialysis improves the prognosis; the patient's size will usually dictate peritoneal dialysis as the technique of choice. Seizures usually respond to control of hypertension and electrolyte abnormalities. It has been suggested that the plasma in some cases lacks a prostacyclin-stimulating factor that is a potent inhibitor of platelet aggregation. Therefore, plasma infusion or plasmapheresis has been advocated in severe cases. Platelet inhibitors have also been tried, but the results have not been impressive, especially late in the disease. Nonetheless, it appears that using a platelet inhibitor early in the disease in an attempt to halt platelet consumption and microvascular occlusion may obviate the need for platelet transfusion and reduce the progression of renal failure. Red cell and platelet transfusions may be necessary; although the risk of volume overload is significant, it can be minimized by dialysis. Erythropoietin (epoetin alfa) treatment may reduce red cell transfusion needs. Although no therapy is universally accepted for patients with this syndrome, the strict control of hypertension and nutrition and the timely use of dialysis reduce morbidity and mortality. If renal failure is "nonoliguric," and thus output is sufficient to ensure against fluid overload and electrolyte abnormalities, management of renal failure without dialysis is possible.

Course & Prognosis

Most commonly, children recover from the acute episode within 2–3 weeks. Some form of residual renal disease (including hypertension) occurs in about 30%, and end-stage renal failure in about 15%. Thus follow-up of children recovering from hemolytic-uremic syndrome should include serial determinations of renal function for 1–2 years and meticulous attention to blood pressure for 5 years. Mortality (about 3–5%) is of greatest concern in the early phase, primarily resulting from CNS complications.

Trachtman H, Christen E: Pathogenesis, treatment, and therapeutic trials in hemolytic uremic syndrome. *Curr Opin Pediatr* 1999;11:162.

RENAL FAILURE

ACUTE RENAL FAILURE

Acute renal failure is the sudden inability to excrete urine of sufficient quantity or adequate composition to maintain body fluid homeostasis. The most common cause in children is dehydration. However, encountering signs of acute renal insufficiency in a hospitalized patient raises many other possibilities: impaired renal perfusion or renal ischemia, acute renal disease, renal vascular compromise, acute tubular necrosis, or obstructive uropathy. Table 22–2 lists such prerenal, renal, and postrenal causes.

Clinical Findings

The hallmark of early renal failure is oliguria. Although an exact etiologic diagnosis may be unclear at the onset,

Table 22–2. Classification of renal failure.

Prerenal

- Dehydration due to gastroenteritis, malnutrition, or diarrhea
- Hemorrhage, aortic or renal vessel injury, trauma, cardiac disease and/or surgery, renal arterial thrombosis
- Diabetic acidosis
- Hypovolemia associated with capillary leak or nephrotic syndrome
- Shock
- Heart failure

Renal

- Hemolytic-uremic syndrome
- Acute glomerulonephritis
- Prolonged renal hypoperfusion
- Nephrotoxins
- Acute tubular necrosis or vascular nephropathy
- Renal (cortical) necrosis
- Intravascular coagulation—septic shock, hemorrhage
- Diseases of renal vessels
- Iatrogenic disorders
- Severe infections
- Drowning, especially fresh water
- Crystalluria: sulfonamide or uric acid
- Hyperuricacidemia from cancer treatment
- Hepatic failure

Postrenal

- Obstruction due to tumor, hematoma, posterior urethral valves, ureteropelvic junction stricture, ureterovesical junction stricture, ureterocele
- Stones
- Trauma to a solitary kidney or collecting system
- Renal vein thrombosis

classifying the oliguria as outlined in Table 22–2 is helpful in determining if any immediately reversible causes are present.

If the cause of an elevation in serum BUN and creatinine or oliguria is unclear, entities that can be quickly addressed and corrected (eg, volume depletion) should be considered first. Once normal renal perfusion is ensured and no clinical evidence for *de novo* renal disease is present, a diagnosis of acute tubular necrosis (vasomotor nephropathy, ischemic injury) may be entertained.

A. PRERENAL CAUSES

The most common cause of decreased renal function in children is compromised renal perfusion. It is usually secondary to dehydration, although abnormalities of renal vasculature and poor cardiac performance may also be considered. Such causes should be sought and, if present, corrected to determine if true renal functional disturbances are present. Table 22–3 lists the urinary indices helpful in distinguishing these “prerenal” conditions from true renal parenchymal diseases, such as acute tubular necrosis.

B. RENAL CAUSES

Causes of renal failure intrinsic to the kidney include acute glomerulonephritides, hemolytic–uremic syndrome, acute interstitial nephritis, and nephrotoxic injury. The diagnosis of acute tubular necrosis (vasomotor nephropathy)—which is reserved for those cases in which renal ischemic insult is believed to be the likely cause—should be considered when correction of prerenal or postrenal problems does not improve renal function.

C. POSTRENAL CAUSES

Postrenal failure, usually found in newborns with urologic anatomic abnormalities, is accompanied by varying degrees of renal insufficiency. Obstruction of the bladder outlet, as in posterior urethral valves, should be

relieved by insertion of a urethral catheter followed by surgical correction. Timely intervention may prevent irreversible renal injury and chronic renal failure. Delayed voiding in the newborn period, anuria, or poor urinary stream usually suggests obstruction. Ureteropelvic junctional obstruction usually presents as an abdominal mass.

Complications

The clinical severity of the complications depends on the degree of renal functional impairment and oliguria. Common complications include (1) fluid overload (hypertension, congestive heart failure, pulmonary edema), (2) electrolyte disturbances (hyperkalemia), (3) metabolic acidosis, (4) hyperphosphatemia, and (5) uremia.

Treatment

An indwelling bladder catheter is inserted to ascertain urine output. If urine volume is insignificant and renal failure is established, the catheter should be removed to minimize infection risks. Prerenal or postrenal factors should be excluded or rectified, and normal circulating volume established and maintained with appropriate fluids. Strict measurements of volume input and output must be maintained, and adjustments made to reduce input as reduction in output dictates. The patient’s response is assessed by physical examination and measurement of urinary output. Measurement of central venous pressure may be indicated. If diuresis does not occur in response to these measures, furosemide (1–5 mg/kg, per dose, intravenously, maximum of 200 mg) may be used. The effective dose will depend on the amount of functional compromise (if < 50% function, initiate attempt at diuresis with maximum dose). If a response does not occur within 1 hour (ie, the urine output remains low [< 0.5 mL/kg/h]), the furosemide dose, if not already at maximum, should be increased up to 5 mg/kg. In some cases the addition of a long-acting thiazide diuretic, such as metolazone, may be useful. If no diuresis occurs with maximum dosing, further administration of diuretics will not be helpful.

If these maneuvers stimulate some urine flow but biochemical evidence of acute renal failure persists, the resulting nonoliguric acute renal failure should be more manageable. Fluid overload and dialysis may be averted. However, if the medications and nutrients required exceed the urinary output, dialysis is indicated. Institution of dialysis before the early complications of acute renal failure develop is likely to improve clinical management and outcome. It is important to adjust medication dosage according to the degree of renal function.

Table 22–3. Urine studies.

Prerenal Failure	Acute Tubular Necrosis
Urine osmolality 50 mOsm/kg greater than plasma osmolality	Urine osmolality equal to or less than plasma osmolality
Urine sodium < 10 mEq/L	Urinary sodium > 20 mEq/L
Ratio of urine creatinine to plasma creatinine > 14:1	Ratio of urine creatinine to plasma creatinine < 14:1
Specific gravity > 1.020	Specific gravity 1.012–1.018

Acute Dialysis

A. INDICATIONS FOR DIALYSIS

Immediate indications for dialysis are (1) severe hyperkalemia; (2) unrelenting metabolic acidosis (usually in a situation where fluid overload prevents sodium bicarbonate administration); (3) fluid overload with or without severe hypertension or congestive heart failure (a situation that would seriously compromise nutrition or drug administration); and (4) symptoms of uremia, usually manifested in children by CNS depression. The rate of rise of both urea nitrogen and creatinine levels may indicate the need for dialysis; it is generally accepted that the urea nitrogen level should not be allowed to exceed 100 mg/dL (keeping in mind nonrenal functional factors contributing to excessive BUN) in small children.

B. METHODS OF DIALYSIS

The choice between peritoneal dialysis and hemodialysis may be dictated by their availability. Peritoneal dialysis is generally preferred in children because of the ease of performance and patient tolerance. Although peritoneal dialysis is technically less efficient than hemodialysis, hemodynamic stability and metabolic control can be better sustained because this technique can be applied on a relatively continuous basis. However, hemodialysis should be considered (1) if rapid removal of toxins is desired, (2) if the size of the patient makes hemodialysis less technically cumbersome and hemodynamically well tolerated, or (3) if impediments to efficient peritoneal dialysis are present (eg, ileus). Furthermore, if vascular access and usage of anticoagulation are not impediments, a slow, continuous hemodialytic process (continuous renal replacement treatment) may be applied, if the technical expertise is available.

C. COMPLICATIONS OF DIALYSIS

Complications of peritoneal dialysis include peritonitis, volume depletion, and technical complications such as dialysate leakage and respiratory compromise from intra-abdominal dialysate fluid. Peritonitis can be avoided by strict observance of aseptic technique. Peritoneal fluid cultures are obtained as clinically indicated. Dialysate can leak around the dialysis catheter or through tissue planes, causing dissection. Leakage is reduced by good catheter placement technique and appropriate intra-abdominal dialysate volumes. Technical problems causing abnormal flow of dialysate in and out of the peritoneal cavity require help from a nephrologist. Dialysis is useful in maintaining electrolyte balance. Potassium (absent from standard dialysate solutions) can be added to the dialysate as required. Phosphate is also absent because hyperphosphatemia is an expected problem in renal failure. Nonetheless, if phosphate intake is inadequate,

hypophosphatemia must be addressed. High dextrose concentrations (maximum 4.25%) can correct fluid overload rapidly at the risk of causing hyperglycemia. Fluid removal may be increased with more frequent exchanges of the dialysate, but rapid osmotic transfer of water may result in hypernatremia.

Even in small infants, hemodialysis can rapidly correct major metabolic and electrolyte disturbances, as well as volume overload. The process is highly efficient, but the speed of the changes can cause problems such as hemodynamic instability. Anticoagulation is usually required. Careful monitoring of the appropriate biochemical parameters is important. Note that during or immediately following the procedure, blood sampling will produce misleading results because equilibration between extravascular compartments and the blood will not yet have been completed. Vascular access must be obtained and carefully monitored.

Course & Prognosis

The period of severe oliguria, if it occurs, usually lasts about 10 days. Oliguria lasting longer than 3 weeks, or anuria, makes a diagnosis of acute tubular necrosis very unlikely and favors vascular injury, severe ischemia (cortical necrosis), GN, or obstruction. The diuretic phase begins with an increase in urinary output to passage of large volumes of isosthenuric urine containing sodium levels of 80–150 mEq/L. During the recovery phase, signs and symptoms subside rapidly, although polyuria may persist for several days or weeks. Urinary abnormalities usually disappear completely within a few months. If renal recovery does not ensue, arrangements are made for chronic dialysis and eventual renal transplantation.

CHRONIC RENAL FAILURE

Chronic renal failure in children most commonly results from developmental abnormalities of the kidneys or urinary tract. The kidneys may develop poorly (dysgenesis) or not at all (agenesis). Cystic development may result in immediate or progressive insufficiency. Abnormal development of the urinary tract may not permit normal renal development. Obstructive uropathy or severe vesicoureteral reflux nephropathy, without (or despite) surgical intervention, continues to cause a significant amount of progressive renal insufficiency in children. In older children, the chronic glomerulonephritides and nephropathies, irreversible nephrotoxic injury, or hemolytic-uremic syndrome may also result in chronic renal failure.

When chronic renal failure is the result of an inadequate amount of normally functioning renal tissue, the inability to concentrate urine results in polyuria, poly-

dipsia, or enuresis. Affected patients often fail to thrive. Without medical care, children with long-standing chronic renal failure may present with complications such as rickets or anemia.

Chronic renal failure may follow acute GN or develop with chronic GN in the absence of an obvious acute episode. Presentations range from hypertension to overt uremic symptoms. Growth failure depends on age at presentation and the rapidity of functional decline. Some of the chronic glomerulonephritides (eg, membranoproliferative GN) can progress unnoticed if subtle abnormalities of the urinary sediment are undetected or ignored. Any child with a history of chronic GN or significant renal injury needs close follow-up and monitoring of renal function. Angiotensin-converting enzyme (ACE) inhibitors decrease the glomerulosclerosis that follows glomerular injury and are often used to treat the associated hypertension.

Complications

The kidney can compensate for gradual loss of functioning nephrons in progressive chronic renal failure until the GFR falls below 15 mL/min/1.73 m². Complications appear as compensatory power is lost. In children who have developmentally reduced function but are unable to concentrate the urine, polyuria and thus dehydration is more likely to be a problem than fluid overload. Output may be expected to gradually diminish with time as renal failure progresses to end stage; however, some children can continue to produce generous quantities of urine (but not of good quality) even though they require dialysis. Moreover, a salt-wasting state can occur. In contrast, children who develop chronic renal failure due to the glomerular disease or renal injury will characteristically retain sodium and water so that hypertension occurs relatively early.

Metabolic acidosis and growth retardation occur early in chronic renal failure. Disturbances in calcium, phosphorus, and vitamin D metabolism leading to renal osteodystrophy require prompt attention. Although renal compensation and increased parathyroid hormone can maintain a normal serum phosphate level early in the course, secondary hyperparathyroidism with resulting skeletal abnormalities will occur. This physiologic response to hyperphosphatemia can be reflected by an increase in serum alkaline phosphatase, but measurement of intact parathyroid hormone is more clinically specific.

Uremic symptoms occur late in chronic renal failure and include anorexia, nausea, and malaise. CNS features range from confusion, apathy, and lethargy to stupor and coma. Associated electrolyte abnormalities may precipitate seizures (more commonly, a result of untreated hypertension). Anemia (normochromic and

normocytic from decreased renal erythropoietin synthesis) is usual. Platelet dysfunction and other abnormalities of the coagulation system may be present. Bleeding phenomena—especially gastrointestinal bleeding—may be a problem. Cardiovascular manifestations may be life-threatening. Uremic pericarditis, congestive heart failure, or hypertension may occur.

Treatment

Treatment of chronic renal failure before dialysis is done to preserve remaining renal function and to avoid complications. Controlling hypertension (see Renal Hypertension section) and hyperphosphatemia and preventing UTI are important. Acidosis may be treated with sodium citrate solutions, as long as the added sodium will not aggravate hypertension. Sodium restriction is advisable when hypertension is present. Hyperphosphatemia is controlled by dietary restriction and dietary phosphate binders (eg, calcium carbonate). Vitamin D should be given to maintain normal serum calcium. When the BUN level exceeds approximately 50 mg/dL, or if the child is lethargic or anorexic, dietary protein should be restricted. Potassium restriction will be necessary as the GFR falls to a level where urinary output decreases sharply. Meanwhile, the diet must continue to provide the child's specific daily requirements.

Renal function must be monitored regularly (creatinine and BUN), and serum electrolytes, calcium, phosphorus, alkaline phosphatase, and hemoglobin and hematocrit levels must be checked. Results guide changes in fluid and dietary management as well as dosages of phosphate binder, citrate buffer, vitamin D, and blood pressure medications. Anemia may be treated with epoetin alfa. These treatment areas require careful monitoring to minimize symptoms while the child's need for chronic dialysis and transplantation continues to be assessed.

Care must be taken to avoid medications that aggravate hypertension; increase the body burden of sodium, potassium, or phosphate; or increase production of BUN. Successful management relies greatly on education of the patient and family.

Attention must also be directed toward the psychosocial needs of the patient and family during adjustment to chronic illness. The strategy for patient management—and the need for family education and adjustment—changes when a plan for chronic dialysis and possible renal transplantation is initiated. These changes may include a reduction in medications or dietary limitations, with the potential for improving growth. Some uremic children will grow significantly when given human recombinant growth hormone.

Dialysis & Transplantation

The best tolerated treatment of end-stage renal disease in a child is a successful and uncomplicated renal transplant. The North American Pediatric Renal Transplant Collaborative Study reports a 1-year graft survival rate of living-related kidney transplants of 90%, with 85% at 2 years and 75% at 5 years. With cadaveric transplantation, percentages of graft survivals are 76%, 71%, and 62%, respectively. Overall, the mortality rate is 4% for recipients of living-related donors and 6.8% for recipients of cadaver organs. These percentages are affected by the increased mortality, reported to be as high as 75% in infants younger than age 1 year, primarily due to technical issues and complications of immunosuppression. Therefore, most transplantation centers are waiting until infants reach a body weight of about 15 kg. This body weight appears to be associated with a significantly improved survival rate. Adequate growth and well-being are directly related to acceptance of the graft, the degree of normal function, and the side effects of medications.

Great advances have also been made in peritoneal dialysis and hemodialysis, both in technique and in our understanding of the specialized approach required. Hemodialysis is now performed in major centers that devote their entire effort to the treatment of pediatric patients and is regarded as a reasonable long-range method of treating the older child with end-stage renal disease. The demonstrated feasibility of chronic peritoneal dialysis in children, however, has made it the primary choice of dialysis therapy, especially for small children. It is well accepted and can be performed in the home.

The best measure of the success of chronic dialysis in children is the level of physical and psychosocial rehabilitation achieved. Patients continue to participate in day-to-day activities and attend school. Although catch-up growth rarely occurs, patients can grow at an acceptable rate even though they may remain in the lower percentiles. Use of epoetin alfa, growth hormone, and better control of renal osteodystrophy contribute to improved outcome.

RENAL HYPERTENSION

Hypertension in children is commonly of renal origin. It is anticipated as a complication of known renal parenchymal disease, but it may be found on routine physical examination in an otherwise normal child. In-

creased understanding of the roles of water and salt retention on the one hand and overactivity of the renin-angiotensin system on the other has done much to guide therapy; nevertheless, not all forms of hypertension can be explained by these two mechanisms.

The causes of renal hypertension in the newborn period include (1) congenital anomalies of the kidneys or renal vasculature, (2) obstruction of the urinary tract, (3) thrombosis of renal vasculature or kidneys, and (4) volume overload. Some instances of apparent paradoxical elevations of blood pressure have been reported in clinical situations in which chronic diuretic therapy is used, such as in bronchopulmonary dysplasia. Hypertensive infants should also be examined for renal, vascular, or aortic abnormalities (eg, thrombosis, neurofibromatosis, coarctation) as well as some endocrine disorders.

Diagnosis

A child is normotensive if the average recorded systolic and diastolic blood pressures are lower than the 90th percentile for age and sex. The 90th percentile in the newborn period is approximately 85–90/55–65 mm Hg for both sexes. In the first year of life, the acceptable levels are 90–100/60–67 mm Hg. Incremental increases with growth occur, gradually approaching young adult ranges of 100–120/65–75 mm Hg in the late teens. Careful measurement of blood pressure includes ensuring correct cuff size and reliable equipment. The cuff should be wide enough to cover two thirds of the upper arm and should encircle the arm completely without causing an overlap in the inflatable bladder. Although an anxious child may have an elevation in blood pressure, abnormal readings must not be too hastily attributed to this cause. Repeat measurement is helpful, especially after the child has been consoled.

Routine laboratory studies include a complete blood count, urinalysis, and urine culture. Radiography and ultrasonography are used to study the anatomy of the urinary tract, the blood flow to the kidneys, and their function. A renal biopsy (which rarely reveals the cause of hypertension unless clinical evidence of renal disease is present) should always be undertaken with special care in the hypertensive patient and preferably after pressures have been controlled by therapy. Figure 22–3 presents a suggested approach to the outpatient work-up of hypertension.

Treatment

A. TREATMENT OF ACUTE EMERGENT HYPERTENSION

A hypertensive emergency exists when CNS signs of hypertension appear, such as papilledema or encephalopathy. Retinal hemorrhages or exudates indicate a need for prompt and effective control. In children, however,

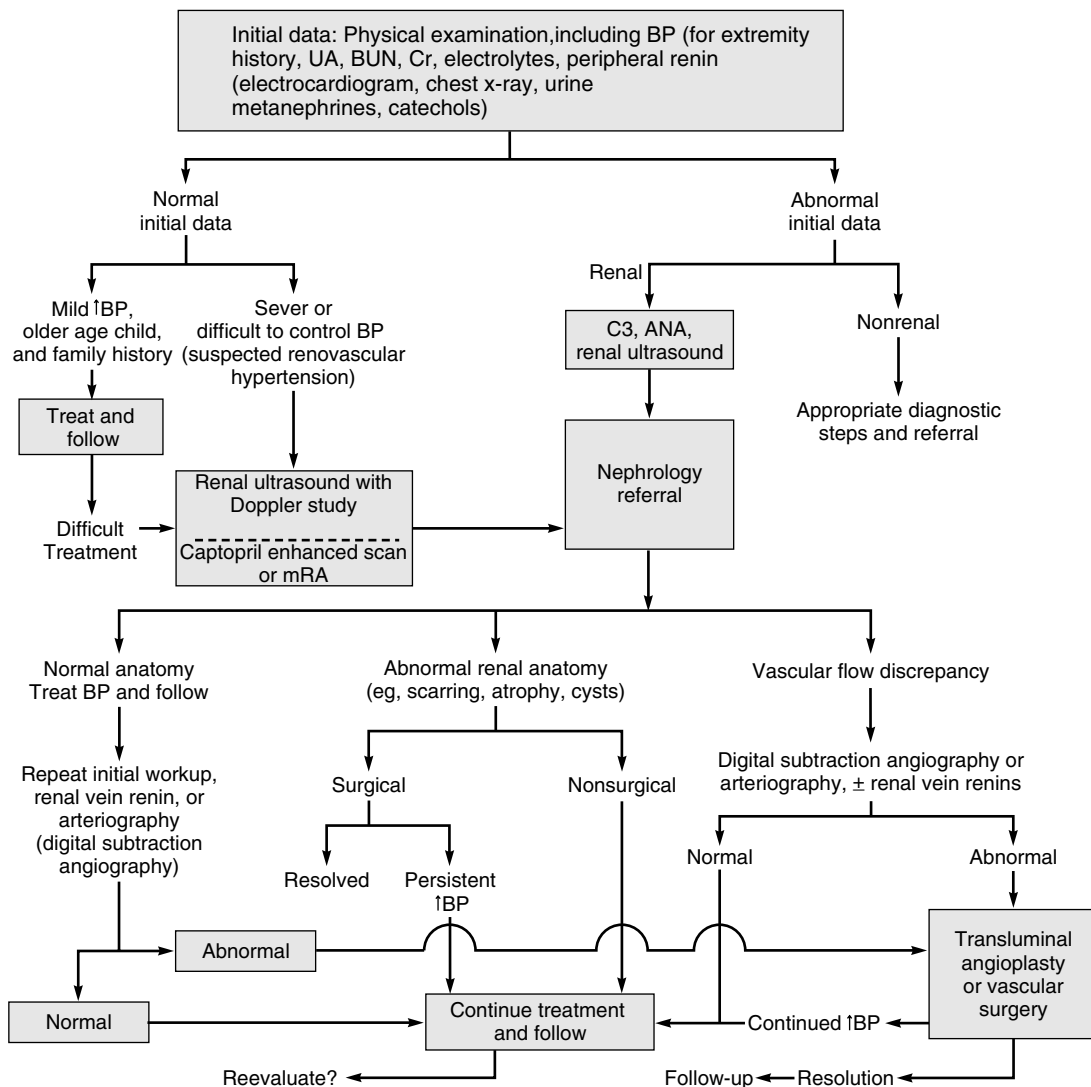

Figure 22-3. Approach to the outpatient work-up of hypertension. ANA = antinuclear antibody; BUN = blood urea nitrogen; Cr = creatinine.

end-organ abnormalities secondary to hypertension commonly are not present. Treatment varies with the clinical presentation. The primary classes of useful antihypertensive drugs are (1) diuretics, (2) α - and β -adrenergic blockers, (3) ACE inhibitors, (4) calcium channel blockers, and (5) vasodilators.

Whatever method is used to control emergent hypertension, medications for sustained control should also be initiated so that the effect will be maintained when the emergent measures are discontinued (Table 22-4). Acute elevations of blood pressure not exceeding

the 95th percentile for age may be treated with oral antihypertensives, aiming for progressive improvement and control within 48 hours.

1. Sublingual nifedipine—This calcium channel blocker is rapid acting, and, in appropriate doses, should not result in hypotensive blood pressure levels. The liquid from a 10-mg capsule can be drawn into a syringe and the dosage approximated. The exact dosage for children who weigh less than 10–30 kg is difficult to ascertain by this method, but 5 mg is a safe starting

Table 22-4. Antihypertensive drugs for emergent treatment.

Drug	Oral Dose	Major Side Effects ^a
Nifedipine	0.25–0.5 mg/kg/SL	Flushing, tachycardia
Labetalol	1–3 mg/kg/h IV	Secondary to β -blocking activity
Sodium nitroprusside	0.5–10 mg/kg/min IV drip	Cyanide toxicity, sodium and water retention
Furosemide	1–5 mg/kg IV	Secondary to severe volume contraction, hypokalemia
Diazoxide	2–10 mg/kg IV bolus	Hyperglycemia, hyperuricemia, sodium and water retention
Hydralazine	0.1–0.2 mg/kg IV	Sodium and water retention, tachycardia, flushing

^aMany more side effects than those listed have been reported.

point. Because the treatment is given for rising blood pressure, it is unlikely that the effects will be greater than desired. Larger children with malignant hypertension require 10 mg. In such cases, the capsule may simply be pierced and the medication squeezed under the patient's tongue.

2. Intravenous hydralazine—This vasodilator is sometimes effective. Dosage varies according to the severity of the hypertension and should begin at about 0.15 mg/kg.

3. Sodium nitroprusside—In an intensive care setting, this powerful vasodilator is very effective for reducing severely elevated blood pressure. Intravenous administration of 0.5–10 mg/kg/min will reduce blood pressure in seconds, and the dose must be monitored carefully. Metabolism of the drug results in thiocyanate; thus, with prolonged usage, levels of thiocyanate must be monitored, especially in renal insufficiency.

4. Furosemide—Administered at 1–5 mg/kg, intravenously, this diuretic will reduce blood volume and enhance the effectiveness of antihypertensive drugs.

B. TREATMENT OF SUSTAINED HYPERTENSION

Several choices are available (Table 22-5). A single drug such as a β -blocker (unless contraindicated, eg, in reactive airway disease) may be adequate to treat mild hypertension. Diuretics are useful to treat renal insuffi-

Table 22-5. Antihypertensive drugs for ambulatory treatment.

Drug	Oral Dose	Major Side Effects ^a
Hydrochlorothiazide	2–4 mg/kg/24 h as single dose or in 2 individual doses	Potassium depletion, hyperuricemia
Furosemide	1–5 mg/kg/dose, 2–3 doses per day	Potassium and volume depletion
Hydralazine	0.75 mg/kg/24 h in 4–6 divided doses	Lupus erythematosus, tachycardia, headache
Amlodipine	0.2 to 0.5 mg/kg/d in 2 divided doses	Fatigue, headache, facial flushing
Propranolol	0.2–5 mg/kg/dose, 2–3 doses per day	Syncope, cardiac failure, hypoglycemia
Minoxidil	0.15 mg/kg/dose, 2–3 doses per day	Tachycardia, angina, fluid retention, hirsutism
Captopril	0.3–2 mg/kg/dose, 2–3 doses per day	Rash, hyperkalemia, glomerulopathy
Enalapril	0.2–0.5 mg/kg/d in 2 divided doses	Proteinuria, cough, hyperkalemia
Nifedipine	0.5–1 mg/kg/d, 3 doses per day	Flushing, tachycardia
Verapamil	3–7 mg/kg/d in 2 or 3 divided doses	AV conduction disturbance

^aMany more side effects than those listed have been reported.

ciency, but disadvantages of possible electrolyte imbalance must be considered. Single-drug therapy with an ACE inhibitor is useful, especially because most hypertension in children has renal causes. Calcium channel blockers are increasingly useful, and appear well tolerated in children. The use of the vasodilator type of antihypertensive drug requires concomitant administration of a diuretic to counter the effect of vasodilation on increasing renal sodium and water retention and a β -blocker to counter reflex tachycardia. Minoxidil, considered the most powerful of the orally administered vasodilators, can be extremely efficacious in the treatment of severe, sustained hypertension, but its effect is greatly offset by the other effects described. Hirsutism is a significant side effect. Hydralazine hydrochloride may still be the most common vasodilator in pediatric use—but, again, the necessity of using two additional drugs for maximum benefit keeps vasodilators in reserve for those severe situations calling for management with three or four drugs. The advice of a pediatric nephrologist should be sought.

■ INHERITED OR DEVELOPMENTAL DEFECTS OF THE URINARY TRACT

There are many developmental, hereditary, or metabolic defects of the kidneys and collecting system. The clinical consequences include metabolic abnormalities, failure to thrive, nephrolithiasis, renal glomerular or

tubular dysfunction, and chronic renal failure. Table 22–6 lists some of the major entities; discussion of the rarer conditions is beyond the scope of this book.

DISORDERS OF THE RENAL TUBULES

Three subtypes of renal tubular acidosis are well recognized: (1) the classic form, called type I or distal renal tubular acidosis; (2) the bicarbonate-wasting form, called type II or proximal renal tubular acidosis; and (3) type IV, or hyperkalemic renal tubular acidosis (rare in children), which is associated with hyporeninemic hypoaldosteronism. Type I and type II and their variants are encountered most frequently in children. Type III is a combination of types I and II.

Table 22–6. Inherited or developmental defects of the urinary tract.

Cystic diseases of genetic origin

Polycystic disease

Autosomal-recessive form (infantile)

Autosomal-dominant form (adult)

Other syndromes that include either form

Cortical cysts

Several syndromes are known to have various renal cystic manifestations, including “simple” cysts; may not have significant effect on renal functional status or be associated with progressive disease

Medullary cysts

Medullary sponge kidney

Medullary cystic disease (nephronophthisis)

Hereditary and familial cystic dysplasia

Congenital nephrosis

“Finnish” disease

Dysplastic renal diseases

Renal aplasia (unilateral, bilateral)

Renal hypoplasia (unilateral, bilateral, total, segmental)

Multicystic renal dysplasia (unilateral, bilateral, multilocular, postobstructive)

Familial and hereditary renal dysplasias

Oligomeganephronia

Hereditary diseases associated with nephritis

Hereditary nephritis with deafness and ocular defects (Alport’s syndrome)

Nail-patella syndrome

Familial hyperprolinemia

Hereditary nephrotic syndrome

Hereditary osteolysis with nephropathy

Hereditary nephritis with thoracic asphyxiant dystrophy syndrome

Hereditary diseases associated with intrarenal deposition of metabolites

Angiokeratoma corporis diffusum (Fabry disease)

Heredopathia atactica polyneuritiformis (Refsum disease)

Various storage diseases (eg, G_{M1} monosialogangliosido-

sis, Hurler syndrome, Niemann-Pick disease, familial metachromatic leukodystrophy, glycogenosis type I [von Gierke disease], glycogenosis type II [Pompe disease])

Hereditary amyloidosis (familial Mediterranean fever, hereditary familial urticaria with deafness and neuropathy, primary familial amyloidosis with polyneuropathy)

Hereditary renal diseases associated with tubular transport defects

Hartnup disease

Fanconi’s anemia

Oculocerebrorenal syndrome of Lowe

Cystinosis (infantile, adolescent, adult types)

Wilson’s disease

Galactosemia

Hereditary fructose intolerance

Renal tubular acidosis (many types)

Hereditary tyrosinemia

Renal glycosuria

Vitamin D-resistant rickets

Pseudohypoparathyroidism

Vasopressin-resistant diabetes insipidus

Hypouricemia

Hereditary diseases associated with lithiasis

Hyperoxaluria

L-Glyceric aciduria

Xanthinuria

Lesch-Nyhan syndrome and variants, gout

Nephropathy due to familial hyperparathyroidism

Cystinuria (types I, II, III)

Glycinuria

Miscellaneous

Hereditary intestinal vitamin B_{12} malabsorption

Total and partial lipodystrophy

Sickle cell anemia

Bartter syndrome

Primary tubular disorders in childhood, such as glycinuria, hypouricemia, or renal glycosuria, may result from a defect in a single tubular transport pathway (see Table 22–6).

1. Distal Renal Tubular Acidosis (Type I)

The most common form of distal renal tubular acidosis in childhood is the hereditary form. The clinical presentation is one of failure to thrive, anorexia, vomiting, and dehydration. Hyperchloremic metabolic acidosis occurs, with hypokalemia and a urinary pH exceeding 6.5. The acidosis is more severe in the presence of a bicarbonate “leak.” This variant of distal renal tubular acidosis with bicarbonate wasting has been called type III, but for clinical purposes need not be considered as a distinct entity. Concomitant hypercalciuria may lead to rickets, nephrocalcinosis, nephrolithiasis, and renal failure.

Other situations that may be responsible for distal renal tubular acidosis are found in some of the entities listed in Table 22–6.

Distal renal tubular acidosis results from a defect in the distal nephron, in the tubular transport of hydrogen ion, or in the maintenance of a steep enough gradient for proper excretion of hydrogen ion. This defect can be accompanied by degrees of bicarbonate wasting.

The classic test for distal renal tubular acidosis is an acid load from NH_4Cl . The test is cumbersome and can produce severe acidosis. A clinical trial of alkali administration should be used to rule out proximal (type II) renal tubular acidosis. The dose of alkali required to achieve a normal plasma bicarbonate concentration in patients with distal renal tubular acidosis is low (seldom exceeding 2–3 mEq/kg/24 h)—in contrast to that required in proximal renal tubular acidosis (> 10 mEq/kg/24 h). Higher doses are needed, however, if distal renal tubular acidosis is accompanied by bicarbonate wasting. Correction of acidosis can result in reduced complications and improved growth.

Distal renal tubular acidosis is usually permanent, although it sometimes occurs as a secondary complication. If the defect is not caused by a greater tubular disorder and renal damage is prevented, the prognosis is good.

2. Proximal Renal Tubular Acidosis (Type II)

Proximal renal tubular acidosis is characterized by an alkaline urine pH, loss of bicarbonate in the urine, and mildly reduced serum bicarbonate concentrations. About 85–90% of bicarbonate reabsorption occurs in the proximal tubules. The lesion in proximal renal tubular acidosis is a lowering of the renal bicarbonate

threshold, that is, the concentration of serum bicarbonate above which bicarbonate appears in the urine. With more severe acidosis, the concentration of serum bicarbonate drops and bicarbonate disappears from the urine; these changes reflect normal distal tubular acidification.

Proximal renal tubular acidosis is the most common type encountered in children. It is often an isolated defect, and in the newborn infant it can be considered an aspect of renal immaturity. Onset in infants is accompanied by failure to thrive, hyperchloremic acidosis, hypokalemia, and, rarely, nephrocalcinosis. Secondary forms result from reflux or obstructive uropathy and occur in association with other tubular disorders (see Table 22–6). Proximal renal tubular acidosis requires greater than 3 mEq/kg of alkali per day to correct the acidosis. Serum bicarbonate should be monitored weekly until a level of at least 20 mEq/L is attained.

Citrate solutions (eg, Bicitra, Polycitra) are somewhat more easily tolerated than sodium bicarbonate. Bicitra contains 1 mEq of Na^+ and citrate per milliliter. Polycitra contains 2 mEq per milliliter of citrate and 1 mEq each of Na^+ and K^+ . The required daily dosage is given in three divided doses. Potassium supplementation may be required, because the added sodium load presented to the distal tubule may exaggerate potassium losses.

The prognosis is excellent in cases of isolated defects, especially when the problem is related to renal immaturity. Alkali therapy can usually be discontinued after several months to 2 years. Growth should be normal, and the gradual increase in the serum bicarbonate level to above 22 mEq/L heralds the presence of a raised bicarbonate threshold in the tubules. If the defect is part of a more complex tubular abnormality (Fanconi syndrome with attendant phosphaturia, glycosuria, and amino aciduria), the prognosis depends on the underlying disorder or syndrome.

OCULOCEREBRORENAL SYNDROME (Lowe Syndrome)

Lowe syndrome results from a range of mutations in the *ORCL1* gene that codes for a Golgi apparatus phosphatase. Affected males have anomalies involving the eyes, brain, and kidneys. The physical stigmas and the degree of mental retardation are variable and depend on the location of the mutation. In addition to congenital cataracts and buphthalmos, the typical facies includes prominent epicanthal folds, frontal prominence, and a tendency to scaphocephaly. Muscle hypotonia is a prominent finding. The renal abnormalities are of tubule function and include hypophosphatemic rickets with low serum phosphorus levels, low to normal serum calcium levels, elevated serum alkaline phosphatase lev-

els, renal tubular acidosis, and aminoaciduria. Treatment includes alkali therapy, phosphate replacement, and vitamin D. Antenatal diagnosis is possible.

Satre et al: Characterization of a germline mosaicism in families with Lowe syndrome, and identification of seven novel mutations in the *ORCL1* gene. *Am J Hum Genet* 1999;65:68.

CONGENITAL HYPOKALEMIC ALKALOSIS (Bartter Syndrome and Gitelman Syndrome)

Bartter syndrome is characterized by severe hypokalemic, hypochloremic metabolic alkalosis, extremely high levels of circulating renin and aldosterone, and a paradoxical absence of hypertension. On renal biopsy, a striking juxtaglomerular hyperplasia is seen.

A neonatal form of Bartter syndrome is thought to result from mutations in two genes affecting either $\text{Na}^+\text{-K}^+$ or K^+ transport. These patients have life-threatening episodes of fever and dehydration with hypercalciuria and early-onset nephrocalcinosis. Classic Bartter syndrome presenting in infancy with polyuria and growth retardation (but not nephrocalcinosis) is thought to result from mutations in a chloride channel gene. Gitelman syndrome occurs in older children and features episodes of muscle weakness, tetany, hypokalemia, and hypomagnesemia. These children have hypocalciuria.

Treatment with prostaglandin inhibitors and potassium-conserving diuretics (eg, amiloride combined with magnesium supplements) and potassium may be beneficial. Although the prognosis is guarded, a few patients seem to have less severe forms of the disease that are compatible with long survival times.

Rodriguez-Soriano J: Bartter's syndrome comes of age. *Pediatrics* 1999;103:663.

CYSTINOSIS

Three types of cystinosis have been identified: adult, adolescent, and infantile. In children the adolescent type is characterized by cystine deposition and, if left untreated with phosphocysteamine (Cystagon), is accompanied by the development of the renal Fanconi syndrome and varying degrees of renal failure; growth is usually normal. The infantile type is both the most common and the most severe. Characteristically, children present in the first or second year of life with Fanconi syndrome and, without the metabolic benefit of Cystagon treatment, progress to end-stage renal failure.

Cystinosis results from mutations in the *CTNS* gene that codes for a cystine transporter. About 50% of patients share an identical deletion. Inheritance is autosomal

recessive. Cystine is stored in cellular lysosomes in virtually all tissues. Eventually, cystine accumulation results in cell damage and cell death, particularly in the renal tubules. Renal failure between ages 6 and 12 years is common.

Whenever the diagnosis of cystinosis is suspected, slitlamp examination of the corneas by an ophthalmologist should be performed, because cystine crystal deposition causes an almost pathognomonic ground-glass "dazzle" appearance. Increased white cell cystine levels are diagnostic. Hypothyroidism is common.

Cystagon therapy is helpful in the treatment of cystinosis. Depending on the progression of chronic renal failure, management is directed toward all side effects of renal failure, with particular attention paid to the control of renal osteodystrophy. Dialysis and transplantation may be needed.

Anikster Y et al: Identification and detection of the common 65-kb deletion breakpoint in the nephropathic cystinosis gene. *Mol Genet Metab* 1999;66:111.

<http://www.cystinosisfoundation.org>

PHOSPHATE-LOSING RENAL TUBULAR SYNDROMES & OTHER FORMS OF RICKETS

Recent investigation of the metabolic products of vitamin D_3 has done much to clarify the causes of various forms of rickets. Those forms due primarily to a lack of available calcium are described in Chapter 10. They include idiopathic hypercalciuria, in which there is excessive urinary calcium loss not responsive to reduction in calcium intake, lack of vitamin D_3 because of low dietary intake or from steatorrhea, and vitamin D dependency and azotemic rickets. In vitamin D_3 dependency, there is an inborn or acquired inability to synthesize 1,25-dihydroxycholecalciferol (the calcium transport stimulating factor, type I), or there may be end-organ insensitivity to this factor (type II). Treatment consists of giving supplementary calcium or vitamin D in appropriate doses.

Diseases associated with decreased availability of phosphorus also cause rickets. Excessive use of antacids may be responsible. Most commonly the defect is an inherited or acquired one in which a defect of phosphorus reabsorption is variably associated with other transport defects (eg, Fanconi syndrome). Certain generalized metabolic diseases—notably Wilson disease, galactosemia, fructose intolerance, and cystinosis—may cause similar tubular damage. Treatment of the primary type includes giving extra phosphorus. Acquired forms are treated in the same manner as the basic disease.

Familial hypophosphatemic vitamin D-resistant rickets is an example of a tubular nephropathy in which

only phosphorus transport is affected. Most patients present during the second year of life, but some conditions have onset in the first 6 months.

Clinical features vary. Changes may be only biochemical, with a strikingly low serum phosphorus and an elevated alkaline phosphatase level. Muscle hypotonia may be severe; growth failure, bowing of the legs, and enlargement of the wrists, knees, and costochondral junctions are often associated with spinal deformities. Craniosynostosis has been described in infants with this disease. Pathologic fractures may be seen on radiograph as well as certain unique findings consisting of an irregular mosaic formation of the haversian system and trabecular “halos” of low-density bone.

In most cases, the serum phosphorus level is less than 2 mg/dL. The urinary calcium level is low, and the serum calcium level may be normal or slightly low. Serum levels of 1,25-dihydroxycholecalciferol are low, probably because high levels of phosphate in the tubule cell shut off the 1α -hydroxylase activity. Aminoaciduria is rare.

Treatment consists of giving 1–3 g of phosphorus daily, either as a buffered monosodium and disodium hydrogen phosphate solution at pH 7.4 or as Fleet’s Phospho-Soda. Magnesium oxide, 10–15 mg/kg/d by mouth, may be of value. Supplementary calcitriol, up to 40 mg/kg/d, should be given if the serum calcium levels remain below normal.

Normal growth is never achieved unless every effort is made to keep the serum phosphorus level over 3 mg/dL.

Gregory MJ, Schwartz GJ: Diagnosis and treatment of renal tubular disorders. *Semin Nephrol* 1998;18:317.

NEPHROGENIC DIABETES INSIPIDUS

In the normal kidney, the interstitial fluid of the papilla is hyperosmolar to the fluid in the collecting duct. The luminal cells have a specific receptor for antidiuretic hormone (ADH), which, acting via cyclic adenosine monophosphate, permits water to move across the cell membrane in response to the osmotic gradient. The congenital X-linked recessive form of nephrogenic diabetes insipidus results from mutations in the vasopressin receptor, *AVPR2*. Autosomal (recessive and dominant) forms of nephrogenic diabetes insipidus are caused by mutations of the *AQP2* gene that codes for a water channel protein, aquaporin-2. Genetic counseling and mutation testing are available.

The symptoms are limited to polyuria, polydipsia, and failure to thrive. In some children, particularly if the solute intake is unrestricted, adjustment to an elevated serum osmolality may develop. These children are particularly susceptible to episodes of dehydration, fever, vomiting, and convulsions.

Clinically, the diagnosis can be made on the basis of a history of polydipsia and polyuria that are not sensitive to the administration of vasopressin, desmopressin acetate, or lypressin. It is wise to confirm this diagnosis by performing a vasopressin test. Carefully monitored water restriction does not increase the tubular reabsorption of water (TcH_2O) to above 3 mL/min/m². Urine osmolality will remain lower than 450 mOsm/kg, whereas serum osmolality rises and total body weight falls. Before weight reduction greater than 5% occurs or before serum osmolality exceeds 320 mOsm/kg, vasopressin should be administered. Urine concentrating ability is impaired in a number of conditions—sickle cell anemia, pyelonephritis, potassium depletion, hypercalcemia, cystinosis and other renal tubular disorders and obstructive uropathy—and as a result of nephrotoxic drugs.

In infants, it is usually best to allow water as demanded and to restrict salt. Serum sodium levels should be evaluated at intervals to avoid hyperosmolality from inadvertent water restriction. In later childhood, sodium intake should continue to be restricted to 2–2.5 mEq/kg/24 h.

Treatment with hydrochlorothiazide is helpful, and many patients show improvement with administration of prostaglandin inhibitors such as indomethacin or tolmetin.

Wilden RS, Cogdell DE: Clinical utility of direct mutation testing for congenital nephrogenic diabetes insipidus in families. *Pediatrics* 1999;103:632.

NEPHROLITHIASIS

Renal calculi in children may result from certain inborn errors of metabolism, such as cystine in cystinosis, glycine in hyperglycinuria, urates in Lesch–Nyhan syndrome, and oxalates in oxalosis. Stones may occur secondary to hypercalciuria in distal tubular acidosis, and large stones are quite often seen in children with spina bifida who have paralyzed lower limbs. Treatment is limited to that of the primary condition, if possible. Surgical removal of stones should be considered only for obstruction, intractable severe pain, and chronic infection.

Cystinuria

Cystinuria, like Hartnup disease and a number of other disorders, is primarily an abnormality of amino acid transport across both the enteric and proximal renal tubular epithelium. There appear to be at least three biochemical types. In the first type, the bowel transport of basic amino acids and cystine is impaired, but transport of cysteine is not impaired. In the renal tubule,

basic amino acids are again rejected by the tubule, but cystine absorption appears to be normal. The reasons for the cystinuria are, therefore, still obscure. Heterozygous individuals have no aminoaciduria. The second type is similar to the first except that heterozygous individuals excrete excess cystine and lysine in the urine, and cystine transport in the bowel is normal. In the third type, only the nephron is involved. The only clinical manifestations are related to stone formation: ureteral colic, dysuria, hematuria, proteinuria, and secondary UTI. Urinary excretion of cystine, lysine, arginine, and ornithine is increased.

The most reliable way to prevent stone formation is to maintain a constantly high free-water clearance. This involves generous fluid intake. Alkalinization of the urine is helpful. If these measures do not prevent significant renal lithiasis, the use of tiopronin (Thiloa) is recommended.

Primary Hyperoxaluria

Oxalate production in humans is derived from the oxidative deamination of glycine to glyoxylate, from the serine-glycolate pathway, and from ascorbic acid. At least two enzymatic blocks have been described. Type 1 is a deficiency of liver-specific peroxisomal alanine:glyoxylate aminotransferase. Type 2 is glyoxylate reductase deficiency.

Excess oxalate combines with calcium to form insoluble deposits in the kidneys, lungs, and other tissues. The onset is during childhood. The joints are occasionally involved, but the main effect is on the kidneys, where progressive oxalate deposition leads to fibrosis and eventual renal failure.

Pyridoxine supplementation and a low-oxalate diet have been tried as therapy, but the overall prognosis is poor, and most patients succumb to uremia by early adulthood. Renal transplantation is not very successful because of destruction of the transplant kidney. However, encouraging results have been obtained with concomitant liver transplantation, correcting the metabolic defect.

Hyperoxaluria may also occur secondary to ileal disease or after ileal resection.

Cochat P: Primary hyperoxaluria type 1. *Kidney Int* 1999;55:2533.

URINARY TRACT INFECTIONS

UTI is common in children, but the frequency decreases with age. It is estimated that 8% of girls and 2% of boys will acquire UTIs in childhood. Girls older

than age 6 months have UTIs far more commonly than boys, whereas uncircumcised boys younger than 3 months of age have more UTIs than girls. Circumcision reduces the likelihood of UTI in boys tenfold. The protective effect of circumcision is mediated by a reduction in the density of distal urethral and periurethral bacterial colonization. Similarly, the density of urethral and periurethral colonization with uropathogenic bacteria is correlated to the risk of UTI in girls.

Dysfunctional voiding, which is uncoordinated relaxation of the urethral sphincter during voiding leading to incomplete emptying of the bladder, may cause frequent UTI. Similarly, any condition that interferes with complete emptying of the bladder, such as constipation or a neurogenic bladder, is associated with an increased risk of UTI. Poor perineal hygiene, structural abnormalities of the urinary tract, catheterization, and instrumentation of the urinary tract are all associated with UTI. In sexually active teenagers, intercourse may introduce bacteria into the urethra and bladder, resulting in acute cystitis.

Most UTIs are ascending infections. Specific adhesins present on the fimbria of uropathogenic bacteria allow colonization of the uroepithelium in the urethra and bladder and increase the likelihood of UTI.

The inflammatory response to infection during pyelonephritis may result in renal parenchymal scars. It is hypothesized that renal parenchymal scars in infancy and childhood may contribute to hypertension, renal disease, and renal failure later in life. Unfortunately, long-term outcome studies of the natural history of pyelonephritis and the effect of medical intervention on the development of adult renal diseases are not available.

The organisms responsible for UTI are normal fecal flora, most commonly *E coli* (> 85%), *Klebsiella*, *Proteus*, other gram-negative bacteria, and, less frequently, *Enterococcus* or coagulase-negative staphylococci.

A. SYMPTOMS AND SIGNS

Newborns and infants demonstrate nonspecific signs, including fever, hypothermia, jaundice, poor feeding, irritability, vomiting, failure to thrive, and sepsis. Strong, foul-smelling or cloudy urine may be noted. Preschool children may have abdominal or flank pain, vomiting, fever, urinary frequency, dysuria, urgency, or enuresis. School-age children commonly have classic signs of cystitis (frequency, dysuria, urgency) or pyelonephritis (fever, vomiting, flank pain). Costovertebral tenderness is unusual in young children, but may be demonstrated by school-age children.

Physical examination should include attention to blood pressure determination, abdominal exam, and a genitourinary exam. Urethritis, poor perineal hygiene,

herpes simplex virus, or other genitourinary infections may be apparent on examination.

B. LABORATORY TESTS

Collection of urine for urinalysis and culture is difficult in children due to frequent contamination of the sample. In toilet-trained, cooperative, older children, a midstream, clean-catch method is satisfactory. Although cleaning of the perineum does not improve specimen quality, straddling of the toilet to separate the labia in girls, retraction of the foreskin in boys, and collecting midstream urine significantly reduce contamination.

In infants and young children, bladder catheterization or suprapubic collection is necessary in most cases to avoid contaminated samples. Bagged urine specimens are helpful only if negative.

Screening urinalysis indicates pyuria (>5 WBC/hpf) in most children with UTI, but many children with pyuria do not have UTI. White cells may be present in urine from the urethra or vagina or be present because of a systemic infection. The leukocyte esterase test correlates well with the presence of pyuria, but has a similar false-positive rate. The detection of urinary nitrite by dipstick is highly correlated with urine culture positive for enteric organisms. Most young children (70%) with UTI have negative nitrite tests because they empty their bladder frequently, and several hours is required for bacteria to convert ingested nitrates to nitrite in the bladder. The sensitivity of nitrite detection is highest on a first morning void. Gram stain of unspun urine correlates well with culture recovery of 10^5 cfu/mL or more, but is infrequently available outside of the hospital.

The gold standard for diagnosis remains the properly collected urine specimen. Specimens that are not immediately cultured should be refrigerated and kept cold during transport. Any growth is considered significant from a suprapubic culture. Quantitative recovery of 10^5 cfu/mL or more is considered significant on clean-catch specimens, and 10^4 – 10^5 is considered significant on catheterized specimens. Usually the recovery of multiple organisms indicates contamination; however, some contaminated specimens will yield only a single species.

Asymptomatic bacteriuria is detected in 0.5–1.0% of children who are screened with urine culture. Asymptomatic bacteriuria is believed to represent colonization of the urinary tract with nonuropathogenic bacteria. Treatment may increase the risk of symptomatic UTI by eliminating nonpathogenic colonization. Screening urine cultures in nonsymptomatic children are, therefore, generally discouraged. The treatment of children with fever, normal urinalysis, and significant growth on quantitative urine culture is controversial,

because differentiating asymptomatic bacteriuria (eg, detected at the time of a febrile viral infection) from true UTI with no or minimal signs of inflammation in the urine can be difficult. Repeated urine cultures are often helpful in differentiating asymptomatic bacteriuria from contamination of the culture versus true UTI.

In children with pyelonephritis, a serum creatinine should be determined.

C. TREATMENT

Management of UTI requires an assessment of toxicity, hydration, ability to tolerate oral intake, and signs of sepsis. Very young children (younger than 3 months) and children with dehydration, toxicity, or sepsis should be admitted to the hospital and treated with parenteral antimicrobials.

Older infants and children who are not seriously ill can be treated as outpatients. Initial antimicrobial therapy is based on prior history of infection and antimicrobial use, as well as location of the infection in the urinary tract. Uncomplicated cystitis can be treated with amoxicillin, trimethoprim–sulfamethoxazole, or a first-generation cephalosporin. Each of these antimicrobials is concentrated in the lower urinary tract, and high cure rates are common. There are significant differences in the rates of antimicrobial resistance, so knowledge of the rates in the local community is important. More seriously ill children are treated parenterally initially with a third-generation cephalosporin or parenteral aminoglycoside. The initial antimicrobial choice is adjusted after culture and susceptibility are known. For sexually mature teenagers, fluoroquinolones such as ciprofloxacin and levofloxacin given for 3 days for cystitis are usually cost-effective.

The recommended duration of antimicrobial therapy for uncomplicated cystitis is 7–10 days. Short-course therapy of cystitis is not recommended in children, because differentiating upper and lower tract disease may be difficult, and higher failure rates are reported in most studies of short-course therapy.

Acute pyelonephritis is usually treated for 10 days, although some very severe infections may require longer therapy. The duration of parenteral therapy in uncomplicated pyelonephritis is not well defined, but most children can complete therapy orally once symptomatic improvement has occurred. A repeat urine culture 24–48 hours after beginning therapy is not needed if the child is improving and doing well.

D. RADIOLOGIC EVALUATION

Because congenital urologic abnormalities increase the risk of UTI, radiologic evaluation of first UTI has been routinely recommended. These recommendations usually include routine ultrasound of the kidneys and void-

ing cystourethrogram (VCUG). These recommendations are controversial because no good data are available to support the theory that the detection and management of vesicourethral reflux (VUR), the most commonly detected abnormality, improves the long-term renal health of most children.

VUR is a congenital abnormality present in about 1% of the population. VUR is graded using the international scale (I—reflux into ureter; II—reflux to the kidney; III—reflux to kidney with dilation of ureter only; IV—reflux with dilation of ureter and mild blunting of renal calyces; V—reflux with dilation of ureter and blunting of renal calyces). Reflux is detected in 30–50% of children 1 year of age and younger. The natural history of reflux is to improve, and 80% of reflux of grades I, II, or III will resolve or significantly improve within 3 years following detection.

VCUG should be done selectively on children with first UTI. Children with suspected urologic abnormality due to weak stream, dribbling, or perineal abnormalities should be studied with VCUG. Boys with first UTI should be studied to detect posterior urethral valves, an important congenital abnormality that requires surgery. Children older than 3 years who are otherwise healthy and growing well usually can be followed clinically and do not need VCUG with first UTI. The yield in sexually active teenagers is also very low.

Ultrasonographic examination of kidneys should be done in children with acute pyelonephritis who have not improved after 3–5 days of antimicrobial treatment adjusted for the susceptibility of the organism. The examination is done to detect renal or perirenal abscesses or obstruction of the kidney. The yield of routine ultrasound examination of first-time UTI in children who are improving on therapy is low in recent studies. Most obstructing lesions of the urinary system are detected prenatally by in utero ultrasound.

E. FOLLOW-UP

Children with UTI should be followed with screening urinalysis 1 and 2 months after resolution of UTI. Dipstick nitrate determination can be used at home by parents on first morning voided urine in children with frequently recurring UTI.

F. PROPHYLACTIC ANTIMICROBIALS

Selected children with frequently recurring UTI may benefit from prophylactic antimicrobials. In children

with grades I–III, IV and V VUR, prophylactic antimicrobials may be beneficial in reducing UTI, as an alternative to surgical correction, or in the interval prior to surgical therapy. Many experts recommend surgical correction of higher grade reflux, particularly grade V. Trimethoprim–sulfamethoxazole and nitrofurantoin are approved for prophylaxis. Use of broader spectrum antimicrobials leads to colonization and infection with resistant strains.

Children with dysfunctional voiding generally do not benefit from prophylactic antimicrobials; rather, addressing the underlying dysfunctional voiding is most important.

In some children, erroneous diagnosis based on contaminated urine specimens leads to recovery of gram-negative rods with increasing antimicrobial resistance. Prophylactic antimicrobials are not helpful—catheterized or suprapubic urine specimens are often helpful in clarifying the underlying contamination.

■ NEUROLOGIC ASSESSMENT & NEURODIAGNOSTIC PROCEDURES

NEUROLOGIC HISTORY & EXAMINATION

Despite recent advances in neurodiagnostic testing and neuroimaging, a thorough history remains the most important tool in accurately diagnosing neurologic disorders. The chief complaint(s) and present illness should clearly delineate the temporal profile and sequence of neurologic symptoms. From a detailed history, the clinician will determine if the neurologic symptoms are acute or chronic, static or progressive, recurrent or monophasic, periodic or randomly intermittent, short or prolonged. The patient's description of his or her symptoms will provide clues as to the anatomic localization of the disturbance and possible pathogenic mechanisms. The history should also include what precipitates, palliates, or changes the symptoms.

The history and review of systems provide essential background information about the patient and may provide evidence for a more generalized disorder or for associated or predisposing conditions. Similarly, the family history and social history frequently provide clues for underlying genetic, hereditary, environmental, or psychological conditions that are the basis of the patient's complaints. The social history also provides insight into how the symptoms affect the child's and family's day-to-day living, school performance, and quality of life. A developmental history may provide the earliest clues of a degenerative disorder. Some developmental milestones are summarized in Table 23-1.

The physical examination should include the child's height, weight, head circumference, blood pressure, pulse rate, general appearance, and level of alertness and attentiveness. It is important to observe the child's spontaneous activity, behavior and responses to light, noise, and touch. Is the child abnormally irritable or demonstrating odd behavior for his or her age? Are there dysmorphic features of the face, head, ears, trunk, extremities, or digits? Are any discolored patches of skin

such as hemangiomas, ash-leaf depigmented patches, or café au lait spots present? Is the fontanel open or closed, too big or too small? A more detailed mental status examination may be appropriate for school-age children (Table 23-2). The child should be observed for truncal sway or loss of balance (Romberg test). Testing for vibratory appreciation requires that the child be old enough to report whether he or she can feel the vibrations of a tuning fork applied to the digits or bony prominences. Muscle mass, consistency, tone, and strength should be assessed in all four limbs, across multiple joints, and in the neck and trunk. Muscle stretch reflexes can be elicited normally from infancy to adulthood at the biceps, triceps, knees, and ankles. The presence, absence, or asymmetry of automatic infantile movements and reflexes (automatisms) should be noted (see Table 23-1).

The examiner should then proceed with a systematic neurologic examination, including an assessment of cranial nerves II through XII, funduscopy, and testing of eye movements and pupillary light and near-vision reflexes. Cerebellar control of body and extremity posture, ambulation, and fine coordinated movements can usually be evaluated by watching the child walk, run, play with or reach for toys, sit, and stand still. Responses to light touch and mildly painful stimulation can be assessed by tickling or touching the child and lightly pinching toes or fingers and observing facial expression and withdrawal and avoidance movements. Position sensation can be assessed in older children by having them stand with eyes closed. The clinician should construct a differential diagnostic list of disorders that could account for the patient's symptoms and develop a systematic approach to neurodiagnostic testing and neuroimaging procedures.

LUMBAR PUNCTURE

Spinal fluid is usually obtained by inserting a small-gauge needle (eg, No. 22) through the L3-L4 intervertebral space into the thecal sack while the patient is lying on his or her side. After an opening pressure is measured, a small amount of fluid is removed most frequently to examine for evidence of infection or inflammation (Table 23-3). Fluid is sent for red and white cell counts, for determination of the concentrations of

Table 23–1. Neurologic developmental milestones.

	Birth	3 Months	6 Months	9 Months	12–15 Months	24 Months
Motor	Flexor posture, lifts head prone, hands grasped	Sits: head forward, bobbing, lifts head supine, hands open, retains briefly	Rolls both ways, begins to sit alone, supports (erect), bounces	Creeps, pulls up standing, pincer grasp, sits well	Walks with one or both hands held, stands alone briefly, releases on command	Walks and runs well, walks downstairs, turns pages singly
Special senses	Regards (vision), may follow 45 degrees	Looks at hands, follows 90–180 degrees	Discriminates voices, localizes sounds	Picks up raisin, “bye-bye”	Localizes noises, localizes pain	Towers six or seven cubes, imitates scribble
Adaptive	Startles to sound, delayed nociceptive response	Smiles socially, vocalizes socially, follows vertically	Holds cube, palmar grasp, retrieves toy, transfers and rakes raisin	Bangs toys together, pat-a-cake	Assists in dressing, attempts spoon feeding, tries two-cube tower	Asks for toilet, pulls on garments, spoon-feeds well, parallel play
Language	Throaty noises	Coos, chuckles, vocal social response	Babbles (polysyllables), “mmm-mmm”	“Ma-ma, Da-da,” one other “word”	Understands simple command, speaks one to three words	Speaks in phrases, names three to five pictures, pronouns: “I, me, you”
Reflex	Tonic neck, palmar grasp	Disappearing tonic neck, Moro reflex	Begins voluntary stepping	Parachute response		
Automatisms	Moro reflex, sucks, roots, stepping, supporting, traction: head lag	Landau response, traction: no head lag	Neck righting, blinks to threat			

Table 23–2. Mental status examination for school-age children.

Orientation: Time, place, situation, name, date, year.

Memory: Recent and remote, eg, “What did you have for lunch?” “What did you do on your birthday?” Remember (for 10 min): “Red flag, Washington’s birthday, Christmas presents.”

Calculation: Depends on educational background. Example: Subtract serial sevens.

Proverbs: Interpret: “Too many cooks spoil the broth.” “A rolling stone gathers no moss.”

Situation: “What would you do if you saw a fire?”

Aphasia: “What’s this?” (chalk). “Stick out your tongue.” “Put your right finger on your left ear.” Sample speech, reading, and writing.

protein and glucose, and for viral and bacterial cultures. In some cases, additional information is obtained with special staining techniques for mycobacteria and fungus. Additional fluid may be sent for polymerase chain reaction (PCR) testing for specific viral agents, antibody titer determinations, cytopathologic study, lactate and pyruvate concentrations, and amino acid and neurotransmitter analysis. Lumbar puncture is imperative when bacterial meningitis is suspected. Caution must be exercised, however, when signs of increased intracranial pressure (eg, papilledema) or focal neurologic signs are present that might indicate a substantial risk of precipitating tentorial or tonsillar herniation.

ELECTROENCEPHALOGRAPHY

Electroencephalography (EEG), a widely used noninvasive electrophysiologic method for recording cerebral activity, has its greatest clinical applicability in the

Table 23–3. Characteristics of cerebrospinal fluid in the normal child and in central nervous system infections and inflammatory conditions.

Condition	Initial Pressure (mm H ₂ O)	Appearance	Cells/ μ L	Protein (mg/dL)	Glucose (mg/dL)	Other Tests	Comments
Normal	< 160	Clear	0–5 lymphocytes; first 3 months, 1–3 PMNs; neonates, up to 30 lymphocytes, 20–50 RBCs	15–35 (lumbar), 5–15 (ventricular); up to 150 (lumbar) for short time after birth; to 6 months up to 65	50–80 (two thirds of blood glucose); may be increased after seizure	CSF-IgG index < 0.7 ^a ; LDH 2–27 units/L	CSF protein in first month may be up to 170 mg/dL in small-for-date or premature infants. No increase in WBCs due to seizure.
Bloody tap	Normal or low	Bloody (sometimes with clot)	One additional WBC/700 RBCs ^b ; RBCs not crenated	One additional milligram per 800 RBCs ^b	Normal	RBC number should fall between first and third tubes; wait 5 min between tubes	Spin down fluid, supernatant will be clear and colorless. ^c
Bacterial meningitis, acute	200–750+	Opalescent to purulent	Up to thousands, mostly PMNs; early, few cells	Up to hundreds	Decreased; may be none	Smear and culture mandatory; LDH > 24 U/L; lactate, IL-8, TNF elevated, correlate with prognosis	Very early, glucose may be normal. PCR (meningococcus and pneumococcus) plasma, CSF may aid diagnosis
Bacterial meningitis, partially treated	Usually increased	Clear or opalescent	Usually increased; PMNs usually predominate	Elevated	Normal or decreased	LDH usually > 24 U/L; PCR	Smear and culture may be negative if antibiotics have been in use.
Tuberculous meningitis	150–750+	Opalescent; fibrin web or pellicle	250–500, mostly lymphocytes; early, more PMNs.	45–500; parallels cell count; increases over time	Decreased; may be none	Smear for acid-fast organism; CSF culture and inoculation; PCR	Consider AIDS.
Fungal meningitis	Increased	Variable; often clear	10–500; early, more PMNs; then mostly lymphocytes	Elevated and increasing	Decreased	India ink preparations, cryptococcal antigen, PCR, culture, inoculations, immunofluorescence tests	Often superimposed in patients who are debilitated or on immunosuppressive therapy.
Aseptic meningoencephalitis (viral meningitis, or parameningeal disease)	Normal or slightly increased	Clear unless cell count > 300/ μ L	None to a few hundred, mostly lymphocytes; PMNs predominate early	20–125	Normal; may be low in mumps, herpes, or other viral infections	CSF, stool, blood, throat washings for viral cultures; LDH < 28 U/L; PCR for HSV, CMV, EBV, enterovirus, etc.	Acute and convalescent antibody titers for some viruses. In mumps, up to 1000 lymphocytes; serum amylase often elevated. Rarely, a thousand cells present in enteroviral infection.

Parainfectious encephalomyelitis (ADEM)	80–450, usually increased	Usually clear	0–50+, mostly lymphocytes	15–75	Normal	CSF-IgG index may be increased; oligoclonal bands variable	No organisms. Fulminant cases resemble bacterial meningitis.
Polyneuritis	Normal and occasionally increased	Early: normal; late: xanthochromic if protein high	Normal; occasionally slight increase	Early: normal; late: 45–1500	Normal	CSF-IgG index may be increased; oligoclonal bands variable.	Try to find cause (viral infections, toxins, lupus, diabetes, etc).
Meningeal carcinomatosis	Often elevated	Clear to opalescent	Cytologic identification of tumor cells	Often mildly to moderately elevated	Often depressed	Cytology	Seen with leukemia, medulloblastoma, meningeal melanosis, histiocytosis X. Notes: May mimic meningitis.
Brain abscess	Normal or increased	Usually clear	5–500 in 80%; mostly PMNs	Usually slightly increased	Normal; occasionally decreased	Imaging study of brain (MRI)	Cell count related to proximity to meninges; findings as in purulent meningitis if abscess perforates.

^aCSF-IgG index = CSF IgG/serum IgG ÷ CSF albumin/serum albumin.

^bMany studies document pitfalls in using these ratios due to WBC lysis. Clinical judgment and repeat taps may be necessary to rule out meningitis in this situation.

^cCSF WBC (predicted) = CSF RBC × (blood WBC/blood RBC). O:P ratio = observed CSF WBC ÷ predicted CSF WBC. Also, do WBC:RBC ratio. If O:P ratio ≤ 0.01, and WBC:RBC ratio ≤ 1:100, meningitis is absent.

PMN = polymorphonuclear neutrophil; CSF = cerebrospinal fluid; WBC = white blood cell; RBC = red blood cell; LDH = lactate dehydrogenase; AIDS = acquired immunodeficiency syndrome; PCR = polymerase chain reaction; HSV = herpes simplex virus; CMV = cytomegalovirus; EBV = Epstein–Barr virus; ADEM = acute disseminated encephalomyelitis; IL-8 = interleukin 8; TNF = tumor necrosis factor.

study of seizure disorders. Activation techniques to accentuate abnormalities or disclose latent abnormalities include photic stimulation, sustained hyperventilation for 3 minutes, and sleep deprivation, the last of which is an excellent, though less widely used, activation method.

EEG is also used in the evaluation of tumors, cerebrovascular accidents, neurodegenerative diseases, and other neurologic disorders causing brain dysfunction. Recordings over a 24-hour period or all-night recordings are invaluable in the diagnosis of sleep disturbances and narcolepsy. EEG with telemetry or simultaneous monitoring of behavior on videotape has great usefulness in selected cases. The EEG can be helpful in determining a possible cause or mechanism of coma and is frequently used to help determine whether coma is irreversible and brain death has occurred.

The limitations of EEG are considerable. In most cases, the duration of the actual tracing is about 45 minutes and reflects only surface cortical function. Many drugs, especially barbiturates and benzodiazepines, have considerable effects on the EEG and may confuse interpretation. Moreover, about 15% of nonepileptic individuals, especially children, may have an abnormal EEG. EEG findings such as those occasionally seen in migraine, learning disabilities, or behavior disorders are often nonspecific and do not reflect permanent brain damage. A major usefulness of EEG is to show epileptiform activity in children with seizure disorders. Sometimes the findings are diagnostic, as in the hypsarrhythmia EEG of infantile spasms or the prolonged 3/s spike-wave of absence seizures.

At present, computed tomography (CT) scans, evoked potentials, positron emission tomography (PET), regional cerebral blood flow studies, single-photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) supplement the EEG as a diagnostic and prognostic tool.

EVOKED POTENTIALS

Cortical auditory, visual, or somatosensory evoked potentials (evoked responses) may be recorded from the scalp surface over the temporal, occipital, or frontoparietal cortex after repetitive stimulation of the retina by light flashes, the cochlea by sounds, or a nerve by galvanic stimuli of varying frequency and intensity, respectively. Computer averaging is used to recognize and enhance these responses while subtracting or suppressing the asynchronous background EEG activity. The presence or absence of evoked potential waves and their latencies (time from stimulus to wave peak or time between peaks) figures in the clinical interpretation.

The reproducible and quantifiable results obtained from brainstem auditory, pattern-shift visual, and

short-latency somatosensory evoked potentials (see Short-Latency Somatosensory Evoked Potentials section) indicate the level of function of the relevant sensory pathway or system and identify the site of anatomic disruption. Although results of these tests alone are usually not diagnostic, the tests are noninvasive, sensitive, objective, and relatively inexpensive extensions of the clinical neurologic examination. Because the auditory and somatosensory tests and one type of visual test are completely passive, requiring only that the patient remain still, they are particularly useful in the evaluation of neonates, young children, and patients unable to cooperate. Knowledge of normal values and experience in testing are mandatory.

Brainstem Auditory Evoked Potentials

A brief auditory stimulus (click) of varying intensity and frequency is delivered to the ear to activate the auditory nerve (nerve VIII) and sequentially activate the cochlear nucleus, tracts and nuclei of the lateral lemniscus, and inferior colliculus. Thus this technique assesses hearing and function of the brainstem auditory tracts.

Hearing in the neonate or uncooperative patient can be assessed objectively, making the technique particularly useful in high-risk infants and in mentally retarded or autistic patients. Brainstem auditory evoked potentials are used to judge brainstem dysfunction in sleep apnea, Arnold–Chiari malformation, and achondroplasia. Because high doses of anesthetic agents or barbiturates do not seriously affect results, the test is used to assess and monitor brainstem function of surgical patients (in the operating room) and those in hypoxic–ischemic coma or coma following head injury. Absence of evoked potential waves beyond the first wave from the auditory nerve usually signifies brain death. Brainstem auditory evoked potentials are also useful in the early evaluation of diseases affecting myelin, that is, the leukodystrophies and multiple sclerosis, although auditory evoked potentials are less valuable than visual evoked potentials in the evaluation of multiple sclerosis. Intrinsic brainstem gliomas can also be evaluated with auditory evoked potentials. They are sometimes useful in evaluation of hereditary ataxias, Wilson disease, and other degenerative disorders of the brainstem.

Pattern-Shift Visual Evoked Potentials

The preferred stimulus is a shift (reversal) of a checkerboard pattern, and the response is a single wave (called P-100) generated in the striate and parastriate visual cortex. The absolute latency of P-100 (time from stimulus to wave peak) and the difference in latency between the two eyes are sensitive indicators of disease. The amplitude of response is affected by any process re-

sulting in poor fixation on the stimulus screen or affecting visual acuity. Ability to focus on a checkerboard pattern is necessary. An LED (light-emitting diode), goggles, or bright flash stimulus can be used in younger and uncooperative children, but the norms are less standardized. Normal evoked potentials in infants age 6–7 months suggest that visual acuity is normal.

Clinical applications of the test include detection and monitoring of strabismus (eg, in amblyopia ex anopsia), optic neuritis, and lesions near the optic nerve and chiasm such as optic gliomas and craniopharyngiomas. Degenerative and immunologic diseases that affect visual transmission may be detected early and followed by serial evaluations. Examples of such diseases include adrenoleukodystrophy, Pelizaeus–Merzbacher disease, some spinocerebellar degenerations, sarcoidosis, and even multiple sclerosis. Flash visual evoked potentials are used to monitor function during surgery on the eyes or optic nerve, to assess cortical or hysterical blindness, and to evaluate patients with photosensitive epilepsy, who may have exaggerated responses.

Short-Latency Somatosensory Evoked Potentials

Responses are commonly produced by electrical stimulation of peripheral sensory nerves, because this evokes potentials of greatest amplitude and clarity. Finger tapping and muscle stretching may also be used to stimulate somatosensory potentials. The function of this test is similar to that of the auditory test in closely correlating wave forms with function of the sensory pathways and permitting localization of conduction defects.

Short-latency somatosensory evoked potentials are used in the assessment of a wide variety of lesions of the peripheral nerve, root, spinal cord, and central nervous system (CNS) following trauma, neuropathies (eg, in diabetes mellitus or Guillain–Barré syndrome), myelodysplasias, cerebral palsy, and many other disorders. The procedure is often performed on an outpatient basis. One method is stimulation of the median nerve at the wrist with small (nonpainful) electrical shocks and recording of responses from the brachial plexus above the clavicle, the neck (cervical cord), and the opposite scalp area overlying the sensorimotor cortex. After stimulation from the knee (peroneal nerve) or ankle (tibial nerve), impulses are recorded from the lower lumbar spinal cord, cervical cord, and sensorimotor cortex. Such potentials are used to monitor spinal cord sensory functioning during surgery for scoliosis, myelodysplasias, tumors, and other lesions of the spinal cord or its blood vessels. The technique is also used in leukodystrophies involving peripheral nerves, in multiple sclerosis, and in the evaluation of hysteria and malingering (anesthetic limbs). In the diagnosis of coma

and brain death, somatosensory evoked potentials supplement the results of auditory evoked potentials.

PEDIATRIC NEURORADIOLOGIC PROCEDURES

Sedation for Procedures

Oral chloral hydrate, 30–60 mg/kg/dose, is safest. Many radiology departments, however, use intravenously administered agents because of the risks of vomiting and aspiration. One favorite is pentobarbital, 6 mg/kg for children weighing less than 15 kg and 5 mg/kg for larger children (up to a maximum of 200 mg) given intramuscularly or rectally (at least 20 minutes before a procedure) or 2–4 mg/kg given intravenously. Equipment to support blood pressure and respiration must be available. This dosage usually achieves sedation for up to 2 hours. If, however, sedation is inadequate 30 minutes after injection, and if the child's condition permits a second dose of pentobarbital, 2 mg/kg is given. General anesthesia may be indicated, especially if the child is to undergo surgery immediately on completion of a radiologic examination.

Computed Tomography

CT scanning consists of a series of cross-sectional (axial) roentgenograms. Radiation exposure is approximately the same as that from a skull radiographic series. The images can be viewed on a television screen, as the scan is being done, and later examined on films. Both record variations in tissue density. CT scanning is of high sensitivity (88–96% of lesions larger than 1–2 cm can be seen) but low specificity (tumor, infection, or infarct may look the same).

The CT scan is often repeated after intravenous injection of iodized contrast for enhancement, which reflects the vascularity of a lesion or its surrounding tissues. Precautions should be taken to ensure that the patient is not sensitive to iodinated dyes and that allergic reactions can be managed promptly. Sufficient information is often obtained from a nonenhanced scan, thus reducing both cost and risk.

Magnetic Resonance Imaging

MRI is a noninvasive technique that uses the magnetic properties of certain nuclei to produce diagnostically useful signals. Currently the technique is based on detecting the response (resonance) of hydrogen proton nuclei to applied radiofrequency electromagnetic radiation. These nuclei are abundant in the body and more sensitive to MRI than other nuclei. The strength of MRI signals varies with the relationship of water to

protein and the amount of lipid in the tissue. The MRI image displayed provides high-resolution contrast of soft tissues. MRI can provide information about the histologic, physiologic, and biochemical status of tissues in addition to gross anatomic data.

MRI has been used to delineate brain tumors, edema, ischemic and hemorrhagic lesions, hydrocephalus, vascular disorders, inflammatory and infectious lesions, and degenerative processes. MRI can be used to study myelination and demyelination and, through the demonstration of changes in relaxation time, metabolic disorders of the brain, muscles, and glands. Because bone causes no artifact in the images, the posterior fossa and its contents can be studied far better using MRI than with CT scans. Even blood vessels and the cranial nerves can be imaged. In contrast, the inability of MRI to detect calcification limits its usefulness in the investigation of calcified lesions such as craniopharyngioma and leptomeningeal angiomas.

Magnetic resonance angiography (MRA) is a noninvasive (no arterial or venous puncture or dye injection) technique to show large extra- and intracranial blood vessels. It often replaces the more hazardous intra-arterial injection angiogram.

Perfusion imaging using a paramagnetic contrast agent is used in stroke patients to evaluate brain ischemic penumbra. Similarly, diffusion imaging (measuring random motion of water molecules) may show reduced diffusion in areas of cytotoxic edema, useful in acute strokes, and toxic or metabolic brain injuries. The area of involvement often exceeds the T1 hypodense or T2 hyperdense stroke area, and possibly reflects recoverable tissue injury as compared with totally infarcted tissue, cell death, or apoptosis (programmed cell death) in the center of the stroke.

Another new MRI technique, proton MR spectroscopy, measures signals of increased cellular (neuronal?) activity, and oxidative metabolism: neuronal acetyl aspartate (NAA), phosphocreatinine (PCR), and phosphomonoester (PME) are increased. Ratios are often calculated to choline and P_i (inorganic phosphate). Or increased lactate (anaerobic metabolism), choline, and creatinine, reflecting increased cell surface—as in gliosis or scarring—can be assessed in a chosen voxel or tiny area of interest. An epileptic focus in the medial temporal lobe is an example: an active seizure site might show increased metabolism. Sclerosis and gliosis (“scar”) would show the converse.

Functional MRI (fMRI) can be performed at the same time as an ongoing regular MRI. Blood oxygenation changes in an area of interest (eg, an area of language acquisition) during rest and then during a verbal work paradigm can identify and lateralize the language cortex. A change in ratio of oxyhemoglobin to deoxyhemoglobin results in a detectable MRI signal.

Positron Emission Tomography

PET is an imaging technique that measures the metabolic rate at a given site by CT scanning. For measurement of local cerebral metabolism, the radiolabeled substrate most frequently used has been intravenously administered fluorodeoxyglucose (^{18}F). Gray matter and white matter are clearly distinguishable; the skull and air- or fluid-filled cavities are least active metabolically.

PET has been used to study the cerebral metabolism of neonates and brain activation by visual or auditory stimuli. Pathologic states that have been studied include epilepsy, brain infarcts, brain tumors, and dementias. This functional test of brain metabolism is useful in preoperative evaluation for epilepsy surgery. The epileptogenic zone will often be hypermetabolic during seizures and hypoactive during the time between seizures. The information from PET scan complements EEG and MRI findings to aid in the decision about tissue removal. In infants with infantile spasms, PET scan has occasionally detected focal lesions, thereby leading to successful surgical removal. Clinical application is limited by the cost of the procedure and the clinician's need for access to a nearby cyclotron for preparation of the radiopharmaceuticals.

Ultrasonography

Ultrasonography offers a pictorial display of the varying densities of tissues in a given anatomic region by recording the echoes of ultrasonic waves reflected from it. These waves, modulated by pulsations, are introduced into the tissue by means of a piezoelectric transducer. The many advantages of ultrasonography include the ability to assess a structure and its positioning quickly with easily portable equipment, without ionizing radiation, and at about one fourth the cost of CT scanning. Sedation is usually not necessary, and the procedure can be repeated as often as needed without risk to the patient. In brain imaging, B-mode and real-time sector scanners are usually used, permitting excellent detail in the coronal and sagittal planes. Contiguous structures can be studied by a continuous sweep and reviewed on videotape.

Ultrasonography has been used for in utero diagnosis of hydrocephalus and other anomalies. In neonates, the thin skull and the open anterior fontanelle have facilitated imaging of the brain, and ultrasonography is used to screen and follow infants of less than 32 weeks' gestation or weighing less than 1500 g for intracranial hemorrhage. Other uses in neonates include detection of hydrocephalus, major brain and spine malformations, and calcifications from intrauterine infection with cytomegalovirus (CMV) or *Toxoplasma*.

Cerebral Angiography

Arteriography remains a useful procedure in the diagnosis of many cerebrovascular disorders, particularly in cerebrovascular accidents or in potentially operable vascular malformations. In some brain tumors, arteriography may be necessary to define the precise location or vascular bed, to differentiate among tumors, or to distinguish tumor from abscess or infarction. Noninvasive CTs, MRIs, and MRAs can diagnose many cases of static or flowing blood disorders (eg, sinus thromboses). If necessary, invasive arteriography is usually done via femoral artery–aorta catheterization.

Myelography

Radiographic examination of the spine may be indicated in cases of spinal cord tumors or various forms of spinal dysraphism and in the rare instance of herniated disks in children. MRI has largely replaced sonography and CT.

DISORDERS AFFECTING THE NERVOUS SYSTEM IN INFANTS & CHILDREN

ALTERED STATES OF CONSCIOUSNESS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Reduction or alteration in cognitive and affective mental functioning and in arousability or attentiveness.*
- *Acute onset.*

General Considerations

Many terms are used to describe the continuum from full alertness to complete unresponsiveness and deep coma, including clouding, obtundation, somnolence or stupor, semicomatose or light coma, and deep coma. Several scales have been used to grade the depth of unconsciousness (Table 23–4). The commonly used Glasgow Coma Scale is summarized in Table 11–5. Physicians should use one of these tables and provide further descriptions in case narratives. These descriptions help subsequent observers quantify unconsciousness and evaluate changes in the patient's condition.

The neurologic substrate for consciousness is the reticular activating system in the brainstem, up to and including the thalamus and paraventricular hypothalamus. Large lesions of the cortex, especially of the left hemisphere, can also cause coma. The term “locked-in syndrome” describes patients who are conscious but have no access to motor or verbal expression because of massive loss of motor function of the brainstem. Coma vigil refers to patients who seem comatose but have some spontaneous motor behavior, such as eye opening or eye tracking, almost always at a reflex level. Persistent vegetative state denotes a chronic condition in which there is preservation of the sleep–wake cycle but no awareness and no recovery of mental function.

Emergency Measures

The clinician's first response is to ensure that the patient will survive. The ABCs of resuscitation are pertinent: Airway must be kept open with positioning or even endotracheal intubation. Breathing and adequate

Table 23–4. Gradation of coma.

	Deep Coma		Light Coma		Stupor
	Grade 4	Grade 3	Grade 2	Grade 1	
Response to pain	0	+	Avoidance	Avoidance	Arousal unsustained
Tone/posture	Flaccid	Decerebrate	Variable	Variable	Normal
Tendon reflexes	0	+/-	+	+	+
Pupil response	0	+	+	+	+
Response to verbal stimuli	0	0	0	0	+
Other corneal reflex	0	+	+	+	+
Gag reflex	0	+	+	+	+

air exchange can be assessed by auscultation; hand bag respiratory assistance with oxygen may be needed. Circulation must be ensured by assessing pulse and blood pressure. An intravenous line is always necessary. Fluids, plasma, blood, or even a dopamine drip (1–20 µg/kg/min) may be required in cases of hypotension. An extremely hypothermic or febrile child may require vigorous cooling or warming to save life. The assessment of vital signs may signal the diagnosis. Slow, insufficient respirations suggest poisoning by hypnotic drugs; apnea may indicate diphenoxylate hydrochloride poisoning. Rapid, deep respirations suggest acidosis, possibly metabolic, as with diabetic coma; toxic, such as that due to aspirin; or neurogenic, as in Reye syndrome. Hyperthermia may indicate infection or heat stroke; hypothermia may indicate cold exposure, ethanol poisoning, or hypoglycemia (especially in infancy).

The signs of impending brain herniation are another priority of the initial assessment. Bradycardia, high blood pressure, irregular breathing, increased extensor tone, and third nerve palsy with the eye deviated outward and the pupil dilated are possible signs of impending temporal lobe or brainstem herniation. These signs suggest a need for hyperventilation, reducing cerebral edema, prompt neurosurgical consultation, and possibly, in an infant with a bulging fontanelle, subdural or ventricular tap (or both). Initial intravenous fluids should contain glucose until further assessment disproves hypoglycemia as a cause.

A history obtained from parents or witnesses is desirable. Sometimes the only history will be obtained from ambulance attendants. An important point is whether the child is known to have a chronic illness, such as diabetes, hemophilia, epilepsy, or cystic fibrosis. Recent acute illness raises the possibility of coma caused

by Reye syndrome or viral or bacterial meningitis. A combination of viral illness, especially varicella or influenza, followed by 1–3 days of intractable vomiting invariably precedes the coma of Reye syndrome. Trauma is a common cause of coma. Lack of a history of trauma, especially in infants, does not rule it out. Nonaccidental trauma or a fall not witnessed by caregivers may have occurred. In coma of unknown cause, poisoning is always a possibility. Absence of a history of ingestion of a toxic substance or of medication in the home does not rule out poisoning as a cause.

Often the history is obtained concurrently with a brief pediatric and neurologic screening examination. After the assessment of vital signs, the general examination proceeds with a trauma assessment. Palpation of the head and fontanelle, inspection of the ears for infection or hemorrhage, and a careful examination for neck stiffness are indicated. If circumstances suggest head or neck trauma, the head and neck must be immobilized so that any fracture or dislocation will not be aggravated. The skin must be inspected for petechiae or purpura that might suggest bacteremia, infection, bleeding disorder, or traumatic bruising. Examination of the chest, abdomen, and limbs is important to exclude enclosed hemorrhage or traumatic fractures.

Neurologic examination quantifies the stimulus response and depth of coma, such as responsiveness to verbal or painful stimuli. Examination of the pupils, optic fundi, and eye movements is important. Are the eye movements spontaneous, or is it necessary to do the doll's-eye maneuver (rotating the head rapidly to see whether the eyes follow)? Motor and sensory examinations assess reflex asymmetries, Babinski sign, and evidence of spontaneous posturing or posturing induced by noxious stimuli (eg, decorticate or decerebrate posturing).

If the cause of the coma is not obvious, emergency laboratory tests must be obtained. Table 23-5 lists some of the causes of coma in children. An immediate blood glucose (or Dextrostix), complete blood count, urine obtained by catheterization if necessary, pH and electrolytes (including bicarbonate), serum urea nitrogen, and aspartate aminotransferase (AST) are initial screens. Urine, blood, and even gastric contents must be saved for toxin screen if the underlying cause is not obvious. Spinal tap is often necessary to rule out CNS infection. Papilledema is a relative contraindication to lumbar puncture. Occasionally, blood culture is obtained, antibiotics started, and imaging study of the brain done prior to a diagnostic spinal tap. If meningitis is suspected and a tap is believed to be hazardous, antibiotics should be started and the diagnostic spinal puncture done later. Tests that are helpful in obscure cases of coma include PO_2 , PCO_2 , ammonia levels, serum and urine osmolality, porphyrins, lead levels, and urine and serum amino acids and urine organic acids.

If head trauma or increased pressure is suspected, an emergency CT scan or MRI is necessary. Bone windows on the former study or skull radiographs can be done at the same sitting. The absence of skull fracture does not rule out coma caused by closed head trauma. Injury that results from shaking a child is one example. In a child with an open fontanelle, a real-time ultrasound may be substituted for the other, more definitive imaging studies if there is good local expertise.

Rarely, an emergency EEG aids in diagnosing the cause of coma. A nonconvulsive status epilepticus or focal finding seen with herpes encephalitis (periodic lateralized epileptiform discharges) and focal slowing as seen with stroke or cerebritis are cases in which the EEG might be helpful. The EEG also may correlate with the stage of coma (eg, in Reye syndrome) and add prognostic information.

Treatment

A. GENERAL MEASURES

Vital signs must be monitored and maintained. Most emergency rooms and intensive care units have flow sheets that provide space for repeated monitoring of the coma; one of the coma scales (described earlier) can be a useful tool for this purpose. The patient's response to vocal or painful stimuli and orientation to time, place, and situation are monitored. Posture and movements of the limbs, either spontaneously or in response to pain, are serially noted. Pupillary size, equality, and reaction to light and movement of the eyes to the doll's-eye maneuver or ice-water calorics should be recorded. Intravenous fluids can be tailored to the situation, as for treatment of acidosis, shock, or hypovolemia. Nasogas-

tric suction is initially important. The bladder should be catheterized for monitoring urine output and for urinalysis.

B. SEIZURES

An EEG should be ordered if seizures are suspected. If obvious motor seizures have occurred, treatment for status epilepticus is given with intravenous drugs (see section on Seizure Disorders). If brainstem herniation or increased pressure is possible, an intracranial monitor may be necessary. This procedure is described in more detail in Chapter 13. Initial treatment of impending herniation includes keeping the patient's head up (15-30 degrees) and providing hyperventilation. The use of mannitol, diuretics, corticosteroids, and drainage of cerebrospinal fluid (CSF) are more heroic measures covered in detail in Chapter 13.

Prognosis

About 50% of children with nontraumatic causes of coma have a good outcome. In studies of adults assessed on admission or within the first days after the onset of coma, an analysis of multiple variables was most helpful in assessing prognosis. Abnormal neuroophthalmologic signs (eg, the absence of pupillary reaction or of eye movement in response to the doll's-eye maneuver or ice water calorics and the absence of corneal responses) were unfavorable. Delay in the return of motor responses, tone, or eye opening was also unfavorable. In children, the assessment done on admission is about as predictive as one done in succeeding days. Approximately two thirds of outcomes can be successfully predicted at an early stage on the basis of coma severity, extraocular movements, pupillary reactions, motor patterns, blood pressure, temperature, and seizure type. Other characteristics, such as the need for assisted respiration, the presence of increased intracranial pressure, and the duration of coma, are not significantly predictive. Published reports suggest that an anoxic (in contrast to traumatic, metabolic, or toxic) coma, such as that caused by near drowning, has a much grimmer outlook.

BRAIN DEATH

Many medical and law associations have endorsed the following definition of death: An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical standards. Representatives from several pediatric and neurologic associations have endorsed the Guidelines for the Determina-

Table 23–5. Some causes of coma in childhood.

Mechanism of Coma	Likely Cause	
	Newborn Infant	Older Child
Anoxia Asphyxia Respiratory obstruction Severe anemia	Birth asphyxia Meconium aspiration, infection (especially respiratory syncytial virus) Hydrops fetalis	CO poisoning Croup, epiglottitis Hemolysis, blood loss
Ischemia Cardiac Shock	Shunting lesions, hypoplastic left heart Asphyxia, sepsis	Shunting lesions, aortic stenosis, myocarditis Blood loss, infection
Head trauma	Birth contusion, hemorrhage, nonaccidental trauma	Falls, auto accidents, athletic injuries
Infection	Gram-negative meningitis, herpes encephalitis, sepsis	Bacterial meningitis, viral encephalitis, postinfectious encephalitis
Vascular	Intraventricular hemorrhage, sinus thrombosis	Arterial or venous occlusion with congenital heart disease
Neoplasm	"Unknown"	Brain stem glioma, increased pressure with posterior fossa tumors
Drugs	Maternal sedatives, injected analgesics	Overdose, many drugs
Epilepsy	Constant minor motor seizures; electrical seizure without motor manifestations	Constant minor motor seizures, petit mal status, postictal state; drugs given to stop seizures
Toxins	Maternal sedatives or injections	Arsenic, alcohol, drugs, pesticides
Hypoglycemia	Birth injury, diabetic progeny, toxemic progeny	Diabetes, "prediabetes," hypoglycemic agents
Increased intracranial pressure	Anoxic brain damage, hydrocephalus, metabolic disorders (urea cycle; amino-, organic acidurias)	Toxic encephalopathy, Reye syndrome, head trauma, tumor of posterior fossa
Hepatic causes	Hepatic failure, inborn metabolic errors in bilirubin conjugation	Hepatic failure
Renal causes	Hypoplastic kidneys	Nephritis, acute and chronic
Hypertensive encephalopathy		Acute nephritis, vasculitis Reversible posterior leucoencephalopathy
Hypercapnia	Congenital lung anomalies, bronchopulmonary dysplasia	Cystic fibrosis
Electrolyte abnormalities Hypernatremia Hyponatremia	Iatrogenic (NaHCO ₃ use), salt poisoning Inappropriate antidiuretic hormone, adrenogenital syndrome, dialysis (iatrogenic)	Diarrhea, dehydration Diarrhea, dehydration
Severe acidosis Hyperkalemia	Septicemia, cold injury, metabolic errors Renal failure, adrenogenital syndrome	Infection, diabetic coma, poisoning (eg, aspirin) Poisoning (aspirin)
Purpuric	Disseminated intravascular coagulation, hemolytic-uremic syndrome	Disseminated intravascular coagulation, leukemia, thrombotic purpura (rare)

Modified and reproduced, with permission, from Lewis J, Moe PG: The unconscious child. In: Conn H, Conn R (eds). *Current Diagnosis*, 5th ed. WB Saunders, 1977.

tion of Brain Death in Children. The criteria in full-term infants (ie, born at greater than 38 weeks' gestation) were applicable 1 week after the neurologic insult. Difficulties in assessing premature infants and full-term infants shortly after birth were acknowledged.

Prerequisites

In assessment of brain death, the history is important. The physician must determine proximate causes to make sure no remediable or reversible conditions are present. Examples of such causes are metabolic conditions, toxic agents, sedative-hypnotic drugs, surgically remediable conditions, hypothermia, and paralytic agents.

Physical Examination Criteria

(See also Chapter 13)

The following criteria are those established by the Task Force on Brain Death in Children:

1. Coexistence of coma and apnea—The patient must exhibit complete loss of consciousness, vocalization, and volitional activity.

2. Absence of brainstem function—As defined by the following: (a) Midposition or fully dilated pupils that do not respond to light. Drugs may influence and invalidate pupillary assessment. (b) Absence of spontaneous eye movements and those induced by side-to-side passive head movements (oculocephalic reflex) and ice water instillation in the external auditory canal (ice water calorics). (c) Absence of movement of bulbar musculature, including facial and oropharyngeal muscles. The corneal, gag, cough, sucking, and rooting reflexes are absent. (d) Absence of respiratory movements when the patient is off the respirator. Apnea testing using standardized methods can be performed but is done after other criteria are met.

3. Temperature and blood pressure—The patient must not be significantly hypothermic or hypotensive for age.

4. Tone—Tone is flaccid, and spontaneous or induced movements are absent, excluding spinal cord events such as reflex withdrawal or spinal myoclonus.

5. General examination findings—The examination should remain consistent with brain death throughout the observation and testing period.

Confirmation

Apnea testing should be carried out at a PCO₂ level greater than 60 mm Hg, and with normal oxygenation maintained throughout the test period. This level may be reached 3–15 minutes after taking the patient off the

respirator. The recommended observation period to confirm brain death (repeated examinations) is 12–24 hours (longer in infants); reversible causes must be ruled out. If an irreversible cause is documented, laboratory testing is not essential. Helpful tests to support the clinical assertion of brain death include EEG and angiography. Electroencephalographic silence on EEG should persist for 30 minutes, and drug concentrations must be insufficient to suppress EEG activity. Absence of intracerebral arterial blood flow can be confirmed by carotid angiography and cerebral radionuclide angiography. Persistence of dural sinus flow does not invalidate the diagnosis of brain death.

Cerebral evoked potentials, intracranial blood pulsations on ultrasound, and xenon-enhanced CT have not been sufficiently studied to be considered definitive in the diagnosis of brain death. In rare cases, preserved intracranial perfusion in the presence of EEG silence has been documented, and the converse has also been reported.

SEIZURE DISORDERS (Epilepsies)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Recurrent nonfebrile seizures.*
- *Often, interictal electroencephalographic changes.*

General Considerations

A seizure is a sudden, transient disturbance of brain function, manifested by involuntary motor, sensory, autonomic, or psychic phenomena, alone or in any combination, often accompanied by alteration or loss

of consciousness. A seizure may occur after a metabolic, traumatic, anoxic, or infectious insult to the brain.

Repeated seizures without evident cause justify the label of epilepsy. Seizures and epilepsy occur most commonly at the extremes of life. The incidence is highest in the newborn period and higher in childhood than in later life. Epilepsy in childhood often remits. Prevalence flattens out after age 10–15 years. The chance of having a second seizure after an initial unprovoked episode is 30%. The chance of remission from epilepsy in childhood is 50%. The recurrence rate after the withdrawal of drugs is about 30%. Factors adversely influencing recurrence include (1) difficulty in getting the seizures under control (ie, the number of seizures occurring before control is achieved), (2) neurologic dysfunction or mental retardation, (3) age at onset younger than 2 years, and (4) abnormal EEG at the time of discontinuing medication. The type of seizure also often determines prognosis.

Seizures are caused by any factor that disturbs brain function. Seizures and epilepsy are often classified as symptomatic (the cause is identified or presumed) or idiopathic (the cause is unknown or presumed to be genetic). The younger the infant or child, the more likely it is the cause can be identified. Idiopathic or genetic epilepsy most often appears between ages 4 and 16 years. A seizure disorder or epilepsy should not be considered idiopathic unless thorough history, examination, and laboratory tests have revealed no apparent cause.

Clinical Findings

A. SYMPTOMS AND SIGNS

The key to the diagnosis of epilepsy is the history. An aura sometimes precedes the seizure itself. The patient describes a feeling of fear, numbness or tingling in the fingers, or bright lights in one visual field. Sometimes the patient recalls nothing because there has been no aura or warning. The parent might report that the patient's eyes deviated to one side or that pallor, trismus, or body stiffening occurred first. Occasionally there is a prodrome. For example, the patient may experience a feeling of unwellness, a premonition that something is about to happen, or a recurrent thought for minutes or hours prior to the aura and seizure itself.

Minute details of the seizure can help determine the site of onset and aid in classification. Did the patient become extremely pale before falling? Was the patient able to respond to queries during the episode? Did the patient become completely unconscious? Did the patient fall stiffly or gradually slump to the floor? Was there an injury? How long did the stiffening or jerking last? Where in the body did the jerking take place?

Events after the seizure can be helpful in diagnosis. Was there loss of speech? Was the patient able to respond accurately before going to sleep? All the events prior to, during, and after the seizure can help to classify the seizure and, indeed, may help to determine if the event actually was an epileptic seizure or a pseudoseizure (a nonepileptic phenomenon mimicking a seizure). Classifying the seizure may aid in diagnosis or prognosis and may suggest appropriate laboratory tests and medications (Tables 23–6 and 23–7).

B. STATUS EPILEPTICUS

Status epilepticus is a clinical or electrical seizure lasting at least 30 minutes, or a series of seizures without complete recovery over the same period of time. After 30 minutes of seizure activity, hypoxia and acidosis occur, with depletion of energy stores, cerebral edema, and structural damage. Eventually, high fever, hypotension, respiratory depression, and even death may occur. Status epilepticus is a medical emergency.

Status epilepticus is classified as (1) convulsive (the common tonic-clonic, or grand mal, status epilepticus) or (2) nonconvulsive (characterized by altered mental status or behavior with subtle or absent motor components). Absence status, or spike-wave stupor, and (very rare) partial complex status epilepticus are examples of the nonconvulsive type (Table 23–8). An EEG may be necessary to aid in diagnosing nonconvulsive status, because these patients sometimes appear merely stuporous and lack typical convulsive movements.

A child with status epilepticus may have a high fever with or without intracranial infection. Studies show that 25–75% of children with status epilepticus experience it as their initial seizure. Often it is a reflection of a remote insult (eg, anoxic or traumatic). Tumor, stroke, or head trauma, which are common causes of status epilepticus in adults, are uncommon causes in childhood. Fifty percent of cases are symptomatic of acute (25%) or chronic (25%) CNS disorders. Infection and metabolic disorders are the most common causes of status epilepticus in children. The cause is unknown in 50% of patients, but many of these patients will be febrile. Status epilepticus occurs most commonly in children age 5 years and younger (85%). The most common age is 1 year or younger (37%), and the distribution is even for each year thereafter (approximately 12% per year). For treatment options, see Table 23–9.

C. FEBRILE SEIZURES

Criteria for febrile seizures are (1) ages 3 months to 5 years (most occur between ages 6 and 18 months), (2) fever of greater than 38.8°C, and (3) non-CNS infection. More than 90% of febrile seizures are generalized, last less than 5 minutes, and occur early in the illness causing the fever. Febrile seizures occur in 2–3%

Table 23–6. Seizures by age at onset, pattern, and preferred treatment.

Age Group and Seizure Type	Age at Onset	Clinical Manifestations	Causative Factors	Electroencephalographic Pattern	Other Diagnostic Studies	Treatment and Comments (Anticonvulsants by Order of Choice)
Neonatal seizures	Birth to 2 wk	Often atypical; sudden limpness or tonic posturing, brief apnea, and cyanosis; odd cry; eyes rolling up; blinking or mouthing or chewing movements; nystagmus, twitchiness or clinic movements—focal, multifocal, or generalized. Some seizures are nonepileptic-decerebrate, or other posturings, release from forebrain inhibition; poor response to drugs.	Neurologic insults (hypoxia/ischemia; intracranial hemorrhage) present more in first 3 d or after eighth day; metabolic disturbances alone between third and eighth days; hypoglycemia, hypocalcemia, hyper- and hyponatremia. Drug withdrawal. Pyridoxine dependency and other metabolic causes. CNS infections and structural abnormalities.	May correlate poorly with clinical seizures. Focal spikes or slow rhythms; multifocal discharges. Electroclinical dissociation may occur: EEG-electrical seizure without clinical manifestations and vice versa.	Lumbar puncture; CSF PCR for herpes, enterovirus; serum Ca^{2+} , PO_4^{3-} , glucose, MG^{2+} ; BUN, amino acid screen, blood ammonia, organic acid screen, TORCHES ^a IgM. Ultrasound or CT scan for suspected intracranial hemorrhage and structural abnormalities	Phenobarbital, IV or IM; if seizures not controlled, add phenytoin IV (loading dose 20 mg/kg each). Diazepam 0.3 mg/kg. Treat underlying disorder. Seizures due to brain damage often resistant to anticonvulsants. When cause in doubt, stop protein feedings until enzyme deficiencies of urea cycle or amino acid metabolism ruled out.
West syndrome infantile spasms. (See also Lennox–Gastaut syndrome, below.)	3–18 mos; occasionally up to 4 y	Sudden, usually symmetric adduction and flexion of limbs with concomitant flexion of head and trunk; also abduction and extensor movements like Moro reflex. Tendency for spasms to occur in clusters, on waking or falling asleep, or when fatigued, or may be noted particularly when the infant is being handled, is ill, or is otherwise irritable. Tendency for each patient to have own stereotyped pattern.	Pre- or perinatal brain damage or malformation in approximately one third; biochemical, infectious, degenerative causes in approximately one third; unknown in approximately one third. With early onset, pyridoxine deficiency, amino- or organic aciduria. Tuberous sclerosis in 5–10%. Chronic inflammatory disease, eg, TORCHES ^a , homeobox gene mutations.	Hypsarrhythmia; chaotic high-voltage slow waves, random spikes, all leads (90%); other abnormalities in 10%. Rarely normal. EEG normalization usually early in course correlates with reduction of seizures; not helpful prognostically regarding mental development.	Funduscopy and skin examination, trial of pyridoxine. Amino and organic acid screen. Chronic inflammatory disease. TORCHES ^a screen, CT, or MRI scan should be done to (1) establish definite diagnosis, (2) aid in genetic counseling. SPECT or PET scan may identify focal lesion.	ACTH preferred (2–4 U/kg/d) IM Acthar gel once daily, then slow withdrawal. Some prefer oral corticosteroids. Clonazepam, valproic acid, vigabatrin, B_6 , pyridoxine trial (Japan). In resistant cases, ketogenic or medium-chain triglyceride diet (see text). New drugs: zonisamide, topiramate, lamotrigine. Retardation of varying degree in approximately 90% of cases. Occasionally, surgical extirpation of focal lesion may be curative.

(continued)

Table 23–6. Seizures by age at onset, pattern, and preferred treatment. (continued)

Age Group and Seizure Type	Age at Onset	Clinical Manifestations	Causative Factors	Electroencephalographic Pattern	Other Diagnostic Studies	Treatment and Comments (Anticonvulsants by Order of Choice)
Febrile convulsions	3 mos to 5 y (maximum 6–18 mos) Most common childhood seizure: incidence 2%	Usually generalized seizures, less than 15 mins; rarely focal in onset. May lead to status epilepticus. Latter usually benign. Recurrence risk of second febrile seizure 30%; 50% if under 1 y of age; recurrence risk is same after status.	Nonneurologic febrile illness (temperature rises to 39°C or higher); positive family history, day care, slow development, prolonged neonatal hospitalization are other risk factors.	Normal interictal EEG, especially when obtained 8–10 d after seizure. In older infants, 3/s generalized spike waves often seen.	Lumbar puncture in infants or whenever suspicion of meningitis exists.	Treat underlying illness, fever. Diazepam orally or rectally as needed, 0.3–0.5 mg/kg tid during illness or for prolonged (>5–15 mins) seizure. Prophylaxis with phenobarbital or valproic acid rarely needed: maybe with neurologic deficits, prolonged seizures, family anxiety.
Myoclonic-astatic (akinetic, atonic) seizures, formerly atypical absence. When mental retardation is presented, this is called Lennox–Gastaut syndrome.	Any time in childhood; normally 2–7 y	Shock-like violent contractions of one or more muscle groups, singly or irregularly repetitive; may fling patient suddenly to side, forward, or backward. Usually no or only brief loss of consciousness. Half of patients or more also have generalized grand mal seizures.	Multiple causes, usually resulting in diffuse neuronal damage. History of West’s syndrome; prenatal or perinatal brain damage; viral meningoencephalitis; CNS degenerative disorders; lead or other encephalopathies; structural cerebral abnormalities; eg, migrational abnormalities.	Atypical slow (1–2.5 Hz) spike-wave complexes (petit mal variant) and bursts of high-voltage generalized spikes, often with diffusely slow background frequencies. See text.	As dictated by index of suspicion. Nerve conduction studies. Skin or conjunctival biopsy for electron microscopy, MRI scan, WBC lysosomal enzymes if metabolic degenerative disease suspected.	Difficult to treat. Valproic acid, clonazepam, ethosuximide. Felbamate. Diazepam. Ketogenic or medium-chain triglyceride diet. ACTH or corticosteroids as in West syndrome. Perhaps lamotrigine, topiramate, zonisamide. Protect head with helmet and chin padding.
Absence (petit mal). Also juvenile and myoclonic absence.	3–15 y	Lapses of consciousness or vacant stares, lasting about 10 s, often in “clusters.” Automatisms of face and hands; clonic activity in 30–45%. Often confused with complex partial seizures but no aura or postictal confusion.	Unknown. Genetic component: probably an autosomal dominant gene.	3/s bilaterally synchronous, symmetric, high-voltage spikes and waves. EEG normalization correlates closely with control of seizures.	Hyperventilation when patient on inadequate or no medication often provokes attacks. CT scan is rarely of value.	Valproic acid or ethosuximide; with latter, add phenobarbital or valproate if major motor seizures. In resistant cases, ketogenic diet, lamotrigine, topiramate, acetazolamide.

Simple partial or focal seizures (motor/sensory/jacksonian).	Any age	Seizure may involve any part of body; may spread in fixed pattern (jacksonian march), becoming generalized. In children, epileptogenic focus often "shifts," and epileptic manifestations may change concomitantly.	Often secondary to birth trauma, inflammatory process, vascular accidents, meningoencephalitis, etc. If seizures are coupled with new or progressive neurologic deficits, a structural lesion (eg, brain tumor) is likely	Focal spikes or slow waves in appropriate cortical region; sometimes diffusely abnormal or even normal. "Rolandic spikes" one typical (often benign) pattern.	If seizures are difficult to control or progressive deficits occur, neuroradiologic studies, particularly MRI brain scan, imperative (see text).	Carbamazepine, phenytoin. Valproic acid useful adjunct. Also used: lamotrigine, gabapentin, topiramate, and levetiracetam
Complex partial seizures (psychomotor, temporal lobe, or limbic seizures are older terms).	Any age	Aura may be a sensation of fear, epigastric discomfort, odd smell or taste (usually unpleasant), visual or auditory hallucination (either vague and "unformed" or well-formed image, words, music). Aura and seizure stereotyped for each patient. Seizure may consist of vague stare; facial, tongue, or swallowing movements and throaty sounds; or various complex automatisms. Unlike absences, complex partial seizures tend not to occur in clusters but singly and to last longer (1 min or more), followed by confusion. History of aura (eg, child running to adult from "vague fear") and of automatisms involving more than face and hands establish diagnosis.	As above. Temporal lobes especially sensitive to hypoxia; thus, this seizure type may be a sequela of birth trauma, febrile convulsions, etc. Also especially vulnerable to certain viral infections, especially herpes simplex. Remediable other causes are small cryptic tumors or vascular malformations.	As above, but occurring in temporal lobe and its connections, eg, frontotemporal, temporoparietal, temporo-occipital regions.	MRI when structural lesions suspected. PCR of cerebrospinal fluid in acute febrile situation for herpes; rarely, temporal lobe biopsy. Carotid amobarbital injection when lateralization of speech dominance in question and surgical extirpation of epileptogenic area is contemplated.	Carbamazepine, phenytoin. More than one drug may be useful. In cases uncontrolled by drugs and where a primary epileptogenic focus is identifiable, excision of anterior third of temporal lobe. Gabapentin, topiramate, lamotrigine, levetiracetam, and tiagabine (for > 16-year-olds).

(continued)

Table 23–6. Seizures by age at onset, pattern, and preferred treatment. (continued)

Age Group and Seizure Type	Age at Onset	Clinical Manifestations	Causative Factors	Electroencephalographic Pattern	Other Diagnostic Studies	Treatment and Comments (Anticonvulsants by Order of Choice)
Benign epilepsy of childhood (with centrotemporal or rolandic foci)	5–16 y	Partial motor or generalized seizures. Similar seizure patterns may be observed in patients with focal cortical lesions. Usually nocturnal simple partial seizures of face, tongue, hand.	Seizure history or abnormal EEG findings in relatives of 40% of affected probands and 18–20% of parents and siblings, suggesting transmission by a single autosomal-dominant gene, possibly with age-dependent penetrance.	Centrotemporal spikes or sharp waves (“rolandic discharges”) appearing paroxysmally against a normal EEG background.	Seldom need CT or MRI scan.	Carbamazepine or phenytoin. (See simple, complex partial seizures.) Often no medication is necessary, especially if seizure is exclusively nocturnal and infrequent. Lamotrigine, topiramate.
Juvenile myoclonic epilepsy (of Janz)	Late childhood and adolescence, peaking at 13 y	Mild myoclonic jerks of neck and shoulder flexor muscles after awakening. Intelligence usually normal. Often absence seizures, and GTCS as well.	40% of relatives have myoclonias, especially in females; 15% have the abnormal EEG pattern with clinical attacks.	Interictal EEG shows variety of spike-and-wave sequences or 4- to 6-Hz multispikes and wave complexes (“fast spikes”)	Differentiate from progressive myoclonic encephalopathy of Unverricht-Lafora and other degenerative disorders by appropriate biopsies (muscles, liver, etc).	Valproic acid. Lamotrigine. topiramate ?Levetiracetam.
Generalized tonic-clonic seizures (grand mal) (GTCS)	Any age	Loss of consciousness; tonic-clonic movements, often preceded by vague aura or cry. Bladder and bowel incontinence in approximately 15%. Postictal confusion; sleep. Often mixed with or masking other seizure patterns.	Often unknown. Genetic component. May be seen with metabolic disturbances, trauma, infection, intoxication, degenerative disorders, brain tumors.	Bilaterally synchronous, symmetrical multiple high-voltage spikes, spikes and waves, mixed patterns. Often normal younger than age 4.	As above	Phenobarbital in infants; carbamazepine or valproic acid; phenytoin; topiramate, oxcarbazepine. Combinations may be necessary.

^aTORCHES is a mnemonic formula for toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and syphilis.

ACTH = adrenocorticotropic hormone; BUN = blood urea nitrogen; CNS = central nervous system; CT = computed tomography; EEG = electroencephalogram; IM = intramuscularly; IV = intravenously; MRI = magnetic resonance imaging; PCR = polymerase chain reaction; PET = positron emission tomography; SPECT = single photon emission computed tomography; WBC = white blood cell.

Table 23-7. Benign childhood epileptic syndromes.

Syndrome	Characteristics
Benign idiopathic neonatal convulsions (BINC)	6% of neonatal convulsions; 97% have onset on 3rd to 7th day of life (so-called 5th day fits); clonic; multifocal; usually brief; occasional status epilepticus
Benign familial neonatal convulsions (BFNC)	Autosomal-dominant; onset in 2–90 d; 20% have linkage to chromosome 20q13; clonic; 86% recover
Generalized tonic-clonic seizures (GTCS)	Age at onset, 3–11 y; may have family or personal history of febrile convulsions; 50% have 3/s spike-wave EEG; may have concurrent absence seizures
Childhood absence seizures	Incidence higher in girls than in boys; age at onset, 3–12 y (peak 6–7 years); 10–200 seizures per day; 3/s spike-wave EEG; 40% have GTCS; most remit at puberty
Juvenile absence seizures	Incidence higher in boys than in girls; age at onset, 10–12 y; uncommon; less frequent seizures; 3–4/s general spike-wave EEG; most have GTCS; some remit
Juvenile myoclonic epilepsy (Janz syndrome)	Age at onset, 12–18 y (average, 15 y); myoclonic jerks upper limbs, seldom fall; 4–6/s general spike-wave EEG; untreated, 90% have GTCS, mostly on waking; 20–30% have absence seizures; 25–40% are photosensitive; 10% remission rate
Benign epilepsy with centrotemporal spikes (BECTS); rolandic epilepsy	Autosomal-dominant; age at onset 3–13 y (most at 4–10 y); 80% have brief, 2–5 min sleep seizures only; usually simple partial seizures (face, tongue, cheek, hand) sensory or motor; occasionally have GTCS; bilateral spikes on EEG; may not need medication if seizures infrequent; remits at puberty

EEG = electroencephalogram.

of children. Acute respiratory illnesses are most commonly associated with febrile seizures. Gastroenteritis, especially when caused by *Shigella* or *Campylobacter*, and urinary tract infections are less common causes. Roseola infantum is a rare but classic cause. One study implicated viral causes in 86% of cases. Immunizations may be a cause.

Rarely status epilepticus may occur during a febrile seizure. Febrile seizures rarely (1–2.4%) lead to epilepsy or recurrent nonfebrile seizures in later childhood and adult life. The chance of later epilepsy is higher if the

Table 23-8. Status epilepticus: clinical types.

Generalized seizure (common)
Convulsive (tonic, clonic, myoclonic); 90%
Nonconvulsive (absence, atypical absence, atonic); 10%
Focal (partial) seizures (rare)
Simple partial
Complex partial
Neonatal
Many clinical varieties
May be electrical (ie, on electroencephalogram) status only with no visible clinical findings; called electroclinical dissociation

febrile seizures have complex features, such as a duration of longer 15 minutes, more than one seizure in the same day, or focal features. Other adverse factors are an abnormal neurologic status preceding the seizures (eg, cerebral palsy or mental retardation), early onset of febrile seizure (before age 1 year), and a family history of epilepsy. Even with adverse factors, the risk of epilepsy after febrile seizures is low, in the range of 15–20%. Recurrent febrile seizures occur in 30–50% of cases but, in general, do not worsen the long-term outlook.

The child with a febrile seizure must be examined. Routine studies such as serum electrolytes, glucose, calcium, skull radiographs, or brain imaging studies are seldom helpful. A white count above 20,000/ μ L or an extreme left shift may correlate with bacteremia. Complete blood count and blood cultures may be appropriate studies. Serum sodium is often slightly low but not low enough to require treatment or to cause the seizure. Meningitis must be ruled out. Patients with bacterial meningitis can present with a fever and seizure. Signs of meningitis (eg, bulging fontanelle, stiff neck, stupor, and irritability) may all be absent, especially in a child younger than age 18 months.

After controlling the fever and stopping an ongoing seizure, the physician must decide whether to do a spinal tap. The fact that the child has had a previous febrile seizure does not rule out meningitis as the cause of the current episode. The younger the child, the more important the tap, because physical findings are less reliable in diagnosing meningitis. Although the yield is low, a tap should probably be done if the child is younger than age 2 years, if recovery is slow, if no other cause for the fever is found, or if close follow-up will not be possible. Occasionally observation in the emergency room for several hours obviates the need for a tap. A negative tap does not rule out the emergence of meningitis during the same febrile illness. Sometimes a second tap must be done.

Table 23–9. Status epilepticus treatment.

1. ABCs
 - a. Airway: Maintain oral airway; intubation may be necessary.
 - b. Breathing: Oxygen.
 - c. Circulation: Assess pulse, blood pressure; support with IV fluids, drugs. Monitor vital signs.
2. Start glucose-containing IV; evaluate serum glucose; electrolytes, HCO₃⁻, CBC, BUN, anticonvulsant levels.
3. May need arterial blood gases, pH.
4. Give 50% glucose if dextrose low (1–2 mL/kg).
5. Begin IV drug therapy; goal is to control status epilepticus in 20–60 min.
 - a. Diazepam 0.3–0.5 mg/kg over 1–5 min (20 mg maximum); may repeat in 5–20 min; or, lorazepam 0.05–0.2 mg/kg (less effective with repeated doses, longer-acting than diazepam). Midazolam IM or IV: 0.1–0.3 mg/kg; intranasally, 0.2 mg/kg.
 - b. Phenytoin 10–20 mg/kg IV (not IM) over 5–20 min; 1000 mg maximum); monitor with blood pressure and ECG. Fosphenytoin may be given more rapidly—even IM—in the same dosage; order 10–20 mg/kg of “phenytoin equivalent.”
 - c. Phenobarbital 5–20 mg/kg (sometimes higher in newborns or refractory status in intubated patients).
6. Correct metabolic perturbations (eg, low-sodium, acidosis).
7. Other drug approaches in refractory status:
 - a. Repeat phenytoin, phenobarbital (10 mg/kg). Monitor blood levels. Support respiration, blood pressure as necessary.
 - b. Midazolam drip: 1–5 µg/kg/min (even to 20 µg/kg/min). Valproate sodium (Depacon), available as 100 mg/mL for IV use; give 15–30 mg/kg over 5–20 min.
 - c. Pentobarb coma. Propofol. General anesthetic.
8. Consider underlying causes:
 - a. Structural disorders or trauma. Consider CT scan.
 - b. Infection: Spinal tap, blood culture, antibiotics.
 - c. Metabolic disorders: Consider lactic acidosis, toxins, uremia. May need to evaluate medication levels, toxin screen, judicious fluid administration.
9. Give maintenance drug (if diazepam only was sufficient to halt status epilepticus): phenytoin 10 mg/kg, phenobarbital 5 mg/kg, daily dose IV (or by mouth) divided every 12 hours.

BUN = blood urea nitrogen; CBC = complete blood count; CT = computed tomography; ECG = electrocardiogram; IM = intramuscularly; IV = intravenously.

Prophylactic anticonvulsants are not required after the uncomplicated febrile seizure. If febrile seizures are complicated or prolonged, or if medical reassurance fails to relieve family anxiety, anticonvulsant prophylaxis may be indicated and can reduce the incidence of recurrent febrile or nonfebrile seizures. One remedy is to use diazepam at the first onset of fever for the dura-

tion of the febrile illness (0.5 mg/kg two or three times per day orally or rectally). Diastat is an expensive rectal diazepam preparation. Phenobarbital, 3–5 mg/kg/d as a single bedtime dose, is an inexpensive and safe prophylaxis. Often, increasing the dosage gradually (eg, starting with 2 mg/kg/d the first week, increasing to 3 mg/kg/d the second week, and so on) decreases side effects and noncompliance. A plasma phenobarbital level in the range of 15–40 mg/mL is desirable. Valproate sodium is more hazardous. In infants, the commonly used liquid suspension has a short half-life and causes more gastrointestinal upset than do the sprinkle capsules. The dosage is 15–60 mg/kg/d in two three or four divided doses. Precautionary laboratory studies are necessary. Phenytoin and carbamazepine have not shown effectiveness in the prophylaxis of febrile seizures (see Table 23–9). Measures to control fever such as sponging or tepid baths, antipyretics, and the administration of antibiotics for proven bacterial illness are reasonable but unproven to prevent recurrent febrile seizures.

Simple febrile seizures do not have any long-term adverse consequences. An EEG should be performed if the febrile seizure is complicated or unusual. In uncomplicated febrile seizures, the EEG is usually normal. About 22% of patients will show slowing or epileptiform abnormalities. Ideally the EEG should be done at least a week after the illness to avoid transient changes due to fever or the seizure itself. In older children, 3/s spike-wave discharge, suggestive of a genetic propensity to epilepsy, may occur. In the young infant, EEG findings seldom aid in assessing the chance of recurrence of febrile seizures or in long-term prognosis.

D. LABORATORY FINDINGS AND IMAGING

Ordering of laboratory tests depends on the child's age, the severity and type of seizure, whether the child is ill or injured, and the clinician's suspicion about the underlying cause. Every case of suspected seizure disorder warrants an EEG. Other studies are used selectively. Seizures in early infancy are often symptomatic. Therefore, the younger the child, the more careful must be the laboratory assessment (Table 23–10).

Metabolic abnormalities are seldom found in the well child with seizures. Unless there is a high clinical suspicion of uremia, hyponatremia, or other serious conditions, laboratory tests are not necessary. Special studies may be necessary in unusual circumstances, for example, when hemolytic-uremic syndrome or lead poisoning is a suspected cause. CT scans are overused in patients with seizures. The youngster with a routine febrile seizure, a nonfebrile generalized seizure with normal examination and normal EEG, or an absence seizure does not need a CT or MRI scan. The yield in a child with normal neurologic examination and EEG is

Table 23–10. Laboratory studies after first seizure (nonneonatal).

Well infant	EEG, calcium, BUN, or urinalysis, and perhaps CT or MRI. (Abnormal examination or focally abnormal EEG: do imaging study.) Rule out nonaccidental trauma.
Well older child	EEG; consider CT or MRI
Ill infant	Calcium, magnesium, CBC, BUN, glucose, electrolytes, blood culture, lumbar puncture, EEG, possibly CT or MRI
Ill older child	CBC, BUN, lumbar puncture, EEG, CT or MRI
Generalized tonic-clonic seizure	Calcium, glucose, CBC, BUN, electrolytes, lumbar puncture (may omit if afebrile, looks well)
Generalized absence	EEG only
Atypical absence	EEG, MRI: Consider studies for mental retardation: serum and urine amino and organic acids and chromosomes, including fragile X. If there is progressive worsening, consider lysosomal enzymes, lumbar puncture (protein, enzymes, IgG), long-chain fatty acids, skin or conjunctival biopsies.
Infantile spasms	See Atypical absence
Myoclonic progressive seizure with mental retardation	See Atypical absence
Focal	EEG. In cases of mental retardation, positive neurologic examination, EEG focal slow wave, or poorly controlled seizures, do MRI. In refractory cases, consider surgical evaluation.

BUN = blood urea nitrogen; CBC = complete blood count; CT = computed tomography; EEG = electroencephalogram; MRI = magnetic resonance imaging.

less than 5%. Conversely, in children with symptomatic epileptic syndromes, the EEG will be abnormal in as many as 60–80% of patients. Examples include infantile spasms, Lennox–Gastaut syndrome, and progressive myoclonic epilepsy.

In focal seizures, children with benign rolandic epilepsy do not need a CT scan; it will invariably be normal. The yield with other focal seizures is 15–30%, with most of the findings unimportant in relation to diagnosis and prognosis (eg, a mildly dilated single ventricle, superficial atrophy). Nonetheless, an imaging study

eases anxiety and rules out the remote possibility of tumor or vascular malformation. Other indications for MRI scan (the superior study) scan include difficulty in controlling seizures, progressive neurologic findings on serial examinations, worsening focal findings on the EEG, suspicion of increased pressure, and, of course, any case in which surgery is being considered. A previous normal scan does not rule out an emerging tumor; if the course is unsatisfactory, repeating the scan may be necessary. A neoplasm or other unexpected treatable lesion is found in a small number, perhaps 2–3%, of scans.

E. ELECTROENCEPHALOGRAPHY

The limitations of EEG—even with epilepsy, for which it is most useful—are considerable. A seizure is a clinical phenomenon; an EEG showing epileptiform activity may confirm and even extend the clinical diagnosis, but it cannot make the diagnosis.

The EEG need not be abnormal in the epileptic child. Normal EEGs are seen following a first generalized seizure in one third of children younger than age 4 years. The initial EEG is normal in about 20% of older epileptic children and in about 10% of epileptic adults. These percentages are reduced when serial tracings are obtained. Focal spikes and generalized spike-wave discharges are seen in 30% of close nonepileptic relatives of patients with epilepsy.

1. Diagnostic value—The greatest value of the EEG in convulsive disorders is to help classify seizure types and select appropriate therapy (see Table 23–6). Petit mal absences and partial complex or psychomotor seizures are sometimes difficult to distinguish, especially when the physician must rely on the history and cannot observe the seizure. The differing EEG patterns of these seizures will then prove most helpful. Finding a mixed seizure EEG pattern in a child who clinically has only major motor seizures or only focal seizures will help the clinician select anticonvulsants effective for both seizure types identified by the EEG. The EEG may help in diagnosing neonatal seizures with minimal or atypical clinical manifestations; it may show hypsarrhythmia (high-amplitude spikes and slow waves with a disorganized background) in infantile spasms or 1–4/s slow spike-wave pattern of the Lennox–Gastaut syndrome. Both are expressions of diffuse brain dysfunction and generally of grave significance. The EEG may show focal slowing that, if constant, particularly when corresponding focal seizure manifestations and abnormal neurologic findings are present, will alert the physician to the presence of a structural lesion. In this case, brain imaging may establish the cause and help determine further investigation and treatment.

2. Prognostic value—A normal EEG following a first convulsion suggests (but does not guarantee) a favorable prognosis. Markedly abnormal EEGs may become normal with treatment (1) immediately following intravenous injection of 50 mg of vitamin B₆ in pyridoxine dependency or deficiency; (2) in infantile spasms and sometimes the Lennox–Gastaut syndrome (with the use of adrenocorticotrophic hormone [ACTH] or corticosteroids); (3) in absence (appropriate anticonvulsants); and (4) in akinetic and other minor motor seizures, including the Lennox–Gastaut syndrome (ketogenic diet). If so, it is likely that seizure control will be achieved (although this offers no clues to the ultimate developmental status of the patient).

Electroencephalography should be repeated when the severity and frequency of seizures increase despite adequate anticonvulsant therapy, when the clinical seizure pattern changes significantly, or when progressive neurologic deficits develop. Emergence of new focal or diffuse slowing may indicate a progressive lesion. A normalized tracing may help confirm remission of absence seizures.

The EEG may be helpful in determining when to discontinue anticonvulsant therapy. The presence or absence of epileptiform activity on the EEG prior to withdrawal of anticonvulsants after a seizure-free period of several years on the medications has been shown to be correlated with the degree of risk of recurrence of seizures.

Differential Diagnosis

It is extremely important to be accurate in the diagnosis of epilepsy and not to make the diagnosis without ample proof. To the layperson, epilepsy often has connotations of brain damage and limitation of activity. A person so diagnosed may be excluded from certain occupations in later life. It is often very difficult to change an inaccurate diagnosis of many years' standing. Some of the common nonepileptic events that mimic seizure disorder are listed in Table 23–11.

Complications

Emotional disturbances—notably anxiety, depression, anger, and feelings of guilt and inadequacy—often occur not only in the patient but also in the parents of the child with seizures. The seizures, particularly the hallucinatory auras and psychomotor attacks, frequently set off in the prepubescent and adolescent patient fantasies (and sometimes obsessive ruminations) about dying and death that may become so strong that they lead to suicidal behavior. The limitations many school systems place on epileptic children add to the problem. Some children may react by acting out.

Pseudoretardation may occur in children with poorly controlled epilepsy because their seizures (or the subclinical paroxysms sustained) interfere with their learning ability. Anticonvulsants are less likely to cause such interference but may do so when given in toxic amounts. Phenobarbital is particularly implicated. True mental retardation is most commonly part of the same pathologic process that causes the seizures but may occasionally be worsened when seizures are frequent, prolonged, and accompanied by hypoxia.

Physical injuries, especially lacerations of the forehead and chin, are frequent in astatic or akinetic seizures (so-called drop attacks), necessitating protective headgear. In all other seizure disorders in childhood, injuries as a direct result of an attack are rare.

Treatment

The ideal treatment of seizures is the correction of specific causes. However, even when a biochemical disorder, a tumor, meningitis, or another specific cause is being treated, anticonvulsant drugs are often still required.

A. PRECAUTIONARY MANAGEMENT OF INDIVIDUAL BRIEF SEIZURES

Caregivers should be instructed to protect the patient against self-injury and aspiration of vomitus; beyond that, no specific therapy is necessary. The less done to the patient during a brief seizure of less than 15 minutes, the better. Thrusting a spoon handle or tongue depressor into the clenched mouth of a convulsing patient or trying to restrain tonic–clonic movements may cause worse injuries than a bitten tongue or bruised limb. Mouth-to-mouth resuscitation is rarely necessary.

B. GENERAL MANAGEMENT OF THE YOUNG EPILEPTIC PATIENT

1. Education—The patient and parents must be helped to understand the problem of seizures and their management. Many children—some even as young as age 3 years—are capable of cooperating with the physician in problems of seizure control.

All bottles containing antiepileptic drugs should be labeled. The parents should know the names and dosage of the anticonvulsants being administered.

Materials on epilepsy—including pamphlets, monographs, films, and videotapes suitable for children and teenagers, parents, teachers, and medical professionals—may be purchased through the Epilepsy Foundation of America, Materials Service Center, 4351 Garden City Drive, Landover, MD 20785. The Foundation's local chapter and other community organizations are eager to provide guidance and other services. Support groups exist in many cities for older chil-

Table 23–11. Nonepileptic paroxysmal events.**Breath-holding attacks**

Age 6 mo to 3 y. Always precipitated by trauma and fright. Cyanosis; sometimes stiffening, tonic (or jerking-clonic) convulsion (anoxic seizure). Patient may sleep following attack. Family history positive in 30%. Electroencephalogram (EEG) normal. Treatment is interpretation and reassurance.

Infantile syncope (pallid breath holding)

No external precipitant (perhaps internal pain, cramp, or fear?). Pallor may be followed by seizure (anoxic–ischemic). Vagally (heart-slowing) mediated, like adult syncope. EEG normal; may see cardiac slowing with vagal stimulation (cold cloth on face) during EEG.

Tics or Tourette syndrome

Simple or complex stereotyped (the same time after time) jerks or movements, coughs, grunts, sniffs. Worse at repose or with stress. May be suppressed during physician visit. Family history often positive. EEG negative. Nonanticonvulsant drugs may benefit.

Night terrors, sleep talking, walking, “sit-ups”

Age 3–10. Usually occur in first sleep cycle (30–90 min after going to sleep), with crying, screaming, and “autonomic discharge” (pupils dilated, perspiring, etc). Lasts minutes. Child goes back to sleep and has no recall of event next day. Sleep studies (polysomnogram and EEG) are normal. Disappears with maturation. Sleep talking and walking and short “sit-ups” in bed are fragmentary arousals. If a spell is recorded, EEG shows arousal from deep sleep, but the behavior seems wakeful. The youngster needs to be protected from injury and gradually settled down and taken back to bed.

Nightmares

Nightmares or vivid dreams occur in subsequent cycles of sleep, often in the early morning hours, and generally are partially recalled the next day. The bizarre and frightening behavior may sometimes be confused with complex partial seizures. These occur during REM (rapid eye movement) sleep; epilepsy usually does not occur during that phase of sleep. In extreme or difficult cases, an all-night sleep EEG may help to differentiate seizures from nightmares.

Migraine

One variant of migraine can be associated with an acute confusional state. There may be the usual migraine prodrome with spots before the eyes, dizziness, visual field defects, and then agitated confusion. A history of other, more typical migraine with severe headache and vomiting but without confusion may aid in the diagnosis. The severe headache with vomiting as the youngster comes out of the spell may aid in distinguishing the attack from epilepsy. Other seizure manifestations are practically never seen, eg, tonic-clonic movements, falling, and complete loss of consciousness. The EEG in migraine is usually normal and seldom has epileptiform abnormalities often seen in patients with epilepsy. Lastly, migraine and epilepsy are sometimes linked: migraine-caused ischemia on the brain surface sometimes leads to later epilepsy.

Benign nocturnal myoclonus

Common in infants and may last even up to school age. Focal or generalized jerks (the latter also called hypnic or sleep jerks) may persist from onset of sleep on and off all night. A video record for physician review can aid in diagnosis. EEG taken during jerks is normal, proving that these jerks are not epilepsy. Treatment is reassurance.

Shuddering

Shuddering or shivering attacks can occur in infancy and be a forerunner of essential tremor in later life. Often, the family history is positive for tremor. The shivering may be very frequent. EEG is normal. There is no clouding or loss of consciousness.

Gastroesophageal reflux

Seen more commonly in children with cerebral palsy or brain damage; reflux of acid gastric contents may cause pain that cannot be described by the child. At times, there may be unusual posturings (dystonic or other) of the head and neck or trunk, an apparent attempt to stretch the esophagus or close the opening. There is no loss of consciousness, but there may be eye rolling, apnea, occasional vomiting that may simulate a seizure. An upper gastrointestinal series, cine of swallowing, sometimes even an EEG (which is always normal) may be necessary to distinguish this from seizures.

Masturbation

Rarely in infants, repetitive rocking or rubbing motions may simulate seizures. The youngster may look out of contact, be poorly responsive to the environment, and have autonomic expressions (eg, perspiration, dilated pupils) that may be confused with seizures. Observation by a skilled individual, sometimes even in a hospital situation, may be necessary to distinguish this from seizures. EEG is of course normal between or during attacks. Interpretation and reassurance are the only necessary treatment.

Conversion reaction/pseudoseizures

As many as 50% of patients with pseudoseizures have epilepsy. Episodes may be writhing, intercourse-like movements, tonic episodes, bizarre jerking and thrashing around, or even apparently sudden unresponsiveness. Often, there is ongoing psychological trauma. Often, but not invariably, the patients are developmentally delayed. The spells must often be seen or recorded on videotape in a controlled situation to distinguish them from epilepsy. A normal EEG during a spell is a key diagnostic feature. Often, the spells are so bizarre that they are easily distinguished. Sometimes, pseudoseizures can be precipitated by suggestion with injection of normal saline in a controlled situation. Combativeness is common; self-injury and incontinence rare.

Temper tantrums and rage attacks

These are sometimes confused with epilepsy. The youngster is often amnesic or at least claims amnesia for events during the spell. The attacks are usually precipitated by frustration or anger and are often directed either verbally

(continued)

Table 23–11. Nonepileptic paroxysmal events. (continued)

or physically and subside with behavior modification and isolation. EEGs are generally normal but unfortunately seldom obtained during an attack. Anterior temporal leads may be helpful in ruling out temporal or lateral frontal abnormalities, the latter sometimes seen in partial complex seizures. Improvement of the attacks with psychotherapy, milieu therapy, or behavioral modification helps rule out epilepsy.

Benign paroxysmal vertigo

These are brief attacks of vertigo in which the youngster often appears frightened and pale and clutches the parent. The attacks last 5–30 s. Sometimes, nystagmus is identified. There is no loss of consciousness. Usually, the child is well and returns to play immediately afterward. The attacks may occur in clusters, then disappear for months. Attacks are usually seen in infants and preschoolers age 2–5. EEG is normal. If calorimetric tests can be obtained (often very difficult

in this age group), abnormalities with hypofunction of one side are sometimes seen. Medications are usually not desirable or necessary.

Staring spells

Teachers often make referral for absence or petit mal seizures in youngsters who stare or seem preoccupied at school. Helpful in the history is the lack of these spells at home, eg, before breakfast, a common time for absence seizures. A lack of other epilepsy in the child or family history often is helpful. Sometimes, these children have difficulties with school and a cognitive or learning disability. The child can generally be brought out of this spell by a firm command. An EEG is sometimes necessary to confirm that absence seizures are not occurring. A 24-hour ambulatory EEG to record attacks during the child's everyday school activities is occasionally necessary.

dren and adolescents and for their parents and others concerned.

2. Privileges and precautions in daily life—Encourage normal living within reasonable bounds. Children should engage in physical activities appropriate to their age and social group. After seizure control is established, swimming is generally permissible with a buddy system or adequate lifeguard coverage. High diving and high climbing should not be permitted. Physical training and sports are usually to be welcomed rather than restricted. Driving is discussed in the next section.

Loss of sleep should be avoided. Emotional disturbances may need to be treated. Alcohol intake should be avoided because it may precipitate seizures. Prompt attention should be given to infections. Further neurologic disturbances should be brought to the physician's attention promptly.

Although every effort should be made to control seizures, this must not interfere with a child's ability to function. Sometimes a child is better off having an occasional mild seizure than being so heavily sedated that function at home, in school, or at play is impaired. Therapy and medication adjustment often require much art and fortitude on the physician's part. Some patients with infrequent seizures, especially if only nocturnal partial seizures (eg, Rolandic seizures) may not need anticonvulsant medications.

3. Driving—Driving becomes important to most young people at age 15 or 16 years. Restrictions vary from state to state. In most states, a learner's permit or driver's license will be issued to an epileptic individual if he or she has been under a physician's care and free of seizures for at least 1 year, provided that the treatment

or basic neurologic problem does not interfere with the ability to drive. A guide to this and other legal matters pertaining to persons with epilepsy is published by the Epilepsy Foundation of America, whose legal department may be able to provide additional information (see reference at the end of this section).

4. Pregnancy—In the pregnant teenager with epilepsy, the possibility of teratogenic effects of anticonvulsants, such as facial clefts (two to three times increased risk), must be weighed against the risks from seizures. Such malformations occur in the infants of about 2.5% of mothers with untreated epilepsy.

C. PRINCIPLES OF ANTICONVULSANT THERAPY

1. Drug selection—Treat with the drug appropriate to the clinical situation, as outlined in Table 23–12.

2. Treatment strategy—Start with one drug in conventional dosage, and increase the dosage until seizures are controlled. If seizures are not controlled on the tolerated maximal dosage of one major anticonvulsant, gradually switch to another before using two-drug therapy. The dosages and usually effective blood levels are listed in Table 23–12. Individual variations must be expected. The therapeutic range may also vary somewhat with the method used to determine levels.

3. Counseling—Advise the parents and the patient that the prolonged use of anticonvulsant drugs will not produce significant or permanent mental slowing (although the underlying cause of the seizures might) and that prevention of seizures for 1–2 years substantially reduces the chances of recurrence. Advise them also that anticonvulsants are given to prevent further seizures and that they should be taken as prescribed.

Table 23–12. Guide to pediatric anticonvulsant drug therapy.^a

Drug	Average Total Dosage (mg/kg/d)	Steady State	Effective Blood Levels ^b	Side Effects and Precautions	Directions and Remarks
Primary anticonvulsant					
Carbamazepine (Tegretol) (Carbatrol, Tegretol XR are sustained release formulations)	15–25 mg/kg/d in 2–4 divided doses	3–6 d	4–12 µg/mL (> 15)	Dizziness, ataxia, diplopia, drowsiness, nausea, rash. <i>Rare:</i> hepatotoxicity, bone marrow depression, dystonia, inappropriate ADH secretion, bizarre behaviors, tics.	Monitor CBC, platelet count, liver function tests periodically. Blood effects usually early and transient. <i>Drug interactions:</i> ↑ by fluoxetine, propoxyphene, erythromycin, cimetidine; ↓ by felbamate, phenobarbital, phenytoin.
Valproic acid (Depakene, Depakote) (Depacon)	15–60 mg/kg/d in 2–4 divided doses	2–4 d	50–120 µg/mL (> 140)	Weight gain, occasional gastric discomfort, constipation. Tremor, hair loss in 5%. <i>Rare:</i> hepatotoxicity, hyperammonemia, leukopenia, polycystic ovaries (more toxic in infants younger than 2 years)	For prophylaxis in febrile convulsions, see text. Monitor CBC, platelets, liver function tests closely in first 6 months, then periodically. Can be given rectally (suspension: 250 mg/5 mL). Depacon is an IV preparation, 100 mg/mL. <i>Drug interactions:</i> ↓ by phenobarbital, phenytoin, carbamazepine, ↑ by lamotrigine felbamate.
Phenytoin (Dilantin)	5–10 mg/kg/d in 1 or 2 doses	5–10 d	5–20 µg/mL (>25)	Gum hypertrophy, hirsutism, ataxia, nystagmus, diplopia, rash, anorexia, nausea, osteomalacia. <i>Rare:</i> macrocytic anemia, lymph node involvement, exfoliative dermatitis, peripheral neuropathy.	Good dental hygiene reduces gum hyperplasia. May aggravate absence and myoclonic seizures. Poorly absorbed by neonatal gut. Use 50 mg Infant tabs in infants (may be crushed to adjust dosage). Suspension not recommended. <i>Drug interactions:</i> ↑ by felbamate; ↓ by carbamazepine, phenobarbital, antacids.
Phenobarbital	3–5 mg/kg/d as single daily dose	10–21 d	15–40 µg/mL (> 45)	Irritability and overactivity in many children; sedative effects in others. Mild ataxia, depression, skin rash. May interfere with learning.	Overall, the safest drug. Bitter taste. Higher blood levels sometimes required and tolerated in severe chronic epileptics. Useful in neonatal seizures and status epilepticus. Valproate increases unbound phenobarbital levels.
Primidone (Mysoline)	10–25 mg/kg/d in 3 or 4 divided doses	1–5 d	4–12 µg/mL (> 15)	Drowsiness, ataxia, vertigo, anorexia, nausea, vomiting, rash. (Like phenobarbital.)	Start slowly with 25–35% of expected maintenance dose; increase every other day until full dose reached.
Ethosuximide (Zarontin)	10–40 mg/kg/d in 1 or 2 doses	5–6 d	40–100 µg/mL (> 150)	Nausea, gastric discomfort, hiccups, blood dyscrasias.	May aggravate generalized seizures. Combine with valproic acid in refractory absence seizures.
Clonazepam (Klonopin)	0.01–0.1 mg/kg/dose 1–2 times/day	5–10 d	15–80 ng/mL (> 80)	Drowsiness (> 50%): soporific effects greatest drawback. Behavior problems in 25%. Slurred speech, ataxia, salivation.	Start slowly with 25% of expected maintenance dosage; increase every 2 or 3 d. Useful with refractory minor motor seizures (astatic, myoclonic, infantile spasms; absences). Tolerance may occur.

(continued)

Table 23–12. Guide to pediatric anticonvulsant drug therapy.^a (continued)

Drug	Average Total Dosage (mg/kg/d)	Steady State	Effective Blood Levels ^b	Side Effects and Precautions	Directions and Remarks
Adjunctive or secondary drug					
Acetazolamide (Diamox)	5–20 mg/kg/d in 2 or 3 divided doses	1–2 d	10–14 µg/mL	Anorexia; numbness and tingling. Urinary frequency, so do not give in evening. Renal stones.	Supplement to other medications, especially in absence and complex partial seizures. Also in females 4 days prior to and in the first 2 or 3 days of menstrual period for catamenial seizures.
Levetiracetam (Keppra)	10–20 mg/kg/d. To maximal 40–60 over 2–6 weeks	1–3 d	20–40 µg/mL	Somnolence, dizziness, headache, asthenia. <i>Rare:</i> decWBC	Complex partial seizures, myoclonic. Little effect on other drugs.
Oxcarbazepine (Trileptal)	8–10 mg/kg/d initial, 20–50 mg/kg/d maint in 2 doses	1–3d	MHD (breakdown product) 12–30 µg/mL	Dizziness, fatigue, somnolence, nausea, ataxia, headache, hyponatremia, rash	Partial, generalized seizures. Little effect on other drug levels. No need for lab (CBC, LFTs).
Felbamate (Felbatol)	15–45 mg/kg/d in 3 or 4 divided doses	5–7 d	22–137 µg/mL	Anorexia, vomiting, insomnia, headache, somnolence. Rash in 1%. Aplastic anemia and hepatic failure are significant hazards.	A dangerous drug. Used in children with Lennox–Gastaut syndrome; in adults with complex partial seizures. Obtain informed consent. <i>Drug interactions:</i> ↓ by phenytoin, carbamazepine.
Vigabatrin (Sabril)	20–100 mg/kg/d in 2–3 divided doses	Not known	Not known	Drowsiness, confusion, weight gain, retinal changes, visual loss	Infantile spasms, especially tuberous sclerosis. Add-on drug for partial seizures. Not licensed by FDA in United States as of 1999
Gabapentin (Neurontin) > 12 years	30–60 mg/kg/d in 3 divided doses (900–4800 mg total per day)	1–2 d	12–25 µg/mL	Drowsiness, dizziness, ataxia.	Add-on drug for partial seizures; no effect on other anticonvulsant drug levels.
Topiramate (Topomax)	Start 0.5–1 mg/kg/d to 10 mg/kg/d in 2 divided doses (maximum, 400 mg/d)	Not known	8–25 µg/mL	Somnolence, slowed mentation, dizziness, language problems, kidney stones (rarely, metabolic acidosis, anorexia).	Adjunctive drug for complex partial seizures. Minimal effect on other drug levels. Lennox–Gastaut, West syndrome. Broad-spectrum drug.
Tiagabine (Gabitril)	0.1–1.5 mg/kg/d in 2 divided doses	1–2 d	20–70 µg/mL	Dizziness, tremor, abnormal thinking	Adjunctive drug for partial seizures.
Zonisamide (Zonegran)	1–2 mg/kg/d to maximum 8–12 mg/kg/d in 1 or 2 divided doses	5–7 d	20–30 µg/mL	Drowsiness, anorexia, GI symptoms, weight loss, behavior changes, renal stones (0.2–2%), hypohidrosis. Rash	Effects in multi seizure types. A sulfonamide (don't use if allergic to sulfa drugs). Hazard: oligohydrosis-fever syndrome. Widely used in Japan.

(continued)

Table 23–12. Guide to pediatric anticonvulsant drug therapy.^a (continued)

Drug	Average Total Dosage (mg/kg/d)	Steady State	Effective Blood Levels ^b	Side Effects and Precautions	Directions and Remarks
Lamotrigine (Lamictal)	5–15 mg/kg/d in 2 divided doses (1–5 mg/kg if taking valproic acid); 5–400 mg/d total	8–15 d	10–20 µg/mL	Dizziness, headaches, diplopia, ataxia, nausea. Rash in 5–10%. 1% Stevens–Johnson usually in first 4–8 wk.	Add-on drug for children older than 16 y with complex partial seizures, Lennox–Gastaut syndrome, absence seizures. Valproate increases drug half-life. Increase dose slowly over 2 mos.
Treatment of status epilepticus^a					
Diazepam (Valium)	0.3 mg/kg IV. Repeat dose: 0.1–0.3 mg/kg IV.			Administer slowly. Monitor pulse and blood pressure. May cause respiratory depression in presence of phenobarbital.	May need to be repeated every 3–4 h. Follow with phenytoin or phenobarbital for long-range control. Note: Intramuscular administration for status epilepticus ineffective.
Phenobarbital	5–20 mg/kg IV initially. Repeat dose: 5–10 mg/kg IV.			See above.	Rule out pyridoxine deficiency. In neonatal seizures, load with 15–20 mg/kg IV.
Phenytoin (Dilantin); (Fosphenytoin newer, safer)	10–20 mg/kg IV initially. Repeat dose: 5–10 mg/kg IV.			Administer IV over a 5-min period. Administer fosphenytoin IM only if no IV access. Monitor blood levels.	Adjunct in neonatal seizures (20 mg/kg IV) if phenobarbital alone fails. Fosphenytoin, new safe preparation. Same dose. May give rapidly IV, over 5 min.
Lorazepam (Ativan)	0.05–0.2 mg/kg IV. May repeat.			Mild respiratory depression.	May be more effective than diazepam. Longer-acting.
Midazolam (Versed)	0.1–0.3 mg/kg IM or IV; 0.2 mg/kg as nasal spray. IV drip 1–5++ µg/kg/min			See other benzodiazepines.	Short-acting.
Valproate sodium (Depacon)	5–60 mg/kg IV (20 mg/min). Depacon rapid injection form (see Table 23–9)			Administer slowly. Dizziness, nausea, and injection-site pain.	Half-life 16 h. Useful when child can't take valproate orally, or for status epilepticus

^aTreatment of infantile spasms: See text regarding use of corticotropin or corticosteroids. See also clonazepam or valproic acid, especially with recurrences. ADH = antidiuretic hormone; CBC = complete blood count; IM = intramuscularly; IV = intravenously; MHD = mono-hydroxy metabolite; LFT = liver function tests.

^bIn parentheses are shown the levels at which clinical toxicity becomes manifest in monotherapy.

^cGeneral anesthesia if other measures fail.

Changes in medications or dosages should not be made without the physician's knowledge. Unsupervised sudden withdrawal of anticonvulsant drugs may precipitate severe seizures or even status epilepticus. Anticonvulsants must be kept where they cannot be ingested by small children or suicidal patients.

4. Follow-up—Check the patient at intervals, depending on the underlying cause of the seizures, the degree of control, and the toxic properties of the anticonvulsant drug or drugs used. Blood counts and liver function tests must be obtained periodically in the case of some anticonvulsants, as indicated in Table 23–12. Pe-

riodic neurologic reevaluation is important. Repeat EEGs are not needed to achieve seizure control. Indications for repeat EEGs are discussed earlier.

5. Long-term management—Continue anticonvulsant treatment until the patient is free of seizures for at least 1–2 years or, in some cases, until the patient reaches adolescence. In about 75% of patients, seizures may not recur. Variables such as younger age at onset, normal EEG, and ease of controlling seizures carry a favorable prognosis, whereas later onset, epileptiform spikes on EEG, difficulty in controlling the seizures, polytherapy, generalized tonic-clonic or myoclonic

seizures, and an abnormal neurologic examination are associated with a higher risk of recurrence.

6. Withdrawal of treatment—In general, there is no need to withdraw anticonvulsants before taking an EEG. Discontinue anticonvulsants gradually. If it becomes necessary to withdraw anticonvulsants abruptly, the patient should be under close medical surveillance. If seizures recur during or after withdrawal, anticonvulsant therapy should be reinstated and again maintained for at least 1–2 years.

D. BLOOD LEVELS OF ANTIPILEPTIC DRUGS

1. General comments—Most anticonvulsants take two or three times the length of their half-life to reach the steady states indicated in Table 23–12. This must be considered when blood levels are assessed after anticonvulsants are started or dosages are changed. Individuals vary in their metabolism and their particular pharmacokinetic characteristics. These and external factors, including, for example, food intake or illness, also affect the blood level. Thus the level reached on a milligram per kilogram basis varies among patients. Experience and clinical research in the determination of antiepileptic blood levels have shown that there is some correlation between (1) drug dose and blood level, (2) blood level and therapeutic effect, and (3) blood level and some toxic effects.

2. Effective levels—The ranges given in Table 23–12 are those within which seizure control without toxicity will be achieved in most patients. The level for any given individual will vary not only with metabolic makeup (including biochemical defects) but also with the nature and severity of the seizures and their underlying cause, and with other medications being taken, among other factors. Seizure control may be achieved at lower levels in some patients, and higher levels may be reached without toxicity in others. When control is achieved at a lower level, the dosage should not be increased merely to get the level into the therapeutic range. Likewise, toxic side effects will be experienced at different levels even within the therapeutic range. Lowering the dosage usually resolves the problem, but sometimes the drug must be withdrawn or another added (or both). Some serious toxic effects, including allergic reactions and bone marrow or liver toxicity, are independent of dosage.

3. Interaction of antiepileptic drugs—Blood levels of anticonvulsants may be affected by other drugs. Individual variations occur; adjustment of dosages may be required. (See Table 23–12.)

4. Indications for determination of blood levels—Drug blood levels should be measured after a new drug is introduced and seizure control without toxicity is achieved to determine the effective level for that pa-

tient. Blood level monitoring is useful also when expected control on a “usual” dosage has not been achieved either with a single drug or after adding another, when seizures recur in a patient with previously well-controlled seizures, or when control is poor in a patient taking anticonvulsants who is being seen for the first time. A low level may indicate inadequate dosage, drug interaction, or noncompliance with the prescribed regimen. A high level may indicate slowed metabolism or excretion or drug interaction.

Blood levels are mandatory when signs and symptoms of toxicity are present, especially when more than one drug is being used or when the dosage of a single drug has been changed. Blood levels may be the only means of detecting intoxication in a comatose patient or very young child. Toxic levels also occur with drug abuse and liver or renal disease. Blood levels of anticonvulsants are unnecessary when the patient’s seizure control is satisfactory and he or she is free of toxic signs or symptoms.

E. SIDE EFFECTS OF ANTIPILEPTIC DRUGS

(See also Table 23–12.)

1. Allergic reactions—Serious allergic reactions usually necessitate discontinuance of a drug. However, not every rash in a child receiving an anticonvulsant is drug-related. If a useful antiepileptic drug is discontinued and the rash disappears, restarting the drug in a smaller dosage may be warranted to see if the rash recurs.

2. Drug toxicity—Signs of drug toxicity often disappear when the daily dosage is reduced by 25–30%.

3. Avoiding sedation—The sedative effect of many of the anticonvulsants may be avoided by slowly working up to the usual therapeutic dose—for example, over 3–4 weeks for phenobarbital.

4. Avoiding side effects—Gingival hyperplasia secondary to phenytoin is best minimized through good dental hygiene but occasionally requires gingivectomy. This condition may recede within about 6 months after the drug is discontinued. The hypertrichosis associated with phenytoin does not regress when the drug is discontinued.

F. ADRENOCORTICOTROPIC HORMONE AND CORTICOSTEROIDS

1. Indications—These drugs are indicated for infantile spasms not due to causes amenable to specific therapy and in the Lennox–Gastaut syndrome, which cannot be controlled by anticonvulsant drugs. Duration of therapy is guided by cessation of clinical seizures and normalization of the EEG. ACTH or oral corticosteroids are usually continued in full doses for 2 weeks and then, if seizures have ceased, tapered over 1 week. Oth-

ers use a total treatment period of about 2 months. If seizures recur, the dosage is increased to the last effective level and repeated for 2–4 weeks, or switching to or from prednisone is tried. Some clinicians keep the patient at this dosage for up to 6 months before attempting withdrawal. There is no strong evidence, however, that longer courses of treatment are more beneficial.

2. Dosages—

a. **ACTH gel**—Start with 2–4 units/kg/d intramuscularly in a single morning dose. Parents can be taught to give injections.

b. **Prednisone**—Start with 2–4 mg/kg/d orally in two or three divided doses.

3. **Precautions**—Give additional potassium, guard against infections, follow for possible hypertension, and discuss the cushingoid appearance and its disappearance. Do not withdraw oral corticosteroids suddenly. Side effects in some series occur in up to 40% of patients, especially with higher dosages than those listed here (used by some authorities). With long-term use, prophylaxis against *Pneumocystis* infection may be required.

G. KETOGENIC OR MEDIUM-CHAIN TRIGLYCERIDE

Diet in Treatment of Epilepsy

A ketogenic diet should be recommended in astatic and myoclonic seizures and absence seizures not responsive to drug therapy. It is occasionally recommended for infantile spasms that do not respond to ACTH or corticosteroids. Ketosis is induced by a diet high in fats and very limited in carbohydrates with sufficient protein for body maintenance and growth. The ratio of fat calories to carbohydrate calories may range from 2.5:1 up to 4:1. Adding medium-chain triglycerides to the diet induces ketosis more readily than does a high level of dietary fats and thus requires less carbohydrate restriction. The mechanism for the anticonvulsant action of the ketogenic diet is not understood. It is, however, the ketosis, not the acidosis, that raises the seizure threshold. The diet is most effective in children younger than age 8 years.

The ketogenic diet is difficult and expensive, tends to be monotonous, and depends on the caregiver's ability to weigh out the foods as well as on absolute adherence to the diet prescribed. Whether the ketosis is achieved by high-fat meals or by adding medium-chain triglycerides to the diet is often a matter of the physician's, the dietitian's, or the patient's preference. The result may also depend on which form of the diet is better tolerated. Full cooperation of all family members is required, including the patient if old enough. However, when seizure control is achieved by this method, the child is alert, he or she often needs no (or only small

amounts of) anticonvulsants, and parental and patient satisfaction is most gratifying.

H. SURGERY

In seizure disorders intractable to anticonvulsant therapy and primarily of focal origin, neurosurgery should be considered. Useful procedures, depending on the lesion, include corticectomy, hemispherectomy, anterior temporal lobectomy (for complex partial seizures), callosotomy (or commissurotomy), and stereotactic ablation. Vagal nerve stimulation with an implanted electrode is another new, expensive surgical approach for intractable epilepsy.

SYNCOPE & FAINTING

Fainting is transient loss of consciousness and postural tone due to cerebral ischemia or anoxia. Up to 20–50% of children (age birth–20 years) will faint at some time. There may be a prodrome of dizziness, lightheadedness, nausea, so-called gray-out, sweating, and pallor. After falling, many children stiffen or have jerking motions when unconscious, a tonic–clonic, anoxic–ischemic seizure mimicking epilepsy. Watching or undergoing a venipuncture is a common precipitant of fainting, as is prolonged standing, fatigue, illness, overheating and sweating, dehydration, hunger, and athleticism with slow baseline pulse. The family history is positive for similar episodes in 90% of patients.

Classification

Ninety-five percent of cases of syncope are of the vasovagal–vasodepressive or neurocardiogenic type (Table 23–13). Vasodilation, cardiac slowing, and hypotension

Table 23–13. Classification of syncope in childhood.

Vasovagal, neurocardiogenic (neurally mediated)

- Orthostatic
- Athleticism
- Pallid breath-holding
- Situational (stress, blood drawing)

Cardiac

- Obstructive
- Arrhythmia
- Prolonged QTc
- Hypercyanotic (eg, in tetralogy of Fallot)

Nonsyncope mimicker

- Migraine with confusion or stupor
- Seizure
- Hypoglycemia
- Hysteria
- Hyperventilation
- Vertigo

cause transient (1–2 minutes) cerebral ischemia and result in the patient passing out. The patient arouses in 1–2 minutes, but full recovery may take an hour or more. Besides those already listed, rare precipitants include hair grooming, cough, micturition, neck stretching, and emotional stress. More ominous is cardiac syncope, which often occurs during exercise. Angina or palpitations may occur. An obstructive lesion such as aortic stenosis, cardiomyopathy, coronary disease, or dysrhythmia may be the cause. Other spells that may mimic syncope are listed in Table 23–13.

Clinical Findings

A. SYMPTOMS AND SIGNS

The work-up of fainting includes the history and a physical examination with emphasis on blood pressure and cardiac and neurologic features. In the adolescent, a blood pressure drop of more than 30 mm Hg after standing for 5–10 minutes or a baseline systolic pressure of less than 80 mm Hg suggests orthostasis.

B. LABORATORY FINDINGS AND IMAGING

Hemoglobin should be checked if anemia is suggested by the history. Electrocardiography should be done. Consider Holter monitoring and echocardiography if cardiac causes seem likely. Tilt testing (though norms are vague) may have a role in frequent recurrent syncope to confirm a vasodepressive cause and avoid more expensive diagnostic investigations.

Treatment

Treatment consists mostly of giving advice about the benign nature of fainting and about avoiding precipi-

tating situations. The patient should be cautioned to lie down if prodromal symptoms occur. Good hydration and reasonable salt intake are advisable. In some cases β -blockers and rarely fludrocortisone may have a role.

HEADACHES

Headache is one of the most common complaints in pediatric neurology clinics, accounting for 25–30% of all referrals. Epidemiologic studies indicate that headache occurs in 37% of children by age 7 years and in 69% of children by age 14 years. Migraine headache occurs in 5% and 15%, respectively, of children at these ages. Successful treatment requires an accurate diagnosis and proper classification of headache. Based on the patient's history, a simplified initial categorization as summarized in Table 23–14 can be made. A more exhaustive classification scheme has been developed by the International Headache Society and modified for use in children. Muscle contraction, tension headaches are common in older children and adolescents. They are frequently generalized over the head with a "hat band" pressure or squeezing quality. Although appetite may be diminished, nausea and vomiting are usually not present. Symptoms specifically referable to the CNS are absent. If this type of headache becomes very frequent (3 or more days per week) consideration should be given to

Table 23–14. Differential features of headaches in children.

	Muscle Contraction (Tension/Psychogenic)	Vascular (Migraine)	Traction and Inflammatory (Increased Intracranial Pressure)
Time course	Chronic, recurrent	Acute, paroxysmal, recurrent	Chronic or intermittent but increasingly frequent; progressive severity
Prodromes	No	Yes (sometimes in children)	No
Description	Diffuse, band-like, tight	Intense, pulsatile, unilateral in older child (70%); usually forehead in or behind one or both eyes.	Diffuse; more occipital with infratentorial mass, more frontal with supratentorial mass
Characteristic findings	Feelings of inadequacy, depression, or anxiety	Neurologic symptoms and signs usually transient	Positive neurologic signs, especially papilledema
Predisposing factors	Problems at home or school or socially (sexually)	Positive family history (75%); trivial head trauma may precipitate	No

drug (analgesic) overuse or misuse, depression, or sleep disorder. The neurologic examination is normal, neuroimaging tests are generally not needed, and treatment is judicious use of ibuprofen with or without a limited trial of amitriptyline. If simple measures are not satisfactory, biofeedback may be useful.

Between 65% and 75% of children referred to neurology clinics for consultation regarding headaches have migraine. Many of these children are referred after they have seen ophthalmologists for “eye strain” or otolaryngologists to rule out sinusitis. Approximately 30% of children are referred after already undergoing one or more neuroimaging tests, the vast majority of which are normal.

Clinical Findings

The diagnosis and proper classification of migraine depends primarily on a thorough and detailed history (Table 23–15). Migraine headaches are paroxysmal, recurrent events separated by symptom-free intervals in a child with normal growth and development and whose neurologic examination is normal. Migraine affects children of all ages but is difficult to diagnose before age 4 years. The family history is positive for vascular, migrainous headaches in 75% of patients. The headaches have a pulsatile quality and are located unilaterally or bilaterally in the frontal or temporal regions, or commonly in the retro-orbital and cheek regions. The headaches last from 2 to more than 24 hours. A nonspecific prodrome of decreased or increased appetite and change in mood and temperament may precede the headache by hours or days. Headaches may be triggered by specific foods, minor head injuries, sleep deprivation, or irregular eating patterns, but more often no precipitant can be identified. An aura such as visual scotomata is uncommon in children. The headache is

frequently accompanied by nausea, vomiting, photophobia, sensitivity to sound, vertigo, lightheadedness, fatigue, and mood alterations. Occasionally children may have loss of speech, hemiparesis, ataxia, confusional states, and bizarre visual distortions (so-called Alice in Wonderland syndrome). Very young children may experience recurrent or cyclical vomiting, abdominal pain, or recurrent self-limited bouts of ataxia or vertigo as the early manifestations of migraine.

Occasionally the frequency of migraine may spontaneously increase and become almost daily, a condition referred to as transformed migraine. When this change in frequency happens, it should at least raise suspicion of medication overuse with development of rebound headache; successful treatment of which requires medication withdrawal for 6–12 weeks or longer.

In contrast to tension and migraine headaches, headaches caused by intracranial disorders or increased intracranial pressure rarely occur in children who are otherwise healthy and well and who have completely normal examinations.

Laboratory studies and neuroimaging tests are rarely needed if a thorough history has been taken and the neurologic examination is normal. If the progression of headache is atypical for migraine or tension-type headaches or if the neurologic examination is abnormal, an MRI scan should be considered. When papilledema is present but the MRI is normal, a lumbar puncture may be needed to diagnose pseudomotor cerebri.

Treatment

Successful treatment of migraine is usually achieved with the systematic use of simple analgesics such as ibuprofen. The key to successful results is to take enough early enough to do the job. As soon as possible

after the headache starts, the child is given ibuprofen 10 mg/kg followed in 45 minutes by 5 mg/kg if needed. Additional doses of analgesics rarely provide additional benefit. The addition of 40–65 mg of caffeine, caffeine-ergotamine combinations, or 65 mg of isometheptene (Midrin) to ibuprofen may provide more reliable relief for some patients. Nausea and vomiting can be treated with metoclopramide (Reglan), taken 10–20 minutes before other medications. For frequently recurring migraine, prophylaxis with propranolol, amitriptyline, cyproheptadine, valproate, or calcium channel blockers should be considered. At this time experience with using triptan and dihydroergotamine (nasal spray) in children is limited, but some studies show sumatriptan, rizatriptan, naratriptan, and dihydroergotamine to be effective. Biofeedback, relaxation therapy, and other nonpharmacologic approaches to managing headache may be useful in children, and they provide an alternative method of treatment that avoids medication-related side effects.

SLEEP DISORDERS

1. Sleep Apnea Syndrome in Older Children

Sleep apnea syndrome should be considered if there is a history of restless sleep with snoring or respiratory noise

during sleep and frequent awakenings in an older child who shows poor school performance associated with excessive daytime sleepiness or irritability and hyperactivity. Children with these problems frequently have hypertrophied tonsils or adenoids, causing partial airway obstruction. Sleep apnea may be associated with facial dysmorphism; neuromuscular disorders with poor pharyngeal muscle control; and conditions with swelling of soft tissue in pharynx and neck such as myxedema, Hodgkin disease, and massive obesity (Pickwickian syndrome). Evaluation includes soft tissue radiographs of the lateral neck; chest radiograph; electrocardiogram (ECG) to rule out cardiomegaly, sinus dysrhythmias, and right-sided heart failure; arterial blood gas determinations while awake and during sleep; and polysomnography. Therapy is generally surgical, ranging from tonsillectomy and adenoidectomy when appropriate, to tracheostomy when medical measures fail.

2. Narcolepsy

Narcolepsy, a primary disorder of sleep, is characterized by chronic, excessive daytime sleeping that occurs regardless of activity or surroundings and is not relieved by increased sleep at night. Onset occurs as early as age 3 years. Of children with narcolepsy, 18% are younger than age 10, and 60% are between puberty and their late teens. Narcolepsy usually interferes severely with normal living. Months to years after onset, there may also be cataplexy (transient partial or total loss of muscle tone, often triggered by laughter, anger, or other emotional upsurge), hypnagogic hallucinations (visual or auditory), and sensations of paralysis on falling asleep. Studies have shown that rapid eye movement (REM) sleep, with loss of muscle tone and an EEG low-amplitude mixed frequency pattern, occurs soon after sleep onset in patients with cataplexy, whereas normal subjects experience 80–100 minutes or longer of non-REM (NREM) sleep before the initial REM period.

Recent research suggests absence of a hypothalamic neuropeptide, hypocretin (from autoimmune injury?), causes narcolepsy and cataplexy. Spinal fluid (but not plasma) levels of hypocretin-1 (also called orexin) are diagnostic (level will be nil or zero).

Narcolepsy is treated with a CNS stimulant (dextroamphetamine or long-acting methylphenidate is preferred). Cataplexy responds to venlafaxine, fluoxetine, or clomipramine. Modafinil is a new effective treatment for excessive daytime sleepiness. The condition persists throughout life.

3. Somnambulism

Somnambulism is one of a group of sleep disturbances known as disorders of arousal. The onset is abrupt, usu-

ally early in the night. It is characterized by coordinated activity (eg, walking, sometimes moving objects without seeming purpose) in a state of veiled consciousness. The episode is relatively brief and ceases spontaneously. There is poor recall of the event on waking in the morning. Somnambulism may be related to mental activities occurring in stages 3 and 4 of NREM sleep. Incidence has been estimated at only 2–3%, but up to 15% of cases are reported in children age 6–16 years. Boys are affected more often than girls, and many have recurrent episodes. Psychopathologic features are rarely demonstrated, but a strong association (30%) between childhood migraine and somnambulism has been noted. Episodes of somnambulism may be triggered in predisposed children by stresses, including febrile illnesses. No treatment of somnambulism is required, and it is not necessary to seek psychiatric consultation.

4. Night Terrors

Night terrors (*pavor nocturnus*) are a disorder of arousal from NREM sleep. Most cases occur in children age 3–8 years, and the disorder rarely occurs after adolescence. It is characterized by sudden (but only partial) waking, with the severely frightened child unable to be fully roused or comforted. Concomitant autonomic symptoms include rapid breathing, tachycardia, and perspiring. The child has no recall of any nightmare. Psychopathologic mechanisms are unclear, but falling asleep after watching scenes of violence on television or hearing frightening stories may play a role. Elimination of such causes and administration of a mild antianxiety agent such as chlordiazepoxide may be helpful. It is important to differentiate these episodes from complex partial (psychomotor) seizures. (See also Chapter 2.)

PSUEDOTUMOR CEREBRI

Pseudotumor cerebri is characterized by increased intracranial pressure in the absence of an identifiable intracranial mass or hydrocephalus. Manifestations of pseudotumor cerebri are those of increased intracranial

Table 23–16. Signs of increased intracranial pressure.

Acute
Macrocephaly

Chronic
Macrocephaly
Growth impairment
Developmental delay
Optic atrophy
Visual field loss

pressure as outlined in Table 23–16. The cause is usually unknown, but pseudotumor cerebri has been described in association with a variety of inflammatory, metabolic, toxic, and connective tissue disorders (Table 23–17). The diagnosis of pseudotumor cerebri is one of exclusion. CT or MRI scans of the head are needed to exclude hydrocephalus and intracranial masses. These studies demonstrate ventricles of small or normal size but no other structural abnormalities. Venous thrombo-

sis, an underrecognized cause, must be ruled out by MRV (magnetic resonance venogram) or even injected venograms of cerebral sinuses. Lumbar puncture should be performed to document elevated CSF pressure. Examination of CSF reveals normal findings except for elevated pressure. In some inflammatory and connective tissue diseases, however, the CSF protein concentration may be increased.

Treatment of pseudotumor cerebri is aimed at correcting the identifiable predisposing condition. In addition, some patients may benefit from the use of furosemide or acetazolamide to decrease the volume and pressure of CSF within the CNS. These drugs may be used in combination with repeated lumbar punctures to remove CSF. If a program of repeated CSF removal and medical management is not successful or if central vision or visual field loss is detected despite these measures, lumboperitoneal shunt or another surgical decompression procedure may be necessary to prevent irreparable visual loss and damage to the optic nerves.

CEREBROVASCULAR DISEASE

Cerebrovascular disorders leading to vascular blockage, or stroke, occur with an age-related incidence in the pediatric population of approximately 28–93:100,000 per year in infancy and 1–8:100,000 per year in childhood. This excludes primary disorders involving vascular hemorrhage, whose incidence is greatest among premature infants. The initial approach to the patient should recognize that the timing of presentation represents a neurologic emergency, for which promptness in diagnosis can affect treatment considerations and outcome. Unfortunately, most pediatric stroke is not recognized until 24–36 hours after onset, when treatment considerations matter most. Following this, one should take into account the patient's age and any underlying systemic or neurologic illness. This should include a thorough history of prior illnesses, especially those associated with varicella (even in the prior 1–2 years), mycoplasma, human immunodeficiency virus (HIV), minor trauma to the head and neck, and familial clotting tendencies. A systematic search for evidence of car-

diac, vascular, or hematologic disease and intracranial disorders should be undertaken (Table 23–18). Though most strokes are not associated with underlying systemic disorders, previously diagnosed congenital heart disease followed by hematologic and neoplastic disorders are the most common predisposing to stroke. In many instances the origin is multifactorial, necessitating a thorough investigation even when the cause may seem obvious. As a result, the cause of childhood stroke is often determined whereas in past studies up to 30% remained idiopathic. This is particularly important when considering that recurrence risk may be as high as 35%.

Clinical Findings

A. SYMPTOMS AND SIGNS

Manifestations of stroke in childhood vary according to the vascular distribution to the brain structure that is involved. Because many conditions leading to childhood stroke result in emboli, multifocal neurologic involvement is common. Children may present with acute hemiplegia similar to stroke in adults. Symptoms of unilateral weakness, sensory disturbance, dysarthria, and dysphagia may develop over a period of minutes, but at times progressive worsening of symptoms may evolve over several hours. Bilateral hemispheric involvement may lead to a depressed level of consciousness. The patient may also demonstrate disturbances of mood and behavior and experience focal or multifocal seizures. Physical examination of the patient is aimed not only at identifying the specific deficits related to impaired cerebral blood flow but also at seeking evidence for any predisposing disorder. Retinal hemorrhages, splinter hemorrhages in the nail beds, cardiac murmurs, and signs of trauma are especially important findings.

B. LABORATORY FINDINGS

In the acute phase, certain investigations should be carried out emergently with consideration of treatment options. This should include complete blood count, erythrocyte sedimentation rate, basic chemistries, blood urea nitrogen, creatinine, prothrombin time/partial thromboplastin time, chest radiograph, ECG, urine toxicology, and imaging (see following section). Subsequent studies can be carried out systematically, with particular attention to disorders involving the heart, blood vessels, platelets, red cells, hemoglobin, and coagulation proteins. Additional laboratory tests for systemic disorders such as systemic lupus erythematosus and polyarteritis nodosa are usually indicated. Neonatal infarctions require pathological examination of the placenta.

Examination of CSF is indicated in patients with fever, nuchal rigidity, or obtundation when the diagnosis of intracranial infection requires exclusion. Lumbar

puncture, however, may be deferred until a neuroimaging scan excluding brain abscess or a space-occupying lesion that might contraindicate lumbar puncture has been obtained. In the absence of infection and frank intracranial subarachnoid hemorrhage, CSF examination is rarely helpful in defining the cause of the cerebrovascular disorder.

C. IMAGING

CT and MRI scans of the brain are often helpful in defining the extent of cerebral involvement with ischemia or hemorrhage. CT scans, however, may be normal within the first 12–24 hours of an ischemic stroke and may need to be repeated several hours later. A CT scan early after the onset of neurologic deficits is valuable in excluding intracranial hemorrhage. This information may be helpful in the early stages of management and in the decision to treat with anticoagulants. State-of-the-art management of stroke in the adult population omits CT scanning but proceeds directly to urgent MRI, magnetic resonance angiography (MRA), and diffusion weighted imaging since these modalities are sensitive to acute stroke in the initial 3 hours when intravenous thrombolytics might be indicated. In consideration of venous occlusion either CT scan with contrast or MRV is indicated.

Except in cases where trauma resulting in arterial dissection is suspected, cerebral angiography (CA) is usually not urgently needed but may be needed to confirm disorders such as fibromuscular dysplasia and cerebral arteritis. If CA is done, all major vessels should be studied from the aortic arch. If evidence of fibromuscular dysplasia is present in the intracranial or extracranial vessels, renal arteriography is indicated. In studies where both MRA or CA have been used, nearly 80% of patients with ischemic stroke demonstrated a cerebrovascular abnormality.

When seizures are prominent, an EEG may be used as an adjunct in the patient's evaluation. An EEG and sequential EEG monitoring may help in patients with severely depressed consciousness.

ECG and echocardiography are useful both in the diagnostic approach to the patient and in ongoing monitoring and management, particularly when hypotension or cardiac arrhythmias complicate the clinical course.

Differential Diagnosis

Patients with an acute onset of neurologic deficits must be evaluated for other disorders that can cause focal neurologic deficits. Hypoglycemia, prolonged focal seizures, a prolonged postictal paresis (Todd paralysis), meningitis, encephalitis, and brain abscess should all be considered. Migraine with focal neurologic deficits may

be difficult to differentiate initially from ischemic stroke. Occasionally the onset of a neurodegenerative disorder (eg, adrenoleukodystrophy or mitochondrial disorder) may begin with the abrupt onset of seizures and focal neurologic deficits. The possibility of drug abuse (particularly cocaine) and other toxic exposures must be investigated diligently.

Treatment

The initial management of stroke in a child is aimed at providing support for pulmonary, cardiovascular, and renal function. Appropriate fluid and electrolyte infusions should be started, and careful monitoring of heart rate and rhythm and blood pressure is required. Typically, maintenance fluids without added glucose are indicated to augment vascular volume. Specific treatment of stroke depends partly on the underlying pathogenesis and the specific predisposing disorder. Generally, aspirin 1–2 mg/kg daily is indicated to begin as soon as diagnosis is made. As clinical trials progress, aspirin use appears safe and has not been associated with Reye syndrome. In some situations, emergent heparinization for arterial dissection, emboli, and consumptive coagulopathies is indicated. In adults with cerebrovascular thrombosis, thrombolytic agents (tissue plasminogen activator) used systemically or delivered directly to a vascular thrombotic lesion using interventional radiologic techniques has been shown to improve outcome; although case reports exist, studies in children have not been completed. Exchange transfusion is indicated in cases of sickle cell disease.

Long-term management requires intensive rehabilitation efforts and therapy aimed at improving the child's language, educational, and psychologic performance. Length of treatment with various agents is still being studied and depends on etiology.

Prognosis

The outcome of stroke in infants and children is variable. Roughly, 40% may have minimal deficits, 30% are moderately affected, and 30% are severely affected. Underlying predisposing conditions and the vascular territory involved all play a role in dictating the outcome for an individual patient. When the stroke involves extremely large portions of one hemisphere or large portions of both hemispheres and cerebral edema develops, the patient's level of consciousness may deteriorate rapidly, and death may occur within the first few days. Some patients may achieve almost complete recovery of neurologic function within several days if the cerebral territory is small. Seizures, either focal or generalized, may occur in 30–50% of patients at some point in the course of their cerebrovascular disorder.

Chronic problems with learning, behavior, and activity are common.

CONGENITAL MALFORMATIONS OF THE NERVOUS SYSTEM

Malformations of the nervous system occur in 1–3% of living neonates and are present in 40% of infants who die. Developmental anomalies of the CNS may result from a variety of causes, including infectious, toxic, metabolic, and vascular insults that affect the fetus. The specific type of malformation that results from such insults, however, may depend more on the gestational period during which the insult occurs than on the specific cause. The period of induction, days 0–28 of gestation, is the period during which the neural plate appears and the neural tube forms and closes. Insults during this phase can result in a major absence of neural structures, such as anencephaly, or in a defect of neural tube closure, such as spina bifida, meningomyelocele, or encephalocele. Cellular proliferation and migration characterize neural development that occurs after 28 days' gestation. Lissencephaly, pachygyria, agyria, and agenesis of the corpus callosum may be the result of disruptions (genetic, toxic, infectious, or metabolic) that can occur during the period of cellular proliferation and migration.

1. Abnormalities of Neural Tube Closure

Defects of neural tube closure constitute some of the most common congenital malformations affecting the

nervous system. Spina bifida with associated meningocele or meningocele is commonly found in the lumbar region. Depending on the extent and severity of the involvement of the spinal cord and peripheral nerves, lower extremity weakness, bowel and bladder dysfunction, and hip dislocation may be present. Delivery via cesarean section followed by early surgical closure of meningoceles and meningocele is usually indicated. Additional treatment is necessary to manage chronic abnormalities of the urinary tract, orthopedic abnormalities such as kyphosis and scoliosis, and paresis of the lower extremities. Hydrocephalus associated with meningocele usually requires ventriculoperitoneal shunting.

Arnold–Chiari Malformations

Arnold–Chiari malformation type I consists of elongation and displacement of the caudal end of the brainstem into the spinal canal with protrusion of the cerebellar tonsils through the foramen magnum. In association with this hindbrain malformation, minor to moderate abnormalities of the base of the skull often occur, including basilar impression (platybasia) and small foramen magnum. Arnold–Chiari malformation type I may remain asymptomatic for years, but in older children and young adults it may cause progressive ataxia, paresis of the lower cranial nerves, and progressive vertigo. Posterior cervical laminectomy may be necessary to provide relief from cervical cord compression. Ventriculoperitoneal shunting is required for hydrocephalus.

Arnold–Chiari malformation type II consists of the malformations found in Arnold–Chiari type I plus an associated lumbar meningocele. Hydrocephalus develops in approximately 90% of children with Arnold–Chiari malformation type II. These patients may also have aqueductal stenosis, hydromyelia or syringomyelia, and cortical dysplasias. The clinical manifestations of Arnold–Chiari malformation type II are most commonly caused by the associated hydrocephalus and meningocele. In addition, dysfunction of the lower cranial nerves may be present. Up to 25% may have epilepsy, likely secondary to the cortical dysplasias. With the advent of “aggressive-selective” therapy, mortality is 14%; of survivors 74% are ambulatory and 73% have a normal IQ.

Arnold–Chiari malformation type III is characterized by occipital encephalocele, a closure defect of the rostral end of the neural tube. Hydrocephalus is extremely common with this malformation.

In general, the diagnosis of neural tube defects is obvious at the time of birth. Diagnosis may be strongly suspected prenatally on the basis of ultrasonographic findings and the presence of elevated α -fetoprotein in

the amniotic fluid. All women of childbearing age should take prophylactic folate, which can prevent these defects and decrease the risk of recurrence by 70%.

2. Disorders of Cellular Proliferation and Migration

Lissencephaly

Lissencephaly is a severe malformation of the brain characterized by an extremely smooth cortical surface with minimal sulcal and gyral development. Such a smooth surface is characteristic of fetal brain at the end of the first trimester. In addition, lissencephalic brains have a primitive cytoarchitectural construction with a four-layered cerebral mantle instead of the mature six-layered mantle. Pachygyria (thick gyri) and agyria (absence of gyri) may vary in an anterior to posterior gradient, which can be suggestive of the underlying genetic defect. Patients with lissencephaly usually have severe neurodevelopmental delay, microcephaly, and seizures (including infantile spasms); however, there is significant phenotypic heterogeneity, which can depend on the specific mutation. These disorders are autosomal recessive, except for the X-linked disorders. *LIS1* mutations on chromosome 17 are associated with dysmorphic features (Miller–Dieker syndrome). X-linked syndromes involving mutations in *DCX* (double cortin) and *ARX* (associated with ambiguous genitalia) affect males with lissencephaly and females with band heterotopias or agenesis of the corpus callosum. Lissencephaly in association with hydrocephalus, cerebellar malformations, and muscular dystrophy may occur in Walker–Warburg syndrome (*POMT1* mutation), Fukuyama muscular dystrophy (*fukutin* mutation), and muscle–eye–brain disease (*POMGnT1* mutation). It is particularly important to identify these syndromes not only because clinical tests are available but also because of their genetic implications. Lissencephaly may also be a component of Zellweger syndrome, a metabolic peroxisomal abnormality associated with the presence of elevated concentrations of very long-chain fatty acids in plasma. No specific treatment for lissencephaly is available and seizures are often difficult to control with standard medications.

MRI scans have helped to define a number of presumed migrational defects that are similar to but anatomically more restricted than lissencephaly. A distinctive example is bilateral perisylvian cortical dysplasia. Patients with this disorder have pseudobulbar palsy, variable cognitive deficits, facial diplegia, dysarthria, developmental delay, and epilepsy. Seizures are often difficult to control with antiepileptic drugs; some patients have benefited from corpus callosotomy. The cause of

this syndrome is as yet unknown, though intrauterine cerebral ischemic injury has been postulated. Therapy is aimed at improving speech and oromotor functions and controlling seizures.

Agensis of the Corpus Callosum

Agensis of the corpus callosum, once thought to be a rare cerebral malformation, is more frequently diagnosed with modern neuroimaging techniques. The cause of this malformation is unknown. Occasionally it appears to be inherited in either an autosomal dominant or recessive pattern. X-linked recessive patterns have also been described (*ARX* as mentioned earlier). Agensis of the corpus callosum has been found in some patients with pyruvate dehydrogenase deficiency and in others with nonketotic hyperglycinemia. Most cases are sporadic. Maldevelopment of the corpus callosum may be partial or complete. No specific syndrome is typical of agensis of the corpus callosum, although many patients have seizures, developmental delay, microcephaly, or mental retardation. Neurologic abnormalities may be related to microscopic cytoarchitectural abnormalities of the brain that occur in association with agensis of the corpus callosum. The malformation may be found coincidentally by neuroimaging studies in otherwise normal patients and has been described as a coincidental finding at autopsy in neurologically normal individuals. A special form of agensis of the corpus callosum occurs in Aicardi syndrome. In this X-linked disorder, agensis of the corpus callosum is associated with other cystic intracerebral abnormalities, infantile spasms, mental retardation, lacunar chorioretinopathy, and vertebral body abnormalities.

Dandy–Walker Malformation

Despite being described nearly a century ago, the exact definition of the Dandy–Walker malformation is in debate. Classically, it is characterized by aplasia of the vermis, cystic enlargement of the fourth ventricle, rostral displacement of the tentorium, and absence or atresia of the foramina of Magendie and Luschka. Although hydrocephalus is usually not present congenitally, it develops within the first few months of life. Ninety percent of patients who develop hydrocephalus do so by age 1 year. “Variants” have cerebellar hypoplasia without dilatation of the fourth ventricle and hydrocephalus and may suggest other subtle cortical abnormalities not classically present and could be confused with other disorders such as Joubert syndrome and its variants. On physical examination, a rounded protuberance or exaggeration of the cranial occiput often exists. In the absence of hydrocephalus and increased intracranial pressure, few physical findings may be present to suggest

neurologic dysfunction. An ataxic syndrome occurs in fewer than 20% of patients and is usually late in appearing. Many long-term neurologic deficits result directly from hydrocephalus. Diagnosis of Dandy–Walker malformation is confirmed by CT or MRI scanning of the head. Treatment is directed at the management of hydrocephalus.

3. Craniosynostosis

Craniosynostosis, or premature closure of cranial sutures, is usually sporadic and idiopathic. However, some patients have hereditary disorders, such as Apert syndrome and Crouzon disease, that are associated with abnormalities of the digits, extremities, and heart. Occasionally craniosynostosis may be associated with an underlying metabolic disturbance such as hyperthyroidism and hypophosphatasia. The most common form of craniosynostosis involves the sagittal suture and results in scaphocephaly, an elongation of the head in the anterior to posterior direction. Premature closure of the coronal sutures causes brachycephaly, an increase in cranial growth from left to right. Unless many or all cranial sutures close prematurely, intracranial volume will not be compromised, and the brain’s growth will not be impaired. Closure of only one or a few sutures will not cause impaired brain growth or neurologic dysfunction. Management of craniosynostosis is directed at preserving normal skull shape and consists of excising the fused suture and applying material to the edge of the craniectomy to prevent reossification of the bone edges. The best cosmetic effect on the skull is achieved when surgery is done during the first 6 months of life.

4. Hydrocephalus

Hydrocephalus is characterized by an increased volume of CSF in association with progressive ventricular dilation. In communicating hydrocephalus, CSF circulates through the ventricular system and into the subarachnoid space without obstruction. In noncommunicating hydrocephalus, an obstruction blocks the flow of CSF within the ventricular system or blocks the egress of CSF from the ventricular system into the subarachnoid space. A wide variety of disorders, such as hemorrhage, infection, tumors, and congenital malformations, may play a causal role in the development of hydrocephalus. Attention to an X-linked inheritance pattern, the presence of radialized thumbs and aqueductal stenosis, is suggestive of X-linked hydrocephalus due to the clinically testable neural cell adhesion molecule (NCAM)–L1 deficiency.

Clinical features of hydrocephalus include macrocephaly, an excessive rate of head growth, irritability, vomiting, loss of appetite, impaired upgaze, impaired

extraocular movements, hypertonia of the lower extremities, and generalized hyperreflexia. Without treatment, optic atrophy may occur. In infants, papilledema may not be present, whereas older children with closed cranial sutures can eventually develop swelling of the optic disk. Hydrocephalus can be diagnosed on the basis of the clinical course, findings on physical examination, and CT or MRI scan.

Treatment of hydrocephalus is directed at providing an alternative outlet for CSF from the intracranial compartment. The most common method is ventriculoperitoneal shunting. Other treatment should be directed, if possible, at the underlying cause of the hydrocephalus. For genetic testing, see www.genetests.org

ABNORMAL HEAD SIZE

Bone plates of the skull have almost no intrinsic capacity to enlarge or grow. Unlike long bones, they depend on extrinsic forces to stimulate new bone formation at the suture lines. Although gravity and traction on bone by muscle and scalp probably stimulate some growth, the single most important stimulus for head growth during infancy and childhood is brain growth. Therefore, accurate assessment of head growth is one of the most important aspects of the neurologic examination of young children. A head circumference that is 2 SD above or below the mean for age requires investigation and explanation.

1. Microcephaly

A head circumference more than 2 SD below the mean for age and sex is by definition microcephaly. More important, however, than a single head circumference measurement is the rate or pattern of head growth through time. Head circumference measurements that progressively drop to lower percentiles with increasing age are indicative of a process or condition that has im-

paired the brain's capacity to grow. The causes of microcephaly are numerous. Some examples are listed in Table 23–19.

Clinical Findings

A. SYMPTOMS AND SIGNS

Microcephaly may be suspected in the full-term newborn and in infants up to age 6 months whose chest circumference exceeds the head circumference (unless the child is very obese). Microcephaly may be discovered when the child is examined because of delayed developmental milestones or neurologic problems, such as seizures or spasticity. There may be a marked backward slope of the forehead (as in familial microcephaly) with narrowing of the bitemporal diameter. The fontanelle may close earlier than expected, and sutures may be prominent.

B. LABORATORY FINDINGS

Laboratory findings vary with the cause. Abnormal dermatoglyphics may be present when the injury occurred

Table 23–19. Microcephaly.

Causes	Examples
Chromosomal	Trisomy 13, 18, 21
Malformation	Lissencephaly, schizencephaly
Syndromes	Rubenstein–Taybi, Cornelia de Lange
Toxins	Alcohol, anticonvulsants (?), maternal phenylketonuria
Infections (intrauterine)	TORCHES ^a
Radiation	Maternal pelvis, first and second trimester
Placental insufficiency	Toxemia, infection
Familial	Autosomal-dominant, autosomal-recessive
Perinatal hypoxia, trauma	Birth asphyxia, injury
Infections (perinatal)	Bacterial meningitis (especially group B streptococci) Viral encephalitis (enterovirus herpes simplex)
Metabolic	Hypoglycemia, phenylketonuria, maple syrup urine disease
Degenerative disease	Tay–Sachs, Krabbe

^aTORCHES is a mnemonic formula for toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and syphilis.

before 19 weeks' gestation. In the newborn, IgM antibody titers for toxoplasmosis, rubella, CMV, herpes simplex virus, and syphilis must be assessed. Elevated specific IgM titer is indicative of congenital infection. The urine culture for CMV will be positive at birth when this virus is the cause of microcephaly. Eye, cardiac, and bone abnormalities may also be clues to congenital infection. The child's serum and urine amino and organic acid determinations are occasionally diagnostic. The mother may require screening for phenylketonuria. Karyotyping, including for fragile X syndrome, should be considered.

C. IMAGING

CT or MRI scans may aid in diagnosis and prognosis. These studies may demonstrate calcifications, malformations, or atrophic patterns that suggest specific congenital infections or genetic syndromes. Plain skull radiographs may show closed sutures, but these studies are of limited value in diagnosis and have been replaced by more sensitive and more informative scanning procedures. Genetic counseling should be offered to the family of any infant with significant microcephaly.

Differential Diagnosis

Congenital craniosynostosis involving multiple sutures is easily differentiated by inspection of the head, history, identification of syndromes, hereditary pattern, and sometimes signs and symptoms of increased intracranial pressure. Common forms of craniosynostosis involving sagittal, coronal, and lambdoidal sutures are associated with abnormally shaped heads but do not cause microcephaly. Recognizing treatable causes of undergrowth of the brain such as hypopituitarism, hypothyroidism, and severe protein-calorie undernutrition is critical so that therapy can be initiated as early as possible.

Treatment & Prognosis

Except for the treatable disorders already noted, treatment is usually supportive and directed at the multiple neurologic and sensory deficits, endocrine disturbances (eg, diabetes insipidus), and seizures. Many children but not all with microcephaly who are developmentally delayed, with head circumferences more than 2 SD below the mean, show variable degrees of mental retardation. The notable exceptions are found in cases of hypopituitarism (rare) or familial autosomal dominant microcephaly.

Mochida GH, Walsh CA: Molecular genetics of human microcephaly. *Curr Opin Neurol* 2001;14:151 [PMID: 11262728].

Vargas JE et al: Congenital microcephaly: Phenotypic features in a consecutive sample of newborn infants. *J Pediatr* 2001;139:210 [PMID: 11487745].

Waternberg N et al: Significance of microcephaly among children with developmental disabilities. *J Child Neurol* 2002;17:117 [PMID: 11952071].

2. Macrocephaly

A head circumference more than 2 SD above the mean for age and sex denotes macrocephaly. Excessive head growth rate through time suggests increased intracranial pressure most likely caused by hydrocephalus, extra-axial fluid collections, or neoplasms. Macrocephaly with normal head growth rate suggests familial macrocephaly or true megalencephaly, as might occur in neurofibromatosis. Other causes and examples of macrocephaly are listed in Table 23–20.

Table 23–20. Macrocephaly.

Causes	Examples
Pseudomacrocephaly, pseudohydrocephalus, catch-up growth crossing percentiles	Growing premature infant; recovery from malnutrition, congenital heart disease, postsurgical correction
Increased intracranial pressure With dilated ventricles With other mass	Progressive hydrocephalus, subdural effusion Arachnoid cyst, porencephalic cyst, brain tumor
Benign familial macrocephaly (idiopathic external hydrocephalus)	External hydrocephalus, benign enlargement of the subarachnoid spaces, benign subdural collections of infancy (synonyms)
Megalencephaly (large brain) With neurocutaneous disorder With gigantism With dwarfism Metabolic Lysosomal Other leukodystrophy	Neurofibromatosis, tuberous sclerosis, etc Sotos' syndrome Achondroplasia Mucopolysaccharidoses Metachromatic leukodystrophy Canavan spongy degeneration
Thickened skull	Fibrous dysplasia (bone), hemolytic anemia (marrow), sicklemlia, thalassemia

Clinical Findings

Clinical and laboratory findings vary with the underlying process. In infants, transillumination of the skull with an intensely bright light in a completely darkened room may disclose subdural effusions, hydrocephalus, hydranencephaly, and cystic defects. A surgically or medically treatable condition must be ruled out. Thus the first decision is whether and when to perform an imaging study.

A. IMAGING STUDY DEFERRED

1. Catch-up growth—Catch-up growth may be evident, as it is in the thriving, neurologically intact premature infant whose rapid head enlargement is most marked in the first weeks of life, or the infant in the early phase of recovery from deprivation dwarfism. As the expected “normal” is reached, head growth slows and then resumes a normal growth pattern. If the fontanelle is open, cranial ultrasonography can assess ventricular size and diagnose or exclude hydrocephalus.

2. Familial macrocephaly—This condition may exist when another family member has an unusually large head with no signs or symptoms referable to such disorders as neurocutaneous dysplasias (especially neurofibromatosis) or cerebral gigantism (Sotos syndrome), or when there is no significant mental or neurologic abnormalities in the child.

B. IMAGING STUDY

CT or MRI scans (or ultrasonography, if the anterior fontanelle is open) are used to define any structural cause of macrocephaly and to identify an operable disorder. Even when the condition is untreatable (or does not require treatment), the information gained may permit more accurate diagnosis and prognosis, guide management and genetic counseling, and serve as a basis for comparison should future abnormal cranial growth or neurologic changes necessitate a repeat study. An imaging study is necessary if signs or symptoms of increased intracranial pressure are present (see Table 23–15).

NEURO CUTANEOUS DYSPLASIAS

Neurocutaneous dysplasias are diseases of the neuroectoderm and sometimes involve endoderm and meso-

derm. Birthmarks and skin growths appearing later often suggest a need to look for brain, spinal cord, and eye disease. Hamartomas (histologically normal tissue growing abnormally rapidly or in aberrant sites) are common. The most common dysplasias are dominantly inherited. Benign and even malignant tumors may develop.

Kandt RS: Tuberous sclerosis complex and neurofibromatosis type 1: The two most common neurocutaneous diseases. *Neurol Clin* 2002;20:941 [PMID: 12616676].

1. Neurofibromatosis (von Recklinghausen Disease)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- More than six café au lait spots 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals.
- Two or more neurofibromas of any type or one plexiform neurofibroma.
- Freckling in the axillary or inguinal regions.
- Optic glioma.
- Two or more Lisch nodules (iris hamartomas).
- Distinctive osseous lesions, such as sphenoid dysplasia or thinning of long bone with or without pseudarthroses.
- First-degree relative (parent, sibling, offspring) with neurofibromatosis type 1 by above criteria.

General Considerations

Neurofibromatosis is a multisystem disorder with a prevalence of 1:4000. Fifty percent of cases are due to new mutations in the NF1 gene. Forty percent of patients will develop medical complications of the disorder in their lifetime.

Clinical Findings

A. SYMPTOMS AND SIGNS

The most common presenting symptoms are cognitive or psychomotor problems; 40% of patients have learning disabilities, and mental retardation occurs in 8%.

The family history is important in identifying dominant gene manifestations in parents. Parents should be examined in detail. The history should focus on lumps or masses causing disfigurement, functional problems, or pain. The clinician should ask about visual problems. Strabismus or amblyopia dictates a search for optic glioma, a common tumor in neurofibromatosis. Any progressive neurologic deficit calls for studies to rule out tumor of the spinal cord or CNS. Tumors of cranial nerve VIII virtually never occur in neurofibromatosis type 1 but are the rule in neurofibromatosis type 2, a rare autosomal dominant disease.

The physician should check blood pressure and examine the spine for scoliosis and the limbs for pseudarthroses. Head measurement often shows macrocephaly. Hearing and vision need to be assessed. The eye examination should include a check for proptosis and iris Lisch nodules. The optic disk should be examined for atrophy or papilledema. Short stature and precocious puberty are occasional findings. An examination for neurologic manifestations of tumors (eg, asymmetrical reflexes, spasticity) is important.

B. LABORATORY FINDINGS

Laboratory tests are not likely to be of value in asymptomatic patients. Selected patients require brain MRI or CT scans with special cuts through the optic nerves to rule out optic glioma. Hypertension necessitates evaluation of renal arteries for dysplasia and stenosis. Cognitive and school achievement testing may be indicated. Scoliosis or limb abnormalities should be studied by appropriate roentgenograms such as an MRI scan of the spinal cord and roots.

Differential Diagnosis

Patients with Albright syndrome often have larger café au lait spots with precocious puberty. One or two café au lait spots are often seen in normal children.

Treatment

Genetic counseling is important. The risk to siblings is up to 50%. The disease may be progressive, with serious complications occasionally seen. Patients sometimes worsen during puberty or pregnancy. Genetic screening of family members is required. Annual or semiannual visits are important in the early detection of school problems or bony or neurologic abnormalities.

Multidisciplinary clinics at medical centers around the United States are excellent resources. Prenatal diagnosis is probably on the horizon, but the variability of manifestations (trivial to severe) will make therapeutic abortion an unlikely option. Chromosomal linkage studies are under way (chromosome 17q11.2). Infor-

mation for laypeople and physicians is available from the National Neurofibromatosis Foundation, Inc., 70 West 40th Street, New York, NY 10018.

Vivarelli R et al: Epilepsy in neurofibromatosis 1. *J Child Neurol* 2003;18:338 [PMID: 12822818].

2. Tuberous Sclerosis (Bourneville Disease)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Facial angiofibromas or subungual fibromas.
- Often hypomelanotic macules, gingival fibromas.
- Retinal hamartomas.
- Cortical tubers or subependymal glial nodules, often calcified.
- Renal angiomyolipomas.

General Considerations

Tuberous sclerosis is a dominantly inherited disease. Almost all patients have deletions on chromosome 9 (*TSC1* gene) or 16 (*TSC2* gene). The gene products hamartin and tuberlin have tumor-suppressing effects. A triad of seizures, mental retardation, and adenoma sebaceum occurs in only 33% of patients. The disease was earlier thought to have a high rate of mutation. As a result of more sophisticated techniques such as MRI, parents formerly thought not to harbor the gene are now being diagnosed as asymptomatic carriers.

Like neurofibromatosis, tuberous sclerosis is associated with a wide variety of symptoms. The patient may be asymptomatic except for skin findings or may be devastated by severe infantile spasms in early infancy, by continuing epilepsy, and by mental retardation.

Seizures in early infancy correlate with later mental retardation.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Dermatologic features—Skin findings bring most patients to the physician's attention. Ninety-six percent of patients have one or more hypomelanotic macules, facial angiofibromas, ungual fibromas, or shagreen patches. Adenoma sebaceum, the facial skin hamartomas, may first appear in early childhood, often on the cheek, chin, and dry sites of the skin where acne is not usually seen. They often have a reddish hue. The off-white hypomelanotic macules are seen more easily in tanned or dark-skinned individuals than in those with lighter skin. The macules often are oval or "ash leaf" in shape and follow dermatomes. A Wood lamp (ultraviolet light) shows the macules more clearly, a great help in the light-skinned patient. In the scalp, poliosis (whitened hair) is the equivalent. In infancy, the presence of these macules accompanied by seizures is virtually diagnostic of the disease. Subungual or periungual fibromas are more common in the toes. Leathery, orange peel-like shagreen patches support the diagnosis. Café au lait spots are occasionally seen. Fibrous or raised plaques may resemble coalescent angiofibromas.

2. Neurologic features—Seizures are the most common presenting symptom. Five percent of patients with infantile spasms (a serious epileptic syndrome) have tuberous sclerosis. Thus any patient presenting with infantile spasms (and the parents as well) should be evaluated for this disorder. An imaging study of the CNS, such as a CT scan, may show calcified subependymal nodules; MRI may show dysmyelinating white matter lesions or cortical tubers. Virtually any kind of symptomatic seizure (eg, atypical absence, partial complex, and generalized tonic-clonic seizures) may occur.

3. Mental retardation—Mental retardation occurs in up to 50% of patients referred to tertiary care centers; the incidence is probably much lower in randomly selected patients. Patients with seizures are more prone to mental retardation or learning disabilities.

4. Renal lesions—Renal cysts or angiomyolipomas may be asymptomatic. Hematuria or obstruction of urine flow sometimes occurs; the latter requires operation. Ultrasonography of the kidneys should be done in any patient suspected of tuberous sclerosis, both to aid in diagnosis if lesions are found and to rule out renal obstructive disease.

5. Cardiopulmonary involvement—Rarely cystic lung disease may occur. Rhabdomyomas of the heart may be asymptomatic but can lead to outflow obstruction,

conduction difficulties, and death. Chest radiographs and echocardiograms can detect these rare manifestations. Cardiac rhabdomyoma may be detected on prenatal ultrasound examination.

6. Eye involvement—Retinal hamartomas are often near the disk.

7. Skeletal involvement—Findings sometimes helpful in diagnosis are cystic rarefactions of the bones of the fingers or toes.

B. DIAGNOSTIC STUDIES

Plain radiographs may detect areas of thickening within the skull, spine, and pelvis, and cystic lesions in the hands and feet. Chest radiographs may show lung honeycombing. More helpful is CT scanning, which can show the virtually pathognomonic subependymal nodular calcifications and sometimes widened gyri or tubers and brain tumors. Contrast material may show the often classically located tumors near the foramen interventriculare. Hypomyelinated lesions may be seen with MRI. EEG is helpful in delineating the presence of seizure discharges.

Treatment

Therapy is as indicated by underlying disease (eg, seizures and tumors of the brain, kidney, and heart). Skin lesions on the face may need dermabrasion or laser treatment. Genetic counseling emphasizes identification of the carrier. The risk of appearance in offspring if either parent is a carrier is 50%. The patient should be seen annually for counseling and reexamination in childhood. Identification of the chromosomes (9,16; *TSC1* and *TSC2* genes) may in the future make intrauterine diagnosis possible.

3. Encephalofacial Angiomatosis (Sturge-Weber Disease)

Sturge-Weber disease consists of a facial port wine nevus involving the upper part of the face (in the first

division of cranial nerve V), a venous angioma of the meninges in the occipitoparietal regions, and choroidal angioma. The syndrome has been described without the facial nevus.

Clinical Findings

In infancy, the eye may show congenital glaucoma, or buphthalmos, with a cloudy, enlarged cornea. In early stages, the facial nevus may be the only indication, with no findings in the brain even on radiologic studies. The characteristic cortical atrophy, calcifications of the cortex, and meningeal angiomatosis may appear with time, solidifying the diagnosis.

Physical examination may show focal seizures or hemiparesis on the side opposite the cerebral lesion. The facial nevus may be much more extensive than the first division of cranial nerve V; it can involve the lower face, mouth, lip, neck, and even torso. Hemiatrophy of the opposite limbs may occur. Mental handicap may result from poorly controlled seizures. Late-appearing glaucoma and, rarely, CNS hemorrhage occur.

Radiologic studies may show calcification of the cortex; CT scanning may show this much earlier than plain radiographic studies. MRI often shows underlying brain involvement.

The EEG often shows depression of voltage over the involved area in early stages; later, epileptiform abnormalities may be present focally.

Treatment

Sturge–Weber disease is sporadic. Early control of seizures is important to avoid consequent developmental setback. If seizures do not occur, normal development can be anticipated. Careful examination of the newborn, with ophthalmologic assessment to detect early glaucoma, is indicated. Rarely, surgical removal of the involved meninges and the involved portion of the brain may be indicated, even hemispherectomy.

4. Von Hippel–Lindau Disease (Retinocerebellar Angiomatosis)

Von Hippel–Lindau disease is a rare, dominantly inherited condition with retinal and cerebellar hemangioblastomas; cysts of the kidneys, pancreas, and epididymis; and sometimes renal cancers. The patient may present with ataxia, slurred speech, and nystagmus due to a hemangioblastoma of the cerebellum or with a medullary spinal cord cystic hemangioblastoma. Retinal detachment may occur from hemorrhage or exudate in the retinal vascular malformation. Rarely a pancreatic cyst or renal tumor may be the presenting symptom.

The diagnostic criteria for the disease are a retinal or cerebellar hemangioblastoma with or without a positive family history, intra-abdominal cyst, or renal cancer.

CENTRAL NERVOUS SYSTEM DEGENERATIVE DISORDERS OF INFANCY & CHILDHOOD

The CNS degenerative disorders of infancy and childhood are characterized by arrest of psychomotor development and loss, usually progressive but at variable rates, of mental and motor functioning and often of vision as well. Seizures are common in some disorders. Symptoms and signs vary with age at onset and primary sites of involvement of specific types.

These disorders are fortunately rare. An early clinical pattern of decline often follows normal early development. Referral for sophisticated biochemical testing is usually necessary before a definitive diagnosis can be made (Tables 23–21 and 23–22).

Table 23–21. Central nervous system degenerative disorders of infancy.

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Somatic Findings
WHITE MATTER					
Globoid (Krabbe) leukodystrophy	Recessive galactocerebroside β -galactosidase deficiency. Chromosome 14.	First 6 mos; late-onset form 2–6 y	Feeding difficulties. Shrill cry. Irritability. Arching of back.	Optic atrophy, mid-course to late. Hyperacusis occasionally.	Head often small. Often underweight.
Metachromatic leukodystrophy	Recessive. Arylsulfatase A deficiency. 22q13.	Second year; less often, later childhood or adult	Incoordination, especially gait disturbance; then general regression. Reverse in juveniles.	Optic atrophy, usually late. Hearing normal.	Head enlarged late. No change in juvenile form.
Neuroaxonal dystrophy	Familial, (?) recessive. More common in girls than boys; defect unknown.	6 mos to 2 y	Arrest of development and dementia. Loss of motor functions. Occasionally hypesthesia over trunk and legs.	Nystagmus occasional; optic atrophy, blindness; abnormal VER.	Early, may lie in "frog position."
Hallervorden–Spatz syndrome	Unknown; may be familial.	By age 10 y	Rigidity, dystonia, gait disturbance, tremor.	Optic atrophy.	None
Pelizaeus–Merzbacher disease	X-linked recessive; rare female. Proteolipid protein (myelin) decreased. Xq22	(?) Birth to 2 y	Eye rolling often shortly after birth. Head bobbing. Slow loss of intellect.	Slowly developing optic atrophy. Hearing normal. Nystagmus.	Head and body normal
DIFFUSE, BUT PRIMARILY GRAY MATTER					
Poliiodystrophy (Alpers's disease)	Occasionally familial, recessive. Possibly viral. Metabolic forms.	Infancy to adolescence	Variable: loss of intellect, seizures, incoordination. Vomiting, hepatic failure.	Cortical blindness and deafness	Head normal initially; may fail to grow
Tay–Sachs disease and G_{M2} gangliosidosis variants: Sandhoff disease; juvenile; chronic-adult	Recessive. Hexosaminidase deficiencies. Tay–Sachs (93% East European Jewish), hexosaminidase A deficiency. Sandhoff-hexosaminidase A and B deficiency. Juvenile-partial hexosaminidase A	Tay–Sachs, and Sandhoff; 3–6 mos; others 2–6 y or later.	Variable: shrill cry, loss of vision, infantile spasms, arrest of development. In juvenile and chronic forms: motor difficulties; later, mental difficulties.	Cherry-red macula, early blindness. Hyperacusis early. Strabismus in juvenile form, blindness late.	Head enlarged late. Liver occasionally enlarged. None in juvenile chronic forms.
Niemann–Pick disease and variants	50% Jewish. Recessive. Sphingomyelinase deficiency in types A and C involving the CNS.	First 6 mos. In variants, later onset: often non-Jewish.	Slow development. Protruding belly.	Cherry-red macula in 35–50%. Blindness late. Deafness occasionally.	Head usually normal. Spleen enlarged more than liver. Occasional xanthomas of skin.
Infantile Gaucher disease (glucosylceramide lipidoses)	Recessive. Glucocerebrosidase deficiency.	First 6 mos; rarely, late infancy	Stridor or hoarse cry; retraction; feeding difficulties	Occasional cherry-red macula. Convergent squint. Deafness occasionally.	Head usually normal. Liver and spleen equally enlarged.

Table 23–21. Central nervous system degenerative disorders of infancy. (continued)

Motor System	Seizures	Laboratory and Tissue Studies	Course
WHITE MATTER			
Early spasticity, occasionally preceded by hypotonia. Prolonged nerve conduction.	Early. Myoclonic and generalized, decerebrate posturing	CSF protein elevated; usually normal in late-onset forms. Sural nerve; nonspecific myelin breakdown. Enzyme deficiency in leukocytes, cultured skin fibroblasts. Demyelination, gliosis with low-signal CT scan, high-signal T ₂ -weighted MRI.	Rapid. Death usually by 1½–2 y. Late-onset cases may live 5–10 y.
Combined upper and lower motor neuron signs. Ataxia. Prolonged nerve conduction.	Infrequent, usually late and generalized	Metachromatic cells in urine: negative sulfatase A test. CSF protein elevated. Urine sulfatide increased. Sural nerve biopsy; metachromasia. Enzyme deficiency in leukocytes, cultured skin fibroblasts. Imaging: Same as globoid leukodystrophy.	Moderately slow. Death in infantile form by 3–8 y, in juvenile form by 10–15 y.
Combined upper and lower motor neuron lesions. Hypotonia, extrapyramidal manifestations.	Variable, but usually not a prominent feature	Denervation on EMG. Increased iron uptake in region of basal ganglia. Brain and sural nerve: axonal swellings or “spheroids” Cerebellar atrophy. Cause unknown. Conjunctival biopsy may yield nerves with “spheroids.”	Progressive, with death early in second decade or earlier.
Extrapyramidal signs, dysarthria, increased deep tendon reflexes.	Variable, EEG may be abnormal	Seablue histiocytes in bone marrow. Iron deposits in basal ganglia on MRI.	Progressive mental/motor deterioration
Cerebellar signs early, hyperactive deep reflexes. Spasticity.	Usually only late	None specific. Brain biopsy: extensive demyelination with small perivascular islands of intact myelin. Exon abnormalities in PLP gene in 10–25%.	Very slow, often seemingly stationary.
DIFFUSE, BUT PRIMARILY GRAY MATTER			
Variable: incoordination, spasticity	Often initial manifestation: myoclinic, akinetic, and generalized	Nonspecific, CSF protein normal or slightly elevated. Extensive neuronal loss in cortex: may occur very late. Variably increased serum pyruvate, lactate; liver steatosis, cirrhosis late.	Usually rapid, with death within 1–3 y after onset.
Initially floppy. Eventual decerebrate rigidity. In juvenile and chronic forms: dysarthria, ataxia, spasticity.	Frequent, in mid-course and late. Infantile spasms and generalized	Blood smears: vacuolated lymphocytes; basophilic hypergranulation. Enzyme deficiencies in serum, leukocytes, culture skin fibroblasts. High-density thalami on CT scan, low-density white matter.	Moderately rapid. Death usually by 2–5 y. In juvenile form, 5–15 y.
Initially floppy. Eventually spastic. Occasionally extrapyramidal signs. Ataxia, dystonia.	Rare and late	Blood: vacuolated lymphocytes; increased lipids. X-rays: “mottled” lungs, decalcified bones. “Foam cells” in bone marrow, spleen, lymph nodes. WBC, fibroblast enzyme studies are diagnostic.	Moderately slow. Death usually by 3–5 y.
Opisthotonos early, followed rapidly by decerebrate rigidity	Rare and late	Anemia. Increased acid phosphatase. X-rays: thinned cortex, trabeculation of bones. “Gaucher cells” in bone marrow, spleen. Enzyme deficiency in leukocytes or cultured skin fibroblasts.	Very rapid

(continued)

Table 23–21. Central nervous system degenerative disorders of infancy. (continued)

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Somatic Findings
DIFFUSE, BUT PRIMARILY GRAY MATTER					
Lipogranulomatosis (Farber disease)	Ceramidase deficiency	Early in infancy	Hoarseness, irritability, restricted joint movements	Usually normal	Painful nodular swelling of joints; subcutaneous nodules
Generalized gangliosidosis and juvenile type (G _{m1} gangliosidoses)	Recessive; β -galactosidase deficiency	First year; less often, second year	Arrest of development. Protruding belly. Coarse facies in infantile (generalized) form.	50% "cherry-red spot." Hearing usually normal. In juvenile type, occasionally retinitis pigmentosa.	Head enlarged early; liver enlarged more than spleen
Subacute necrotizing encephalomyelopathy (Leigh disease)	Recessive or variable. May have deficiency of pyruvate carboxylase, pyruvate dehydrogenase, cytochrome enzymes.	Infancy to late childhood	Difficulties in feeding; feeble or absent cry; floppiness	Optic atrophy, often early. Roving eye movements. Ophthalmoplegia.	Head usually normal, occasionally small; cardiac and renal tubular dysfunction occasionally
Menkes disease (kinky hair disease)	X-linked recessive; defect in copper absorption	Infancy	Peculiar facies; secondary hair white, twisted, split; hypothermia	May show optic disk pallor and microcysts of pigment epithelium	Normal to small
Carbohydrate-deficient glycoprotein syndrome	Recessive glycoprotein abnormality; glycosylation faulty	Infancy	Failure to thrive, retardation	Strabismus Retinopathy	Dysmorphic facies. Prominent fat pads.
Abetalipoproteinemia (Bassen-Kornzweig disease)	Recessive; primary defect unknown	Early childhood	Diarrhea in infancy	Retinitis pigmentosa; late ophthalmoplegia	None

ATAXIAS OF CHILDHOOD

1. Acute Cerebellar Ataxia

Acute cerebellar ataxia occurs most commonly in children age 2–6 years. The onset is abrupt, and the evolution of symptoms is rapid. In about 50% of patients, a prodromal illness occurs with fever, respiratory or gastrointestinal symptoms, or an exanthem within 3 weeks of onset. Associated viral infections include varicella, rubella, mumps, rubella, echovirus infections, poliomyelitis, infectious mononucleosis, and influenza. Bacterial infections such as scarlet fever and salmonellosis have also been incriminated.

Clinical Findings

A. SYMPTOMS AND SIGNS

Ataxia of the trunk and extremities may be so severe that the child exhibits a staggering, reeling gait and inability to sit without support or to reach for objects; or he or she may show only mild unsteadiness. Hypotonia, tremor of the extremities, and horizontal nystagmus may be present. Speech may be slurred. The child is frequently irritable, and vomiting may occur.

There are no clinical signs of increased intracranial pressure. Sensory and reflex testing usually shows no abnormalities.

B. LABORATORY FINDINGS

CSF pressure and protein and glucose levels are normal; slight lymphocytosis (≤ 30 /mL) may be present. At-

Table 23–21. Central nervous system degenerative disorders of infancy. (continued)

Motor System	Seizures	Laboratory and Tissue Studies	Course
DIFFUSE, BUT PRIMARILY GRAY MATTER			
Psychomotor retardation and progressive paralysis	Usually none	Chest radiographs may show pulmonary infiltrates. Nodules: granulomatous lesions, resembling those in reticuloendotheliosis. Multiple infarcts on CNS imaging.	Rapid: death usually in 1–2 y.
Initially floppy, eventually spastic	Usually late	Blood: vacuolated lymphocytes. X-rays: dorsolumbar kyphosis, “beaking” of vertebrae. “Foam cells” similar to those in Niemann–Pick disease.	Very rapid. Death within a few years. Slower in juvenile type (to 10 y).
Flaccid and immobile; may become spastic. Spinocerebellar forms; ataxia.	Rare and late	Increased CSF and blood lactate and pyruvate. High-signal MRI T ₂ foci in thalami; globus pallidus, subthalamic nuclei.	Usually rapid in infants, but may be slow with death after several years. Central hypoventilation a frequent cause of death.
Variable: floppy to spastic	Myoclonic infantile spasms, status epilepticus	Defective absorption of copper. Cerebral angiography shows elongated arteries. Hair shows pili torti, split shafts. Copper and ceruloplasmin low.	Moderately rapid. Death usually by 3–4 ys.
Variable hypotonia Neuropathy	Rare	Normal transferrin decreased. Carbohydrate-deficient transferrin increased. Liver steatosis. Cerebellar hypoplasia.	Cardiomyopathy, thrombosis
Ataxia, late extrapyramidal movement disorder	None	Abetalipoproteinemia: acanthocytosis, low serum vitamin E; cerebellar atrophy on imaging.	Progression arrested with vitamin E

CSF = cerebrospinal fluid; CT = computed tomography; EEG = electroencephalogram; EMG = electromyogram; MRI = magnetic resonance imaging; VER = visual evoked potential; WBC = white blood cell.

tempts should be made to identify the etiologic viral agent.

C. IMAGING

CT scans are normal; MRI may show cerebellar postinfectious demyelinating lesions. The EEG may be normal or may show nonspecific slowing.

Differential Diagnosis

Acute cerebellar ataxia must be differentiated from acute cerebellar syndromes due to phenytoin, phenobarbital, primidone, or lead intoxication. For phenytoin, the toxic level in serum is usually above 25 µg/mL; for phenobarbital, above 50 µg/mL; for primidone, above 14 µg/mL. (See Seizure Disorders

section.) Papilledema, anemia, basophilic stippling of erythrocytes, proteinuria, typical radiographs, and elevated CSF protein are clinical clues to lead intoxication, which is confirmed by serum, urine, or hair lead levels. An occult neuroblastoma, usually seen with the polymyoclonus–opsoclonus syndrome (see following section) occasionally begins as acute cerebellar ataxia.

In rare cases, acute cerebellar ataxia may be the presenting sign of acute bacterial meningitis or may be mimicked by corticosteroid withdrawal, vasculitides such as in polyarteritis nodosa, trauma, the first attack of ataxia in a metabolic disorder such as Hartnup disease, or the onset of acute disseminated encephalomyelitis or of multiple sclerosis. The history and physical findings may differentiate these disturbances, but appropriate laboratory studies are often necessary.

Table 23–22. Central nervous system degenerative disorders of childhood.^a

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Motor System	Seizures	Laboratory and Tissue Studies	Course
Adrenoleukodystrophy and variants	X-linked recessive. Neonatal form recessive Xq28. Acyl-CoA synthetase deficiency.	5–10 years May also present as newborn, adolescent or adult.	Impaired intellect; behavioral problems	Cortical blindness and deafness	Ataxia, spasticity; motor deficits may be asymmetrical or one-sided initially; adrenomyeloneuropathy in adults	Occasionally	Hyperpigmentation and adrenocortical insufficiency. ACTH elevated. Accumulation of very long chain fatty acids in plasma.	Fairly rapid. Death usually within 2–3 y after onset.
Neuronal ceroid lipofuscinosis (NCL; cerebromacular degeneration); infantile NCL (INCL); late infantile (LINCL); juvenile NCL (JNCL; Batten disease)	Recessive; multiple gene mutations, polymorphisms. (See Ref. Gene Reviews.)	6–24 months INCL: 2–4 y LINCL; 4–8 y JNCL	Ataxia; visual difficulties; arrested intellectual development. Seizures	Pigmentary degeneration of macula; optic atrophy; ERG, VER abnormal	Ataxia; spasticity progressing to decerebrate rigidity	Often early: myoclonus and later generalized; refractory	Blood: vacuolated lymphocytes. Biopsy, EM of skin, conjunctiva; WBC: “curvilinear bodies, fingerprint profiles.” Molecular testing of CLN1, CLN2, CLN3. Protein gene product testing for CLN1 and CLN2.	Moderately slow. Death in 3–8 y.
Subacute sclerosing panencephalitis (Dawson disease)	None. Measles “slow virus” infection. Also reported as result of rubella.	3–22 years; rarely earlier or later	Impaired intellect; emotional lability; incoordination	Occasionally chorioretinitis or optic atrophy; hearing normal	Ataxia; slurred speech; occasionally involuntary movements; spasticity progressing to decerebrate rigidity	Myoclonic and akinetic seizures relatively early; later, focal and generalized	CSF protein normal to moderately elevated. High CSF IgG; ^b oligoclonal bands. Elevated CSF (and serum) measles (or rubella) antibody titers. Characteristic EEG. Brain biopsy; inclusion body encephalitis; culturing of measles virus, perhaps rubella virus.	Variable, death in months to years. Remissions of variable duration may occur.

Multiple sclerosis	None. Diagnosis difficult in childhood.	Adolescent; rare in childhood	Highly variable: may strike one or more sites of CNS; paresthesias common	Optic neuritis; diplopia, nystagmus at some time; vestibulocochlear nerves occasionally affected	Motor weakness; spasticity; ataxia; sphincter disturbances; slurred speech; mental difficulties.	Rare: focal or generalized	CSF may show slight pleocytosis, elevation of protein and gamma globulin; ^b oligoclonal bands present. CT scan may show areas of demyelination. Auditory, visual, and somatosensory evoked responses often show lesions in respective pathways. Changes in T-cell subsets.	Variable: complete remission possible. Recurrent attacks and involvement of multiple sites are prerequisites for diagnosis.
Cerebrotendinous xanthomatosis	?Recessive. Abnormal accumulation of cholesterol.	Late childhood to adolescence	Xanthomas in tendons; mental deterioration	Cataracts; xanthelasma	Cerebellar defects; bulbar paralysis late	Myoclonus	Xanthomas may appear in lungs. Xanthomas in tendons (especially Achilles).	Very slowly progressive into middle life. Replace deficient bile acid.
Huntington disease	Dominant. Chromosome 4p CAG repeat.	10% childhood onset	Rigidity; dementia	Ophthalmoplegia late	Rigidity; chorea frequently absent in children	50% with major motor seizures	CT scan may show "butterfly" atrophy of caudate and putamen	Moderately rapid with death in 15 y
Refsum disease	Recessive. Phytanic acid oxidase deficiency.	5–10 y	Ataxia; ichthyosis; cardiomyopathy	Retinitis pigmentosa; nystagmus	Ataxia; neuropathy; tendon reflexes absent	None	Serum phytanic acid elevated. Slow nerve conduction velocity. Elevated CSF protein. Peroxisomal disease.	Treat with low phytanic acid diet

^aFor late infantile metachromatic leukodystrophy, Pelizaeus-Merzbacher disease, poliodystrophy, Gaucher's disease of later onset, and subacute necrotizing encephalomyelopathy, see Table 22–22.

^bCSF γ -globulin (IgG) is considered elevated in children when > 9% of total protein (possibly even > 8.3%); definitively elevated when > 14%.

ACTH = adrenocorticotrophic hormone; CSF = cerebrospinal fluid; CT = computed tomography; EEG = electroencephalogram; ERG = electroretinogram; VER = visual evoked response; CLN = ceroid lipofuscinosis.

For ataxias with more chronic onset and course, see the sections on spinocerebellar degeneration and the other degenerative disorders.

Treatment & Prognosis

Treatment is supportive. The use of corticosteroids has no rational justification. Between 80% and 90% of children with acute cerebellar ataxia not secondary to drug toxicity recover without sequelae within 6–8 weeks. In the remainder, neurologic disturbances, including disorders of behavior and of learning, ataxia, abnormal eye movements, and speech impairment, may persist for months or years, and recovery may remain incomplete.

2. Polymyoclonia–Opsoclonus Syndrome of Childhood (Infantile Myoclonic Encephalopathy, “Dancing Eyes–Dancing Feet” Syndrome)

The symptoms and signs of this syndrome are at first similar to those of acute cerebellar ataxia. Often of sudden onset, polymyoclonus–opsoclonus syndrome is characterized by severe incoordination of the trunk and extremities with lightning-like jerking or flinging movements of a group of muscles, causing the child to be in constant motion while awake. Extraocular muscle involvement results in sudden irregular eye movements (opsoclonus). Irritability and vomiting are often present, but there is no depression of level of consciousness. This syndrome occurs in association with viral infections and tumors of neural crest origin among other disorders. Immunologic mechanisms have been postulated. Usually no signs of increased intracranial pressure are present. CSF may show normal or mildly increased protein levels. Special techniques show increased CSF levels of plasmacytes and abnormal immunoglobulins. The EEG may be slightly slow, but when performed together with EMG, it shows no evidence of association between cortical discharges and the muscle movements. An assiduous search must be made to rule out tumor of neural crest origin by chest radiographs and CT scan or ultrasound (or both) of the adrenal area as well as by assays of urinary catecholamine metabolites (vanillylmandelic acid and so on) and cystathionine.

The symptoms respond (often dramatically) to large doses of corticotropin. Plasmapheresis has been successful. When a neural crest (or other) tumor is found, surgical excision should be followed by irradiation and chemotherapy. Life span is determined by the biologic behavior of the tumor. The syndrome is usually self-limited but may be characterized by exacerbations and remissions. Even after removal of a neural crest tumor and without other evidence of its recurrence, symptoms may reappear. Mild mental retardation may be a sequela.

3. Spinocerebellar Degeneration Disorders

Spinocerebellar degeneration disorders may be hereditary or may occur in sporadic distribution. Hereditary disorders include Friedreich ataxia, dominant hereditary ataxia, and a group of miscellaneous diseases.

Friedreich Ataxia

This is a recessive disorder characterized by onset of gait ataxia or scoliosis before puberty that becomes progressively worse. Reflexes, light touch, and position sensation are reduced. Dysarthria becomes progressively more severe. Cardiomyopathy usually develops, and diabetes mellitus occurs in 40% of patients, half of whom require insulin. Pes cavus typically is found. The GAA trinucleotide repeats on chromosome 9 can be used for laboratory diagnosis.

Treatment includes surgery for scoliosis and intervention as needed for cardiac disease and diabetes. Patients are usually confined to a wheelchair after age 20 years. Death occurs, usually from heart failure or dysrhythmias, in the third or fourth decade; some patients survive longer.

Dominant Ataxia

These diseases (in the past known as olivopontocerebellar atrophy, Holmes ataxia, Marie ataxia, and the like) occur with varying manifestations, even among members of the same family. Ataxia occurs at onset, and progression continues with ophthalmoplegias (in some patients), extrapyramidal syndromes, polyneuropathy, and dementia. Several types have been found to be

caused by CAG trinucleotide repeats. Levodopa may ameliorate rigidity and bradykinesia, but no other therapy is available. Only 10% of patients experience onset in childhood, and the course in these patients is often more rapid.

Miscellaneous Hereditary Ataxias

Associated findings permit identification of these recessive disorders. These include ataxia–telangiectasia (telangiectasia, immune defects; see below); Wilson disease (Kayser–Fleischer rings); Refsum disease (ichthyosis, cardiomyopathy, retinitis pigmentosa, large nerves); Rett syndrome (regression to autism at age 7–18 months in girls, loss of use of hands, progressive failure of brain growth); and abetalipoproteinemia (infantile diarrhea, acanthocytosis, retinitis pigmentosa). Gluten sensitivity may cause ataxia. Patients with juvenile and chronic gangliosidoses and some hemolytic anemias and long-term survivors of Chédiak–Higashi disease may develop spinocerebellar degeneration. Idiopathic familial ataxia is called Behr syndrome. Neuropathies such as Charcot–Marie–Tooth disease produce ataxia.

ATAXIA–TELANGIECTASIA (Louis-Bar Syndrome)

Ataxia–telangiectasia is a multisystem disorder inherited as an autosomal recessive trait. It is characterized by progressive ataxia; telangiectasia of the bulbar conjunctiva, external ears, nares, and (later) other body surfaces, appearing in the third to sixth year; and recurrent respiratory, sinus, and ear infections. Ocular dyspraxia, slurred speech, choreoathetosis, hypotonia and areflexia, and psychomotor and growth retardation may be present. Endocrinopathies are common. Nerve conduc-

tion velocities may be reduced. The entire nervous system may be affected in late stages of the disease. A spectrum of involvement may be seen in the same family. Immunodeficiencies of IgA and IgE are common (see Chapter 29), and the incidence of certain cancers is high. Elevated serum α -fetoprotein is a screen for this disease.

EXTRAPYRAMIDAL DISORDERS

Extrapyramidal disorders are characterized by the presence in the waking state of one or more of the following features: dyskinesias, athetosis, ballismus, tremors, rigidity, and dystonias.

For the most part, the precise pathologic and anatomic localization of these disorders is not understood. Motor pathways synapsing in the striatum (putamen and caudate nucleus), globus pallidus, red nucleus, substantia nigra, and the body of Luys are involved; this system is modulated by pathways originating in the thalamus, cerebellum, and reticular formation.

1. Sydenham Post-rheumatic Chorea

Sydenham chorea is characterized by an acute onset of choreiform movements and variable degrees of psychological disturbance. It is frequently associated with rheumatic endocarditis and arthritis. Although the disorder follows infections with group A β -hemolytic streptococci, the interval between infection and chorea may be greatly prolonged; throat cultures and antistreptolysin O (ASO) titers may therefore be negative. Chorea has also been associated with hypocalcemia; with vascular lupus erythematosus; and with toxic, viral, infectious, parainfectious, and degenerative encephalopathies.

Clinical Findings

A. SYMPTOMS AND SIGNS

Chorea, or rapid involuntary movements of the limbs and face, is the hallmark physical finding. In addition to the jerky incoordinate movements, the following are noted: emotional lability, waxing and waning (“milk-

maid's") grip, darting tongue, "spooning" of the extended hands and their tendency to pronate, and knee jerks slow to return from the extended to their prestimulus position ("hung up"). Seizures, while uncommon, may be masked by choreic jerks.

B. LABORATORY FINDINGS

Anemia, leukocytosis, and an increased erythrocyte sedimentation rate may be present. The ASO titer may be elevated and C-reactive protein present. Throat culture is sometimes positive for group A-hemolytic streptococci.

ECG and echocardiography are often essential to detect cardiac involvement. Antineuronal antibodies are present in most patients but are not specific for this disease. Specialized radiologic procedures (MRI, SPECT) may show basal ganglia abnormalities.

Differential Diagnosis

The diagnosis of Sydenham chorea is usually not difficult. Tics, drug-induced extrapyramidal syndromes, Huntington chorea, and hepatolenticular degeneration (Wilson disease), as well as other rare movement disorders, can usually be ruled out on historical and clinical grounds. Immunologic linkages among chorea, tics, and obsessive-compulsive disorder are being studied in pediatric patients. Other causes of chorea can be ruled out by laboratory tests, such as antinuclear antibody for lupus, thyroid screening tests, serum calcium for hypocalcemia, and immunologic tests for Epstein-Barr virus infection.

Treatment

There is no specific treatment. Dopaminergic blockers such as haloperidol, 0.5 mg to 3–6 mg/d, and pimozide, 4–12 mg/d, have been used. Parkinsonian side effects such as rigidity and masked facies and, with high doses, tardive dyskinesia rarely occur in childhood. A variety of other drugs have been used with success in individual cases, such as the anticonvulsant sodium valproate, 50–60 mg/kg/d in divided doses; or prednisone, 0.5–2 mg/kg/d in divided doses. Emotional lability and depression sometimes warrant administration of antidepressants such as amitriptyline. All patients should be given antistreptococcal rheumatic fever prophylaxis, possibly through child-bearing age.

Prognosis

Sydenham chorea is a self-limited disease that may last from a few weeks to months. Relapse of chorea may occur with nonspecific stress or illness—or with breakthrough streptococcus infections (if penicillin prophylaxis is not done). Two thirds of patients relapse one or

more times, but the ultimate outcome does not appear to be worse in those with recurrences. In older studies, valvular heart disease occurs in about one third of patients, particularly if other rheumatic manifestations appear. Psychoneurotic disturbances occur in a significant percentage of patients.

2. Tics (Habit Spasms)

Clinical Findings

Tics, or habit spasms, are quick repetitive but irregular movements, often stereotyped, and briefly suppressible. Coordination and muscle tone are not affected. A psychogenic basis is seldom discernible. Transient tics of childhood (12–24% incidence in school-age children) last from 1 month to 1 year and seldom need treatment. Many children with tics have a history of encephalopathic past events, neurologic soft signs, and school problems. Facial tics such as grimaces, twitches, and blinking predominate, but the trunk and extremities are often involved and twisting or flinging movements may be present. Vocal tics are less common.

Tourette syndrome is characterized by multiple fluctuating motor and vocal tics with no obvious cause lasting more than 1 year. Tics evolve slowly, new ones being added to or replacing old ones. Coprolalia and echolalia are relatively infrequent. Partial forms are common. The usual age at onset is 2–15 years, and the familial incidence is 35–50%. The disorder occurs in all ethnic groups. Tourette syndrome may be triggered by stimulants such as methylphenidate and dextroamphetamine. An imbalance of neurotransmitters, especially dopamine and serotonin, has been hypothesized.

In mild cases, tics are self-limited and, when disregarded, disappear. When attention is paid to one tic, it may disappear only to be replaced by another that is often worse. If the tic and its underlying anxiety or

compulsive neuroses are severe, psychiatric evaluation and treatment are needed.

Important comorbidities are attention-deficit/hyperactivity disorder and obsessive-compulsive disorder. Learning disabilities, sleep difficulties, anxiety states, and mood swings are also common. Medications such as methylphenidate and dextroamphetamine should be carefully titrated to treat attention-deficit/hyperactivity disorder and avoid worsening tics. Fluoxetine and clomipramine may be useful for obsessive-compulsive disorder and rage episodes in patients with tics.

Treatment

The most effective medications for treating Tourette syndrome are dopamine blockers; however, many pediatric patients can manage without drug treatment. Medications are generally reserved for patients with disabling symptoms; treatment may be relaxed or discontinued when the symptoms abate (Table 23–23). Nonpharmacologic treatment of Tourette syndrome includes education of patients, family members, and school personnel. In some cases, restructuring the school environment to prevent tension and teasing may be necessary. Supportive counseling, either at or outside school, should be provided. Medications usually do not eradicate the tics. The goal of treatment should be to reduce the tics to tolerable levels without inducing undesirable side effects. Medication dosage should be increased at weekly intervals until a satisfactory response is obtained. Often a single dose at bedtime is sufficient. The two neuroleptic

Other

Clonazepam (Klonopin)
Baclofen (Lioresal)

tic agents used most often are pimozide and risperidone. Sleepiness and weight gain are the most common side effects; rare are prolonged QT interval (ECG), akathisia, and tardive dyskinesia. Clonidine, clonazepam, and calcium channel blockers have been used in individual patients with some success. Sometimes these agents are used in combination (eg, clonidine with pimozide).

Sydenham chorea is a well-documented pediatric autoimmune disorder associated with streptococcal infections (PANDAS). Patients with tic disorders occasionally have obsessive-compulsive disorder precipitated or exacerbated by streptococcal infections. Less definite (much less frequent) are tic flare-ups with streptococcal infection. Active prospective antibody (antineuronal and antistreptococcal) and clinical studies are in progress. Research centers have used experimental treatments (IVIG, plasmapheresis, steroids) in severe cases. At present, most patients with a tic do not worsen with group A streptococcal infections; with rare exceptions, penicillin prophylaxis is not generally necessary for the majority of patients with tic disorders.

3. Paroxysmal Dyskinesias/Chronic Dystonia

Sudden-onset, short-duration choreoathetosis or dystonia episodes occur in childhood. Most often these

^aUseful for obsessive-compulsive disorder.

^bUseful for attention-deficit/hyperactivity disorder.

episodes are familial and genetic. Episodes may occur spontaneously or be set off by actions (“kinesiogenic,” or movement-induced) such as rising from a chair, reaching for a glass, or walking. Sometimes only hard sustained exercise will induce the dyskinesia. (Nocturnal dyskinesia/dystonic episodes are currently thought to be frontal lobe seizures.)

The diagnosis is clinical. Onset is usually in childhood (1.5–14 years). The patient is alert and often disconcerted during an episode.

Episodes may last seconds to 5–20 minutes and occur several times daily or monthly. Laboratory work is normal. EEG is normal between or during an attack; brain imaging is normal. Inheritance is usually autosomal dominant. Anticonvulsants (eg, carbamazepine) usually prevent further attacks. Patients often grow out of this disease in one or two decades.

Nonkinesiogenic dyskinesia is often secondary to an identifiable brain lesion, less or not responsive to medications, and nongenetic.

Disorders of ion channels underlie many of the genetic cases; some cases are linked to epilepsy and hemiplegic migraine. Chromosome loci are known.

The diagnosis of chronic persistent dystonia (sometimes Ldopa-responsive) may be aided by spinal fluid neurotransmitter and genetic chromosome studies. Rarely, dyskinesia (e.g., dystonia) may be precipitated by fever. And, chorea (rarely) may be a benign life-long genetic disease.

■ INFECTIONS & INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

Infections of the CNS are among the most common neurologic disorders encountered by pediatricians. Although infections are among the CNS disorders most amenable to treatment, they also have a very high po-

tential for causing catastrophic destruction of the nervous system. It is imperative for the clinician to recognize infections early in order to treat and prevent massive tissue destruction.

Clinical Findings

A. SYMPTOMS AND SIGNS

Patients with CNS infections, whether caused by bacteria, viruses, or other microorganisms, present with similar manifestations. Systemic signs of infection include fever; malaise; and impaired heart, lung, liver, or kidney function. General features suggesting CNS infection include headache, stiff neck, fever or hypothermia, changes in mental status (including hyperirritability evolving into lethargy and coma), seizures, and focal sensory and motor deficits. Meningeal irritation is manifested by the presence of Kernig and Brudzinski signs. In very young infants, signs of meningeal irritation may be absent, and temperature instability and hypothermia are often more prominent than fever. In young infants, a bulging fontanelle and an increased head circumference are common. Papilledema may eventually develop, particularly in older children and adolescents. Cranial nerve palsies may develop acutely or gradually during the course of neurologic infections. No specific clinical sign or symptom is reliable in distinguishing bacterial infections from infections caused by other microbes.

During the initial clinical assessment, conditions that predispose the patient to infection of the CNS should be sought. Infections involving the sinuses or other structures in the head and neck region can result in direct extension of infection into the intracranial compartment. Open head injuries, recent neurosurgical procedures, immunodeficiency, and the presence of a mechanical shunt may predispose to intracranial infection.

B. LABORATORY FINDINGS

When CNS infections are suspected, blood should be obtained for a complete blood count, general chemistry panel, and culture. Most important, however, is obtaining CSF. In the absence of focal neurologic deficits or signs of increased intracranial pressure, CSF should be obtained immediately from any patient in whom serious CNS infection is suspected. When papilledema or focal motor signs are present, a lumbar puncture may be delayed until a neuroimaging procedure has been done to exclude brain abscess or other space-occupying lesion. It is generally safe to obtain spinal fluid from infants with nonfocal neurologic examination even if the fontanelle is bulging. Spinal fluid should be examined for the presence of red and white blood cells, protein concentration, glucose concentration, bacteria, and other microorganisms; a sample should be cultured. In addition, sero-

logic, immunologic, and nucleic acid detection (PCR) tests may be performed on the spinal fluid in an attempt to identify the specific organism. As a general rule, spinal fluid that contains a high proportion of polymorphonuclear leukocytes, a high protein concentration, and a low glucose concentration strongly suggests bacterial infection (see Chapter 38). CSF containing predominantly lymphocytes, a high protein concentration, and a low glucose concentration suggests infection with mycobacteria, fungi, uncommon bacteria, and some viruses such as lymphocytic choriomeningitis virus, herpes simplex virus, mumps virus, and arboviruses (see Chapters 36 and 39). CSF that contains a high proportion of lymphocytes, normal or only slightly elevated protein concentration, and a normal glucose concentration is most suggestive of viral infections, although partially treated bacterial meningitis and parameningeal infections may also result in this type of CSF formula. Typical CSF findings in a variety of infectious and inflammatory disorders are shown in Table 23–3.

In some cases, brain biopsy may be needed to identify the presence of specific organisms and clarify the diagnosis. Herpes simplex virus infections can be confirmed using the PCR test to assay for herpes DNA in spinal fluid. This test has a 95% sensitivity and 99% specificity. Brain biopsy may be needed to detect the rare PCR-negative case of herpes simplex and various parasitic infections, brain tumors, and other structural abnormalities.

C. IMAGING

Neuroimaging with CT and MRI scans may be helpful in demonstrating the presence of brain abscess, meningeal inflammation, or secondary problems such as venous and arterial infarctions, hemorrhages, and subdural effusions when these are expected. In addition, these procedures may identify sinus or other focal infections in the head or neck region that are related to the CNS infection. CT scanning may demonstrate bony abnormalities, such as basilar fractures.

EEGs may be helpful in the assessment of patients who have had seizures at the time of presentation. The changes are often nonspecific and characterized by generalized slowing. In some instances, such as herpes simplex virus infection, focal electronegative activity may be seen early in the course and may be one of the earliest laboratory abnormalities to suggest the diagnosis. EEGs may also show focal slowing over regions of abscesses. Unusual but characteristic electroencephalographic patterns are seen in some patients with subacute sclerosing panencephalitis.

BACTERIAL MENINGITIS

Bacterial infections of the CNS may present acutely (symptoms evolving rapidly over 1–24 hours), sub-

cutely (symptoms evolving over 1–7 days), or chronically (symptoms evolving over more than 1 week). Diffuse bacterial infections involve the leptomeninges, superficial cortical structures, and blood vessels. Although the term “meningitis” is used to describe these infections, it should not be forgotten that the brain parenchyma is also inflamed and that blood vessel walls may be infiltrated by inflammatory cells that result in endothelial cell injury, vessel stenosis, and secondary ischemia and infarction.

Pathologically, the inflammatory process involves all intracranial structures to some degree. Acutely, this inflammatory process may result in cerebral edema or impaired CSF flow through and out of the ventricular system, resulting in hydrocephalus.

Treatment

A. SPECIFIC MEASURES

(See also Chapter 35 and the *Haemophilus influenzae* Type B Infections section in Chapter 38.)

While awaiting the results of diagnostic tests, the physician should start broad-spectrum antibiotic coverage as noted in the following discussion. After specific organisms are identified, antibiotic therapy can be tailored based on antibiotic sensitivity patterns. Bacterial meningitis in children younger than age 3 months is treated initially with cefotaxime (or ceftriaxone if the child is older than age 1 month) and ampicillin; the latter agent is used to treat *Listeria* and enterococci infections, which rarely affect older children. Children older than age 3 months are given ceftriaxone, cefotaxime, or ampicillin plus gentamicin. If *Streptococcus pneumoniae* cannot be ruled out by the initial Gram stain, vancomycin or rifampin is added until cultures are reported, because penicillin-resistant pneumococci are common in the United States. Therapy may be narrowed when organism sensitivity allows. Duration of therapy is 7 days for meningococcal infections, 10 days for *H influenzae* or pneumococcal infection, and 14–21 days for other organisms. Slow clinical response or the occurrence of complications may prolong the need for therapy. Although therapy for 7 days has proved successful in many children with *H influenzae* infection, it cannot be recommended without further study if steroids are also used (see following discussion).

B. GENERAL AND SUPPORTIVE MEASURES

Children with bacterial meningitis are often systemically ill. The following complications should be looked for and treated aggressively: hypovolemia, hypoglycemia, hyponatremia, acidosis, septic shock, increased intracranial pressure, seizures, disseminated intravascular coagulation, and metastatic infection (eg, pericarditis, arthritis, pneumonia). Children should initially be monitored

closely (cardiorespiratory monitor, strict fluid balance and frequent urine specific gravity assessment, daily weights, neurologic assessment every few hours), not fed until neurologically very stable, isolated until the organism is known, rehydrated with isotonic solutions until euvolemic, and then given intravenous fluids containing dextrose and sodium at no more than maintenance rate (assuming no unusual losses occur).

Complications

Abnormalities of water and electrolyte balance result from either excessive or insufficient production of antidiuretic hormone and require careful monitoring and appropriate adjustments in fluid administration. Monitoring serum sodium every 8–12 hours during the first 1–2 days, and urine sodium if the inappropriate secretion of antidiuretic hormone is suspected, usually uncovers significant problems.

Seizures occur in up to 30% of children with bacterial meningitis. Seizures tend to be most common in neonates and less common in older children. Persistent focal seizures or focal seizures associated with focal neurologic deficits strongly suggest subdural effusion, abscess, or vascular lesions such as arterial infarct, cortical venous infarcts, or dural sinus thrombosis. Because generalized seizures in a metabolically compromised child may have severe sequelae, early recognition and therapy are critical; some practitioners prefer phenytoin for acute management because it is less sedating than phenobarbital.

Subdural effusions occur in as many as 50% of young children with *H influenzae* meningitis. Subdural effusions are often seen on CT scans of the head during the course of meningitis. They do not require treatment unless they are producing increased intracranial pressure or progressive mass effect. Although subdural effusions may be detected in children who have persistent fever, such effusions do not usually have to be sampled or drained if

the infecting organism is *H influenzae*, *Meningococcus*, or *Pneumococcus*. These are usually sterilized with the standard treatment duration, and slowly waning fever during an otherwise uncomplicated recovery may be followed clinically. Under any other circumstance, however, aspiration of the fluid for documentation of sterilization or for relief of pressure should be considered.

Cerebral edema can participate in the production of increased intracranial pressure, requiring treatment with dexamethasone, osmotic agents, diuretics, or hyperventilation; continuous pressure monitoring may be needed.

Long-term sequelae of meningitis result from direct inflammatory destruction of brain cells, vascular injuries, or secondary gliosis. Focal motor and sensory deficits, visual impairment, hearing loss, seizures, hydrocephalus, and a variety of cranial nerve deficits can result from meningitis. Sensorineural hearing loss in *H influenzae* meningitis occurs in approximately 5–10% of patients during long-term follow-up. Recent studies have suggested that early addition of dexamethasone to the antibiotic regimen may modestly decrease the risk of hearing loss in some children with *H influenzae* meningitis (see Chapter 38).

In addition to the variety of disorders mentioned earlier in this section, some patients with meningitis have mental retardation and severe behavioral disorders that limit their function at school and later performance in life. Table 23–24 lists the overall mortality and morbidity figures for the most common organisms associated with acute bacterial meningitis in childhood.

BRAIN ABSCESS

Clinical Findings

Patients with brain abscess often appear to have systemic illness similar to patients with bacterial meningitis, but in addition they show signs of focal neurologic deficits,

Table 23–24. Outcome of acute bacterial meningitis by organism.

Organism	Mortality (%)	Motor Handicap (%)		Intellect (%)	
		None	Severe	Normal	Severe Mental Retardation
<i>Escherichia coli</i> , other coliforms	20–50	62	25	75	25
<i>Haemophilus influenzae</i>	5–10	87	3	82	5
<i>Streptococcus pneumoniae</i>	10–30	96	0	83	0
<i>Neisseria meningitidis</i>	5–10	100	0	93	0
Group B streptococci	20	85	10–15	100	0
Overall total	10–25	85	5	82	6

papilledema, and other evidence of increased intracranial pressure or a mass lesion. Symptoms may be present for a week or more; children with bacterial meningitis usually present within a few days. Conditions predisposing to development of brain abscess include penetrating head trauma; chronic infection of the middle ear, mastoid, or sinuses (especially the frontal sinus); chronic dental or pulmonary infection; cardiovascular lesions allowing right-to-left shunting of blood (including arteriovenous malformations); and endocarditis.

When brain abscess is strongly suspected, a neuroimaging procedure such as CT or MRI scans should be done prior to lumbar puncture. If a brain abscess is identified, lumbar puncture may be dangerous and rarely alters the choice of antibiotic or clinical management since the CSF abnormalities usually reflect only parameningeal inflammation. With spread from contagious septic foci, streptococci and anaerobic bacteria are most common. Staphylococci most often enter from trauma or from infections. Enteric organisms may form an abscess from chronic otitis. Unfortunately, cultures from a large number of brain abscesses remain negative.

The diagnosis of brain abscess is based primarily on a strong clinical suspicion and confirmed by a neuroimaging procedure. EEG changes are nonspecific but frequently demonstrate focal slowing in the region of brain abscess.

Treatment

Initial therapy for infection from presumed contagious foci uses penicillin and metronidazole. Cefotaxime is a good alternative to penicillin, especially if enteric organisms are suspected. Enteric organisms are also often susceptible to trimethoprim-sulfamethoxazole. Suspicion of infection by staphylococci, or their recovery from an aspirate, should be treated with nafcillin or vancomycin. Treatment may include neurologic consultation and anticonvulsant and edema therapy if necessary. In their early stages, brain abscesses are areas of focal cerebritis and can be "cured" with antibiotic treatment alone. Well-developed abscesses require surgical drainage.

Differential Diagnosis

Differential diagnosis of brain abscess includes any condition that produces focal neurologic deficits and increased intracranial pressure, such as neoplasms, subdural effusions, cerebral infarctions, and certain infections (herpes simplex, cysticercosis, and toxocariasis).

Prognosis

The surgical mortality rate in the treatment of brain abscess is lower than 5%. Untreated cerebral abscesses

lead to irreversible tissue destruction and may rupture into the ventricle, producing catastrophic deterioration in neurologic function and death. Because brain abscesses are often associated with systemic illness and systemic infections, the death rate is frequently high in these patients.

VIRAL INFECTIONS

Viral infections of the CNS can involve primarily meninges (meningitis) (see Chapter 36) or cerebral parenchyma (encephalitis). All patients, however, have some degree of involvement of both the meninges and cerebral parenchyma (meningoencephalitis). Many viral infections are generalized and diffuse, but some viruses, notably herpes simplex and some arboviruses, characteristically cause prominent focal disease. Focal cerebral involvement is clearly evident on neuroimaging procedures. Some viruses have an affinity for specific CNS cell populations. Poliovirus and other enteroviruses can selectively infect anterior horn cells (poliomyelitis) and some intracranial motor neurons.

Although most viral infections of the nervous system have an acute or subacute course in childhood, chronic infections can occur. Subacute sclerosing panencephalitis, for example, represents a chronic indolent infection caused by measles virus and is characterized clinically by progressive neurodegeneration and seizures.

Inflammatory reactions within the nervous system may occur during the convalescent stage of systemic viral infections. Parainfectious or postinfectious inflammation of the CNS results in several well-recognized disorders: acute disseminated encephalomyelitis (25% of encephalitis), transverse myelitis, optic neuritis, polyneuritis, and Guillain-Barré syndrome.

Congenital viral infections can also affect the CNS. CMV, herpes simplex virus, and rubella virus are the most notable causes of viral brain injury in utero.

Treatment of CNS viral infections is usually limited to symptomatic and supportive measures, except for herpes simplex virus. Acyclovir is the treatment in suspected or proved cases of herpes simplex virus encephalitis. Acyclovir is also useful in some patients with varicella-zoster virus infections of the CNS. West Nile virus, new in the United States, is an arthropod-borne flavivirus. It is found in mosquitoes, birds, and horses, and accounts for 27% of hospitalized patients in New York (1991) with encephalitis and muscle weakness. Fourteen percent had encephalitis alone, and 6% had aseptic meningitis. CSF antibody studies and PCR (57% positive for viral RNA) were diagnostic aids. The infection is now endemic as far as the western United States, particularly in Colorado. Recent studies have suggested spread of the infection to mosquitoes further south along the Atlantic seaboard.

Encephalopathy of HIV Infection

Neurologic syndromes associated directly with HIV infection include subacute encephalitis, meningitis, myelopathy, polyneuropathy, and myositis. In addition, secondary opportunistic infections of the CNS occur in patients with HIV-induced immunosuppression. Toxoplasma and CMV infections are particularly common. Progressive multifocal leukoencephalopathy, a secondary papillomavirus infection, and herpes simplex and varicella-zoster infections also occur frequently in patients with HIV infection. A variety of fungal (especially cryptococcal), mycobacterial, and bacterial infections have been described.

Neurologic abnormalities in these patients can also be the result of noninfectious neoplastic disorders. Primary CNS lymphoma and metastatic lymphoma to the nervous system are the most frequent neoplasms of the nervous system in these patients. See Chapters 29, 35, and 37 for diagnosis and management of HIV infection.

OTHER INFECTIONS

A wide variety of other microorganisms, including *Toxoplasma*, mycobacteria, spirochetes, rickettsiae, amoebae, and mycoplasmas, can cause CNS infections. CNS involvement in these infections is usually secondary to systemic infection or other predisposing factors. Appropriate cultures and serologic testing are required to confirm infections by these organisms. Parenteral antimicrobial treatment for these infections is discussed in Chapter 35.

NONINFECTIOUS INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

The differential diagnosis of bacterial, viral, and other microbial infections of the CNS includes disorders that cause inflammation but for which no specific causal organism has been identified. Sarcoidosis, Behçet disease, systemic lupus erythematosus, other collagen-vascular disorders, and Kawasaki disease are examples. In these disorders, CNS inflammation usually occurs in association with characteristic systemic manifestations that allow proper diagnosis. Management of CNS involvement in these disorders is the same as the treatment of the systemic illness.

OTHER PARAINFECTIOUS ENCEPHALOPATHIES

In association with systemic infections or other illnesses, CNS dysfunction may occur in the absence of

direct CNS inflammation or infection. Reye syndrome is a prominent example of this type of encephalopathy that often occurs in association with varicella virus or other respiratory or systemic viral infections. In Reye syndrome, cerebral edema and cerebral dysfunction occur, but there is no evidence of any direct involvement of the nervous system by the associated microorganism or inflammation. Cerebral edema in Reye syndrome is accompanied by liver dysfunction and fatty infiltration of the liver. As a result of efforts to discourage use of aspirin in childhood febrile illnesses, the number of patients with Reye syndrome has markedly decreased. The precise relationship, however, between aspirin and Reye syndrome is unclear.

SYNDROMES PRESENTING AS ACUTE FLACCID PARALYSIS

Flaccid paralysis evolving over hours or a few days suggests involvement of the lower motor neuron complex (see Floppy Infant Syndrome section). Anterior horn cells (spinal cord) may be involved by viral infection (paralytic poliomyelitis) or by paraviral or postviral immunologically mediated disease (acute transverse

myelitis). The nerve trunks (polyneuritis) may be diseased as in Guillain-Barré syndrome or affected by toxins (diphtheria, porphyria). The neuromuscular junction may be blocked by tick toxin or botulinum toxin. The paralysis rarely will be due to metabolic (periodic paralysis) or inflammatory muscle disease (myositis). A lesion compressing the spinal cord must be ruled out.

Clinical Findings

A. SYMPTOMS AND SIGNS

Features assisting diagnosis are age, a history of preceding or waning illness, the presence (at time of paralysis) of fever, rapidity of progression, cranial nerve findings, and sensory findings (Table 23–25). The examination may show long tract findings (pyramidal tract), causing increased reflexes and a positive Babinski sign. The spinothalamic tract may be interrupted, causing loss of pain and temperature. Back pain, even tenderness to percussion, may occur, as well as bowel and bladder incontinence. Often the paralysis is ascending, symmetric, and painful (muscle tenderness or myalgia). Laboratory findings occasionally are diagnostic.

B. LABORATORY FINDINGS (SEE TABLE 23–25)

Examination of CSF is helpful. Imaging studies of the spinal column (plain radiographs) and spinal cord (MRI, myelogram) are occasionally essential. Viral cultures (CSF, throat, stool) and titers aid in diagnosing poliomyelitis. A high sedimentation rate may suggest tumor or abscess; the presence of antinuclear antibody may suggest lupus arteritis.

EMG and nerve conduction velocity can be helpful in diagnosing polyneuropathy. Nerve conduction is usually slowed after 7–10 days. Findings in botulism and tick-bite paralysis can be specific and diagnostic. Rarely, elevation of muscle enzymes or even myoglobinuria may aid in diagnosis of myopathic paralysis. Porphyrin urine studies and heavy-metal assays (arsenic, thallium, lead) can reveal those rare toxic causes of polyneuropathic paralysis.

Differential Diagnosis

The child who has been well and becomes paralyzed often has polyneuritis. Acute transverse myelitis sometimes occurs in an afebrile child. The child who is ill and febrile at the time of paralysis often has acute transverse myelitis or poliomyelitis. Acute epidural spinal cord abscess (or other compressive lesion) must be ruled out. Poliomyelitis is very rare in our immunized population. Paralysis due to tick bites occurs seasonally (spring and summer). The tick is usually found in the occipital hair. Removal is curative.

Paralysis due to botulinum toxin occurs most commonly younger than age 1 year (see Chapter 38). Intra-

venous drug abuse can lead to myelitis and paralysis. Furthermore, chronic myelopathy occurs with two human immunodeficiency virus infections: HTLV-I and HTLV-III (now called HIV-1).

Complications

A. RESPIRATORY PARALYSIS

Early and careful attention to oxygenation is essential. Administration of oxygen, intubation, mechanical respiratory assistance, and careful suctioning of secretions may be required. Increasing anxiety and a rise in diastolic and systolic blood pressures are early signs of hypoxia. Cyanosis is a late sign. Deteriorating spirometric findings (forced expiratory volume in 1 second [FEV₁] and total vital capacity) may indicate the need for controlled intubation and respiratory support. Blood gases (usually late changes with increased CO₂, decreased O₂) can aid decisions.

B. INFECTIONS

Pneumonia is common, especially in patients with respiratory paralysis. Antibiotic therapy is best guided by results of cultures. Bladder infections occur when an indwelling catheter is required because of bladder paralysis. Recovery from myelitis may be delayed by urinary tract infection.

C. AUTONOMIC CRISIS

This may be a cause of death in Guillain-Barré syndrome. Strict attention to vital signs to detect and treat hypotension or hypertension and cardiac arrhythmias in an intensive care setting is advisable, at least early in the course and in severely ill patients.

Treatment

Most of these syndromes have no specific treatment. Ticks causing paralysis must be removed. Other therapies include the use of erythromycin in *Mycoplasma* infections and botulism equine antitoxin in wound botulism. Recognized associated disorders (eg, endocrine, neoplastic, toxic) should be treated by appropriate means. Supportive care also involves pulmonary toilet, adequate fluids and nutrition, bladder and bowel care, prevention of decubiti, and, in many cases, psychiatric support.

A. CORTICOSTEROIDS

These agents are believed by most to be of no benefit in Guillain-Barré syndrome. Autonomic symptoms (eg, hypertension) in polyneuritis may require treatment.

B. PLASMAPHERESIS

Plasma exchange or intravenous IgG has been beneficial in severe cases of Guillain-Barré syndrome.

Table 23–25. Acute flaccid paralysis in children.

	Poliomyelitis (Paralytic, Spinal, and Bulbar), With or Without Encephalitis	Landry-Guillain-Barré Syndrome (“Acute Idiopathic Polyneuritis”)	Botulism	Tick-Bite Paralysis	Transverse Myelitis and Neuromyelitis Optica
Etiology	Poliovirus types I, II, and III; other enteroviruses; enteroviruses, eg EV71; vaccine strain polio virus (rare); West Nile virus: epidemic in birds. Mosquitoes infect horses, humans	Likely delayed hypersensitivity—with T-cell-mediated anti-ganglioside antibodies. Mycoplasmal and viral infections (EBV, CMV), <i>Campylobacter jejuni</i> , Hepatitis B.	<i>Clostridium botulinum</i> toxin. Block at neuromuscular junction. Under age 1, toxin synthesized in bowel by organisms in ingested dust or honey. At older ages toxin injected in food. Rarely from wound infection.	Probable interference with transmission of nerve impulse caused by toxin in tick saliva	Usually unknown; multiple viruses (herpes, EBV, varicella, hepatitis A) often postviral (see Guillain-Barré syndrome)
History	None, or inadequate polio immunization. Upper respiratory or gastrointestinal symptoms followed by brief respite. Bulbar paralysis more frequent after tonsillectomy. Often in epidemics, in summer and early fall.	Nonspecific respiratory or gastrointestinal symptoms in preceding 5–14 d common. Any season, though slightly lower incidence in summer.	Infancy: dusty environment (eg, construction area), honey. Older: food poisoning. Multiple cases hours to days after ingesting contaminated food.	Exposure to ticks (dog tick in eastern United States; wood ticks). Irritability 12–24 h before onset of a rapidly progressive ascending paralysis.	Rarely symptoms compatible with multiple sclerosis or optic neuritis. Progression from onset to paraplegia often rapid, usually without a history of bacterial infection.
Presenting complaints	Febrile at time of paralysis. Meningeal signs, muscle tenderness, and spasm. Asymmetrical weakness widespread or segmental (cervical, thoracic, lumbar). Bulbar symptoms early or before extremity weakness; anxiety; delirium.	Symmetrical weakness of lower extremities, which may ascend rapidly to arms, trunk, and face. Verbal child may complain of paresthesias. Fever uncommon. Facial weakness early. Miller-Fisher variant presents as ataxia and ophthalmoplegia (rare).	Infancy: constipation, poor suck and cry. “Floppy.” Apnea. Lethargy. Choking (cause of SIDS?). Older: blurred vision, diplopia, ptosis, choking, weakness.	Rapid onset and progression of ascending flaccid paralysis; often accompanied by pain and paresthesias. Paralysis of upper extremities usually occurs on second day after onset.	Root and back pain in about one-third to one-half of cases. Sensory loss below level of lesion accompanying rapidly developing paralysis. Sphincter difficulties common.
Findings	Flaccid weakness, usually asymmetrical. Cord level: Lumbar: legs, lower abdomen Cervical: shoulder, arm, neck, diaphragm Bulbar: respiratory, lower cranial nerves Encephalopathy accompanies paralysis in West Nile.	Flaccid weakness, symmetric, usually greater proximally, but may be more distal or equal in distribution. Rarely cranial nerves IX–XI, III–VI. Miller-Fisher variant: ophthalmoplegia, ataxia. Bulbar involvement may occur. Slight distal impairment of position, vibration, touch; difficult to assess in young children.	Infants: Flaccid weakness. Alert. Eye, pupil, facial weakness. Deep tendon reflexes decreased. Absent suck, gag. Constipation. Older: paralysis accommodation, eye movements. Weak swallow. Respiratory paralysis.	Flaccid, symmetric paralysis. Cranial nerve and bulbar (respiratory) paralysis, ataxia, sphincter disturbances, and sensory deficits may occur. Some fever. Diagnosis rests on finding tick, which is especially likely to be on occipital scalp.	Paraplegia with areflexia below level of lesion early; later, may have hyperreflexia. Sensory loss below and hyperesthesia or normal sensation above level of lesion. Paralysis of bladder and rectum. Optic neuritis rarely may be present.

Table 23–25. Acute flaccid paralysis in children. (continued)

	Poliomyelitis (Paralytic, Spinal, and Bulbar), With or Without Encephalitis	Landry-Guillain-Barré Syndrome (“Acute Idiopathic Polyneuritis”)	Botulism	Tick-Bite Paralysis	Transverse Myelitis and Neuromyelitis Optica
CSF	Pleocytosis (20–500+ cells) with PMN predominance in first few days, later monocytic preponderance. Protein frequently elevated (50–150 mg/dL). CSF IgM + in West Nile	Cytoalbuminologic dissociation; ten or fewer mononuclear cells with high protein after first week. Normal glucose. IgG may be elevated. West Nile will have cells; nerves can be involved in a myeloradiculitis	Normal	Normal	Usually no monometric block; CSF may show increased protein, pleocytosis with predominantly mononuclear cells, increased IgG
Electromyogram (EMG)	Denervation after 10–21 days. Nerve conduction normal. Amplitude reduced in West Nile	Nerve conduction velocities markedly decreased; may be normal early, or if axon only damage.	EMG distinctive: BSAP (brief small abundant potentials).	Nerve conduction slowed; returns rapidly to normal after removal of tick	Normal early. Denervation at level of lesion after 10–21 d.
Other studies	Virus in stool and throat. Serial serologic titers IgG, IgM in West Nile Hyponatremia 30% in West Nile.	Search for specific cause such as infection, intoxication, auto-immune disease. Anti-ganglioside antibodies to GM ₁ (GQ1b in Miller-Fisher)	Infancy: stool culture, toxin. Rare serum toxin positive. Older: serum (or wound) toxin.	Leukocytosis, often with moderate eosinophilia	Normal spine x-rays do not exclude spinal epidural abscess. MRI to rule out cord-compressive lesions. Cord may be swollen in myelitis.
Course and prognosis	Paralysis usually maximal 3–5 d after onset. Transient bladder paralysis may occur. Outlook varies with extent and severity of involvement. Note: Mortality greatest from respiratory failure and superinfection. West Nile paralysis may be permanent	Course progressive over a few days to about 2 weeks. Note: Threat greatest from respiratory failure (10%), autonomic crises (eg, widely variable blood pressure, arrhythmia), and superinfection. Majority recover completely. Plasmapheresis may have a role. Intravenous IgG. Relapses occasionally occur.	Infancy: supportive. Penicillin. Botulism immune globulin intravenous (BIG-IV). Respiratory support, gavage feeding. Avoid aminoglycosides. Older: penicillin, antitoxin, prolonged respiratory support. Prognosis: excellent Fatality 3%	Total removal of tick is followed by rapid improvement and recovery. Otherwise, mortality rate due to respiratory paralysis is very high.	Large degree of functional recovery possible. Corticosteroids are of controversial benefit in shortening duration of acute attack or altering the overall course.

CMV = cytomegalovirus; CSF = cerebrospinal fluid; EBV = Epstein-Barr virus; PMN = polymorphonuclear neutrophil; SIDS = sudden infant death syndrome.

C. PHYSICAL THERAPY

Rehabilitative measures are best instituted when acute symptoms have subsided and the patient is stable.

D. ANTIBIOTICS

Appropriate antibiotics and drainage are required for epidural abscess.

Electromyography

EMG is often helpful in grossly differentiating myopathic from neurogenic processes. Fibrillations occur in both. In the myopathies, very low spikes are more typical, and the motor unit action potentials seen during contraction characteristically are of short duration, are polyphasic, and are increased in number for the strength of the contraction (increased interference pattern). Neurogenic findings include decreased numbers of motor units, which may be polyphasic, larger than normal, or both. The interference pattern is decreased. In myotonic dystrophy, the EMG is characterized by prolonged discharge of electrical activity on movement of the probing needle (so-called dive bomber sound).

Muscle Biopsy

Properly executed (by open biopsy or by using the Bergstrom muscle biopsy needle), this procedure is usually helpful. Histochemical techniques, histogram analysis of muscle fiber types and sizes, and electron microscopy are offering new classifications of the myopathies. Findings common to the muscular dystrophies include variation in the size and shape of muscle fibers, increase in connective tissue, interstitial infiltration of fatty tissue, degenerative changes in muscle fibers, and central location of nuclei.

Dystrophin is a normal intracellular plasma membrane protein in muscle, the gene product missing in Duchenne and Becker muscular dystrophies. Staining the muscle for dystrophin aids in differentiating Duchenne and Becker muscular dystrophies; dystrophin is absent in Duchenne muscular dystrophy and reduced in Becker muscular dystrophy. Electrophoresis can confirm whether the dystrophin is absent or present in small amounts and whether there is a qualitative difference from normal dystrophin, the latter two patterns being characteristic of Becker muscular dystrophy.

DISORDERS OF CHILDHOOD AFFECTING MUSCLES (Table 23–26)

DIAGNOSTIC STUDIES

Serum Enzymes

Creatine kinase reflects muscle damage or “leaks” from muscle into plasma. Blood should be drawn before EMG or muscle biopsy, which may lead to release of the enzyme. Corticosteroids may suppress levels despite very active muscle disease, for example, as in polymyositis.

Genetic Testing & Carrier Detection

Previously, detection of carriers for Duchenne muscular dystrophy (mothers and sisters of affected boys) rested on creatine kinase elevations (two thirds of patients will have this finding); physical findings of mild dystrophy (large calves, muscle weakness); abnormal muscle EMGs; or biopsy results. All are unreliable for diagnostic purposes.

DNA probes are now available for carrier detection and prenatal diagnosis of Duchenne and Becker muscular dystrophies. Deletions are often (60%) found on the short arm of the X chromosome; it is postulated that all patients and most mothers will show deletions when

sufficient probes are developed to search the whole Duchenne genome (perhaps 4000 kb in length).

Amplification of DNA by the PCR test can detect the deletion. Moreover, this technique plus Southern blot analysis can detect abnormal DNA base repeats. For example, in myotonic dystrophy, a GCT triplet excess is currently the most sensitive test for that disease. The tests can be used for intrauterine diagnosis and prediction of whether the triplet is within the normal or mutant range. Thus, in many cases, the greater the number of repeats, the more severely involved the fetus or patient.

Mutations (especially deletions) of survivor motor neuron (SMN) and neuronal apoptosis inhibitory protein (NAIP) genes on chromosome 5q13 are present in 95% of patients with spinal muscular atrophy.

Finally, Kearns–Sayre progressive external ophthalmoplegia with retinopathy is inherited via maternal cytoplasmic mitochondria. Assay of mutations and deletions from blood or muscle samples are now commercially available.

Therapy for Duchenne muscular dystrophy continues to be frustrating. Prednisone in low doses has increased muscle strength and prolonged ambulation. Research emphasis is on gene therapy, but there is great difficulty in finding viral vectors able to carry the very large dystrophin gene into muscle cells.

BENIGN ACUTE CHILDHOOD MYOSITIS

Benign acute childhood myositis (myalgia cruris epidemica) is characterized by transient severe muscle pain and weakness affecting mainly the calves and occurring 1–2 days following an upper respiratory tract infection. Although symptoms involve mainly the gastrocnemius muscles, all skeletal muscles appear to be invaded directly by virus; recurrent episodes are due to different viral types. By seroconversion or isolation of the virus, acute myositis has been shown to be largely due to influenza types B and A and occasionally due to parainfluenza and adenovirus.

MYASTHENIA GRAVIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Weakness, chiefly of muscles innervated by the brainstem, usually coming on or increasing with use (fatigue).*

Table 23–26. Muscular dystrophies and myotonias of childhood.

Disease	Genetic Pattern	Age at Onset	Early Manifestations	Involved Muscles	Reflexes
Muscular dystrophies Duchenne muscular dystrophy (pseudohypertrophic infantile)	X-linked recessive; autosomal-recessive unusual. 30–50% have no family history.	2–6 y; rarely in infancy	Clumsiness, easy fatigability on walking, running, and climbing stairs. Walking on toes; waddling gait. Lordosis. (Climbing up on legs rising from supine position—Gower maneuver.)	Axial and proximal before distal. Pelvic girdle; pseudohypertrophy of gastrocnemius (90%), triceps brachii, and vastus lateralis. Shoulder girdle usually later, also articulation difficulties. Eventually cardiomyopathy (50%).	Knee jerks ± or 0; ankle jerks + to ++
Becker muscular dystrophy (late onset)	X-linked recessive. (Allele at Xp21)	Childhood (usually later than in Duchenne)	Similar to Duchenne.	Similar to Duchenne	Similar to Duchenne
Limb-girdle muscular dystrophy A. Pelvifemoral (Leyden–Möbius) B. Scapulohumeral (Erb juvenile)	Autosomal-recessive in 60%; high sporadic incidence. A. Relatively common B. Rare	Variable; early childhood to adulthood	Weakness, with distribution according to type. Waddling gait, difficulty climbing stairs. Lordosis.	A. Pelvic girdle usually involved first and to greater extent. B. Shoulder girdle often asymmetric. Quadriceps and hamstrings may be weakest.	Usually present
Facioscapulohumeral muscular dystrophy (Landouzy–Déjérine) scapuloperoneal variant (rare)	Autosomal-dominant; sporadic cases not uncommon: Linkage to 4q35	Usually late in childhood and adolescence; rare in infancy; not uncommon in 20s	Diminished facial movements with inability to close eyes, smile, or whistle. Face may be flat; unlined. Difficulty in raising arms over head. Lordosis. Tripping in scapuloperoneal type.	Facial muscles followed by shoulder girdle, with occasional spread to hips or distal legs (scapuloperoneal variant)	Present
Spinal muscular atrophy (SMA) Infantile SMA (Werdnig–Hoffman disease)	Autosomal-recessive	0–2 y	Floppy infant	Pelvic and shoulder girdle. Tongue. Intercostals. Fingers and toes spared.	0 or nearly so
Juvenile SMA (Kugelburg–Welander disease)	Autosomal-recessive	Onset after age 2 usually (age 5–15 typical)	Weakness. “Fasciculations” 50%. Rarely a cause of floppy infant.	Same	Same
Metabolic myopathies Carnitine deficiency (lipid storage myopathy) Primary (rare) Secondary: multiple forms	Genetics variable, often recessive	Infancy to adolescence	Fasting hypoglycemia and coma; less ketosis than expected. Myopathy. Cardiomyopathy. Fatty liver. Don’t confuse with Reye, SIDS.	Weakness variable; may be precipitated by exercise (with resultant myoglobinuria) or fasting	Normal to decreased

Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
Degeneration and variation in fiber size; proliferation of connective tissue. Basophilia, phagocytosis. Poor differentiation of fiber types on ATPase reaction; deficiency of type IIB fibers. Dystrophin absent.	EMG myopathic. CK (4000–5000 IU) very high with decrease toward normal over the years. 60% have C-terminal Xp21 deletion on blood, amniotic fluid or chorionic villi. Positive test obviates need for muscle biopsy	Physical therapy, braces, wheelchair eventually, weight control. Prednisone, deflazacort improve motor function temporarily. Creatine. Some benefit. Gene transfer minidystrophin by viral vectors. Utrophin.	Ten percent show nonprogressive mental retardation. Osteoporosis, scoliosis common. Death from cardiac or respiratory failure 10–15 y after diagnosis with 75% of patients dead by age 20.
Similar to above, except type IIB fibers present. Reduced or abnormal size dystrophin.	Similar to above, although muscle enzymes may not be as elevated	As above. Wheelchair in late childhood or early adult life.	Slower progression than Duchenne's, with death usually in adulthood
Dystrophic muscle changes (see Duchenne). Dystrophin normal. Special stains for sarcoglycan (dystrophin associated glycoprotein–DAG deficiency).	EMG myopathic. CK variable; many severe cases have sarcoglycan deficiency (severe autosomal recessive type). Must exclude dystrophinopathy and SMA.	Physical therapy, weight control	Mildly progressive: spread from lower to upper limbs may take 15–20 y. Life expectancy mid to late adulthood.
Predominantly large fibers with scattered tiny atrophic fibers, "moth-eaten" and whorled fibers. Inflammatory response. Little or no fiber splitting, fibrosis, or type 1 fiber predominance.	EMG myopathic. Muscle enzymes usually normal. 4q35ter deletion. If blood test positive, biopsy unnecessary	Physical therapy where indicated. Wheelchair in 20%. Forty percent of biopsies show inflammation; steroids ineffective, however.	Very slowly progressive, often with plateaus, except in infantile form where there may be difficulties in walking by adolescence. Usually normal life span.
Small, group atrophy. Twin peak fiber size. Fiber type grouping. Minimal fibrosis.	EMG neuropathic. Nerve conduction, CSF, muscle enzymes normal. 90–95% have deletions or abnormalities in <i>SMN</i> (survival motor neuron) or other genes at band 5q13.	Supportive: respiratory care, positioning, secretion management. Genetic counseling.	80–95% of patients 0–4 y die of pneumonia and respiratory failure.
Same		Physical therapy, wheelchair positioning to avoid scoliosis. May walk, usually later lose this.	Fairly normal life expectancy. 4–40+ y.
Lipid droplets ± or ragged red fibers may be present.	Muscle biochemistry (carnitine, CPT enzyme). Urine organic acids (at time of illness). Plasma carnitine: deficiency may be in blood alone or blood and muscle.	Avoid fasting and mitochondrial toxins, eg, ASA, valproic acid. Carbohydrate. Treat acidosis. Carnitine orally.	Variable: occasionally fatal in infants. Progressive weakness, developmental delay, cardiomyopathy may occur.

(continued)

Table 23–26. Muscular dystrophies and myotonias of childhood. (continued)

Disease	Genetic Pattern	Age at Onset	Early Manifestations	Involved Muscles	Reflexes
“Oculocraniosomatic syndrome” (ophthalmoplegia and “ragged reds”; progressive external ophthalmoplegia) Kearns–Sayre	Mitochondrial DNA deletion; other hereditary neurologic disorders may be found in patient or family	Variable; from infancy to adult life; most at about 10 y of age	Ptosis and limitation of eye movements; hearing and visual loss (retinitis pigmentosa); intellectual loss; cerebellar disturbance (ataxia)	Extraocular muscles, often asymmetric. Variable involvement of axial muscles; cardiac muscles, with conduction defect.	Depressed to \pm or 0
Myasthenia gravis Transient neonatal	Variable	At birth	Difficulty sucking, swallowing; trouble with secretions	Somatic and cranial muscles	Normal to decreased
Myasthenia gravis Persistent neonatal	Variable	Variable: birth, neonatal, infancy	Same as transient form.	Same as transient form.	Same as transient form.
Congenital myopathies Myotonic dystrophy (Neonatal onset)	Autosomal-dominant	At birth	Same as myasthenia. Ptosis. Facial diplegia. Arthrogryposis, club feet, thin ribs.	Cranial and somatic, pharyngeal.	Decreased to 0
“Other” myopathies Central core Nemaline (rod body) Myotubular (centronuclear)	Dominant or rarely autosomal-recessive x-linked recessive in neonatal form	Severe variants present at birth; milder variants (more common) infancy, childhood	Severe variant, newborns with severe hypotonia and respiratory failure is rare. Later presentation—facial weakness, mild to moderate weakness, even “toe walking” only.	Similar to myotonic dystrophy	Decreased to 0
Congenital muscular dystrophy (Fukayama) (FCMD)	Genetic; recessive. chromosome 9q31–33. fuKutin mutations	Birth to 9 mos.	Hypotonia, joint contractures, mental retardation.	Heterogenous. Facial (cranial) and somatic. Contracture common.	Variable
Congenital muscular dystrophy (occidental)	Unknown; usually not familial; merosin-deficient variant 6q2 Many variants (8)	Birth (or early infancy)	As above. Normal IQ.	Same (merosin negative may involve heart, nerves, and brain).	Same
Benign congenital hypotonia (Oppenheim)	Variable	Variable	Hypotonia only. Deep tendon reflexes positive. Laboratory tests, biopsy normal.	Somatic muscles (respiratory muscles spared)	Normal to decreased
Myotonias Myotonia congenita (Thomsen)	Autosomal-dominant (autosomal-recessive cases reported)	Early infancy to late childhood	Difficulty in relaxing muscles after contracting them, especially after sleep; aggravated by cold, excitement.	Hands especially; muscles may be diffusely enlarged, giving patient herculean appearance.	Normal

Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
Mitochondrial abnormalities. "Ragged red" fibers. Changes in fiber size, usually due to type 2 fiber atrophy.	CK usually normal. ECG with conduction block. CSF protein elevated. Nerve conduction slowed. MRI of brain and brain stem auditory evoked response may be abnormal. Mitochondrial deletions.	Plastic retraction of eyelids. Cardiac support. Anticipate diabetes mellitus. Coenzyme Q?	Dysphagia may develop (50%) as well as generalized muscle weakness. Prognosis poor. In severe cases, spongy vacuolization of brain and brain stem.
Unnecessary	Edrophonium or neostigmine tests. Acetylcholine receptor (AChR) antibodies. Repetitive nerve stimulation, EMG.	Supportive. Anticholinergic drugs.	Usually transient (< 2 months)
Sophisticated end plate, nerve terminal ultrastructural studies may be necessary.	May be similar to above. AChR antibodies negative.	May not respond to ACh-ase drugs, steroids, or immunosuppressants	Variable, may have long-term severe course.
Generalized fiber hypertrophy, delay in maturation. Type I atrophy. Internal nuclei.	EMG myotonic in some (waning amplitude and pitch). Test mother. CK often normal. DNA testing (chromosome 19) for GCT repeat.	Supportive, even respiratory support. Genetic counseling.	Severely involved infant may improve dramatically over months; expect mental retardation in this same variant.
Distinctive diagnostic histochemistry, eg, "central cores," "nemaline rods," myotubes type II-I fibers of unequal size.	Myopathic EMG.	Supportive. Genetic counseling.	Variable. May shorten life. Death in infancy or severe handicap in severe neonatal form. Scoliosis prominent.
"Dystrophic" changes. Fibrosis. Necrotic fibers. Internal nuclei. ? regenerative fibers.	Myopathic EMG. CK increased. Positive CT, MRI scans: white matter low density, etc.	Supportive.	Physical and mental handicap lifelong. Virtually all are of Japanese ancestry.
Same. Evaluate for merosin (α -laminin-2 deficiency).	Brain imaging normal in pure form. Merosin-deficient form may have white matter abnormalities.	Supportive.	May improve, walk. Scoliosis.
Normal with sophisticated studies (histochemistry, electron microscopy, even metabolic studies).	Use of this diagnosis is shrinking with increasingly sophisticated biochemical (eg, cytochrome oxidase) studies.	Supportive	Good (by definition). (Few documented long-term studies.)
Nonspecific and minor changes; type IIB fibers may be absent.	EMG myotonic.	Usually none. Phenytoin, especially in cold weather, may improve muscle functioning.	Normal life expectancy, with only mild disability.

(continued)

Table 23–26. Muscular dystrophies and myotonias of childhood. (continued)

Disease	Genetic Pattern	Age at Onset	Early Manifestations	Involved Muscles	Reflexes
Myotonic dystrophy I (Steinert) (childhood and adult form)	Autosomal-dominant	Late childhood to adolescence; neonatal and infantile forms increasingly recognized (see above)	Myotonia of grasp, tongue; worsened by cold, emotions. "Hatchet-face." Nasal voice. Weakness and easy fatigability. Mild to moderate mental retardation noted.	Wasting, weakness of facial muscles, (mastication); sternocleidomastoids, hands. Myotonic phenomena: "bunching up" of muscles of tongue, thenar eminence, finger extensors after tapping with percussion hammer.	In infantile form, marked hyporeflexia
Myotonic dystrophy II [Proximal myotonic myopathy (PROMM)]					

- Positive response to neostigmine and edrophonium.
- Acetylcholine receptor antibodies in serum (except in congenital form).

General Considerations

Myasthenia gravis is characterized by easy fatigability of muscles, particularly the extraocular muscles and those of mastication, swallowing, and respiration. In the neonatal period, however, or in early infancy, the weakness may be so constant and general that an affected infant may present nonspecifically as a "floppy infant." Girls are affected more frequently than boys. The age at onset is older than 10 years in 75% of patients, often shortly after menarche. If diagnosed before age 10 years, congenital myasthenia should be considered in retrospect. Thyrotoxicosis is found in almost 10% of affected female patients. The essential abnormality is a circulating antibody that binds to the acetylcholine receptor protein and thus reduces the number of motor end plates for binding by acetylcholine.

Clinical Findings

A. SYMPTOMS AND SIGNS

1. Neonatal (transient) myasthenia gravis—This disorder occurs in 12% of infants born to myasthenic mothers. The condition is due to maternal acetylcholine receptor antibody transferred across the placenta; a thymic factor in the infant may also be involved.

2. Congenital (persistent) myasthenia gravis—In this form of the disease, the mothers of the affected infants

rarely have myasthenia gravis, but other relatives may. Sex distribution is equal. Symptoms are often subtle and not recognized initially. Differential diagnosis includes many other causes of the "floppy infant" syndrome, such as infant botulism, ocular myopathy, congenital ptosis, and Möbius syndrome (facial nuclear aplasia and other anomalies). Congenital myasthenia gravis is not caused by receptor antibodies and often responds poorly to therapy. It may result from a genetic abnormality of the acetylcholine receptor protein, postsynaptic membrane structure, or other myoneural transmission defects.

3. Juvenile myasthenia gravis—In this autoimmune form, the symptoms and signs are similar to those in adults. Receptor antibodies are usually present. The patient may be first seen by an otolaryngologist or psychiatrist. The more prominent signs are difficulty in chewing, dysphagia, a nasal voice, ptosis, and ophthalmoplegia. Pathologic fatigability of limbs, chiefly involving the proximal limb and neck muscles, may be more prominent than the bulbar signs and may lead to an initial diagnosis of conversion hysteria, muscular dystrophy, or polymyositis. Weakness may be limited to ocular muscles only. Associated disorders include autoimmune conditions, especially thyroid disease.

An acute fulminant form of myasthenia gravis has been reported in children age 2–10 years, who present with rapidly progressive respiratory difficulties. Bulbar paralysis may evolve within 24 hours. There is no history of myasthenia. The differential diagnosis includes Guillain-Barré syndrome and bulbar poliomyelitis. Administration of anticholinesterase agents establishes the diagnosis and is lifesaving.

B. LABORATORY FINDINGS

1. Neostigmine test—In newborns and very young infants, the neostigmine test may be preferable to the

Table 23–26. (continued)

Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
Type I fiber atrophy, type II hypertrophy, sarcoplasmic masses, internal nuclei, phagocytosis, fibrosis, and cellular reaction.	EMG markedly myotonic. Glucose tolerance test, thyroid tests. ECG. Chest radiograph and pulmonary function tests. Immunoglobulins. PCR amplification of GCT repeat on chromosome 19q13 to distinguish normal from mutant alleles. CCTG repeat in zinc finger protein gene.	Procainamide, 250 mg tid orally, increased to tolerance; phenytoin 5–7 mg/kg/d orally. (Drugs usually little role.)	Frontal baldness, cataracts (85%), gonadal atrophy (85% of males), thyroid dysfunction, diabetes mellitus (20%). Cardiac conduction defects; impaired pulmonary function. Low IgG. Life expectancy decreased. Type II—slowly progressive weakening; good outlook

ASA = acetyl salicylic acid; CK = creatine kinase; CPT = carnitine palmitoyl transferase; CSF = cerebrospinal fluid; ECG = electrocardiogram; EMG = electromyogram; PCR = polymerase chain reaction; SIDS = sudden infant death syndrome.

edrophonium (Tensilon) test because the longer duration of its response permits better observation, especially of sucking and swallowing movements. The test dose of neostigmine is 0.02 mg/kg subcutaneously, usually given with atropine, 0.01 mg/kg subcutaneously. There is a delay of about 10 minutes before the effect may be manifest. The physician should be prepared to suction secretions.

2. Edrophonium test—Testing with edrophonium is used in older children who are capable of cooperating in certain tasks, such as raising and lowering their eyelids and squeezing a sphygmomanometer bulb or the examiner's hands. The test dose is 0.1–1 mL intravenously, depending on the size of the child. Maximum improvement occurs within 2 minutes.

3. Other laboratory tests—Serum acetylcholine receptor antibodies are often found in the neonatal and juvenile forms. Ophthalmologic tests of ocular motility with edrophonium are often positive in patients able to cooperate. In juveniles, thyroid studies are appropriate.

C. ELECTRICAL STUDIES OF MUSCLE

Repetitive stimulation of a motor nerve at slow rates (3/s) with recording over the appropriate muscle reveals a progressive fall in amplitude of the muscle potential in myasthenic patients. A maximal stimulus must be given. At higher rates of stimulation (50/s), there may be a transient repair of this defect before the progressive decline is seen. If this study is negative, single-fiber EMG may be helpful diagnostically.

D. IMAGING

Chest radiograph and CT scanning in older children may disclose benign thymus enlargement. Thymus tumors are rare in children.

Treatment

A. GENERAL AND SUPPORTIVE CARE

In the newborn or in a child in myasthenic or cholinergic crisis (see item 5 in the following section), suctioning of secretions is essential. Respiratory assistance may be required. Treatment should be conducted by physicians with experience in this disorder.

B. ANTICHOLINESTERASE DRUG THERAPY

1. Pyridostigmine bromide—The dosage must be adjusted for each patient. A frequent starting dosage is 15–30 mg orally every 6 hours.

2. Neostigmine—Fifteen milligrams of neostigmine are roughly equivalent to 60 mg of pyridostigmine bromide. Neostigmine often causes gastric hypermotility with diarrhea, but it is the drug of choice in newborns, in whom prompt treatment may be lifesaving. It may be given parenterally.

3. Atropine—Atropine may be added on a maintenance basis to control mild cholinergic side effects such as hypersecretion, abdominal cramps, and nausea and vomiting.

4. Immunologic intervention—Such intervention is achieved primarily with prednisone. Plasmapheresis is effective in removing acetylcholine receptor antibody in severely affected patients.

5. Myasthenic crisis—Relatively sudden difficulties in swallowing and respiration may be observed in myasthenic patients. Edrophonium results in dramatic but brief improvement; this may make evaluation of the condition of the small child difficult. Suctioning, tracheostomy, respiratory assistance, and fluid and electrolyte maintenance may be required.

6. Cholinergic crisis—Cholinergic crisis may result from overdosage of anticholinesterase drugs. The resulting weakness may be similar to that of myasthenia, and the muscarinic effects (diarrhea, sweating, lacrimation, miosis, bradycardia, hypotension) are often absent or difficult to evaluate. The edrophonium test may help to determine whether the patient is receiving too little of the drug or is manifesting toxic symptoms due to overdosage. Improvement after the drugs are withdrawn suggests cholinergic crisis. A respirator should be available. The patient may require atropine and tracheostomy.

C. SURGICAL MEASURES

Early thymectomy is beneficial in many patients whose disease is not confined to ocular symptoms; the effects may be delayed. Experienced surgical and postsurgical care are prerequisites.

Prognosis

Neonatal (transient) myasthenia presents a great threat to life, primarily because of secretion aspiration. With proper treatment, the symptoms usually begin to disappear within a few days to 2–3 weeks, after which the child usually requires no further treatment. In the congenital (persistent) form, the symptoms may initially be as acute as in the transient variety. More commonly, however, they are relatively benign and constant, with gradual worsening as the child grows older. Fatal cases occur. In the juvenile form, patients may become resistant or unresponsive to anticholinesterase compounds and require corticosteroids or treatment in a hospital where respiratory assistance can be given. The overall prognosis for survival, for remission, and for improvement after therapy with prednisone and thymectomy is favorable. Death in myasthenic or cholinergic crisis may occur unless prompt treatment is given.

PERIPHERAL NERVE PALSIES

1. Facial Weakness

Facial asymmetry may be present at birth or may develop later, either suddenly or gradually, unilaterally or

bilaterally. Nuclear or peripheral involvement of the facial nerves results in sagging or drooping of the mouth and inability to close one or both eyes, particularly when newborns and infants cry. Inability to wrinkle the forehead may be demonstrated in infants and young children by getting them to follow a light moved vertically above the forehead. Loss of taste of the anterior two thirds of the tongue on the involved side may be demonstrated in cooperative children by age 4 or 5 years. Playing with a younger child and the judicious use of a tongue blade may enable the physician to note whether the child's face puckers up when something sour (eg, lemon juice) is applied with a swab to the anterior tongue. Ability to wrinkle the forehead is preserved, owing to bilateral innervation, in supranuclear facial paralysis.

Injuries to the facial nerve at birth occur in 0.25–6.5% of consecutive live births. Forceps delivery is the cause in some cases; in others, the side of the face affected may have abutted in utero against the sacral prominence. Often, no cause can be established.

Acquired peripheral facial weakness (Bell's palsy) of sudden onset and unknown cause is common in children. It often follows a viral illness (postinfectious) or physical trauma (eg, cold). It may be a presenting sign of tumor, Lyme disease, infectious mononucleosis, herpes simplex, or Guillain-Barré syndrome and is usually diagnosable by the history, physical examination, and appropriate laboratory tests.

Bilateral facial weakness in early life may be due to agenesis of the affected muscles or to nuclear causes (part of Möbius syndrome) or may even be familial. Myasthenia gravis, polyneuritis, and myotonic dystrophy must be considered.

Asymmetrical crying facies, in which one side of the lower lip depresses with crying (this is the normal side) and the other does not, is a common innocent form of autosomal dominant inherited congenital malformation. The defect in the parent (the asymmetry often improves with age) may be almost inapparent. EMG suggests congenital absence of the depressor anguli oris muscle of the lower lip. Forceps pressure is often erroneously incriminated as a cause of this innocent congenital anomaly. Occasionally other major (eg, cardiac septal defects) congenital defects accompany the palsy.

In the vast majority of cases of isolated peripheral facial palsy—both those present at birth and those acquired later—improvement begins within 1–2 weeks, and near or total recovery of function is observed within 2 months. Methylcellulose drops, 1%, should be instilled into the eyes to protect the cornea during the day; at night, the lid should be taped down with cellophane tape. Upward massage of the face for 5–10 minutes three or four times a day may help maintain muscle tone. Prednisone therapy likely does not aid

recovery. Acyclovir (herpes antiviral agent) therapy may have a role in Bell's palsy.

In the few children with permanent and cosmetically disfiguring facial weakness, plastic surgical intervention at age 6 years or older may be of benefit. New procedures, such as attachment of facial muscles to the temporal muscle and transplantation of cranial nerve XI, are being developed.

CHRONIC POLYNEUROPATHY

Polyneuropathy, usually insidious in onset and slowly progressive, occurs in children of any age. The presenting complaints are chiefly disturbances of gait and easy fatigability in walking or running and, slightly less often, weakness or clumsiness of the hands. Pain, tenderness, or paresthesias are mentioned less frequently. Neurologic examination discloses muscular weakness, greatest in the distal portions of the extremities, with steppage gait and depressed or absent deep tendon reflexes. Cranial nerves are sometimes affected. Sensory deficits occur in a stocking and glove distribution. The muscles may be tender, and trophic changes such as glassy or parchment skin and absent sweating may occur. Thickening of the ulnar and peroneal nerves may be felt. Pure sensory neuropathies show up as chronic trauma. That is, the patient does not feel minor trauma or burns, and thus allows trauma to occur.

Known causes include (1) toxins (lead, arsenic, mercurials, vincristine, and benzene); (2) systemic disorders (diabetes mellitus, chronic uremia, recurrent hypoglycemia, porphyria, polyarteritis nodosa, and lupus erythematosus); (3) inflammatory states (chronic or recurrent Guillain-Barré syndrome and neuritis associated with mumps or diphtheria); (4) hereditary, often degenerative conditions, which in some classifications include certain storage diseases, leukodystrophies, spinocerebellar degenerations with neurogenic components, and Bassen-Kornzweig syndrome; and (5) hereditary sensory or combined motor and sensory neuropathies (Table 23-27). Polyneuropathies associated with carcinomas, beriberi or other vitamin deficiencies, or excessive vitamin B₆ intake are not reported or are exceedingly rare in children.

The most common chronic neuropathy of insidious onset often has no identifiable cause. This chronic idiopathic neuropathy is assumed to be immunologically

mediated and may have a relapsing course. Sometimes facial weakness occurs. CSF protein levels are elevated. Nerve conduction is slowed, and nerve biopsies are abnormal. Immunologic abnormalities are seldom demonstrated, although nerve biopsies may show round cell infiltration. Corticosteroids and other immunosuppressants may give long-term benefit.

Of the four defined hereditary sensory neuropathies, one rarer variant is familial dysautonomia, also called Riley-Day syndrome. Transmitted as an autosomal recessive trait and occurring mostly in Jewish children, this disorder has its onset in infancy. It is characterized by vomiting and difficulties in feeding that are due to abnormal esophageal motility, pulmonary infections, decreased or absent tearing, indifference to pain, diminished or absent tendon reflexes, absence of fungiform papillae of the tongue, emotional lability, abnormal temperature control with excessive sweating, labile blood pressure, abnormal intradermal histamine responses, and other evidences of autonomic dysfunction.

Rarely, a careful genetic history (pedigree) and examination and electrical testing (motor and sensory nerve conduction, EMG) of relatives are keys to diagnosis of hereditary neuropathy. This is the most common cause of chronic neuropathy in children. Other hereditary neuropathies may have ataxia as a prominent finding often overshadowing the neuropathy. Examples are Friedreich ataxia, dominant cerebellar ataxia, and Marinesco-Sjögren syndrome. Finally, some hereditary neuropathies are associated with identifiable and occasionally treatable metabolic errors. (see Table 23-22). These disorders are described in more detail in Chapter 32 (see also Table 23-21).

Laboratory diagnosis of chronic polyneuropathy is made by measurement of motor and sensory nerve conduction velocities. EMG may show a neurogenic polyphasic pattern. CSF protein levels are often elevated, sometimes with an increased IgG index. Nerve biopsy, with teasing of the fibers and staining for metachromasia, may demonstrate loss of myelin and, to a lesser degree, loss of axons and increased connective tissue or concentric lamellas (so-called onion skin appearance) around the nerve fiber. Muscle biopsy may show the pattern associated with denervation. Other laboratory studies directed toward specific causes mentioned above include screening for heavy metals and for metabolic, renal, or vascular disorders. Chronic lead intoxication, which rarely causes neuropathy in childhood, may escape detection until the child is given edetate calcium disodium and lead levels are determined in timed urine samples.

Therapy is directed at specific disorders whenever possible. Occasionally the weakness is profound and involves bulbar nerves, in which case tracheostomy and

Table 23–27. Hereditary motor and sensory neuropathies; metabolic error unknown.

Name	Prototype	Inheritance	Clinical Features	Nerve Biopsy
Sensory and autonomic neuropathy	Familial dysautonomia	Autosomal-recessive	See text	Decreased unmyelinated fibers posterior column and cord
HMSN I (if tremor is present, Roussy-Lévy syndrome) (60–90% of HMSN are type I) (CMT I)	“Classic” Charcot-Marie-Tooth (CMT) type I (1) CMT 1A (2) CMT 1B (3) CMT 1C (4) X-linked (5) Type 4	Autosomal-dominant 17p11.2 1g22 Connexin 32	Onset 0–15 y. Weakness, atrophy of feet, calves (pes cavus, “stork legs”), hands. Sensory loss 0 or variable. Deep tendon reflexes 0. Motor nerve conduction velocities slowed. 10% have hypertrophic (palpable) nerves. Type 1B is linked to Duffy blood group.	Segmental demyelination
HMSN II (10–30% of cases) (CMT 2)	Neuronal, axonal type 2	Autosomal-dominant Multiple gene sites	Less severe; onset 10–y. Leg cramps, numbness, motor nerve conduction velocities normal or slightly slow. CSF protein often normal.	Axonal loss, secondary demyelination
HMSN III (CMT 3)	Hypertrophic CMT disease; Déjérine-Sottas disease	Autosomal-recessive (or AD, sporadic)	Onset in infancy. Severe. CSF protein increased. Very slow MNCV. Slowly progressive.	Hypertrophic (“onion bulb”) interstitial changes
HMSN IV (CMT 4)	Refsum disease	Autosomal-recessive demyelinating, or axonal	Severe sensory, mild motor. Thick nerves. CSF protein elevated. Ichthyosis, retinitis pigmentosa, ataxia, deafness. Urine phytanic acid.	See HMSN III
HMSN V	CMT disease with spastic paraparesis		Abnormal pyramidal tract findings. Rule out adrenomyelopathy.	Defined in pedigrees. Rule out adrenomyelopathy with long-chain fatty acids.
HNPP	Hereditary neuropathy with pressure palsies	Autosomal-dominant PMP22 17p11.2 deletion	Adolescent onset. Episodic numbness, peroneal palsy, carpal tunnel syndrome.	Occasional “tomaculous sausage” nerve formations.

¹CSF = cerebrospinal fluid; MNCV = motor nerve conduction velocity; HMSN = hereditary motor and sensory neuropathy; HNPP = hereditary neuropathy (with ability to) pressure palsies; PMP = peripheral myelin protein; MPZ/PO = myelin protein zero.

respiratory assistance are required. Corticosteroid therapy may be of considerable benefit in cases where the cause is unknown or neuropathy is considered to be due to chronic inflammation (this is not the case in acute Guillain-Barré syndrome). Prednisone is recommended, 1–2.5 mg/kg/d orally, with tapering to the lowest effective dose—discontinued if the process seems to be arresting and reinstated when symptoms recur. Prednisone should probably not be used for treatment

of hereditary neuropathy. In all cases considered for corticosteroid therapy, the risks and benefits should be carefully weighed. When treatment is available, symptoms regress and may disappear altogether over a period of months.

The long-term prognosis varies with the cause and the ability to offer specific therapy. In the corticosteroid-dependent group, residual deficits and deaths within a few years are more frequent.

MISCELLANEOUS NEUROMUSCULAR DISORDERS

FLOPPY INFANT SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *In early infancy, decreased muscular activity, both spontaneous and in response to postural reflex testing and to passive motion.*
- *In young infants, "frog posture" or other unusual positions at rest.*
- *In older infants, delay in motor milestones.*

General Considerations

In the young infant, ventral suspension (ie, supporting the infant with a hand under the chest) normally results in the infant's holding its head slightly up (45 degrees or less), the back straight or nearly so, the arms flexed at the elbows and slightly abducted, and the knees partly flexed. The "floppy" infant droops over the hand like an inverted U. The normal newborn attempts to keep the head in the same plane as the body when pulled up from supine to sitting by the hands (traction response). Marked head lag is characteristic of the floppy infant. Hyperextensibility of the joints is not a dependable criterion.

The usual reasons for seeking medical evaluation in older infants are delays in walking, running, or climb-

ing stairs or motor difficulties and lack of endurance. Hypotonia or decreased motor activity is a frequent presenting complaint in neuromuscular disorders but may also accompany a variety of systemic conditions or may be due to certain disorders of connective tissue.

1. Paralytic Group

The hypotonic infant who is weak (appearing paralyzed) usually has a lesion of the lower motor neuron complex (Table 23–28). The child has significant lack of movement against gravity (eg, fails to kick the legs, hold up the arms, or attempt to stand when held) or in response to stimuli such as tickling or slight pain. Infantile progressive spinal muscular atrophy (Werdnig–Hoffman disease) is the most common cause. Neuro-ropathy is rare. Botulism and myasthenia gravis (rare) are neuromuscular junction causes. Myotonic dystrophy and rare myopathies (eg, central core myopathy) are muscle disease entities.

In anterior horn cell or muscle disease, weakness is proximal (ie, in shoulders and hips); finger movement is preserved. Tendon reflexes are absent or depressed; strength (to noxious stimuli) is decreased (paralytic). Intelligence is preserved. Fine motor, language, and personal and social milestones are normal, as measured, for example, on a Denver Developmental Screening Test (DDST, or Denver II) (see Chapter 2).

Myopathies

The congenital, relatively nonprogressive myopathies, muscular dystrophy, myotonic dystrophy, polymyositis, and periodic paralysis were discussed earlier in this chapter. Most cases of congenital or early infantile muscular dystrophy reported in the past probably represented congenital myopathies (see Table 23–28). Congenital muscular dystrophy, diagnosed by muscle biopsy, occurs in two forms: (1) a benign form, with gradual improvement in strength; and (2) a severe form, in which either weakness progresses rapidly and death occurs in the first months or year of life or severe disability is present with little or no progression but lifelong marked limitation of activity.

Glycogenosis with Muscle Involvement

Glycogen storage diseases are described in Chapter 32. Patients with type II disease (Pompe disease, due to a deficiency of acid maltase) are most likely to present as floppy infants. Muscle cramps on exertion or easy fatigability, rather than floppiness in infancy, is the presenting complaint in type V disease (McArdle phosphorylase deficiency) or in the glycogenosis due to

Table 23–28. Floppy infant: paralytic causes.

Disease	Genetic	Early Manifestations
IP SMA (Infantile progressive spinal muscular atrophy) “Malignant” form	AR	In utero movements decreased by one third. Gradual weakness, delay in gross motor milestones. Weak cry. Abdominal breathing. Poor limb motion (“no kicking”). No deep tendon reflexes. Fasciculations of tongue. Normal personal-social behavior.
“Intermediate” form	AR	Onset under age 1 year usual. <i>Progression slower</i> : may be impossible to predict early course of IP SMA. Hand tremors common.
Infantile botulism	Acquired younger than age 1 y (mostly under 6 mos); botulism spore in stool makes toxin	Poor feeding. Constipation. Weak cry. Failure to thrive. Lethargy. Facial weakness, ptosis, ocular muscle palsy. Inability to suck, swallow. Apnea. Source: soil dust (outdoor construction workers or family gardeners may bring it home on clothes), honey.
Myasthenia gravis Neonatal transient	12% of infants born from a myasthenia mother	Floppiness. Poor sucking and feeding; choking. Respiratory distress. Weak cry.
Congenital persistent	Mother normal. Rare AR (AD)	As above; may improve and later exacerbate.
Myotonic dystrophy	AD 99%—mother transmits gene	Polyhydramnios; failure of suck, respirations. Facial diplegia. Ptosis. Arthrogryposis. Thin ribs. Later, developmental delay. Examine mother for myotonia, physiognomy.
Neonatal “rare myopathy,” severe variant Nemaline, central core, “minimal change,” etc	AR, AD	Virtually all of the rare myopathies may have a severe (even fatal) neonatal or early infant form. Clinical features similar in infancy to infantile myotonic dystrophy.
Congenital muscular dystrophy Fukayama (FCMD)	Genetic	Early onset. Facial weakness. Joint contractures. Severe mental retardation. Seizures. Brain structural abnormalities.
Other		Severe or benign. No mental retardation (see text).
Infantile neuropathy	HSMN most common cause	Demyelinating or axonal; a rare cause of floppy infant. Rule out mimicking IP SMA (deletion study). EMG, NCV are key studies.
Benign congenital hypotonia	Unknown cause	Diagnosis of exclusion. Family history variable. Mild to moderate hypotonia with weakness. (This term being used less with increasing genetic, microscopy advances)

AD = autosomal dominant; AR = autosomal recessive; HSMN = hereditary sensory motor neuropathy; EMG = electromyogram; NCV = nerve conduction velocity.

phosphofructokinase deficiency or phosphohexose isomerase inhibition.

Myasthenia Gravis

Neonatal transient and congenital persistent myasthenia gravis, with patients presenting as paralytic floppy infants, is described earlier in this chapter.

Arthrogryposis Multiplex (Congenital Deformities About Multiple Joints)

This symptom complex, sometimes associated with hypotonia, may be of neurogenic or myopathic origin (or

both) and may be associated with a variety of other anomalies. Orthopedic aspects are discussed in Chapter 24.

Spinal Cord Lesions

Severe limpness in newborns following breech extraction with stretching or actual tearing of the lower cervical to upper thoracic spinal cord is rarely seen today, owing to improved obstetric delivery. Klumpke lower brachial plexus paralysis may be present; the abdomen is usually exceedingly soft, and the lower extremities are flaccid. Urinary retention is present initially; later, the bladder

may function autonomously. Myelography or MRI scanning may define the lesion. After a few weeks, spasticity of the lower limbs becomes obvious. Treatment is symptomatic and consists of bladder and skin care and eventual mobilization on crutches or in a wheelchair.

2. Nonparalytic Group

The nonparalytic hypotonic infant often has a damaged brain (Table 23–29). Deep tendon reflexes may be depressed or absent in this group. Brisk reflexes with hypotonia point to suprasegmental or general cerebral dysfunction. Intrauterine or perinatal insults to brain or spinal cord, while sometimes difficult to document, are major causes. (Occasionally, severe congenital myopathies presenting in the newborn period simulate nonparalytic hypotonia.) Persisting severe hypotonia is ominous. Tone will often vary. Spasticity and other forms of cerebral palsy may emerge; hypertonia and hy-

potonia may occur at varying times in the same infant. Choreoathetoid or ataxic movements and developmental delay can clarify the diagnosis. Reflexes are often increased; pathologic reflexes (Babinski, tonic neck) may persist or worsen.

The creatine kinase level and the EMG are usually normal. Prolonged nerve conduction velocities point to polyneuritis or leukodystrophy. Muscle biopsies, using special stains and histographic analysis, often show a remarkable reduction in size of type II fibers associated with decreased voluntary motor activity.

Limpness in the neonatal period and early infancy and subsequent delay in achieving motor milestones are the presenting features in a large number of children with a variety of CNS disorders, including mental retardation, as in trisomy 21. In many such cases, no specific diagnosis can be made. Close observation and scoring of motor patterns and adaptive behavior, as by the DDST, are helpful.

Table 23–29. Floppy infant: nonparalytic causes.

	Causes	Manifestations
Central nervous system disorders		
Atonic diplegia (prespastic diplegia)	Intrauterine, perinatal asphyxia, cord injury	Limpness, stupor; poor suck, cry, Moro reflex, grasp; later, irritability, increased tone and reflexes
Choreoathetosis	As above; kernicterus	Hypotonic early; movement disorder emerges later (6–18 mos)
Ataxic cerebral palsy	Same as choreoathetosis	Same as choreoathetosis
Syndromes with hypotonia (CNS origin)		
Trisomy 21	Genetic	All have hypotonia early
Prader–Willi syndrome	Genetic deletion 15q11	Hypotonia, hypomentia, hypogonadism, obesity (“H ₃ O”)
Marfan syndrome	Autosomal-dominant	Arachnodactyly
Dysautonomia	Autosomal-recessive	Respiratory infections, corneal anesthesia
Turner syndrome	45X, or mosaic	Somatic stigmata (see Chapter 32)
Degenerative disorders		
Tay–Sachs disease	Autosomal-recessive	Cherry-red spot on macula
Metachromatic leukodystrophy	Autosomal-recessive	Deep tendon reflexes increased early, polyneuropathy late; mental retardation
Systemic diseases^a		
Malnutrition	Deprivation, cystic fibrosis, celiac disease	
Chronic illness	Congenital heart disease; chronic pulmonary disease (eg, bronchopulmonary dysplasia); uremia, renal acidosis	
Metabolic disease	Hypercalcemia, Lowe disease	
Endocrinopathy	Hypothyroid

CEREBRAL PALSY

The term “cerebral palsy” is a nonspecific term used to describe a chronic, static impairment of muscle tone, strength, coordination, or movements. The term implies that the condition is nonprogressive and originated from some type of cerebral insult or injury before birth, during delivery, or in the perinatal period. There is no implication in the use of this term about the child’s intellect or whether other neurologic deficits or disorders (eg, blindness, deafness, epilepsy) exist. Some form of cerebral palsy occurs in about 0.2% of neonatal survivors. The fundamental course, severity, precise manifestations, and prognosis vary widely.

The most common forms of cerebral palsy (75% of cases) involve spasticity of the limbs. A variety of terms denote the specific limb or combination of limbs affected: monoplegia (one limb); hemiplegia (arm and leg on same side of body, but arm more affected than leg); diplegia (leg affected more than arms); paraplegia (both legs affected with arms unaffected); quadriplegia (all four limbs affected equally).

Ataxia is the second most common form of cerebral palsy, accounting for about 15% of cases. The ataxia frequently affects fine coordinated movements of the upper extremities, but may also involve lower extremities and trunk. An involuntary movement disorder usually in the form of choreoathetosis accounts for 5% of cases and persistent hypertonia without spasticity 1%.

Depending on the type and severity of the motor deficits, associated neurologic deficits or disorders may occur: seizure in up to 50%, mild mental retardation in 26%, and severe retardation in up to 27%. Disorders of language, speech, vision, hearing, and sensory perception are found in varying degrees and combinations.

The findings on physical examination are variable and are predominately those of spasticity, hyperreflexia,

ataxia, and involuntary movements. Microcephaly is frequently present. In patients with hemiplegia, the affected arm and leg may be smaller and shorter than the unaffected limbs. Cataracts, retinopathy, and congenital heart defects may be indicative of congenital infections such as CMV and rubella.

Appropriate laboratory studies depend on the history and physical findings. MRI scans may be helpful in understanding the full extent of cerebral injury, and occasionally neuroimaging results suggest specific etiologies (eg, periventricular calcifications in congenital CMV infections). Other diagnostic tests that may be considered include IgG and IgM antibody determinations for specific infective agents; urine amino acids and organic acids; blood amino acids, lactate, pyruvate, and ammonia concentrations.

The determination that a child has cerebral palsy is based in part on excluding other neurologic disorders and following the child for a sufficient amount of time to ascertain the static, nonprogressive nature of the disorder.

Treatment and management are directed at assisting the child to attain maximal physical functioning and potential physical, occupational, and speech therapy; orthopedic monitoring and intervention and special educational assistance may all contribute to an improved outcome. Medications for spasticity and seizures are needed in many children. Also important is the general support of the parents and family with counseling, educational programs, and support groups.

The prognosis for patients with cerebral palsy depends greatly on the severity of the motor deficits and the degree of incapacity the patients ultimately experience. In severe cases, life span is greatly shortened to 10 years or less. Aspiration, pneumonia, or other intercurrent infections are the most common causes of death.

In contrast, patients with mild cerebral palsy may improve with age. Some patients experience resolution of their motor deficits by age 7 years. Many children with normal intellect have normal life spans and are able to lead productive, satisfying lives.

The cause is often obscure or multifactorial. No definite etiologic diagnosis is possible in over one third of cases. The incidence is high among infants small for gestational age. Intrauterine hypoxia is a frequent cause. Other known causes are intrauterine bleeding, infections, toxins, congenital malformations, obstetric complications (including birth hypoxia), neonatal infections, kernicterus, neonatal hypoglycemia, acidosis, and a small number of genetic syndromes.

Orthopedics is the medical discipline that deals with disorders of the neuromuscular and skeletal systems. Patients with orthopedic problems present with one or more of the following complaints: pain, loss of function, or deformity. Although review of the history reveals the patient's expectation, physical examination is the most important feature of orthopedic diagnosis.

■ DISTURBANCES OF PRENATAL ORIGIN

CONGENITAL AMPUTATIONS AND LIMB DEFICIENCIES

Congenital amputations may be due to teratogens (eg, drugs or viruses), amniotic bands, or metabolic diseases (eg, diabetes in the mother). The incidence of multiple limb involvement is 30%.

Children with congenital limb deficiencies, such as absence of the femur, tibia, or fibula, also have a high incidence of associated congenital anomalies, including genitourinary and cardiac defects and cleft palate. A limb deficiency usually consists of partial absence of structures in the extremity along one side or the other. For example, in radial clubhand, the entire radius is absent, but the thumb may be either hypoplastic or completely absent; that is, the effect on structures distal to the amputation varies. Complex tissue defects are nearly always associated with longitudinal bone deficiency in that the associated nerves and muscles are not completely represented when a bone is absent.

Terminal amputations are treated by prosthesis, for example, to compensate for shortness of one leg. For certain types of severe anomalies, operative treatment is indicated to remove a portion of the malformed extremity (eg, foot) so that a prosthesis can be fitted early. An extension prosthesis fitted over the foot to equalize limb length is a reasonable nonsurgical alternative.

Lower extremity prostheses are best fitted between ages 12 and 15 months, when walking starts. They are consistently well accepted, because they are necessary for balancing and walking. For a unilateral upper extremity amputation, fitting the child with dummy-type prosthesis as early as age 6 months has the advantage of

instilling an accustomed pattern of proper length and bimanual manipulation. Although myoelectric prostheses have a technologic appeal, the majority of patients use the simplest construct in the long run.

Children quickly learn how to function with their prostheses and can lead active lives, even participating in sports with peers.

DEFORMITIES OF THE EXTREMITIES

1. Metatarsus Varus

Metatarsus varus is a common congenital foot deformity characterized by inward deviation of the forefoot. A vertical crease in the arch occurs when the deformity is more rigid. The angulation is at the level of the base of the fifth metatarsal, and this bone will be prominent. Most flexible deformities are secondary to intrauterine posture and usually resolve spontaneously. Several investigators have noticed that 10–15% of children with metatarsus varus have hip dysplasia; therefore, a careful hip examination is necessary. If the deformity is rigid and cannot be manipulated past the midline, it is worthwhile to use a cast changed at intervals of 2 weeks to correct the deformity. So-called corrective shoes do not live up to their name, although they can be used to maintain correction obtained by casting.

Lincoln TL, Suen PW: Common rotational variations in children. *J Am Acad Orthop Surg* 2003;11(5):312 [PMID: 14565753].

2. Clubfoot (*Talipes Equinovarus*)

The diagnosis of classic talipes equinovarus, or clubfoot, requires three features: (1) plantar flexion of the foot at the ankle joint (equinus), (2) inversion deformity of the heel (varus), and (3) medial deviation of the forefoot (varus). The incidence of clubfoot is approximately 1:1000 live births. There are three major categories of clubfoot: (1) idiopathic, (2) neurogenic, and

(3) those associated with syndromes such as arthrogyrosis and Larsen syndrome. Any infant with a clubfoot should be examined carefully for associated anomalies, especially of the spine. Idiopathic clubfeet may be hereditary.

Treatment consists of manipulation of the foot to stretch the contracted tissues on the medial and posterior aspects, followed by splinting to hold the correction. When this treatment is instituted shortly after birth, correction is rapid. When treatment is delayed, the foot tends to become more rigid within a matter of days. After full correction is obtained, a night brace is necessary for long-term maintenance of correction. Treatment by means of casting requires patience and experience, but fewer patients require surgery when attention is paid to details of the Ponsetti technique. If the foot is rigid and resistant to cast treatment, surgical release and correction are appropriate. Fifteen percent to 50% require a surgical release.

Tredwell SJ et al: Review of the effect of early amniocentesis on foot deformity in the neonate. *J Pediatr Orthop* 2001;21:636 [PMID: 11521033].

3. Infantile Dysplasia of the Hip Joint

The definition of dysplasia is abnormal growth or development. Dysplasia of the hip encompasses a spectrum of conditions in which an abnormal relationship exists between the proximal femur and the acetabulum. In the most severe condition, the femoral head is not in contact with the acetabulum and is classified as a dislocated hip. A dislocatable hip is one in which the hip is within the acetabulum but can be dislocated with a provocative maneuver. A subluxatable hip is one in which the femoral head comes partially out of the joint with a provocative maneuver. Acetabular dysplasia is the term used to denote insufficient acetabular development on radiograph.

Congenital dislocation of the hip occurs in approximately 1:1000 live births. At birth, both the acetabulum and femur are underdeveloped. The dysplasia is progressive with growth unless the dislocation is corrected. If the dislocation is corrected in the first few days or weeks of life, the dysplasia is completely reversible and a normal hip will develop. As the child becomes older and the dislocation or subluxation persists, the deformity will worsen to the point where it will not be completely reversible, especially after the walking age. For this reason, it is important to diagnose the deformity early.

Clinical Findings

The diagnosis of hip dislocation in the newborn depends on demonstrating instability of the joint by placing the infant on its back and obtaining complete relaxation by feeding with a bottle if necessary. The examiner's long finger is then placed over the greater trochanter and the thumb over the inner side of the thigh. Both hips are flexed 90 degrees and then slowly abducted from the midline, one hip at a time. With gentle pressure, an attempt is made to lift the greater trochanter forward. A feeling of slipping as the head relocates is a sign of instability (Ortolani sign). When the joint is more stable, the deformity must be provoked by applying slight pressure with the thumb on the medial side of the thigh as the thigh is adducted, thus slipping the hip posteriorly and eliciting a jerk as the hip dislocates (Barlow sign). The signs of instability are more reliable than a radiograph for diagnosing congenital dislocation of the hip in the newborn. Ultrasonography can be used but tends to result in overdiagnosis in the newborn. Asymmetrical skinfolds are present in about 40% of newborns and therefore are not particularly helpful.

After the first month of life, the signs of instability become less evident. Contractures begin to develop about the hip joint, limiting abduction to less than 90 degrees. It is important to hold the pelvis level to detect asymmetry of abduction. If the knees are at unequal heights when the hips and knees are flexed, the dislocated hip will be on the side with the lower knee. After the first 6 weeks of life, radiologic examination becomes more valuable, with lateral displacement of the femoral head being the most reliable sign. In mild cases, the only abnormality may be increased steepness of acetabular alignment, so that the acetabular angle is greater than 35 degrees.

If dysplasia of the hip has not been diagnosed during the first year of life and the child begins to walk, there will be a painless limp and a lurch to the affected side. When the child stands on the affected leg, a dip of the pelvis will be evident on the opposite side, owing to weakness of the gluteus medius muscle. This is called the Trendelenburg sign and accounts for the unusual swaying gait. In children with bilateral dislocations, the loss of abduction is almost symmetrical and may be deceiving. A radiograph of the pelvis is indicated in children with incomplete abduction in the first few months of life. As a child with bilateral dislocation of the hips begins to walk, the gait is waddling. The perineum is widened as a result of lateral displacement of the hips, and there is flexion contracture as a result of posterior displacement of the hips. This flexion contracture contributes to marked lumbar lordosis, and the greater trochanters are easily palpable in their elevated position. Treatment is still possible in the first 2 years of life, but

the results are not nearly as effective as in children receiving treatment in the nursery.

Treatment

Dislocation or dysplasia diagnosed in the first few weeks or months of life can easily be treated by splinting, with the hip maintained in flexion and abduction. Forced abduction is contraindicated, because this can lead to avascular necrosis of the femoral head. The use of double or triple diapers is never indicated because diapers are not adequate to obtain proper positioning of the hip. An orthopedic surgeon with experience managing the problem is best to supervise treatment of children requiring splints.

In the first 4 months of life, reduction can be obtained by simply flexing and abducting the hip; no other manipulation is usually necessary. In late cases, preoperative traction for 2–3 weeks relaxes soft tissues about the hip. Following traction in which the femur is brought down opposite the acetabulum, reduction can be easily achieved without force under general anesthesia. After reduction a hip spica is used for 6 months. If the reduction is not stable within a reasonable range of motion after closed reduction, open reduction is indicated. If reduction is done at an older age, operations to correct the deformities of the acetabulum and femur may be necessary as well as open reduction.

Committee on Quality Improvement, Subcommittee on Developmental Dysplasia of the Hip. American Academy of Pediatrics: Clinical practice guideline: Early detection of developmental dysplasia of the hip. *Pediatrics* 2000;105(4 Pt 1):896 [PMID: 10742345].

4. Torticollis

Wryneck deformities in infancy may be due either to injury to the sternocleidomastoid muscle during delivery or to disease affecting the cervical spine. When contracture of the sternocleidomastoid muscle causes torticollis, the chin is rotated to the side opposite to the affected muscle, and the head is tilted toward the side of the contracture. A mass felt in the midportion of the sternocleidomastoid muscle is not a true tumor but rather fibrous transformation within the muscle.

In most cases, passive stretching is effective. If the deformity has not been corrected by passive stretching within the first year of life, surgical release of the muscle origin and insertion will correct it. Excising the “tumor” of the sternocleidomastoid muscle creates an unsightly scar and is unnecessary. If the deformity is left untreated, a striking facial asymmetry will persist.

Torticollis is occasionally associated with congenital deformities of the cervical spine, and radiographs of the

spine are indicated in all cases. In addition, there is a 20% incidence of hip dysplasia.

Acute torticollis may follow upper respiratory infection or mild trauma in children. Rotatory subluxation of the upper cervical spine requires computed tomography for accurate imaging. Traction or a cervical collar usually results in resolution of the symptoms within 1 or 2 days. Other causes of torticollis include spinal cord or cerebellar tumors, syringomyelia, and rheumatoid arthritis.

Fernandez Cornejo VJ et al: Inflammatory atlanto-axial subluxation (Grisel's syndrome) in children: Clinical diagnosis and management. *Childs Nerv Syst* 2003;19(5-6):342 [PMID: 12783261].

GENERALIZED DISORDERS OF SKELETAL OR MESODERMAL TISSUES

1. Arthrogryposis Multiplex Congenita (Amyoplasia Congenita)

Arthrogryposis multiplex congenita consists of incomplete fibrous ankylosis (usually bilateral) of many or all joints of the body. Upper extremity contractures usually consist of adduction of the shoulders; extension of the elbows; flexion of the wrists; and stiff, straight fingers with poor muscle control of the thumbs. In the lower extremities, common deformities are dislocation of the hips, extension contractures of the knees, and severe club feet. The joints are fusiform and the joint capsules decreased in volume due to lack of movement during fetal development. Various investigations have attributed the basic defect to an abnormality of muscle or the lower motor neurons. Muscle development is poor, and muscles may be represented only by fibrous bands. Passive mobilization of joints is the early treatment. Prolonged casting for correction of deformities is contraindicated in these children because further stiffness results. Use of removable splints combined with vigorous therapy is the most effective conservative treatment. Surgical release of the affected joints is often necessary. The clubfoot associated with arthrogryposis is very stiff and nearly always requires an operation. Surgery about the knees, including capsulotomy, osteotomy, and tendon lengthening, is used to correct deformity. In the young child, a dislocated hip may be reduced operatively by the medial approach. Multiple operative procedures about the hip are contraindicated because further stiffness may be produced with consequent impairment of motion. Affected children are often able to walk if the dislocations and contractures are reduced surgically. The long-term prognosis for physical and vocational independence is guarded. These

patients have normal intelligence, but they have such severe physical restrictions that gainful employment is hard to find.

Bernstein RM: Arthrogryposis and amyoplasia. *J Am Acad Orthop Surg* 2002;10(6):417 [PMID: 12470044].

2. Marfan Syndrome

Marfan syndrome is a connective tissue disorder characterized by unusually long fingers and toes (arachnodactyly); hypermobility of the joints; subluxation of the ocular lenses; other eye abnormalities including cataract, coloboma, megalocornea, strabismus, and nystagmus; a high-arched palate; a strong tendency to scoliosis; pectus carinatum; and thoracic aortic aneurysms due to weakness of the media of the vessels (see Chapter 33). Serum mucoproteins may be decreased, and urinary excretion of hydroxyproline increased. The condition is easily confused with homocystinuria, because the phenotypic presentation is identical. The two diseases are differentiated by detecting homocystine in the urine of patients with homocystinuria.

Treatment is usually supportive for associated problems such as flatfoot. Scoliosis may involve more vigorous treatment by bracing or spine fusion. The long-term prognosis has improved for patients because better treatment for their aortic aneurysms has been devised.

Aburawi EH et al: Marfan's syndrome: A review. *Hosp Med* 2001;62:153 [PMID: 11291465].

3. Klippel–Feil Syndrome

Klippel–Feil syndrome is characterized by failure of segmentation of some or all of the cervical vertebrae. Multiple congenital spinal anomalies may be present, with hemivertebrae and scoliosis. The neck is short and stiff, the hairline is low, and the ears are low-set. Common associated defects include congenital scoliosis, cervical rib, spina bifida, torticollis, web neck, high scapula, renal anomalies, and deafness. If there is evidence of abnormal renal function, renal ultrasound is indicated as well as a hearing test. Scoliotic deformities, if progressive, are an indication for spinal arthrodesis.

Guilde JT et al: The natural history of Klippel–Feil syndrome: Clinical roentgenographic and magnetic resonance imaging findings at adulthood. *J Pediatr Orthop* 1995;15:617 [PMID: 7593574].

4. Sprengel Deformity

Sprengel deformity is a congenital condition in which one or both scapulas are elevated and small. The child cannot raise the arm completely on the affected side,

and torticollis may be present. The deformity occurs alone or in association with Klippel–Feil syndrome. If the deformity is functionally limiting, the scapula may be surgically relocated lower in the thorax. Excision of the upper portion of the scapula improves cosmetic appearance but has little effect on function.

Williams MS: Developmental anomalies of the scapula—the “om”st forgotten bone. *Am J Med Genet* 2003;120A(4):583 [PMID: 12884444].

5. Osteogenesis Imperfecta

Osteogenesis imperfecta is a rare genetic connective tissue disease characterized by multiple and recurrent fractures. The severe fetal type (osteogenesis imperfecta congenita) is characterized by multiple intrauterine or perinatal fractures. Moderately affected children have numerous fractures and are dwarfed as a result of bony deformities and growth retardation. Intelligence is not affected. The shafts of the long bones are reduced in cortical thickness, and wormian bones are present in the skull. Other features include blue scleras, thin skin, hyperextensibility of ligaments, otosclerosis with significant hearing loss, and hypoplastic and deformed teeth. In the tarda type, fractures begin to occur at variable times after the perinatal period, resulting in relatively fewer fractures and deformities. Affected patients are sometimes suspected of having suffered induced fractures, and the condition should be ruled out in any case of nonaccidental trauma.

Molecular genetic studies have identified more than 150 mutations of the *COL1A1* and *COL1A2* genes, which encode for type I procollagen. Parents without this mutation can be counseled that the likelihood of a second affected child is negligible.

Bisphosphonates show promise for decreasing the incidence of fractures. Surgical treatment involves correction of deformity of the long bones. Multiple intramedullary rods have been used to prevent deformity from poor healing of fractures. Patients are often confined to wheelchairs during adulthood.

Chevrel G, Meunier PJ: Osteogenesis imperfecta: Lifelong management is imperative and feasible. *Joint Bone Spine* 2001;68:125 [PMID: 11324928].

6. Osteopetrosis (Osteitis Condensans Generalisata, Marble Bone Disease, Albers–Schönberg Disease)

Osteopetrosis is a rare disorder of osteoclastic resorption of bone, resulting in abnormally dense bones. The marrow spaces are reduced, resulting in anemia. There are two types: a milder autosomal dominant type and a

more malignant autosomal recessive type. The findings may appear at any age. On radiologic examination, the bones show increased density, transverse bands in the shafts, clubbing of ends, and vertical striations of long bones. Thickening about the cranial foramina is present, and heterotopic calcification of soft tissues is possible.

The autosomal recessive form of osteopetrosis can be treated successfully by allogeneic bone marrow transplantation.

Armstrong DG et al: Orthopaedic management of osteopetrosis: Results of a survey and review of the literature. *J Pediatr Orthop* 1999;19:122 [PMID: 9890301].

7. Achondroplasia (Classic Chondrodystrophy)

Skeletal dysplasia is suspected based on abnormal stature, disproportion, dysmorphism, or deformity. Measurement of height is an excellent clinical screening tool. Achondroplasia is the most common form of short-limbed dwarfism. The upper arms and thighs are proportionately shorter than the forearms and legs. Findings frequently include bowing of the extremities, a waddling gait, limitation of motion of major joints, relaxation of the ligaments, short stubby fingers of almost equal length, frontal bossing, moderate hydrocephalus, depressed nasal bridge, and lumbar lordosis. Intelligence and sexual function are normal. The disorder is transmitted as an autosomal dominant trait, but 80% of cases result from a random mutation. Radiographs demonstrate short, thick tubular bones and irregular epiphysal plates. The ends of the bones are thick, with broadening and cupping. Epiphysal ossification may be delayed. Because the spinal canal is narrowed, a herniated disk in adulthood may lead to acute paraplegia. Growth hormone is given to some children with bone dysplasia. Limb lengthening is controversial, but possible.

Aldegheri R, Dall'Oca C: Limb lengthening in short stature patients. *J Pediatr Orthop B* 2001;10:238 [PMID: 11497369].

Kanaka-Gantenbein C: Present status of the use of growth hormone in short children with bone diseases (diseases of the skeleton). *J Pediatr Endocrinol Metab* 2001;14:17 [PMID: 11220700].

8. Osteochondrodystrophy (Morquio Disease)

Morquio disease is an autosomal recessive disorder of mucopolysaccharide storage. Skeletal abnormalities include shortening of the spine, kyphosis, scoliosis, shortened extremities, pectus carinatum, genu valgum, and a

hypoplastic odontoid with atlantoaxial instability. The child generally appears normal at birth and begins to develop deformities between ages 1 and 4 years as a result of abnormal deposition of mucopolysaccharides.

Radiographs demonstrate wedge-shaped flattened vertebrae and irregular, malformed epiphyses. The ribs are broad and have been likened to canoe paddles. The lower extremities are more severely involved than the upper ones.

The major treatment issue revolves around the prevention of cervical myelopathy. Bone marrow transplantation has been successful in alleviating some of the symptoms.

Peters C, Steward CG: Hematopoietic cell transplantation for inherited metabolic diseases: An overview of outcomes and practice guidelines. *Bone Marrow Transplant* 2003;31(4): 229 [PMID: 12621457].

GROWTH DISTURBANCES OF THE MUSCULOSKELETAL SYSTEM

SCOLIOSIS

Scoliosis is characterized by lateral curvature of the spine associated with rotation of the involved vertebrae. Scoliosis is classified by its anatomic location, in either the thoracic or lumbar spine, with rare involvement of the cervical spine. The convexity of the curve is designated right or left. Thus a right thoracic scoliosis would denote a thoracic curve in which the convexity is to the right; which is the most common type of idiopathic curve. Posterior curvature of the spine (kyphosis) is normal in the thoracic area, although excessive curvature is pathologic. Anterior curvature of the spine, or lordosis, is normal in the lumbar and cervical spines. Idiopathic scoliosis generally begins at age 8 or 10 years and usually progresses during growth. In rare instances, infantile scoliosis may be seen in children age 2 years or younger.

Idiopathic scoliosis is about four or five times more common in girls. The disorder is usually asymptomatic in the adolescent years, but severe curvature can cause pain or loss of pulmonary function in later years. The screening examination for scoliosis is performed by having the patient bend forward 90 degrees with the hands joined in the midline. An abnormal finding consists of asymmetry of the height of the ribs or paravertebral muscles on one side, indicating rotation of the trunk associated with lateral curvature.

Diseases that may be associated with scoliosis include neurofibromatosis, Marfan syndrome, cerebral palsy, muscular dystrophy, poliomyelitis, and myelodysplasia.

Between 5% and 7% of cases of scoliosis are due to congenital vertebral anomalies such as a hemivertebra or unilateral vertebral bridge. These curves are more rigid than the more common idiopathic curve (see later discussion) and will often increase with growth, especially during adolescence. Eighty percent of cases of scoliosis are idiopathic. Because 30% of family members are also affected, siblings of an affected child should be examined.

Idiopathic infantile scoliosis, occurring in children age 2–4 years, is uncommon in the United States but more common in Great Britain. If the rib–vertebral angle of Mehta is less than 20 degrees, the curve will resolve spontaneously. If the angle is greater, the curve will progress. Sciatic scoliosis may result from pressure on the spinal cord or roots by infectious processes or herniation of the nucleus pulposus; the underlying cause must be sought. Secondary curvature will resolve as the primary problem is treated.

Clinical Findings

A. SYMPTOMS AND SIGNS

Scoliosis in adolescents does not cause significant pain. If a patient has significant pain, seek the underlying cause because the scoliosis is usually secondary to some other disorder such as a bone or spinal cord tumor. Deformity of the rib cage and asymmetry of the waistline are evident with curvatures of 30 degrees or more. A lesser curvature may be detected by the forward bending test described in the preceding section, which is designed to detect early abnormalities of rotation that may not be apparent when the patient is standing erect.

B. IMAGING

The most valuable radiographs are those taken of the entire spine in the standing position in both the anteroposterior and lateral planes. Usually one primary curvature is evident with a compensatory curvature that develops to balance the body. At times two primary curvatures may be seen, usually in the right thoracic and left lumbar regions. Any left thoracic curvature should be suspected of being secondary to neurologic disease, prompting a more meticulous neurologic examination. If the curvatures of the spine are balanced (compensated), the head is centered over the center of the pelvis and the patient is “in balance.” If the spinal alignment is uncompensated, the head will be displaced to one side, which produces an unsightly deformity. Rotation of the spine may be measured by scoliometer. This rotation is associated with a marked rib hump as

the lateral curvature increases in severity. Deformity of the rib cage causes long-term problems when lung volumes are reduced.

Treatment

Treatment of scoliosis depends on curve magnitude, skeletal maturity, and risk of progression. Curvatures of less than 20 degrees usually do not require treatment unless they show progression. Bracing is indicated for curvature of 20–40 degrees in a skeletally immature child. Treatment is indicated for any curvature that demonstrates progression on serial radiologic examination. Curvatures greater than 40 degrees are resistant to treatment by bracing. Thoracic curvatures greater than 60 degrees have been correlated with poor pulmonary function in adult life. Curvatures of such severity are an indication for surgical correction and posterior spinal fusion to maintain the correction. Curvatures of 40–60 degrees may also require spinal fusion if they are progressive, are causing decompensation of the spine, or cause unacceptable deformity.

Surgical fusion involves decortication of the bone over the laminae and spinous processes, with the addition of bone graft. Rods, hooks, or pedicle screws maintain postoperative correction, with activity restriction for several months until the bone fusion is solid. Treatment requires a team approach and is best done in centers with full support facilities.

Prognosis

Compensated small curves that do not progress may be well tolerated throughout life, with minor deformity. Counsel the patients regarding the genetic transmission of scoliosis and caution that their children’s backs should be examined as part of routine physicals. Large thoracic curvatures greater than 60 degrees are associated with shortened life span and may progress during adult life. Large lumbar curvatures may lead to subluxation of the vertebrae and premature arthritic degeneration of the spine, producing disabling pain in adulthood. Early detection allows for simple brace treatment.

Danielsson A, L Nachemson A: Back pain and function 22 years after brace treatment for adolescent idiopathic scoliosis: A case-control study—part I. *Spine* 2003;28(18):2078.

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Slipped capital femoral epiphysis is a condition caused by displacement of the proximal femoral epiphysis due to disruption of the growth plate. The head of the femur is usually displaced medially and posteriorly relative to the femoral neck. The condition occurs in ado-

lence and is most common in obese males. The cause is unclear, although some authorities have shown experimentally that the strength of the perichondrial ring stabilizing the epiphysal area is sufficiently weakened by hormonal changes during adolescence such that the overload of excessive body weight can produce a pathologic fracture through the growth plate. Hormonal studies in these children are usually normal, although slipped capital femoral epiphysis is associated with hypothyroidism.

The condition occasionally occurs acutely following a fall or direct trauma to the hip. More commonly, vague symptoms occur over a protracted period in an otherwise healthy child who presents with pain and limp. The pain can be referred into the thigh or the medial side of the knee. Examine the hip joint in any obese child complaining of knee pain! The consistent finding on physical examination is limitation of internal rotation of the hip. The diagnosis may be clearly apparent only in the lateral radiographic view.

Treatment is based on the same principles that govern treatment of any fracture of the femoral neck in that the head of the femur is internally fixed to the neck of the femur and the fracture line allowed to heal. Unfortunately, the severe complication of avascular necrosis occurs in 30% of these patients. There is a positive correlation between forceful reduction of the slip and avascular necrosis. In cases of acute slip, as evidenced by the absence of any callus formation about the growth plate, it may be possible to reduce the hip by gentle traction. In more chronic cases, a more expeditious procedure is to pin the slip as it lies. Remodeling of the fracture site often improves the position of the hip without further surgery.

The long-term prognosis is guarded because most of these patients continue to be overweight and overstress their hip joints. Follow-up studies have shown a high incidence of premature degenerative arthritis in this disease, even in those who do not develop avascular necrosis. The development of avascular necrosis almost guarantees a poor prognosis, because new bone does not readily replace the dead bone at this late stage of skeletal development. About 30% of patients have bilateral involvement, which may occur as late as 1 or 2 years after the primary episode.

Dobbs MB, Weinstein SL: Natural history and long-term outcomes of slipped capital femoral epiphysis. *Instr Course Lect* 2001;50:571.

GENU VARUM & GENU VALGUM

Genu varum (bowleg) is normal from infancy through age 2 years. The alignment then changes to genu valgum (knock-knee) until about age 8 years, at which

time adult alignment is attained. Criteria for referral to an orthopedist include persistent bowing beyond age 2 years, bowing that is increasing rather than decreasing, bowing of one leg only, and knock-knee associated with short stature.

Bracing may be appropriate. Rarely an osteotomy is necessary for a severe problem such as Blount disease (proximal tibial epiphysal dysplasia).

Zayer M: Long-term results after physiological genu varum. *J Pediatr Orthop B* 2000;9:271.

TIBIAL TORSION

“Toeing in” in small children is a common parental concern. Tibial torsion is rotation of the leg between the knee and the ankle. Internal rotation amounts to about 20 degrees at birth but decreases to neutral rotation by age 16 months. The deformity is sometimes accentuated by laxity of the knee ligaments, allowing excessive internal rotation of the leg in small children. In children who have a persistent internal rotation of the tibia beyond age 16–18 months, the condition is often due to sleeping with feet turned in and can be reversed with an external rotation splint worn only at night.

Arazi M et al: Normal development of the tibiofemoral angle in children: A clinical study of 590 normal subjects from 3 to 17 years of age. *J Pediatr Orthop* 2001;21:264.

FEMORAL ANTEVERSION

Toeing in beyond age 2 or 3 years is usually secondary to femoral anteversion, which is characterized by more internal rotation of the hip compared with external rotation. This femoral alignment follows a natural history of progressive decrease toward neutral during growth. Studies comparing the results of treatment with shoes or braces to the natural history have shown that little is gained by active treatment. Active external rotation exercises, such as skating or bicycle riding, can be encouraged. Osteotomy for rotational correction is rarely required. Children who have no external rotation of hip in extension are candidates for orthopedic consultation.

Lincoln TL, Suen PW: Common rotational variations in children. *J Am Acad Orthop Surg* 2003;11(5):312.

COMMON FOOT PROBLEMS

When a child begins to stand and walk, the long arch of the foot is flat with a medial bulge over the inner border of the foot. The forefeet are mildly pronated or rotated inward, with a slight valgus alignment of the knees. As the child grows and joint laxity decreases, the long arch is better supported and more normal relation-

ships occur in the lower extremities. (See also sections on Metatarsus Varus and Talipes Equinovarus.)

1. Flatfoot

Flatfoot is a normal condition in infants. If the heel cord is of normal length, full dorsiflexion is possible with the heel in the neutral position. As long as the heel cord is of normal length and a longitudinal arch is noted when the child is sitting in a non-weight-bearing position, the parents can be assured that a normal arch will probably develop. There is usually a familial incidence of relaxed flatfeet in children who have no apparent arch. In any child with a shortened heel cord or stiffness of the foot, other causes of flatfoot such as tarsal coalition or vertical talus should be ruled out by a complete orthopedic examination and radiograph.

In the child with an ordinary relaxed flatfoot, no active treatment is indicated unless calf or leg pain is present. In children who have leg pains attributable to flatfoot, a supportive shoe with scaphoid pad, such as a good-quality sports shoe, is useful. An orthotic that holds the heel in neutral and supports the arch may relieve discomfort if more support is needed. An arch insert should not be prescribed unless passive correction of the arch is easily accomplished; otherwise, the skin over the medial side of the foot will be irritated.

Song KM: Flexible flatfeet in pre-school children. *J Pediatr Orthop* 2002;22(1):134.

2. Talipes Calcaneovalgus

Talipes calcaneovalgus is characterized by excessive dorsiflexion at the ankle and eversion of the foot. It is often present at birth and is due to intrauterine position. Treatment consists of passive exercises, stretching the foot into plantar flexion. In rare instances, it may be necessary to use plaster casts to help with manipulation and positioning. Complete correction is the rule.

3. Cavus Foot

This deformity consists of an unusually high longitudinal arch of the foot. It may be hereditary or associated with neurologic conditions such as poliomyelitis, Charcot-Marie-Tooth disease, Friedreich ataxia, and distastomatomyelia. There is usually an associated contracture of the toe extensor, producing a claw toe deformity in which the metatarsal phalangeal joints are hyperextended and the interphalangeal joints acutely flexed. Any child presenting with cavus feet should receive a careful neurologic examination and radiographs of the spine.

Conservative therapy is ineffective. In symptomatic cases, surgery may be necessary to lengthen the contracted extensor and flexor tendons and to release the plantar fascia and other tight plantar structures. The associated varus heel deformity causes more problems than the high arch.

Mosca VS: The cavus foot. *J Pediatr Orthop* 2001;21:423.

4. Bunions (Hallux Valgus)

Adolescents may present with lateral deviation of the great toe associated with a prominence over the head of the first metatarsal. This deformity is painful only with shoe wear and almost always can be relieved by fitting shoes that are wide enough in the toe. Surgery should be avoided in the adolescent, because further growth tends to cause recurrence of the deformity.

Talab YA: Hallux valgus in children: A 5–14-year follow-up study of 30 feet treated with a modified Mitchell osteotomy. *Acta Orthop Scand* 2002;73(2):195.

DEGENERATIVE PROBLEMS (ARTHRITIS, BURSTITIS, & TENOSYNOVITIS)

Degenerative arthritis may follow childhood skeletal problems, such as infection, slipped capital femoral epiphysis, avascular necrosis, or trauma, or it may occur in association with hemophilia. Early effective treatment of these disorders can prevent arthritis. Degenerative changes in the soft tissues around joints may occur as a result of overuse syndrome in adolescent athletes. Young boys throwing excessive numbers of pitches, especially curve balls, may develop “little leaguer” elbow, consisting of degenerative changes around the humeral condyles associated with pain, swelling, and limitation of motion (see Chapter 25). In order to enforce the rest necessary for healing, a plaster cast may be necessary. A more reasonable preventive measure is to limit the number of pitches thrown by children.

Acute bursitis is uncommon in childhood, and other causes should be ruled out before this diagnosis is accepted.

Tenosynovitis is most common in the region of the knees and feet. Children taking dancing lessons, particularly toe dancing, may have pain around the flexor tendon sheaths in the toes or ankles. Rest is effective treatment. At the knee level, the patellar ligament may be irritated, with associated swelling in the infrapatellar fat pad. Synovitis in this area is usually due to overuse

and is treated by rest and nonsteroidal anti-inflammatory drugs (NSAIDs). Corticosteroid injections are contraindicated.

■ TRAUMA

SOFT TISSUE TRAUMA (Sprains, Strains, & Contusions)

A sprain is the stretching of a ligament, and a strain is a stretch of a muscle or tendon. Contusions are generally due to tissue compression, with damage to blood vessels within the tissue and the formation of hematoma.

A severe sprain is one in which the ligament is completely disrupted, resulting in instability of the joint. A mild or moderate sprain is one in which incomplete tearing of the ligament occurs but in which local pain and swelling results.

Mild or moderate sprains are treated by rest of the affected joint, with ice and elevation to prevent prolonged symptoms. By definition, mild or moderate sprain is not associated with instability of the joint.

If more severe trauma occurs, resulting in tearing of a ligament, instability of the joint may be demonstrated by gross examination or by stress testing with radiographic documentation. Such deformity of the joint may cause persistent instability resulting from inaccurate apposition of the ligament ends during healing. If instability is evident, surgical repair of the torn ligament may be indicated. If a muscle is torn at its tendinous insertion, it should be repaired.

The initial treatment of any sprain consists of ice, compression, and elevation. Splinting of the affected joint protects against further injury and relieves swelling and pain. Ibuprofen and other NSAIDs are useful for pain.

1. Ankle Sprains

The history will indicate that the injury was by either forceful inversion or eversion. The more common inversion injury results in tearing or injury to the lateral ligaments, whereas an eversion injury will injure the medial ligaments of the ankle. The injured ligaments may be identified by means of careful palpation for point tenderness around the ankle. The joint should be supported or immobilized at a right angle, which is the functional position. Adhesive taping may be effective but should be changed frequently to prevent blisters. Use of a posterior plaster splint or air splint produces joint rest, and the extremity can be protected by using crutches. Prolonged use of a plaster cast is usually not necessary, but the sprained ankle should be rested suffi-

ciently to allow complete healing, which may take 3–6 weeks. Rehabilitation to include strengthening and restitution of kinesthetic sensation can prevent long-term disability.

McGuine TA et al: Balance as a predictor of ankle injuries in high school basketball players. *Clin J Sport Med* 2000;10:239.

Tabrizi P et al: Limited dorsiflexion predisposes to injuries of the ankle in children. *J Bone Joint Surg Br* 2000;82:1103.

2. Knee Sprains

Sprains of the collateral and cruciate ligaments are uncommon in children. These ligaments are so strong that it is more common to injure the epiphysal growth plates, which are the weakest structures in the region of the knees of children. In adolescence, however, the physes have started to close, and the knee joint is more like that of an adult, so that rupture of the anterior cruciate ligament can result from a hyperextension injury. If the injury produces avulsion of the tibial spine, open anatomic reduction is often required.

Effusion of the knee after trauma deserves referral to an orthopedic specialist. The differential diagnosis includes torn ligament, torn meniscus, and osteochondral fracture. Nontraumatic effusion should be evaluated for inflammatory conditions (eg, juvenile rheumatoid arthritis) or patellar malalignment.

Gabriel SE et al: Change in diagnosis among orthopedists compared to non-orthopedists in the management of acute knee injuries. *J Rheumatol* 2000;27:2412.

3. Internal Derangements of the Knee

Meniscal injuries are uncommon in children younger than age 12 years. Clicking or locking of the knee may occur in young children as a result of a discoid lateral meniscus, which is a rare congenital anomaly. As the child approaches adolescence, internal damage to the knee from a torsion weight-bearing injury may result in locking of the knee if tearing and displacement of a meniscus occurs. Osteochondral fractures secondary to osteochondritis dissecans may also present as internal derangements of the knee in adolescence. Posttraumatic synovitis may mimic a meniscal lesion. In any severe injury to the knee, epiphysal injury should be suspected; stress films will sometimes demonstrate separation of the distal femoral epiphysis in such cases. Epiphysal injury should be suspected whenever tenderness is present on both sides of the metaphysis of the femur after injury.

Smith AD: The skeletally immature knee: What's new in overuse injuries. *Instr Course Lect* 2003;52:691.

4. Back Sprains

Sprains of the ligaments and muscles of the back are unusual in children but may occur as a result of violent trauma from automobile accidents or athletic injuries. Back pain in a child may be the only symptom of significant disease and warrants clinical investigation. Inflammation, infection, renal disease, or tumors can cause back pain in children, and sprain should not be accepted as a routine diagnosis.

Balague F et al: Low-back pain in children. *Lancet* 2003;361(9367):1403.

Wall EJ et al: Backpacks and back pain: Where's the epidemic? *J Pediatr Orthop* 2003;23(4):437.

5. Contusions

Contusion of muscle with hematoma formation produces the familiar "charley horse" injury. Treatment of such injuries is by application of ice, compression, and rest. Exercise should be avoided for 5–7 days. Local heat may hasten healing once the acute phase of tenderness and swelling is past.

6. Myositis Ossificans

Ossification within muscle occurs when there is sufficient trauma to cause a hematoma that later heals in the manner of a fracture. The injury is usually a contusion and occurs most commonly in the quadriceps of the thigh or the triceps of the arm. When a severe injury with hematoma is recognized, it is important to splint the extremity and avoid activity. If further trauma causes recurrent injury, ossification may reach spectacular proportions and resemble an osteosarcoma.

Disability is great, with local swelling and heat and extreme pain on the slightest motion of the adjacent joint. The limb should be rested, with the knee in extension or the elbow in 90 degrees of flexion, until the local reaction has subsided. After local heat and tenderness have decreased, gentle active exercises may be initiated. Passive stretching exercises are not indicated, because they may stimulate the ossification reaction. If surgery is necessary, it should not be attempted before 9 months to 1 year after injury, because it may restart the process and lead to an even more severe reaction.

TRAUMATIC SUBLUXATIONS & DISLOCATIONS

Dislocation of a joint is always associated with severe damage to the ligaments and joint capsule. In contrast to fracture reduction, which may be safely postponed, dislocations must be reduced immediately. Dislocations

can usually be reduced by gentle sustained traction. It often happens that no anesthetic is necessary for several hours after the injury, because of the protective anesthesia produced by the injury. Following reduction, the joint should be splinted for transportation of the patient.

The dislocated joint should be treated by immobilization for at least 3 weeks, followed by graduated active exercises through a full range of motion. Vigorous passive manipulation of the joint by a therapist may be harmful.

1. Subluxation of the Radial Head (Nursemaid Elbow)

Infants may sustain subluxation of the radial head as a result of being lifted or pulled by the hand. The child appears with the elbow fully pronated and painful. The usual complaint is that the child's elbow will not bend. Radiographic findings are normal, but there is point tenderness over the radial head. When the elbow is placed in full supination and slowly moved from full flexion to full extension, a click may be palpated at the level of the radial head. The relief of pain is remarkable, as the child usually stops crying immediately. The elbow may be immobilized in a sling for comfort for a day. Occasionally, symptoms last for several days, requiring more prolonged immobilization.

Pulled elbow may be a clue to battering. This should be considered during examination, especially if the problem is recurrent.

2. Recurrent Dislocation of the Patella

Recurrent dislocation of the patella is more common in loose-jointed individuals, especially adolescent girls. If the patella completely dislocates, it nearly always goes laterally. Pain is severe, and the patient is brought to the doctor with the knee slightly flexed and an obvious bony mass lateral to the knee joint associated with a flat area over the anterior knee. Radiologic examination confirms the diagnosis. The patella may be reduced by extending the knee and placing slight pressure on the patella while gentle traction is exerted on the leg. In subluxation of the patella, the symptoms may be more subtle, and the patient will complain that the knee "gives out" or "jumps out of place."

In the case of complete dislocation, the knee should be immobilized for 3–4 weeks, followed by a physical therapy program for strengthening the quadriceps muscle. Operation may be necessary to tighten the knee joint capsule if dislocation or subluxation is recurrent. In such instances, if the patella is not stabilized, repeated dislocation produces damage to the articular car-

tilage of the patellofemoral joint and premature degenerative arthritis.

Eilert RE: Congenital dislocation of the patella. *Clin Orthop* 2001;:22.

FRACTURES

1. Epiphyseal Separations

In children, epiphyseal separations and fractures are more common than ligamentous injuries. This finding is based on the fact that the ligaments of the joints are generally stronger than the associated growth plates. In instances in which dislocation is suspected, a radiograph should be taken in order to rule out epiphyseal fracture. Radiographs of the opposite extremity, especially for injuries around the elbow, may be valuable for comparison. Reduction of a fractured epiphysis should be done under anesthesia to align the growth plate with the least amount of force. Fractures across the growth plate may produce bony bridges that will cause premature cessation of growth or angular deformities of the extremity. Epiphyseal fractures around the shoulder, wrist, and fingers can usually be treated by closed reduction, but fractures of the epiphyses around the elbow often require open reduction. In the lower extremity, accurate reduction of the epiphyseal plate is necessary to prevent joint deformity if a joint surface is involved. If angular deformities result, corrective osteotomy may be necessary.

Peterson HA: Physeal fractures: Part 3. Classification. *J Pediatr Orthop* 1994;14:439 [PMID: 8077424].

2. Torus Fractures

Torus fractures consist of “buckling” of the cortex due to compression of the bone. They usually occur in the distal radius or ulna. Alignment is usually satisfactory, and simple immobilization for 3 weeks is sufficient.

3. Greenstick Fractures

Greenstick fractures involve frank disruption of the cortex on one side of the bone but no discernible cleavage plane on the opposite side. These fractures are angulated but not displaced, because the bone ends are not separated. Reduction is achieved by straightening the arm into normal alignment, and reduction is maintained by a snugly fitting plaster cast. It is necessary to get a radiograph of greenstick fractures again in a week to 10 days to make certain that the reduction has been maintained in the cast. A slight angular deformity can be corrected by remodeling of the bone. The farther the fracture is from the growing end of the bone, the longer

the time required for remodeling. The fracture can be considered healed when no tenderness or local heat is present and when adequate bony callus is seen on radiograph.

4. Fracture of the Clavicle

Clavicular fractures are very common injuries in infants and children. The patient can be immobilized in a sling for comfort. The healing callus will be apparent when the fracture has consolidated, but this unsightly lump will generally resolve over a period of months to a year.

5. Supracondylar Fractures of the Humerus

Supracondylar fractures tend to occur in children age 3–6 years and are potentially dangerous because of the proximity to the brachial artery in the distal arm. They are usually associated with a significant amount of trauma, so that swelling may be severe. Most often, these fractures are treated by closed reduction and percutaneous pinning. Complications associated with supracondylar fractures include Volkmann ischemic contracture of the forearm due to vascular compromise and cubitus varus (decreased carrying angle) secondary to poor reduction. The so-called gunstock deformity of the elbow may be somewhat unsightly but does not usually interfere with joint function.

Gosens T, Bongers KJ: Neurovascular complications and functional outcome in displaced supracondylar fractures of the humerus in children. *Injury* 2003;34(4):267 [PMID: 12667778].

6. General Comments on Other Fractures in Children

Reduction of fractures in children is usually accomplished by simple traction and manipulation; open reduction is indicated if a satisfactory alignment is not obtained. Remodeling of the fracture callus usually produces an almost normal appearance of the bone over a matter of months. The younger the child, the more remodeling is possible. Angular deformities remodel reliably. Rotatory malalignment does not remodel.

The physician should be suspicious of child abuse whenever the age of a fracture does not match the history given or when the severity of the injury is more than the alleged accident would have produced. In suspected cases of battering where no fracture is present on the initial radiograph, a repeat radiograph 10 days later is in order. Bleeding beneath the periosteum will be calcified by 7–10 days, and the radiographic appearance is

almost diagnostic of severe closed trauma characteristic of a battered child.

■ INFECTIONS OF THE BONES & JOINTS

OSTEOMYELITIS

Osteomyelitis is an infectious process that usually starts in the spongy or medullary bone and then extends to involve compact or cortical bone. The lower extremities are most often affected, and there is commonly a history of trauma. Osteomyelitis may occur as a result of direct invasion from the outside through a penetrating wound (nail) or open fracture, but hematogenous spread of infection (eg, pyoderma or upper respiratory tract infection) from other infected areas is much more common. The most common infecting organism is *Staphylococcus aureus*, which has a tendency to infect the metaphyses of growing bones. Anatomically, circulation in the long bones is such that the arterial supply to the metaphysis just below the growth plate is close to end arteries, which turn sharply to end in venous sinuoids, causing a relative stasis. In the infant younger than age 1 year, there is direct vascular communication with the epiphysis across the growth plate, so that direct spread may occur from the metaphysis to the epiphysis and subsequently into the joint. In the older child, the growth plate provides an effective barrier, the epiphysis is usually not involved, and the infection spreads retrograde from the metaphysis into the diaphysis and, by rupture through the cortical bone, down along the diaphysis beneath the periosteum.

1. Exogenous Osteomyelitis

To avoid osteomyelitis by direct extension, all wounds must be carefully examined and cleansed. Osteomyelitis is a common occurrence from pressure sores in anesthetic areas, such as in patients with spina bifida. Cultures of the wound made at the time of exploration and debridement may be useful if signs of infection develop subsequently. Copious irrigation is necessary, and all nonviable skin, subcutaneous tissue, fascia, and muscle must be excised. In extensive or contaminated wounds, antibiotic coverage is indicated. Contaminated lacerations should be left open and secondary closure performed 3–5 days later. If at the time of delayed closure further necrotic tissue is present, it should be excised. Leaving the wound open allows the infection to stay at the surface rather than extend inward to the bone.

Puncture wounds are especially liable to lead to osteomyelitis and should be carefully debrided.

Initially, broad-spectrum antibiotics should be administered, but the final choice of antibiotics is directed by culture results. A tetanus toxoid booster may be indicated. Gas gangrene is best prevented by adequate debridement.

After exogenous osteomyelitis has become established, treatment becomes more complicated, requiring extensive surgical debridement and intravenous antibiotics.

2. Hematogenous Osteomyelitis

Hematogenous osteomyelitis is usually caused by pyogenic bacteria; 85% of cases are due to staphylococci. Streptococci are a less common cause of osteomyelitis. *Pseudomonas* organisms are common in cases of nail puncture wounds. Children with sickle cell anemia are especially prone to osteomyelitis caused by salmonellae.

Clinical Findings

A. SYMPTOMS AND SIGNS

In infants, the manifestations of osteomyelitis may be subtle, presenting as irritability, diarrhea, or failure to feed properly; the temperature may be normal or slightly low; and the white blood count may be normal or only slightly elevated. There may be pseudoparalysis of the involved limb. In older children, the manifestations are more striking, with severe local tenderness and pain, often high fever, rapid pulse, and elevated white blood count and erythrocyte sedimentation rate (ESR). Osteomyelitis of a lower extremity often occurs around the knee joint in children age 7–10 years. Tenderness is most marked over the metaphysis of the bone where the process has its origin. For a child who refuses to bear weight, osteomyelitis is high in the differential diagnosis.

B. LABORATORY FINDINGS

Blood cultures are often positive early. The most significant test in infancy is the aspiration of pus. It is useful to needle the bone in the area of suspected infection and aspirate any fluid present. This fluid should be stained for organisms and cultured. Even edema fluid may be useful for determining the causative organism. Elevation of the ESR above 50 mm/h is typical for osteomyelitis. C reactive protein is elevated earlier than the ESR.

C. IMAGING

Nonspecific local swelling is the first radiographic finding. This is followed by elevation of the periosteum, with formation of new bone from the cambium layer of the periosteum occurring after 3–6 days. As the infec-

tion becomes chronic, areas of cortical bone are isolated by pus spreading down the medullary canal, causing rarefaction and demineralization of the bone. Such isolated pieces of cortex become ischemic and form sequestra (dead bone fragments). These radiographic findings are late but specific. Osteomyelitis should be diagnosed clinically before significant radiographic findings are present. Bone scan is sensitive but nonspecific and should be interpreted in the clinical context before radiographic findings become positive. Magnetic resonance imaging can demonstrate edema early or soft tissue thickening later.

Treatment

A. SPECIFIC MEASURES

Antibiotics should be started intravenously as soon as the diagnosis of osteomyelitis is made. Oral antibiotics are begun when tenderness, fever, the white cell count, and the ESR are all decreasing and the culture is positive. Agents that cover *S aureus* and *Streptococcus pyogenes* (eg, oxacillin, nafcillin, cefazolin, clindamycin) are appropriate for most cases. For specific recommendations and for possible *Pseudomonas* infection, see Chapter 38.

Chronic infections are treated for months. Following surgical debridement, *Pseudomonas* foot infections usually respond to 1–2 weeks of antibiotic treatment.

B. GENERAL MEASURES

Splinting of the limb minimizes pain and decreases spread of the infection by lymphatic channels through the soft tissue. The splint should be removed periodically to allow active use of adjacent joints and prevent stiffening and muscle atrophy. In chronic osteomyelitis, splinting may be necessary to guard against fracture of the weakened bone.

C. SURGICAL MEASURES

Aspiration of the metaphysis for culture and Gram stain is the most useful diagnostic measure in any case of suspected osteomyelitis. In the first 24–72 hours, it may be possible to treat osteomyelitis with antibiotics alone. If frank pus is aspirated from the bone, however, surgical drainage is indicated. If the infection has not shown a dramatic response within 24 hours, surgical drainage is also indicated. It is important that all devitalized soft tissue be removed and adequate exposure of the bone obtained to permit free drainage. Excessive amounts of bone should not be removed when draining acute osteomyelitis, because it will not be completely replaced by the normal healing process. Bone damage is limited by surgical drainage, whereas failure to evacuate pus in acute cases may lead to widespread damage.

Prognosis

When osteomyelitis is diagnosed in the early clinical stages and prompt antibiotic therapy is begun, the prognosis is excellent. If the process has been unattended for a week to 10 days, there is almost always some permanent loss of bone structure, as well as the possibility of growth abnormality.

Song KM, Sloboda JF: Acute hematogenous osteomyelitis in children. *J Am Acad Orthop Surg* 2001;9:166 [PMID: 11421574].

PYOGENIC ARTHRITIS

The source of pyogenic arthritis varies according to the child's age. In the infant, pyogenic arthritis often develops by spread from adjacent osteomyelitis. In the older child, it presents as an isolated infection, usually without bony involvement. In teenagers with pyogenic arthritis, an underlying systemic disease or an organism (eg, the gonococcus) that has an affinity for joints is usually the cause.

The infecting organism varies with age: group B streptococcus and *S aureus* in those younger than age 4 months; *Haemophilus influenzae* and *S aureus* in those age 4 months to 4 years; and *S aureus* and *S pyogenes* in older children and adolescents. *H influenzae* is now uncommon because of effective immunization. *Kingella kingae* is a gram-negative bacterium that occasionally causes pyarthrosis.

The initial effusion of the joint rapidly becomes purulent. An effusion of the joint may accompany osteomyelitis in the adjacent bone. A white cell count exceeding 100,000/μL in the joint fluid indicates a definite purulent infection. Generally, spread of infection is from the bone into the joint, but unattended pyogenic arthritis may also affect adjacent bone. The ESR is often above 50 mm/h.

Clinical Findings

A. SYMPTOMS AND SIGNS

In older children, the signs may be striking, with fever, malaise, vomiting, and restriction of motion. In infants, paralysis of the limb due to inflammatory neuritis may be evident. Infection of the hip joint in infants should be suspected if decreased abduction of the hip is present in an infant who is irritable or feeding poorly. A history of umbilical catheter treatment in the newborn nursery should alert the physician to the possibility of pyogenic arthritis of the hip.

B. IMAGING

Early distention of the joint capsule is nonspecific and difficult to measure by radiograph. In the infant with unrecognized pyogenic arthritis, dislocation of the joint may follow within a few days as a result of distention of the capsule by pus. Later changes include destruction of the joint space, resorption of epiphysal cartilage, and erosion of the adjacent bone of the metaphysis. The bone scan shows increased flow and increased uptake about the joint.

Treatment

Aspiration of the joint is the key to diagnosis. In the hip joint, pyogenic arthritis is most easily treated by surgical drainage because the joint is deep and difficult to aspirate and is also inaccessible to thorough cleaning through needle aspiration. Arthroscopic irrigation and debridement have been successful in treating pyogenic arthritis of the knee. If fever and clinical symptoms do not subside within 24 hours after treatment is begun, open surgical drainage is indicated. Antibiotics can be selected based on the child's age, results of the Gram stain, and culture of the aspirated pus. Reasonable empiric therapy in infants is nafcillin or oxacillin plus a third-generation cephalosporin. An antistaphylococcal agent alone is usually adequate for children older than age 5 years. For staphylococcal infections, 3 weeks of therapy is recommended; for other organisms, 2 weeks is usually sufficient. Oral therapy may be begun when clinical signs have improved markedly. It is not necessary to give intra-articular antibiotics, because good levels are achieved in the synovial fluid with parenteral administration.

Prognosis

The prognosis for the patient with pyogenic arthritis is excellent if the joint is drained early, before damage to the articular cartilage has occurred. If infection is present for more than 24 hours, dissolution of the proteoglycans in the articular cartilage takes place, with subsequent arthrosis and fibrosis of the joint. Damage to the growth plate may also occur, especially within the hip joint, where the epiphysal plate is intracapsular.

Kothari NA et al: Imaging of musculoskeletal infections. *Radiol Clin North Am* 2001;39:653 [PMID: 11549164].

TUBERCULOUS ARTHRITIS

Tuberculous arthritis is now a rare disease in the United States. Children in poor social circumstances, however, such as homeless families, are prone to tuberculous arthritis. Generally the infection may be ruled

out by negative skin testing. The joints most commonly affected in children are the intervertebral disks, resulting in gibbus or dorsal angular deformity at the site of involvement.

Treatment is by local drainage of the abscess, followed by antituberculous therapy. Prolonged immobilization in a plaster cast or prolonged bed rest is necessary to promote healing. Spinal fusion may be required to preserve stability of the vertebral column.

Rasool MN: Osseous manifestations of tuberculosis in children. *J Pediatr Orthop* 2001;21:749 [PMID: 11675548].

DISKITIS

Results of a study of 47 patients support the view that so-called diskitis is pyogenic infectious spondylitis in children and that supportive treatment and intravenous antibiotics are likely to lead to rapid relief of symptoms and signs without recurrence.

Brown R et al: Discitis in young children. *J Bone Joint Surg Br* 2001;83:106 [PMID: 11245515].

TRANSIENT SYNOVITIS OF THE HIP

The most common cause of limping and pain in the hip in children in the United States is transitory synovitis, an acute inflammatory reaction that often follows an upper respiratory infection and is generally self-limited. In questionable cases, aspiration of the hip yields only yellowish fluid, ruling out pyogenic arthritis. Generally, however, toxic synovitis of the hip is not associated with elevation of the ESR, white blood count, or temperature above 38.3°C. It classically affects children age 3–10 years and is more common in boys than girls. There is limitation of motion of the hip joint, particularly internal rotation, and radiographic changes are nonspecific, with some swelling apparent in the soft tissues around the joint.

Treatment consists of bed rest and the use of traction with slight flexion of the hip. NSAIDs shorten the course of the disease, although even with no treatment, the disease usually runs its course in days. It is important to maintain radiographic follow-up because toxic synovitis may be the precursor of avascular necrosis of the femoral head (described in the next section) in a small percentage of patients. Radiographs can be obtained at 6 weeks, or earlier if either a persistent limp or pain is present.

Vila-Verde VM, da Silva KC: Bone age delay in Perthes disease and transient synovitis of the hip. *Clin Orthop* 2001;4:118 [PMID: 11302301].

VASCULAR LESIONS & AVASCULAR NECROSIS (Osteochondroses)

Osteochondrosis due to vascular lesions may affect various growth centers. Table 24–1 indicates the common sites and the typical ages at presentation.

In contrast to other body tissues that undergo infarction, bone removes necrotic tissue and replaces it with living bone in a process called creeping substitution. This replacement of necrotic bone may be so complete and so perfect that a completely normal bone results. Adequacy of replacement depends on the patient's age, the presence or absence of associated infection, the congruity of the involved joint, and other physiologic and mechanical factors.

Because of their rapid growth in relation to their blood supply, the secondary ossification centers in the epiphyses are subject to avascular necrosis. Despite the number of different names referring to avascular necrosis of the epiphyses, the process is identical, necrosis of bone followed by replacement (see Table 24–1).

Even though the pathologic and radiographic features of avascular necrosis of the epiphyses are well known, the cause is not generally agreed on. Necrosis may follow known causes such as trauma or infection, but idiopathic lesions usually develop during periods of rapid growth of the epiphyses.

AVASCULAR NECROSIS OF THE PROXIMAL FEMUR (Legg–Calvé–Perthes Disease)

The vascular supply of the proximal femur is precarious, and when it is interrupted, necrosis results.

Clinical Findings

A. SYMPTOMS AND SIGNS

The highest incidence of Legg–Calvé–Perthes disease is between ages 4 and 8 years. Persistent pain is the most common symptom, and the patient may present with limp or limitation of motion.

B. LABORATORY FINDINGS

Laboratory findings, including studies of joint aspirates, are normal.

C. IMAGING

Radiographic findings correlate with the progression of the process and the extent of necrosis. The early finding

Table 24–1. The osteochondroses.

Ossification Center	Eponym	Typical Age (years)
Capital femoral	Legg–Calvé–Perthes disease	4–8
Tarsal navicular	Köhler bone disease	6
Second metatarsal head	Freiberg disease	12–14
Vertebral ring	Scheuermann disease	13–16
Capitellum	Panner disease	9–11
Tibial tubercle	Osgood–Schlatter disease	11–13
Calcaneus	Sever disease	8–9

is effusion of the joint associated with slight widening of the joint space and periarticular swelling. Decreased bone density in and around the joint is apparent after a few weeks. The necrotic ossification center appears more dense than the surrounding viable structures, and the femoral head is collapsed or narrowed.

As replacement of the necrotic ossification center occurs, rarefaction of the bone occurs in a patchwork fashion, producing alternating areas of rarefaction and relative density, referred to as “fragmentation” of the epiphysis.

In the hip, widening of the femoral head may occur associated with flattening, or coxa plana. If infarction has extended across the growth plate, a radiolucent lesion will be evident within the metaphysis. If the growth center of the femoral head has been damaged so that normal growth is arrested, shortening of the femoral neck results.

Eventually, complete replacement of the epiphysis develops as living bone replaces necrotic bone by creeping substitution. The final shape of the head depends on the extent of the necrosis and collapse of weakened bone.

Differential Diagnosis

Differential diagnosis must include inflammation and infection and dysplasia. Transient synovitis of the hip may be distinguished from Legg–Calvé–Perthes disease by serial radiographs.

Treatment

The principle of treatment is protection of the joint. If the joint is deeply seated within the acetabulum and

normal joint motion is maintained, a reasonably good hip can result. Little benefit has been shown from bracing.

Prognosis

The prognosis for complete replacement of the necrotic femoral head in a child is excellent, but the functional result depends on the amount of deformity that develops during the time the softened structure exists. In Legg–Calvé–Perthes disease, the prognosis depends on the completeness of involvement of the epiphysal center. In general, patients with metaphysal defects, those in whom the disease develops late in childhood, and those who have more complete involvement of the femoral head have a poorer prognosis.

Joseph B et al: Natural evolution of Perthes disease: A study of 610 children under 12 years of age at disease onset. *J Pediatr Orthop* 2003;23(5):590 [PMID: 12960621].

Hesse B, Kohler G: Does it always have to be Perthes' disease? What is epiphysal dysplasia? *Clin Orthop* 2003(414):219 [PMID: 12966296].

OSTEOCHONDRITIS DISSECANS

In osteochondritis dissecans, a wedge-shaped necrotic area of bone and cartilage develops adjacent to the articular surface. The fragment of bone may be broken off from the host bone and displaced into the joint as a loose body. If it remains attached, the necrotic fragment may be completely replaced by creeping substitution.

The pathologic process is the same as that described previously for avascular necrosing lesions of ossification centers. Because these lesions are adjacent to articular cartilage, however, joint damage may occur.

The most common sites of these lesions are the knee (medial femoral condyle), the elbow joint (capitellum), and the talus (superior lateral dome). Joint pain is the usual presenting complaint. However, local swelling or locking may be present, particularly if a fragment is free in the joint. Laboratory studies are normal.

Treatment consists of protection of the involved area from mechanical damage. If a fragment is free within the joint as a loose body, it must be removed. For some marginal lesions, it may be worthwhile to drill the necrotic fragment to encourage more rapid vascular ingrowth and replacement. If large areas of a weight-bearing joint are involved, secondary degenerative arthritis may result.

Wall E, Von Stein D: Juvenile osteochondritis dissecans. *Orthop Clin North Am* 2003;34(3):341 [PMID: 12974484].

NEUROLOGIC DISORDERS INVOLVING THE MUSCULOSKELETAL SYSTEM

ORTHOPEDIC ASPECTS OF CEREBRAL PALSY

Early physical therapy to encourage completion of the normal developmental patterns may benefit patients with cerebral palsy. The greatest gains from this therapy are obtained during the first few years of life, and therapy should not be continued when no improvement is apparent.

Bracing and splinting are of questionable benefit, although night splints may be useful in preventing equinus deformity of the feet or adduction contractures of the hips. Orthopedic surgery is useful for treating joint contractures that interfere with function. In general, muscle transfers are unpredictable in cerebral palsy, and most orthopedic procedures are directed at tendon lengthening or bony stabilization by osteotomy or arthrodesis.

Flexion and adduction of the hip due to hyperactivity of the adductors and flexors may produce a progressive paralytic dislocation of the hip, which can lead to pain and dysfunction. Treatment of this dislocation is difficult and unsatisfactory. The principal preventive measure is abduction bracing, but this must often be supplemented by release of the adductors and hip flexors in order to prevent dislocation. In severe cases, osteotomy of the femur may also be necessary to correct the bony deformities of femoral anteversion and coxa valga that are invariably present. Patients with a predominantly athetotic pattern are poor candidates for any surgical procedure or bracing.

Because it is difficult to predict the outcome of surgical procedures in cerebral palsy, the surgeon must examine patients on several occasions before any operative procedure is undertaken. Follow-up care by a physical therapist to maximize the anticipated long-term gains should be arranged before the operation.

Koman LA: Cerebral palsy: Past, present, and future. *J South Orthop Assoc* 2002;11(2):93 [PMID: 12741589].

ORTHOPEDIC ASPECTS OF MYELODYSPLASIA

Patients born with spina bifida cystica (aperta) should be examined early by an orthopedic surgeon. The level of neurologic involvement determines the muscle im-

balance that will be present and apt to produce deformity with growth. The involvement is often asymmetrical and tends to change during the first 12–18 months of life. Early closure of the sac is the rule, although there has been some hesitancy to provide treatment to all of these patients because of the extremely poor prognosis associated with congenital hydrocephalus, high levels of paralysis, and associated congenital anomalies. A high percentage of these children have hydrocephalus, which may be evident at birth or shortly thereafter, requiring shunting. Associated musculoskeletal problems may include clubfoot, congenital dislocation of the hip, arthrogryposis-type changes of the lower extremities, and congenital scoliosis. The most common lesions are at the level of L3–4 and tend to affect the hip joint, with progressive dislocation occurring during growth. Foot deformities may be in any direction and are complicated by the fact that sensation is generally absent. Spinal deformities develop in a high percentage of these children, with scoliosis present in approximately 40%. Ambulation may require long leg braces. Careful urologic follow-up must be obtained to prevent complications from bladder dysfunction.

In children who have a reasonable likelihood of walking, operative treatment consists of reduction of the hip and alignment of the feet in the weight-bearing position as well as stabilization of the scoliosis. In children who lack active quadriceps function and extensor power of the knee, the likelihood of ambulation is greatly decreased. In such patients, aggressive surgery in the hip region may result in stiffening of the joints, thus preventing sitting. Multiple foot operations are also contraindicated in these children.

The overall treatment of the child with spina bifida should be coordinated in a multidisciplinary clinic where various medial specialists work with therapists, social workers, and teachers to provide the best possible care.

Bartonek A, Saraste H: Factors influencing ambulation in myelomeningocele: A cross-sectional study. *Dev Med Child Neurol* 2001;43:253 [PMID: 11305403].

NEOPLASIA OF THE MUSCULOSKELETAL SYSTEM

Neoplastic diseases of the musculoskeletal system are a serious problem because of the poor prognosis of malignant tumors arising in bone or other tissues derived from mesoderm. Fortunately, few of the benign lesions undergo malignant transformation. Accurate diagnosis depends on correlation of the clinical, radiograph, and microscopic findings. Complaints about the knee should be investigated for tumor, although the usual

causes of knee pain are traumatic, infectious, or developmental in origin.

Miller SL, Hoffer FA: Malignant and benign bone tumors. *Radiol Clin North Am* 2001;39:673 [PMID: 11549165].

Osteochondroma

Osteochondroma is the most common bone tumor in children. It usually presents as a pain-free mass. When present, pain is caused by adventitious bursitis or tenosynovitis due to irritation by the tumor. The lesion may be single or multiple. Pathologically, the lesion is a bone mass capped with cartilage. These masses tend to grow during childhood and adolescence in proportion to the child's growth.

On radiograph the tumors tend to be in the metaphyseal region of long bones and may be pedunculated or sessile. The cortex of the underlying bone "flows" into the base of the tumor.

An osteochondroma should be excised if it interferes with function, is frequently traumatized, or is large enough to be deforming. The prognosis is excellent. Malignant transformation is very rare.

Bottner F et al: Surgical treatment of symptomatic osteochondroma: A three- to eight-year follow-up study. *J Bone Joint Surg Br* 2003;85(8):1161 [PMID: 14653600].

Osteoid Osteoma

Osteoid osteoma classically produces night pain that can be relieved by aspirin. On physical examination there usually is tenderness over the lesion. An osteoid osteoma in the upper femur may cause pain referred to the knee.

On radiograph the lesion is a radiolucent nidus surrounded by dense osteosclerosis that may obscure the nidus. Bone scan shows intense uptake in the lesion.

Surgical incision of the nidus is curative and may be done using computed tomography imaging and minimally invasive technique. The prognosis is excellent, with no known cases of malignant transformation, although the lesion has a tendency to recur.

Enchondroma

Enchondroma is usually a silent lesion unless it produces a pathologic fracture. On radiograph it is radiolucent, usually in a long bone. A speckled calcification may be present. The classic lesion looks as though someone dragged his or her fingernails through clay, making streaks in the bones. Enchondroma is treated by surgical curettage and bone grafting. The prognosis is excellent. Malignant transformation may occur but is very rare in childhood.

Chondroblastoma

In chondroblastoma, the presenting complaint is pain around a joint. This neoplasm may produce a pathologic fracture. On radiograph the lesion is radiolucent and can perforate the epiphysal cartilage. Calcification is unusual, with little or no reactive bone. The lesion is treated by surgical curettage and bone grafting. The prognosis is excellent if complete curettage is performed. There is no known malignant transformation.

Masui F et al: Chondroblastoma: A study of 11 cases. *Eur J Surg Oncol* 2002;28(8):869 [PMID: 12477480].

Nonossifying Fibroma

Nonossifying fibroma is also called benign cortical defect and is nearly always an incidental finding on radiograph. The most frequent sites are the distal femur and proximal tibia. Nonossifying fibroma is a radiolucent lesion eccentrically located in the bone. Usually a thin sclerotic border is evident. Multiple lesions may be present. No treatment is needed because these lesions heal as they ossify with maturation of the bone and growth.

Osteosarcoma

In osteosarcoma, the presenting complaint is usually pain in a long bone, although functional loss, the mass of the tumor, or limp may be the complaint. Pathologic fracture is common. The malignant osseous tumor produces a destructive expanding and invasive lesion. A triangle may be adjacent to the tumor produced by elevated periosteum and subsequent tumor ossification. The lesion may contain calcification and violates the cortex of the bone. Femur, tibia, humerus, and other long bones are the sites usually affected.

Surgical excision (limb salvage) or amputation is indicated based on the extent of the tumor. The lesion is radioresistant and does not respond to chemotherapy. Adjuvant chemotherapy is routinely used prior to surgical excision. The prognosis is improving, with 30% 5-year survival rates being reported in modern series. Death usually occurs as a result of lung metastasis.

Smeland S et al; Scandinavian Sarcoma Group Osteosarcoma Study SSG VIII: Prognostic factors for outcome and the role of replacement salvage chemotherapy for poor histological responders. *Eur J Cancer* 2003;39(4):488 [PMID: 12751380].

Ewing Sarcoma

In Ewing sarcoma, the presenting complaint is usually pain and tenderness. Fever and leukocytosis may also be present, which makes osteomyelitis the main differen-

tial diagnosis. The lesion may be multicentric. Ewing sarcoma is radiolucent and destroys the cortex, frequently in the diaphysal region. Reactive bone formation may occur about the lesion, seen as successive layers of so-called onion skin layering.

Treatment is with multiagent chemotherapy, radiation, and surgical resection. The prognosis is poor with large tumor size, pelvic lesions, and poor response to chemotherapy.

MISCELLANEOUS DISEASES OF BONE

FIBROUS DYSPLASIA

Dysplastic fibrous tissue replacement of the medullary canal is accompanied by the formation of metaplastic bone in fibrous dysplasia. Three forms of the disease are recognized: monostotic, polyostotic, and polyostotic with endocrine disturbances (precocious puberty in females, hyperthyroidism, and hyperadrenalism [Albright syndrome]).

Clinical Findings

A. SYMPTOMS AND SIGNS

The lesion or lesions may be asymptomatic. Pain, if present, is probably due to pathologic fractures. In females, endocrine disturbances may be present in the polyostotic variety and associated with café au lait spots.

B. LABORATORY FINDINGS

Laboratory findings are normal unless endocrine disturbances are present, in which case secretion of gonadotropic, thyroid, or adrenal hormones may be increased.

C. IMAGING

The lesion begins centrally within the medullary canal, usually of a long bone, and expands slowly. Pathologic fracture may occur. If metaplastic bone predominates, the contents of the lesion will be of the density of bone. The disease is often asymmetrical, and limb length disturbances may occur as a result of stimulation of epiphysal cartilage growth. Marked deformity of the bone may result, and a shepherd's crook deformity of the upper femur is a classic feature of the disease.

Differential Diagnosis

The differential diagnosis includes other fibrous lesions of bone as well as destructive lesions such as unicameral

bone cyst, eosinophilic granuloma, aneurysmal bone cyst, nonossifying fibroma, enchondroma, and chondromyxoid fibroma.

Treatment

If the lesion is small and asymptomatic, no treatment is needed. If the lesion is large and produces or threatens pathologic fracture, curettage and bone grafting are indicated.

Prognosis

Unless the lesions impair epiphyseal growth, the prognosis for patients with fibrous dysplasia is good. Lesions tend to enlarge during the growth period but are stable during adult life. Malignant transformation is rare.

UNICAMERAL BONE CYST

Unicameral bone cyst occurs in the metaphysis of a long bone, usually in the femur or humerus. It begins within the medullary canal adjacent to the epiphyseal cartilage. It probably results from some fault in enchondral ossification. The cyst is considered active as long as it abuts onto the metaphyseal side of the epiphyseal cartilage, and there is a risk of growth arrest with or without treatment.

When a border of normal bone exists between the cyst and the epiphyseal cartilage, the cyst is inactive. The lesion is usually identified when a pathologic fracture occurs, producing pain. Laboratory findings are normal. On radiograph, the cyst is identified centrally within the medullary canal, producing expansion of the cortex and thinning over the widest portion of the cyst.

Treatment consists of curettage and bone grafting. The cyst may heal after a fracture.

Wilkins RM: Unicameral bone cysts. *J Am Acad Orthop Surg* 2000;8(4):217 [PMID: 10951110].

ANEURYSMAL BONE CYST

Aneurysmal bone cyst is similar to unicameral bone cyst, but it contains blood rather than clear fluid. It usually occurs in a slightly eccentric position in the long bone, expanding the cortex of the bone but not breaking the cortex. Involvement of the flat bones of the pelvis is less common. On radiographs, the lesion appears somewhat larger than the width of the epiphyseal cartilage. This feature distinguishes it from unicameral bone cyst.

Chromosomal abnormalities have been associated with aneurysmal bone cyst. The lesion may appear aggressive histologically, and it is important to differenti-

ate it from osteosarcoma or hemangioma. Treatment is by curettage and bone grafting. The prognosis is good.

Papagelopoulos PJ et al: Treatment of aneurysmal bone cysts of the pelvis and sacrum. *J Bone Joint Surg Am* 2001;83:1674 [PMID: 11701790].

Wyatt-Ashmead J et al: Primary aneurysmal bone cysts: 16q22 and/or 17p13 chromosome abnormalities. *Pediatr Dev Pathol* 2001;4:418 [PMID: 11441369].

INFANTILE CORTICAL HYPEROSTOSIS (Caffey Syndrome)

Infantile cortical hyperostosis is a benign disease of unknown cause that has its onset before age 6 months and is characterized by irritability; fever; and nonsuppurating, tender, painful swellings. Swellings may involve almost any bone of the body and are frequently widespread. Classically, swellings of the mandible and clavicle occur in 50% of patients; swellings of the ulna, humerus, and ribs also occur. The disease is limited to the shafts of bones and does not involve subcutaneous tissues or joints. It is self-limited but may persist for weeks or months. Anemia, leukocytosis, an increased ESR, and elevation of the serum alkaline phosphatase concentration are usually present. Cortical hyperostosis is demonstrable by a typical radiographic appearance and may be diagnosed on physical examination by an experienced pediatrician.

Fortunately the disease appears to be decreasing in frequency. Indomethacin may be useful for treatment. The prognosis is good, and the disease usually terminates without deformity.

GANGLION

A ganglion is a smooth, small cystic mass connected by a pedicle to the joint capsule, usually on the dorsum of the wrist. It may also occur in the tendon sheath over the flexor surfaces of the fingers. These ganglia can be excised if they interfere with function or cause persistent pain.

BAKER CYST

A Baker cyst is a herniation of the synovium in the knee joint into the popliteal region. In children, the diagnosis may be made by aspiration of mucinous fluid, but the cyst nearly always disappears with time. Whereas Baker cysts may be indicative of intra-articular disease in the adult, they occur without internal derangement in children and rarely require excision.

Van Rhijn LW et al: Long-term follow-up of conservatively treated popliteal cysts in children. *J Pediatr Orthop B* 2000;9(1):62 [PMID: 10647115].

Pamela E. Wilson, MD, & Dennis J. Matthews, MD

The development of sports medicine as a unique discipline has grown since the 1980s in response to the expanding body of knowledge in the areas of exercise physiology, biomechanics, and musculoskeletal medicine. The boom in physical fitness and physical activity has generated a need for specialty training in these areas. With the current popularity of starting younger children in more structured athletics, it is essential that the pediatric general practitioner have an understanding of sports medicine.

BASIC PRINCIPLES

The basic unit of the musculoskeletal system is the muscle fiber, which can be classified as slow twitch, fast twitch, or of intermediate type. Slow twitch, or type I, fibers are smaller, are recruited in muscle contractions first, and are innervated by smaller motor neurons. Fast twitch, or type II, fibers make up white muscle and have a tendency to be larger. They are recruited when the body needs to produce rapid muscle tension. In general they produce more lactic acid than type I fibers. An intermediate type IIa fiber, called fast oxidative glycolytic or FOG, also exists. Untrained individuals have a 50:50 proportion of type I to type II fibers. Elite long-distance runners can have up to 90% type I fibers. This apparent adaptation raises the interesting question as to whether an athlete is genetically programmed or can develop adaptations to be successful in sports.

Exercise generates specific effects on the cardiorespiratory system that include increased VO_2 max (maximum amount of oxygen that can be consumed), increased cardiac output, reduced resting heart rate, and improved blood pressure responses.

Biomechanics, the study of movement and how the forces generated by the neuromuscular system translate into these movements, integrates principles of biology and physics. Through biomechanics we can understand the intricacies of movement and how these movements affect athletic performance and result in injuries.

Types of Muscle Contraction

Dynamic contractions are those movements that result in motion of a limb or rotation around a joint axis. These contractions can be further divided into isotonic and isokinetic contractions. In an isotonic contraction, constant tension is generated during muscle contraction; in an isokinetic contraction, constant velocity is maintained during the contraction. Isotonic exercises can be further classified as detailed in the following sections:

A. CONCENTRIC

In concentric exercises the force of a muscle contraction overcomes an external resistance, which results in shortening of the muscle. These muscles accelerate a distal segment in the kinetic chain and are therefore referred to as open-chain movements. An example of such an exercise is a biceps curl, during which the biceps is actively contracting or shortening to lift the weight.

B. ECCENTRIC

In eccentric exercises, contractions increase muscle tension associated with lengthening of the muscle and are used to decelerate a distal segment in the kinetic chain. This type of exercise is exemplified by the squatting motion, in which the quadriceps are lengthening under tension to control downward motion. If the terminal segment in the chain is fixed, this type of movement is called closed kinetic chain movement.

C. ISOMETRIC

In contrast to dynamic contractions, isometric contractions increase muscle tension without a change in length. An example of this type of exercise would be pushing against a wall. Tension is generated in the muscle, but no movement occurs.

Young JL, Press JM: The physiologic basis of sports rehabilitation. *Phys Med Rehabil Clin North Am* 1994;5:9.

Strength Training

Strength is defined as the peak force that can be generated during a maximal single contraction. Strength training is therefore the use of progressive resistance to improve an athlete's ability to resist or exert force. This can be achieved by a variety of techniques, including body weight, free weight, and machine resistance. The benefits of weight training programs are improved performance, endurance, and muscular strength. These programs can be started in prepubescent athletes and, if designed appropriately, can be done safely with minimal risk for injury. Tanner staging (see Chapter 30) helps to define readiness for progression into more strenuous programs. Power lifting and weight lifting should be restricted to those athletes who have reached or passed Tanner stage V. Individuals at Tanner stage IV or less can safely participate in a strength training program that is specifically and carefully designed for younger athletes. These programs incorporate submaximal resistance with multiple repetitions. They can be generalized or sport-specific. Care should be taken to prevent injuries while using weight training equipment at home.

PREPARTICIPATION HISTORY & PHYSICAL EXAMINATION

The preparticipation medical examination is designed to evaluate children and screen for potential medical problems that could occur during athletic participation. The objectives of this evaluation are to establish baseline medical information, detect any medical condition that may limit athletic participation, evaluate the athlete for preventable injuries, meet the legal or insurance requirements of most states, assess the athlete's maturity, and make recommendations for necessary protective equipment. The ideal timing of this examination is in preseason, at least 4–6 weeks before training starts. This allows time for any needed interventions by the physician.

Preparticipation History

The history is the most important part of the encounter. Many key elements need to be explored with the athlete. Several standardized forms are available, in-

cluding the example in Figure 25–1. The history must include the following areas:

A. CARDIOVASCULAR HISTORY

The physician should note any history of cardiac murmurs, chest pain at rest or with exertion, syncope episodes or sudden fatigue, shortness of breath, or recent illnesses with chest pain. The family history should specifically ask about underlying cardiac diseases, including hypertrophic cardiomyopathy, prolonged QT syndrome, Marfan syndrome, arrhythmias, and sudden death in family members. These questions are necessary to identify potentially life-threatening cardiac lesions. The most common cause of sudden death in young athletes on the playing field is hypertrophic cardiomyopathy and congenital heart lesions.

B. HISTORY OF HYPERTENSION

Any history of hypertension requires further investigation. The current guidelines for the diagnosis of hypertension are blood pressure over 130/75 mm Hg in a child younger than age 10 years or blood pressure over 140/85 mm Hg in a child age 10 years and older.

C. HISTORY OF CHRONIC DISEASES

Diseases such as asthma or exercise-induced asthma, diabetes, renal disease, neurologic disorders, and hematologic diseases should be noted.

D. MUSCULOSKELETAL LIMITATIONS AND PRIOR INJURIES

The physician should explore abnormal range of motion or prior injuries that may affect future performance.

E. MENSTRUAL HISTORY IN FEMALES

The physician should pay particular attention to the so-called female athletic triad: amenorrhea, eating disorders, and osteoporosis.

F. NUTRITIONAL ISSUES

The physician should record methods the athlete uses to maintain, gain, or lose weight.

G. MEDICATION HISTORY

This information will provide data on current medications along with the opportunity to discuss the possible use of performance-enhancing supplements such as anabolic steroids, creatine, stimulants, and narcotics.

Physical Examination

The physical examination should be focused on the needs of the athlete. It may be the only time that an athlete has contact with medical personnel and can be used to promote wellness along with screening for

Answer questions by checking Yes (Y)/no (N)/don't know (?)

	Y	N	?
General Health			
1. Have you had any injuries or illnesses?			
2. Have you ever been hospitalized?			
3. Do you think you are too thin or overweight?			
4. Have you ever used anything to gain or loss weight?			
5. Any problems exercising in the heat: heat cramps, heat exhaustion or heat stroke?			
6. Ever had frostbite?			
7. Any vision problems?			
8. Do you wear glasses, contact lens, or eye protection?			
9. Any dental appliances?			
10. Have you had any surgeries?			
11. Any organs missing?			
12. Immunizations (tetanus/ hepatitis B) are they current?			
13. Any concerns about participating in sports?			
Cardiac/Respiratory History			
1. Has any family member died suddenly, have heart disease before age 50 or other heart problems?			
2. Do you have any dizziness, chest pain, a racing heart, or shortness of breath with exercise?			
3. Have you ever passed out?			
4. Do you have a heart murmur, high blood pressure, or any heart condition?			
5. Can you exercise as much as your friends?			
6. Any history of asthma, problems breathing, coughing with exercise?			
Neurologic History			
1. Any history of a head injury/concussion: being knocked out, dazed, or having memory loss?			
2. Have you ever had a seizure or convulsion?			
3. Any nerve problems: stingers, burners, pinched nerves or numbness?			
4. Any problems with headaches?			
Musculoskeletal History			
1. Do you have a history of sprains, strains or fractures?			
2. Any hip, knee or ankle injuries?			
3. Any shoulder, elbow, wrist, hand or finger injuries?			
4. Any back or neck problems?			
5. Ever have to be in a splint, cast or use crutches?			
6. Do you use any special equipment when competing (braces, orthotics, pads etc)			
Females Only			
1. Any problems with menstruation: cramps, irregularity, etc.			
2. When was your last period? _____			

COMMENT ON YES ANSWERS

Figure 25–1. Preparticipation history.

physical activity. Figure 25–2 is an example of a standardized physical examination form. The examination should include routine vital signs including blood pressure measurements obtained in the upper extremity. The cardiovascular examination should include palpation of pulses, auscultation for murmurs with the patient both sitting and standing, and evaluation of the effects of exercise on the individual. The musculoskeletal examination is used to determine strength, range of motion, flexibility, and previous injuries. Table 25–1 is a quick guide that can be used to screen for abnormalities in this area. The remainder of the examination should emphasize the following areas:

A. SKIN

Are there any contagious lesions such as herpes or impetigo?

B. VISUAL

Are there any visual problems? Is there any evidence of retinal problems? Are both eyes intact?

C. ABDOMINAL

Is there any evidence of hepatosplenomegaly?

D. GENITOURINARY

Is there any history of testicular abnormalities or hernia symptoms?

E. NEUROLOGIC

Are there any problems with coordination, gait, or mental processing?

F. SEXUAL MATURITY

What Tanner stage is this individual?

Recommendations for Participation

After completing the medical examination (history and physical) the physician can make recommendations to the athlete on sports clearance. The options are unrestricted participation, limited participation, or no participation. The American Academy of Pediatrics (AAP) has a list of guidelines, which can be found on their Website. Table 25–2 shows considerations and recommendations for sports activities based on body systems.

REHABILITATION OF SPORTS INJURIES

Participation in sports can have tremendous benefits for the individual. It provides physical activity, acquisition of motor skills, and social opportunities. All sports participation, however, carries an inherent risk of injuries. These injuries are classified as either acute or chronic. Chronic injuries occur over time and are related to repetitive stress. These injuries develop in response to overuse, repeated microtrauma, and inadequate repair of injured tissue. Acute injuries, or macrotrauma, are one-time events that can cause alterations in biomechanics and physiology. In response to an acute injury the body responds in a predictable fashion. The first week is characterized by an acute inflammatory response. During this time initial vasoconstriction is followed by vasodilatation. Chemical mediators of inflammation are released and result in the classical physical findings of local swelling, warmth, pain, and loss of function. This phase is essential for injury healing. The next phase occurs over 2–4 weeks and involves repair and clean-up. Fibroblasts infiltrate and lay down new collagen. This allows for repair of the injured area.

The management of acute sports injuries is geared toward optimizing healing and restoring function. The goals of immediate care are to minimize the effects of the injury by reducing pain and swelling, to educate the athlete about the nature of the injury and how to take care of it, and to maintain the health of the rest of the body. The treatment for an acute injury is captured in the acronym PRICE:

- Protect the injury from further damage (taping, splints, braces)
- Rest the area
- Ice
- Compression of the injury
- Elevation immediately

The use of nonsteroidal anti-inflammatory agents reduces the inflammatory response and reduces discomfort. These medications may be used immediately after the injury. Glucocorticoids should be administered judiciously. If administered inappropriately they may prolong the acute phase of recovery. Therapeutic use of physical modalities, including early cold and later heat, hydrotherapy, massage, electrical stimulation, iontophoresis, and ultrasound, can enhance recovery in the acute phase.

The recovery phase can be lengthy and requires athlete participation. Initial treatment is focused on joint range of motion and flexibility. Range-of-motion exercises should follow a logical progression of starting with passive motion, then moving to active assistive, and finally to active movement. Active range of motion is in-

Figure 25-2. Preparticipation physical evaluation.

Table 25–1. The screening sports exam.^a

General evaluation	<p>Have person stand in front of the examiner and evaluate both front and back along with posture</p> <p>Look at general body habitus</p> <p>Look for asymmetry in muscle bulk, scars or unusual postures</p> <p>Watch how the patient moves when instructed</p>
Neck evaluation	<p>Evaluate ROM by having person bend head forward (chin to chest), rotate from side to side, and laterally bend (ear to shoulder)</p> <p>Observe for asymmetry, lack of motion or pain with movement</p>
Shoulder and upper extremity evaluation	<p>Observe clavicles, shoulder position, scapular position, elbow position, and fingers</p> <p>ROM screening</p> <p>Fully abduct arms with palms in jumping jack position</p> <p>Internally and externally rotate shoulder</p> <p>Flex and extend wrist, pronate and supinate wrist, flex and extend fingers</p> <p>Do the following manual muscle testing:</p> <p>Have person shrug shoulders (testing trapezius)</p> <p>Abduct to 90 degrees (testing deltoid)</p> <p>Flex elbow (testing biceps)</p> <p>Extend elbow over head (testing triceps)</p> <p>Test wrist flexion and extension</p> <p>Have person grasp fingers</p>
Back evaluation	<p>General inspection to look for scoliosis or kyphosis</p> <p>ROM screening</p> <p>Bend forward touching toes with knees straight (spine flexion and hamstring range)</p> <p>Rotation, side bending, and spine extension</p>
Gait and lower extremity evaluation	<p>General observation while walking</p> <p>Walk short distance normally (look at symmetry, heel-toe gait pattern, look at all joints involved in gait and leg lengths, any evidence of joint effusions or pain)</p> <p>Have person toe-walk and heel-walk for short distance and check tandem walking (balance beam walking)</p>

^aIf any abnormalities are found, then a more focused evaluation is required.

tiated once normal joint range has been reestablished. Flexibility is sport-specific and aimed at reducing tight musculature. Strength training can begin early in this phase of rehabilitation. Initially only isometric exercises are encouraged. As recovery progresses and flexibility increases, isotonic and isokinetic exercises can be added to the program. These should be done at least three times per week. As the athlete approaches near-normal strength and is pain-free, the final maintenance phase can be introduced. During this phase the athlete will continue to build strength and work on endurance. The biomechanics of sport-specific activity needs to be analyzed and retraining incorporated into the exercise program. Generalized cardiovascular conditioning should continue during the entire rehabilitation treatment.

COMMON SPORTS MEDICINE ISSUES AND INJURIES

INFECTIOUS DISEASES

Infectious diseases are common in both recreational and competitive athletes. These illnesses have an effect on basic physiologic function and athletic performance. Given this knowledge, physicians, parents, and coaches can adopt the common-sense guidelines listed in Table 25–3.

American Academy of Pediatrics Committee on Sports Medicine and Fitness: Human immunodeficiency virus (acquired immunodeficiency syndrome—AIDS virus) in the athletic setting. *Pediatrics* 1991;88:640 [PMID: 1881749].

HEAD & NECK INJURIES

Head and neck injuries occur most commonly in contact and individual sports. The sports with the highest incidence of brain injury are football, bicycling, baseball, horseback riding, and golf. The treatment of these is controversial, with multiple guidelines being developed. Because young children have developing central nervous systems, injuries in these children should be treated conservatively.

Concussion is a temporary and immediate impairment of neurologic function and is classified by length of unconsciousness, posttraumatic amnesia (PTA), and confusion. Concussions are categorized as grade 1 (mild), grade 2 (moderate), or grade 3 (severe). Return-to-competition guidelines have been developed by several resources. Table 25–4 reviews guidelines for return to play.

Table 25–2. Recommendations and considerations for participation in sports

Disorders	Considerations and Recommendations	References
Cardiac		
Anticoagulation treatment	Need to avoid all contact sports	
Aortic stenosis	Individualize treatment based on disease and systolic gradient Mild: < 20 mm Hg, all sports if asymptomatic. Moderate: limited sports. Severe: no competitive sports.	
Arrhythmias	Consult with cardiologist as WPW and long QT syndrome can have serious consequences.	
Congestive heart failure (CHF)	Screen patient with LVEF < 30 % for ischemia. Use AHA risk stratification criteria to define exercise capacity.	Braith, 2002
Heart implants	No jumping, swimming, or contact sports.	
Hypertrophic cardiomyopathy	Single most common cause of cardiac death in young athletes. Athletes should not participate in sports except possibly low intensity forms (eg, golf, bowling). Consult with cardiologist.	Maron, 2002a,b
Marfan syndrome	Aortic root dilation is associated with mitral valve prolapse and regurgitation. Participate in sports with minimal physical demands.	Salim et al, 2001
Mitral valve prolapse	Fairly common condition. No restrictions unless there is a history of syncope, positive family history of sudden death, arrhythmias with exercise, or moderate regurgitation.	
Syncope	Unexplained syncopal episodes during exercise must be evaluated by ECG, echocardiograph, Holter, and tilt test prior to resumption of any activities.	Firoozi, 2002
Endocrine		
Diabetes type I	No restrictions to activity, however: Short-term exercise = no insulin changes. Vigorous exercise = 25% reduction in insulin with 15–30 g of carbohydrates before and every 30 min during exercise. Strenuous exercise = may require up to an 80% reduction in insulin with extra carbohydrates. Generally monitor blood glucose closely.	Birrer et al, 2003 Draznin, 2000
Eye		
Detached retina	Do not participate in strenuous sports regardless of contact risk.	Moeller, 1996
One eye	Consider avoiding contact sports although if patient does participate use of eye protection is a must.	Vinger, 2000
Gentiourinary		
One testicle	Need to wear protective cups in collision/contact sports.	
Solitary kidney	Advise not to participate in collision/contact sports.	Terrell, 1997
Hematologic		
Hemophilia	Avoid contact/collision sports.	
Sickle cell trait	No restrictions if disorder well under control. Athletes should avoid dehydration and acclimate to altitude. There is however a known association between exercise and sudden death.	

(continued)

Table 25–2. Recommendations and considerations for participation in sports (continued)

Disorders	Considerations and Recommendations	References
Infectious Disease		
General considerations	Fevers; should not participate in activities with moderate fevers; exercise affects fluid balance, immune system function, and temperature regulation. Intense exercise may worsen or prolong some viral illnesses.	Howe, 2003 Primos, 1996
Enterovirus, coxsackie virus	Causes respiratory and GI symptoms but more importantly can cause myocarditis. Anyone with systemic symptoms such as fever or myalgias should avoid strenuous exercise.	Primos, 1996
Herpes simplex, impetigo, tinea corpora	Close contact is required for transmission; use common sense guidelines. For contact sports participation should not be allowed until lesions are crusted over or healed.	Moeller, 1996
Infectious mononucleosis	Splenic rupture is most important consideration. Risk of spleen rupture highest during second and third weeks of illness. No athletic participation for a minimum of 21 days! Splenic ultrasounds should be considered in decision making. Too early a return to sports could cause EBV reactivation and relapse. First week of return to activity should be noncontact. Graded increases in intensity if fatigue tolerance is improved. Return to full activity if: no abdominal pain, normal spleen and normal labs.	MacKnight, 2002
Sinusitis	Similar considerations as cold (see below) except diving should be restricted until symptoms resolve.	
<i>Streptococcus A</i>	Restrict from activity until afebrile and on antibiotics for > 24 h	O’Kane, 2002
Upper respiratory infections (including common cold)	“Neck check,” with symptoms (fevers, myalgias, arthralgias, etc) above the neck participation can be allowed; however, if they migrate below that level activity should be limited.	Primos 1996
Neurologic		
Epilepsy	Majority of sports are safe with good seizure control; contact sports are allowed with proper protection. Definitely wear a helmet. Fitness may reduce number of seizures. Swimming and water sports should be supervised. Sports such as free climbing, hang gliding, scuba not recommended.	Howard, 2004
Herniated disk (with cord compression)	Avoid contact and collision sports.	
Muscle disease or myopathy	Exercise within physical limits. Low to moderate intensity activity is appropriate for patients with slow progressive disorders. Patients with disorder that are rapidly progressing should avoid high resistance and eccentric muscle activity. Modification of exercise with intercurrent illness.	Tarnopolsky, 2002 Ansved, 2003
Spinal stenosis	Avoid contact and collision sports.	
Orthopedic		
Scoliosis	No restrictions unless severe.	
Spondylolisthesis	Grade 2 and above should avoid high-risk sports.	
Spondylolysis	Pars intrarticularis stress fracture. No restrictions if pain-free.	

(continued)

Table 25–2. Recommendations and considerations for participation in sports (continued)

Disorders	Considerations and Recommendations	References
Respiratory		
Asthma	No activity restrictions. Use common sense about when to use medications.	Disabella et al. 1998
Pneumothorax	Can occur in sports, especially in males. Increased risk for reoccurrence; should consider not participating in strenuous and contact sports.	
TB	Not allowed to participate because of exposure to other athletes.	
Other		
Cerebral palsy	Full participation with modifications.	
Developmental disabilities	Athletes with developmental disabilities often have associated medical problems including diabetes, obesity, and hypokinesia.	Platt, 2001
Downs syndrome	10–20% have atlantoaxial instability. All athletes need to be cleared with a lateral view radiograph including flexion and extension. If abnormal no contact sports should be allowed. Evaluation of underlying congenital heart disorders should be considered in this population.	Platt, 2001 Winell, 2003
Spinal cord injury/ spina bifida	Full participation. Consider modification of equipment to accommodate activity and/or modification of activity to accommodate disability. Consider how modification affects performance. Beaware of thermoregulatory dysfunction, medications, and pressure areas.	

Second impact syndrome is a rare but potentially deadly complication of head injuries. It occurs in athletes who have a second brain injury before recovering from a prior brain injury. It results in loss of vascular autoregulation and subsequent malignant cerebral edema.

Cervical spine injuries are fairly common but potentially serious. They can cause ligamentous injuries along with spinal cord injuries. The most frequent neck injury is a cervical strain. Return to play is allowed when neck range of motion is full and pain-free, and strength is normal.

Atlantoaxial instability is common in children with Down syndrome because of underlying ligamentous laxity. Cervical neck films including the neck in flexion and extension evaluate the atlantodens interval. Normal is less than 2.5 mm, but up to 4.5 mm is acceptable in this population. Children with an interval greater than 4.5 mm should be restricted in activities.

Colorado Medical Society: *Report of the Sports Medicine Committee: Guidelines for the Management of Concussion in Sports* (revised). Colorado Medical Society, 1991.

Burners and stingers are common injuries in contact sports, especially football. These types of cervical radiculopathies or brachial plexopathies occur when the head is laterally bent and the shoulder depressed. Symptoms include immediate burning pain and paresthesias down one arm, generally lasting only minutes. Weakness in the muscles of the upper trunk (supraspinatus, deltoid, and bicep) can persist for weeks. Work-up includes a thorough neurologic assessment. If symptoms persist, then a diagnostic evaluation should include cervical spine radiographs, magnetic resonance imaging (MRI) scans, and electromyography. The athlete can return to play once symptoms have resolved, neck and shoulder range of motion is pain-free,

Table 25–3. Sports participation guidelines: infectious diseases.

Athletes with temperatures higher than 100°F should not participate in sporting activities.
Athletes who have had recent infectious mononucleosis can return to noncontact training at 3 wk as long as there is no splenic enlargement. They may return to contact sports after 4 wk and a normal abdominal examination.
Athletes with a streptococcal pharyngitis can resume activity once treatment has been initiated and they are afebrile.
If a localized herpes gladiatorum or impetigo lesion is present, no contact sports are allowed until the lesions have resolved. Athletes with herpes zoster have the same restrictions. There are no restrictions for athletes with common warts. Athletes with molluscum contagiosum can compete if the affected areas are covered. Athletes with furuncles cannot be involved in contact sports or swimming until the lesions are healed.
Athletes with HIV infection may compete in all types of sports. Universal precautions should be used with all athletes who have sustained injuries.

reflexes and strength are normal, and the Spurling's test is negative. Preventative strategies include always wearing protective gear, proper blocking and tackling techniques, and maintaining good neck and shoulder strength.

SPINE INJURIES

Injuries to the spine are fairly common even in the pediatric population. As children have become more competitive in sports, the number of reported injuries has increased. Sports with a fairly high incidence of back injuries are golf, gymnastics, football, dance, wrestling, and weight lifting. Pain lasting more than 2 weeks indicates a possible structural problem and needs to be investigated.

Herniated discs account for a small percentage of back injuries in children. These injuries are almost unheard of in preadolescence. Most injuries occur at the L4–5 and L5–S1 vertebrae. Symptoms include back and leg pain. Pain may be increased with activities such as bending, sitting, and coughing. Pain often radiates down the lower extremity in a radicular pattern. Evaluation comprises a physical and neurologic exam, including straight-leg testing, sensory testing, and checking reflexes. If symptoms persist, then the evaluation should include electromyographic, computed tomographic,

and MRI scans. Treatment generally is conservative because most back injuries improve spontaneously. The athlete can rest the back for a short period and then begin on a structured exercise program of extension and isometrics followed by flexion exercises. If symptoms persist, then a short course of steroids may be indicated. Surgery is recommended only if neurologic compromise persists.

Spondylolysis is an injury to the pars interarticularis. Pars defects are present in 4–6 % of the population. Repetitive stress to this area results in fractures. The injury is common in gymnasts, dancers, and football players. Spondylolysis occurs at L5 in 85% of cases. Pain usually develops during an adolescent growth spurt. Back pain may radiate into the buttocks or thigh area. Extension of the spine increases pain. Evaluation includes an oblique radiographic view of the spine to look for the “Scottie dog sign.” Treatment includes rest

Table 25–4. Return-to-competition guidelines following concussion.

Grade 1 or mild concussion

No loss of consciousness (LOC)

PTA or confusion lasting less than 15 min

First Injury

- Remove from game
- Return to play in 15 minutes if exam is normal

Second injury

- Return to play if asymptomatic after one week

Grade 2 or moderate concussion

No LOC

PTA or confusion lasting longer than 15 minutes

First Injury

- Remove from game
- Hospital evaluation if symptoms persist for more than one hour
- Return to play if asymptomatic after one week
- CT or MRI if symptoms persist for more than 1 wk

Second Injury

- Return to play if asymptomatic after two weeks

Third Injury

- Out for season

Grade 3 or severe concussion

Any LOC

First Injury

- Transport to hospital for evaluation
- With a brief LOC (seconds), return to play if asymptomatic after one week
- With a longer LOC (minutes), return to play if asymptomatic after 2 wk

Second Injury

- No play for at least one month following absence of symptoms; consider ending season
-

from sporting activities, stretching of the hamstrings, stabilization exercises, lumbosacral bracing, and occasionally surgery.

If a bilateral pars injury occurs, then slippage of one vertebra over another (**spondylolisthesis**) can occur. These injuries are graded on a scale of 1 to 4 based on the percentage of slippage: grade 1, 0–25%; grade 2, 25–49%; grade 3, 50–74%; and grade 4, 75–100%. Diagnosis is based on lateral radiographs, and treatment is symptomatic. Asymptomatic athletes with less than 30% slippage have no restrictions and are followed up on a routine basis. Slippage of 50% requires interventions of stretching hip flexors and hamstrings, along with bracing or surgery.

Letts M, McDonald P: Sports injuries to the pediatric spine. *Spine: State of the Art Review* 1990;4:49.

SHOULDER INJURIES

In evaluating shoulder injuries it is necessary to look at both macro- and microtrauma. Fractures and dislocations account for most macrotrauma. The balance of other injuries are related to repetitive overuse and tissue failure. Rotator **cuff injuries** are common in athletics that require repetitive overhead motions (eg, gymnastics, and pitching in baseball). Muscle imbalances and injury cause the position of the humeral head to be abnormal which may cause impingement of the supraspinatus tendon under the acromial arch. Pain is usually reported in the anterior and lateral shoulder and is increased with overhead activities. Diagnostic work-up includes plain radiographs and an outlet view to look for anatomic variability. The rehabilitation of this injury is geared toward reduction of inflammation, improved flexibility, and strengthening of the scapular stabilizers and rotator cuff muscles. This is achieved by a progression of isometric followed by isotonic or isokinetic exercises. A biomechanics evaluation can assist in the recovery process by building sport-specific skills and eliminating substitution patterns.

Tytherleigh-Strong G et al: Rotator cuff disease. *Curr Opin Rheumatol* 2001;13;2:135 [PMID: 11224738].

ELBOW & FOREARM INJURIES

Injuries in the forearm are quite common, with both chronic and acute causes (eg, the chronic overuse “little league elbow” and the frequent childhood fracture when falling on an outstretched arm).

Medial Elbow Pain

Medial elbow pain can have multiple causes, but one of the most common is **medial epicondylitis**, an overuse injury caused by valgus stress at the elbow. **Little league elbow** consists of a group of abnormalities that develop in young baseball pitchers. These abnormalities are secondary to the biomechanical forces generated around the elbow during throwing. These forces can result in shearing, inflammation, traction, and abnormal bone development. Pitching can be divided into four phases: wind-up, cocking, acceleration, and follow-through. The acceleration phase is where most forces are generated. The symptoms are primarily swelling, pain, performance difficulties, and weakness. The pain localizes to the medial epicondyle, which may be tender to palpation. Wrist flexion and pronation increase symptoms. The different phases of throwing should be analyzed to isolate when the pain appears. If pain is present in all phases this may indicate a severe injury. Work-up includes a series of elbow radiographs, including stress films and comparison films, to look for widening of the epiphysal lines, and MRI studies. Treatment of the acute injury includes rest. It is not uncommon for a player to be benched for up to 6 weeks. Competition can be resumed once the player is asymptomatic.

The key to treating this injury is prevention. Children should be properly conditioned and coached in correct throwing biomechanics. Guidelines are available for pitching limits in youth baseball. Little League limits 10- to 12-year-old children to six innings/week and 13- to 15-year-old children to nine innings/week. Limiting pitches per game has been outlined as shown in Table 25–5.

Other causes of medial elbow pain include ulnar collateral ligament injury, ulnar neuritis, apophysitis, and fractures.

Table 25–5. Guidelines for pitching limits in youth baseball.

Age (years)	Pitches/game ^a
8–10	52 ± 15
11–12	68 ± 18
13–14	76 ± 16
15–16	91 ± 16
16–17	106 ± 16

^aBased on 2 games/week.

Lateral Elbow Pain

Lateral elbow pain can be the result of a few unique problems in growing athletes. **Panner disease** is also caused by valgus stress at the elbow. It is a focal process in the capitellum and occurs in players age 5–12 years. The child presents with dull aching in the lateral elbow that generally worsens when the child throws something. Swelling and reduced elbow extension are usually present. Radiographs show an abnormal capitellum with fragmentation and areas of sclerosis. Treatment is conservative, using rest, ice, and splinting. The child can return to play after the radiographs normalize.

The same type of pain in a 13- to 15-year-old athlete is usually **osteochondritis dissecans**. This injury is basically avascular necrosis of the capitellum, which can result in the formation of loose bodies. Radiographs are needed in the diagnosis and help to classify the injury into one of three categories. Treatment is based on the classification and can be either conservative or surgical in nature. The child should be seen by an orthopedic specialist.

Lateral epicondylitis is common in racquet sports, particularly tennis. It is an overuse of the extensor muscle in the forearm and causes pain in the lateral elbow. Pain is increased by wrist extension. Initial treatment is aimed at inflammation control. Stretching and strengthening of forearm muscles are the primary interventions during the subsequent phases. Stroke mechanics may need to be altered and a forearm brace used to decrease the forces in the extensor muscles.

Posterior Elbow Pain

Posterior elbow pain is not very common. Causes include dislocations, fractures, triceps avulsions, and olecranon bursitis.

HAND & WRIST INJURIES

All hand and wrist injuries have the potential for long-term, often serious disability and deserve a thorough evaluation.

1. Hand Injuries

Distal Phalanx Injuries

Tuft injury requires splinting for 6 weeks or until the patient is pain-free. If displacement is significant, then a K-wire can be used for reduction. **Nail bed injury** often requires splinting and drainage of subungual hematomas.

Distal Interphalangeal Injuries

Mallet finger or **extensor tendon avulsion** occurs in ball-handling sports. The mechanism of injury is a force applied to an extended finger. Treatment is splinting in extension for 6 weeks for fractures and 8 weeks for tendon rupture.

Thumb Injuries

Gamekeeper's thumb is an injury to the ulnar collateral ligament from forced abduction of the metacarpal phalangeal joint. It is a common skiing injury. If a radiograph shows an avulsed fragment is displaced less than 2 mm, a thumb spica cast can be used. If no fragment is apparent and less than 35 degrees of lateral joint space opening occurs, a spica cast is indicated for 6 weeks. Surgery is required for more serious injuries.

Fractures

Boxer's fracture is a neck fracture of the fifth digit. These fractures can be treated by closed reduction and casting for 3 weeks. A displaced fracture requires open reduction and internal fixation.

2. Wrist Injuries

Most swollen wrists without evidence of instability can be splinted for several weeks. Radial and ulnar fractures must be ruled out because these are fairly common in children.

Scaphoid fractures are caused by a force applied to a hyperextended wrist. If evidence of snuff box tenderness and swelling is present, the wrist must be immobilized for 10 days and then reassessed, even if radiographs are normal. A nondisplaced fracture requires at least 6 weeks of immobilization in a thumb spica cast.

HIP INJURIES

Because the pelvis and hip articulate with both the lower extremities and the spine, this is an area rich in ligaments, muscle attachments, and nerves. Injuries in young children are rare, but sprains and strains are common.

Groin pull, or adductor strain, is generally caused by forced abduction as in running, falling, twisting, or tackling. The associated pain is in the adductor muscle. Pain may arise with adduction or hip flexion, and tenderness may be present over the adductor tubercle. Treatment includes rest, ice, protection, and strengthening of the muscle when it heals.

Quadriceps contusion is caused by a direct macroinjury to the muscle, resulting in bruising, swelling, and pain. The anterior and lateral thigh regions are most commonly injured. If the muscle remains firm on examination after 2 weeks, then radiographs of the thigh should be done to rule out myositis ossificans. (**Myositis ossificans** is an abnormal deposition of calcium in the muscle that may be induced by aggressive stretching of the muscle too early in the clinical course.) Treatment is rest, ice, and protection for the first 24 hours. The knee should be kept in a fully flexed position. Two to three days after the injury, range-of-motion exercises may begin in both flexion and extension. Once 120 degrees of motion has been established and movement does not cause pain, the athlete may return to competitive activity.

Hamstring strain is very common in many sports. The mechanism of injury is forced extension of the knee. Examination reveals pain on palpation of the muscle. Pain also occurs with knee flexion against resistance. Treatment is rest, ice, and compression. The athlete can walk as soon as he or she can tolerate the activity. It is particularly important to stretch the hamstring because, as a two-joint muscle, it is more susceptible to injury than other types of muscle.

The bursa is a structure that allows for improved motion by reducing friction. When a bursa becomes inflamed, movement is painful and may be limited. Areas susceptible to bursal inflammation are the shoulder, elbow, patella, and hip. **Trochanteric bursitis,** causing pain when the hip is flexed, often results from reduced flexibility of the iliotibial band and gluteus medius tendons. It is best evaluated in a side-lying position, and pain is reproduced when the hip is actively flexed from a fully extended hip. Initial treatment is to alter the offending activity and then start a stretching program geared at the iliotibial band and hip abductors. Corticosteroid injections may be used after conservative treatment has failed.

Most **hip dislocations** are in the posterior direction. Athletes with this injury classically present with hip flexion, adduction, and internal rotation.

Hip dislocations in skeletally mature athletes are almost always associated with acetabular and femoral neck fracture. The preadolescent, skeletally immature competitor may have an isolated injury. This is a true on-field emergency, and the athlete should be transported to the nearest facility that has an orthopedic surgeon available. Severe bleeding, avascular necrosis, and nerve damage can result. Once reduction has been established in a noncomplicated case, protected weight bearing on crutches for 6 weeks is recommended, followed by another 6 weeks of range-of-motion and strengthening exercises. An athlete may return gradually to competition after 3 months when strength and motion are normal.

Femoral neck fractures (**stress fractures**) are generally the result of repetitive microtrauma. They commonly occur in track athletes who have increased their mileage. Athletes with this type of injury present with persistent pain in the groin and pain with internal and external rotation. Range of motion may be limited in hip flexion and internal rotation. If plain radiographs are negative, then a bone scan is indicated. Treatment is based on the type of fracture. A **transverse fracture** generally requires internal fixation to prevent femoral displacement from occurring and potentially causing avascular necrosis. A **compression fracture** is less likely to be displaced; treatment is conservative and involves resting the hip until it heals. Cardiovascular conditioning can be maintained easily through nonimpact exercises and activity.

KNEE INJURIES

Knee injuries are one of the most common problems evaluated by any practitioner. The function of the knee is for mobility and stability. Knee movements include flexion, extension, rotation, rolling, and gliding. The knee is stabilized through a variety of ligaments, tendons, and the meniscus.

Anterior Knee Pain

The most common knee complaint is anterior knee pain. This complaint can have multiple causes but should always include hip pathology as a possibility. Patellofemoral syndrome is a common cause of anterior knee pain. The differential diagnosis is quite extensive and requires a thorough examination.

Patellofemoral overuse syndrome occurs in runners and in athletes participating in sports with repetitive stress in the lower extremity. Classically, pain is located over the medial surface and under surface of the patella. It is asso-

ciated with swelling and crepitus of the knee joint. The Q-angle often is increased. The Q-angle is measured by drawing a line from the anterior superior iliac spine down to the center of the patella and then through the tibial tubercle. The intersecting angle is the Q-angle. Normal is 14 degrees for males and 17 degrees for females. Q-angles greater than 20 degrees tend to track the patella laterally, changing the knee biomechanics.

Plicae alares are normal synovial folds in the knee joint. If they become thickened or fibrosed they can become entrapped. This happens with direct macrotrauma or repetitive microtrauma. The athlete complains of snapping or popping in the knee. The knee pain is worse with knee flexion, and activity intensifies symptoms. On examination the hamstrings may be tight. Physical findings include localized tenderness and occasionally popping palpable at 30–60 degrees of knee flexion.

Tendonitis of the patellar tendon is caused by overuse. The mechanism is repetitive loading of the quadriceps during running or jumping. **Osgood–Schlatter disease** occurs in the preteen and adolescent years. It is most common in boys age 12–15 years and in girls age 11–13 years. Pain usually is present at the tibial tubercle, and activities using eccentric quadriceps muscle movement aggravate the pain. The pain can become so extensive that routine activity must be curtailed. Radiographs may or may not show abnormalities. Type 1 disease has no findings, whereas type 2 shows evidence of fragmentation of the tibial tubercle. Many other conditions can cause anterior knee pain and need to be ruled out, including arthritis, complex regional pain syndrome, infections, and neoplasm. Finally, **chondromalacia patellae** is an arthroscopic diagnosis and should not be used as a clinical diagnosis.

Treatment of Anterior Knee Pain

As with any acute injury, control of inflammation is essential. This begins with rest and ice. Alignment problems should be corrected with stretching and strengthening. Orthotics may need to be used for correction of foot deformities. Quadriceps strengthening begins with isometric exercises that progress to a concentric program. These include short-arc (the last 10 degrees of knee extension) contractions of the vastus medialis. In the last part of the therapy program, eccentric loading of the quadriceps can be incorporated. During this time the athlete should be working on endurance and cardiovascular conditioning. Knee bracing is controversial, and the major benefits are proprioceptive feedback and patellar tracking.

Lateral Knee Pain

Lateral knee pain is most commonly associated with a tight iliotibial band, which can lead to **tendonitis** and

bursitis. Pain over the lateral femoral condyle is present along with a positive Ober test. The Ober test is done with the athlete in a side-lying position. The knee and hip are flexed to 90 degrees, then the hip is maximally abducted and extended. From this position the leg is allowed to drop by gravity while the knee is still controlled. It will not relax if the iliotibial band is tight. Treatment involves rest and stretching. Athletics should not be resumed until the patient is pain-free. This may take up to 6 weeks. Other sources of lateral knee pain are popliteus tendonitis and biceps tendonitis.

Posterior Knee Pain

Posterior knee pain usually results from an injury to the gastrocnemius–soleus complex caused by overuse. It can also include a Baker cyst, tibial stress fracture, or tendonitis of the hamstring. Treatment is rest, ice, and strengthening exercises after symptoms have improved.

Meniscal Injuries

The meniscus of the knee cushions forces in the knee joint, increases nutrient supply to the cartilage, and stabilizes the knee. Most injuries are related to directional changes on a weight-bearing extremity. **Medial meniscus injuries** have a history of tibial rotation in a weight-bearing position. This happens frequently in ball-handling sports. **Lateral meniscus injuries** occur with tibial rotation with a flexed knee. These injuries are uncommon in children younger than age 10 years. The athlete with such an injury has a history of knee pain, swelling, snapping, or locking, or may report a feeling of the knee giving way. Physical examination reveals joint line tenderness and a positive McMurray hyperflexion/rotation test. The diagnostic test of choice is MRI of the knee, although standard knee radiographs should be included. Arthrograms are still used by some practitioners. Treatment may be symptomatic for isolated injuries of the meniscus with no ligamentous involvement or mechanical blocks. . If surgery is needed, the athlete should not bear weight on the knee for 3 weeks. During this time, range-of-motion and strengthening exercises can be done.

Medial & Lateral Collateral Ligament Injuries

The medial and lateral collateral ligaments are positioned along either side of the knee and act to stabilize it. They help to control varus and valgus stress applied to the knee joint. Excessive varus or valgus stress causes stretching of the ligament, producing tears. Medial injuries occur with a blow to the lateral aspect of the knee, as seen in a football tackle. The athlete may feel a

pop or lose sensation along the medial aspect of the knee. The examination reveals an effusion and tenderness medially. A valgus stress test done in full extension and 20–30 degrees of flexion will reproduce pain. Diagnosis is made by routine and stress radiographs of the knee.

Treatment is almost always conservative. Initial injuries should be iced and elevated. A protective brace needs to be worn, and full knee motion in the brace can be done after 7 days. Weight bearing is allowed, and a strengthening program can be started. The athlete should use the brace until he or she is pain-free and has full range of motion. The use of a functional brace is often required when a player returns to competition. This is only temporary until the ligaments heal properly.

Anterior Cruciate Ligament Injuries

The anterior cruciate ligament (ACL) has three bands and prevents anterior subluxation of the tibia. The ACL is injured by deceleration, twisting, and cutting motions. The mechanism of the injury involves force applied to the knee during hyperextension, with excessive valgus stress and forced external rotation of the femur on a fixed tibia. Evaluation of the knee begins with examining the noninjured knee. The Lachman test will provide information on knee stability in relation to the ACL. All other structures of the knee need to be examined to rule out concomitant injuries. Imaging of the knee includes plain radiographs along with MRI scan.

Treatment options include both conservative and surgical procedures. Conservative treatment includes bracing, strengthening, and restricting physical activity. The braces used today enhance proprioception and control terminal extension. Surgical repair is quite popular, and a patellar tendon graft is used frequently. Rehabilitation of the knee starts immediately after surgery. A continuous passive range-of-motion machine is used postoperatively. Partial weight bearing is allowed in a brace that is set in full extension as the quadriceps strengthen. After 2 weeks, partial weight bearing and walking are started. The goals of the subsequent program are continued strength, muscle reeducation, endurance, agility, and coordination.

Posterior Cruciate Ligament Injuries

The posterior cruciate ligament (PCL) runs from the medial femoral condyle to the posterior tibial plateau and has two parts. Its main function is to prevent posterior tibial subluxation. This is an extremely rare injury and occurs when the individual falls on a flexed knee with the ankle in plantarflexion or with forced hy-

perflexion of the knee. The examination begins with the noninjured knee and proceeds to the injured side. Confirmatory testing includes the posterior drawer test done with the patient supine with the knee flexed to 90 degrees and the foot stabilized. Grading is based on the amount of translation. Grade 1 (mild) is translation up to 5 mm, grade 2 (moderate) is 5–10 mm, and grade 3 (severe) is greater than 10 mm. Diagnostic imaging includes plain radiographs and MRI scan.

Treatment can be determined as soon as the exact injury has been isolated. The use of surgical versus non-surgical management is controversial. The use of braces and a progressive rehabilitation program have been used successfully in athletes with grade 1 and 2 injuries. Grade 3 injuries generally require surgery.

FOOT & ANKLE INJURIES

Injuries in the lower leg, ankle, and foot are quite common in pediatric athletes. The types of injuries sustained tend to depend on the age group. Young children tend to have diaphysal injuries, in contrast to older children in rapid growth, who tend to have epiphysal and apophysal injuries. Perhaps the most common injury evaluated is the **ankle sprain**. When a ligament is overloaded, tearing occurs. These injuries are graded on a scale of 1 to 3. A grade 1 injury is a stretch without instability, grade 2 is a partial tear with some instability, and grade 3 is a total disruption of the ligament with instability of the joint. The ankle has three lateral ligaments (anterior talofibular, calcaneofibular, and posterior talofibular) and a medial deltoid ligament. Inversion of the foot generally damages the anterior talofibular ligament, whereas eversion injures the deltoid ligament. Physical examination often reveals swelling, bruising, and pain. The anterior drawer test is an easy to perform and reliable test of the anterior talofibular ligament. Other maneuvers include the talar tilt and valgus stress test. Diagnostic testing should be done when a bony injury is suspected. The adult Ottawa criteria do not pertain to patients younger than 18 year old. Tenderness over the malleoli, tenderness beyond ligament attachments, and excessive swelling are reasons to obtain radiographs.

Treatment of ankle injuries is imperative to ensure full recovery and should begin immediately after the in-

jury. Phase 1 care involves immediate compressive wrapping and icing to control swelling and inflammation. Protected weight bearing is allowed in the early phase of rehabilitation. The second phase begins when the athlete can ambulate without pain. During this time ankle range of motion is emphasized, along with isometric contractions of the ankle dorsiflexors. Once 90% of strength has returned, active eccentric and concentric exercises can be added. Phase 3 is designed to increase strength, improve proprioception, and add ballistic activity. The “foot alphabet” and “tilt board” are excellent methods for improving ankle proprioception. This program may take up to 6 weeks before an athlete can return to full activity. The athlete should wear a protective brace for 3 to 4 months and continue to ice after exercising.

Plantar fasciitis is common problem that manifests itself as heel pain. It happens in runners who log more than 30 miles per week and in athletes who have tight Achilles tendons or poorly fitting shoes. It is common in people with cavus feet and in individuals who are overweight. The pain is worse on first standing up in the morning and taking a few steps. A bone spur is often found on examination. Treatment involves local massage, stretching of the gastrocnemius, nonsteroidal anti-inflammatory drugs, arch supports, and local steroid injections. Runners may need to cut back on their weekly mileage until these measures eliminate pain.

PREVENTION

As in all activities most sports-related injuries can be prevented by the use of protective equipment, common sense, and proper training. Protective equipment should be properly fitted and maintained by an individual with training and instruction. Helmets should be used in football, baseball, hockey, bicycling, skiing, inline skating, skateboarding, or any sport with risk for head injury. Eye protection should be used in sports that have a high incidence of eye injuries. Proper protective padding should be identified and used, including chest pads for catchers; shin guards in soccer; shoulder, arm, chest, and leg padding in hockey; and wrist and elbow protectors in skating. A few common-sense concepts should be addressed by coaches, parents, and

physicians in order to ensure the safety of children participating in sports. These include inspecting playing fields for potential hazards, adapting rules to the developmental level of the participants, and matching opponents equally.

The use of the preparticipation history and physical examination can identify potential problems and allow for prevention and early intervention. Proper training techniques reduce injuries by encouraging flexibility, promoting endurance, and teaching correct biomechanics. Sports education reinforces the concepts of fitness and a healthy lifestyle along with sport-specific training. Early identification of an injury allows the athlete to modify techniques and avoid micro- and macrotrauma. Once an injury has occurred, it needs to be identified properly and appropriate measures used to minimize inflammation. Rehabilitation of the injury starts as soon as it has been identified. Early and appropriate care offers the athlete an optimal chance for full recovery and return to full participation.

JUVENILE RHEUMATOID ARTHRITIS (JUVENILE CHRONIC ARTHRITIS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Nonmigratory monarticular or polyarticular arthropathy, with a tendency to involve large joints or proximal interphalangeal joints and lasting more than 3 months.*
- *Systemic manifestations with fever, erythematous rashes, nodules, leukocytosis, and, occasionally, iridocyclitis, pleuritis, pericarditis, anemia, fatigue, and growth failure.*

General Considerations

Patients with juvenile rheumatoid arthritis (JRA) have immunogenetic traits different from those of adults with rheumatoid arthritis. In JRA, human leukocyte antigen (HLA)-DR5 is associated with iritis and the production of antinuclear antibodies (ANA), whereas HLA-DR4 is found in seropositive, polyarticular disease. These traits may be important in the formation of ant-suppressor cell antibodies, immune complex generation, and consequent chronic inflammatory disease. Genomics by microarray analysis show great promise in understanding the genetic predisposition to JRA. Tumor necrosis factor (TNF) may be the final common cytokine that perpetuates inflammation.

Clinical Findings

A. SYMPTOMS AND SIGNS

Three major clinical presentations in JRA provide clues to the prognosis and possible sequelae of the disease. In the acute febrile form, an evanescent salmon-pink macular rash, arthritis, hepatosplenomegaly, leukocytosis, and polyserositis characterize the constellation described by George Still. Patients with this form have episodic illness, and remission of the systemic features

can be expected within 1 year. They do not develop iridocyclitis.

The polyarticular pattern resembles the adult disease, with chronic pain and swelling of many joints in a symmetrical fashion. Both large and small joints are usually involved. Systemic features are less prominent, although low-grade fever, fatigue, rheumatoid nodules, and anemia may be present. Patients with this form tend to have long-standing arthritis, although the disease may wax and wane. Iridocyclitis occurs occasionally in this group. Older children may have a positive rheumatoid factor test.

The third pattern is characterized by pauciarticular disease, a chronic arthritis of a few joints—often the large weight-bearing joints—in an asymmetrical distribution. The synovitis is usually mild and may be painless. Systemic features are uncommon, but extra-articular involvement is severe, with inflammation in the eye. Up to 30% of children with pauciarticular JRA develop insidious, asymptomatic iridocyclitis, which may cause blindness if untreated. The activity of the eye disease does not correlate with that of the arthritis. Therefore, routine ophthalmologic screening with slitlamp examination must be performed at 3-month intervals if the ANA test is positive and at 6-month intervals if the ANA test is negative for 4 years after the onset of arthritis.

B. LABORATORY FINDINGS

No completely reliable diagnostic test is available for JRA. Rheumatoid factor is positive in about 15% of patients, usually in patients with polyarticular disease whose onset occurs after age 8 years. ANA are most often present in pauciarticular disease with iridocyclitis and may be an indicator of this complication; they are also fairly common in the late-onset rheumatoid factor-positive group. A normal erythrocyte sedimentation rate (ESR) does not exclude the diagnosis.

Table 26-1 lists the general characteristics of joint fluid in various conditions. A positive Gram stain or culture is the only definitive test for infection. A leukocyte count over 2000/ μ L suggests inflammation due to infection, any of the collagen-vascular diseases, leukemia, or reactive arthritis. A very low glucose concentration (< 40 mg/dL) or very high polymorphonuclear leukocyte count (> 60,000/ μ L) is highly sugges-

Table 26–1. Joint fluid analysis.

Disorder	Cells/ μ L	Glucose ^a
Trauma	More red cells than white cells; usually < 2000 white cells	Normal
Reactive arthritis	3000–10,000 white cells, mostly mononuclears	Normal
Juvenile rheumatoid arthritis and other inflammatory arthritides	5000–60,000 white cells, mostly neutrophils	Usually normal or slightly low
Septic arthritis	> 60,000 white cells, > 90% neutrophils	Low to normal

^aNormal value is 75% or more of serum glucose value.

tive of bacterial arthritis in a child. Chemical analysis of synovial fluid is otherwise of little diagnostic benefit.

C. IMAGING

In the early stages of the disease, only soft tissue swelling and regional osteoporosis are seen. Magnetic resonance imaging (MRI) of involved joints may show joint damage earlier in the course of the disease than other imaging modalities.

Differential Diagnosis

Table 26–2 lists the most common causes of limb pain in childhood. A few points of information may indicate the most likely diagnosis. For instance, orthopedic causes are due to increased physical activity, not major trauma. Reactive arthritides are suggested by a preceding viral infection, strep throat, or purpuric rash, and their course waxes and wanes over several days.

Monarticular arthritis is the most important disorder in the differential diagnosis to establish. Pain in the hip or lower extremity is a frequent symptom of childhood cancer, especially leukemia, neuroblastoma, and rhabdomyosarcoma. Infiltration of bone by tumor and actual joint effusion may be seen. Radiographs of the affected site and a careful examination of the blood smear for unusual cells and thrombocytopenia are necessary. A normal lactate dehydrogenase value is helpful in the exclusion of neoplastic disease. In doubtful cases, bone marrow examination is indicated.

Bacterial arthritis is usually acute and monarticular except for arthritis associated with gonorrhea, which may be associated with a migratory pattern. Fever, leukocytosis, and increased ESR with an acute process

in a single joint demand synovial fluid examination and culture to identify the pathogen.

The arthritis of rheumatic fever is migratory, transient, and often more painful than that of JRA. Rheumatic fever is rare in children younger than age 5 years. Evidence of rheumatic carditis should be sought. Evidence of recent streptococcal infection is essential to the diagnosis. The fever pattern in rheumatic fever is low grade and persistent compared with the spiking fever in the systemic form of JRA. Lyme arthri-

- Reticuloendotheliosis
- Osteoid osteoma
- Bone tumors (benign or malignant)

Syndromes of psycho-organic origin

- Growing pains
- Fibromyalgia
- Reflex neurovascular dystrophy

tis resembles pauciarticular JRA, but the former occurs as discrete, recurrent episodes of arthritis lasting 2–6 weeks. A negative test for antibodies to *Borrelia burgdorferi* argues strongly against this diagnosis.

Treatment

The objectives of therapy are to restore function, relieve pain, and maintain joint motion. In recent years, other nonsteroidal anti-inflammatory drugs (NSAIDs) have replaced salicylates in the medical treatment of JRA. Although their anti-inflammatory potency is not different from that of aspirin, their liquid form, decreased frequency of dosing, and diminished side effects appear to enhance compliance, cause fewer side effects, and justify their increased cost. Naproxen, 7.5 mg/kg twice daily; ibuprofen, 10 mg/kg four times daily; or diclofenac, 1 mg/kg given twice daily, may be used. If benefit occurs in the first 2 days, improvement will continue, with the maximum effect occurring at 6 weeks. Celecoxib and rofecoxib, two NSAIDs that are selective cyclo-oxygenase-2 (COX) inhibitors, show promise in relieving the gastrointestinal irritation seen with older NSAIDs which have both COX 1 and 2 activity. Dosages for children are under investigation. Range-of-motion and muscle-strengthening exercises should be taught and supervised by a therapist, and a home program should be instituted. Bed rest is to be avoided except in the most acute stages. Joint casting is almost never indicated.

Patients with JRA unresponsive to aspirin or other NSAIDs have a number of alternatives. Methotrexate is the second-line medication of choice. Symptomatic response usually occurs within 3–4 weeks. The low dosages used (5–10 mg/m²/wk as a single dose) have been associated with few side effects. Stomatitis usually resolves with continued administration. Nausea may be prevented by splitting the dose. Hepatotoxicity, including fibrosis, has been reported. A complete blood count and liver function tests should be obtained at 2-month intervals. Liver biopsy may be performed if there are recurrent elevations of aminotransferases. Two new second-line agents are available for patients with progressive disease. Leflunomide is an antipyrimidine medication that is as effective as methotrexate. Side effects may include diarrhea and alopecia. Etanercept is a TNF α receptor construct that must be administered subcutaneously twice a week (0.4 mg/kg/dose). Infliximab, an anti-TNF α antibody, administered in combination with methotrexate, is another second-line treatment. Iridocyclitis should be treated by an ophthalmologist, and methotrexate may be used in difficult cases. Local corticosteroid injections into joints, synovectomy, or joint replacement may be indicated in selected patients.

Prognosis

In the primarily articular forms of JRA, disease activity diminishes progressively with age and ceases by puberty in about 85% of patients. In a few instances, the disorder will persist into adult life. Problems after puberty relate primarily to residual joint damage. Presentation in the teen years usually presages adult disease. The children most liable to be handicapped permanently are those with unremitting synovitis, hip involvement, or positive rheumatoid factor tests.

SPONDYLOARTHROPATHY

Lower extremity arthritis, particularly in males older than age 10 years, suggests a form of spondyloarthropathy. Inflammation of tendinous insertions (enthesopathy) such as the tibial tubercle or the heel occurs in these diseases and not in JRA. Low back pain and sacroiliitis are quite specific for this form of arthritis. Carriage of HLA-B27 antigen occurs in 80% of patients with this disorder. No autoantibodies are found, but inflammatory indicators such as an elevated ESR or C-reactive protein are usually present. The episodes are usually intermittent, in contrast to the more chronic symptoms of JRA. Acute, not chronic, uveitis may occur.

The NSAIDs, particularly indomethacin (2–4 mg/kg/d) and naproxen (15 mg/kg/d), are more effective than salicylates in treating the spondyloarthropathies. Refractory cases may respond to methotrexate, etanercept, or infliximab. Local corticosteroid injections are contraindicated in Achilles tendinitis.

The disorder does not frequently progress to joint destruction or ankylosis in children as it does in adults.

Burgos-Vargas R: Juvenile onset spondyloarthropathies: Therapeutic aspects. *Ann Rheum Dis* 2002;61 (Suppl) 3:iii33.

ENTEROPATHIC ARTHRITIS

Enteropathic arthritis comprises several syndromes, including Reiter syndrome, reactive arthritis, and the arthritis of inflammatory bowel disease and celiac disease. The unifying feature of these arthritides is the association of lower extremity arthritis with antecedent or concurrent gastrointestinal symptoms. Reactive arthritis after diarrhea caused by *Salmonella*, *Shigella*, *Yersinia*, or *Chlamydia* infection occurs in individuals who are HLA-B27-positive. The human gene product shares a six-amino acid homology with the cell wall of the provocative organism. Transfection experiments in which human HLA-B27 genes are inserted into rats and mice have supported the central role of the genetic predisposition in this form of arthritis. However, animals raised in a germ-free environment have less disease, emphasizing the role of enteric organisms in these spondyloarthropathies. In an analogous manner, the arthritis associated with Crohn disease and ulcerative colitis usually begins after or concurrent with active bowel disease. Other extraintestinal manifestations such as uveitis, stomatitis, hepatitis, and erythema nodosum may occur in these individuals.

Treatment for the musculoskeletal manifestations of inflammatory bowel disease includes controlling bowel disease and the use of NSAIDs, as in ankylosing spondylitis.

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Multisystem inflammatory disease of joints, serous linings, skin, kidneys, and the CNS.*
- *ANA must be present in active, untreated disease.*

General Considerations

Systemic lupus erythematosus (SLE) is the prototype of immune complex diseases; its pathogenesis is related to the deposition in the tissue of circulating soluble immune complexes. The spectrum of symptoms appears

to be due not to tissue-specific autoantibodies but rather to tissue damage by lymphocytes, neutrophils, and complement evoked by the deposition of antigen–antibody complexes. Many antigen–antibody systems are present in this disorder, but disease activity correlates best with DNA/anti-DNA complexes. Laboratory tests of these antibodies and complement components give an objective assessment of disease pathogenesis and response to therapy. Autoreactive T lymphocytes that have escaped clonal deletion and unregulated B-lymphocyte production of autoantibodies may initiate the disease. A genetic predisposition to lupus appears critical to causation of the disease.

Clinical Findings

A. SYMPTOMS AND SIGNS

SLE is more common in girls than boys (8:1). Disease onset most often occurs between ages 9 and 15 years. The symptoms depend on the organ involved with immune complex deposition.

- 1. Joint symptoms**—Joint symptoms are the most common presenting feature. Nondeforming arthritis may involve any joint, often in a symmetrical manner. Myositis may also occur and is more painful than the inflammation in dermatomyositis.
- 2. Systemic manifestations**—These include weakness, anorexia, fever, fatigue, and weight loss.
- 3. Skin lesions**—Lesions include butterfly erythema and induration, small ulcerations in skin and mucous membranes, purpura, alopecia, and Raynaud phenomenon. The sun sensitivity of the dermal lesions may be striking.
- 4. Polyserositis**—Polyserositis may include pleurisy with effusions, peritonitis, and pericarditis. Libman–Sacks endocarditis may occur in patients with antiphospholipid antibodies.
- 5. Gastrointestinal findings**—Hepatosplenomegaly and lymphadenopathy may occur. Gastrointestinal presentations of SLE are unusual, with the exception of acute pancreatitis.
- 6. Renal manifestations**—Renal SLE produces few symptoms at onset but is often progressive and is the leading cause of death among patients with SLE. Renal biopsy is indicated in patients who do not respond to corticosteroids or who cannot have corticosteroids tapered to a less-toxic, alternate-day regimen. The histologic pattern of diffuse proliferative nephritis requires the most aggressive treatment. Late complications are nephrosis and uremia. Control of hypertension is critical to maintaining renal function.

7. Central nervous system (CNS)—CNS involvement produces a variety of symptoms such as seizures; coma; hemiplegia; focal neuropathies; chorea; and behavior disturbances, including psychosis.

B. LABORATORY FINDINGS

Leukopenia and anemia are frequently found with a low incidence of Coombs positivity. Thrombocytopenia and purpura may be early manifestations even in the absence of other organ involvement. The ESR is elevated, and hypergammaglobulinemia is often present. Renal involvement is indicated by the presence of red cells, white cells, red cell casts, and protein in the urine. The ANA test is invariably positive in patients with active untreated SLE, and a negative ANA test excludes the diagnosis. For patients with a positive ANA test, a profile identifying individual disease-specific antibodies should be ordered. Anticardiolipin antibody and the lupus anticoagulant are two autoantibodies that identify lupus patients at risk for thrombotic events.

In managing the disease, elevated titers of anti-DNA antibody and depressed levels of serum complement (C3) accurately reflect active disease, especially renal, CNS, and skin disease. A computed tomography or MRI scan may identify pathologic conditions of the brain in lupus cerebritis, such as infarction, vasculitis, or atrophy.

Differential Diagnosis

SLE may simulate many inflammatory diseases such as rheumatic fever, rheumatoid arthritis, and viral infections. It is essential to review all organ systems carefully to establish a clinical pattern. Renal and CNS involvement is unique to SLE. A negative ANA test excludes the diagnosis of SLE. Tests yielding false-positive results are usually of low titer (1:320).

An overlap syndrome known as mixed connective tissue disease, with features of several collagen-vascular diseases, occurs in adults and children. The symptom complex is diverse and does not readily fit previous classifications. Arthritis, fever, skin tightening, Raynaud phenomenon, muscle weakness, and rashes are commonly present. Important factors in recognition of this disease entity are the relative infrequency of renal disease, which implies a better prognosis than SLE, and the corticosteroid responsiveness of symptoms, which distinguishes mixed connective tissue disease from scleroderma. The definition of the disease includes the presence of serum antibody to a ribonuclear protein. The initial ANA test is positive in very high titers. The ANA profile demonstrates the antibody to ribonuclear protein. Pulmonary disease in childhood produces major morbidity.

Treatment

The treatment of SLE should be tailored to the organ system involved so that toxicities are minimized. Prednisone, 0.5–1 mg/kg/d orally, has significantly lowered the mortality rate in SLE and should be used in all patients with renal, cardiac, or CNS involvement. The dosage should be varied using clinical and laboratory parameters of disease activity, and the minimum amount necessary to control the disease should be used. Alternate-day regimens of corticosteroid are frequently possible. Skin manifestations, arthritis, and fatigue may be treated with antimalarials such as hydroxychloroquine, 5–7 mg/kg/d orally. Pleuritic pain or arthritis can usually be managed with NSAIDs.

If disease control is inadequate with prednisone or if the dose required produces intolerable side effects, an immunosuppressant should be added. Either azathioprine, 2–3 mg/kg/d orally, or cyclophosphamide, 0.5–1 g/m², administered intravenously once a month, has been most widely used. Recent studies indicate that mycophenolate mofetil may be used in place of intravenous cyclophosphamide to induce remission or sustain remission after intravenous cyclophosphamide therapy. These drugs are ineffective during acute crises such as seizures. Thrombotic events due to clotting antibodies require long-term anticoagulation.

The toxicities of the regimens must be carefully considered. Growth failure, osteoporosis, Cushing syndrome, adrenal suppression, and aseptic necrosis are serious side effects of chronic use of prednisone. When high doses of corticosteroids are used (> 2 mg/kg/d), the risk of sepsis is real. Cyclophosphamide causes bladder epithelial dysplasia, hemorrhagic cystitis, and sterility. Azathioprine has been associated with liver damage, pancreatitis, and bone marrow suppression. Immunosuppressant treatment should be withheld if the total white count falls below 3000/μL or the neutrophil count below 1000/μL. Retinal damage from chloroquine derivatives has not been observed with recommended dosages. Intravenous pulse steroid therapy and plasmapheresis are treatments that may be useful in selected cases.

Amenorrhea may be a result of uncontrolled SLE but may also be a consequence of treatment with prednisone, cyclophosphamide, or azathioprine.

Course & Prognosis

The prognosis in SLE relates to the severity of renal involvement or infectious complications of treatment. With improved diagnosis, milder cases are now identified. Nonetheless, the survival rate has improved from 51% at 5 years in 1954 to 90% today. The disease has a natural waxing and waning cycle, and periods of complete remission are not unusual.

DERMATOMYOSITIS (POLYMYOSITIS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Pathognomonic skin rash.*
- *Weakness of proximal muscles and occasionally of pharyngeal and laryngeal groups.*
- *Pathogenesis related to vasculitis.*

General Considerations

Dermatomyositis, a rare inflammatory disease of muscle and skin in childhood, is uniquely responsive to corticosteroid treatment. The vasculitis in childhood dermatomyositis differs pathologically from the adult disease. Small arteries and veins are involved, with an exudate of neutrophils, lymphocytes, plasma cells, and histiocytes. The lesion progresses to intimal proliferation and thrombus formation. These vascular changes are found in the skin, muscle, kidney, retina, and gastrointestinal tract. Postinflammatory calcinosis is frequent.

The autoimmune pathogenesis of dermatomyositis has been difficult to unravel. Recent studies have shown that both cellular and humoral mechanisms may be involved. Lymphocytes from patients undergo blastogenesis in the presence of muscle tissue and release lymphotoxin, which destroys cultured fetal muscle cells. Biopsies studied with immunofluorescence techniques demonstrate immunoglobulin and complement in perivascular distribution. The putative antigen has not been identified, and results of viral studies have been negative.

Clinical Findings

A. SYMPTOMS AND SIGNS

The predominant symptom is proximal muscular weakness affecting pelvic and shoulder girdles. Tenderness,

stiffness, and swelling may be found but are not striking. Neurologic findings, such as absence of tendon reflexes, are not seen until late in the disease. Pharyngeal and respiratory involvement can be life-threatening. Flexion contractures and muscle atrophy produce significant residual deformities. Calcinosis may follow the inflammation in muscle and skin.

The rash of dermatomyositis is very helpful in the diagnosis. Characteristically, the rash involves the upper eyelids and extensor surfaces of the knuckles, elbows, and knees with a distinctive heliotrope color that progresses to a scaling and atrophic appearance. Periorbital edema is not uncommon. Nail-fold capillary abnormalities are associated with poorer prognosis. None of the rashes associated with other childhood rheumatic diseases have these features of distribution. The severity of the rash frequently does not parallel that of the muscle disease.

B. LABORATORY FINDINGS

Determination of muscle enzyme levels in blood is the most helpful tool in diagnosis and treatment. All enzymes, including serum aldolase, should be screened to detect an abnormality that reflects activity of the disease. In later years of the illness, MRI of weak muscles may show disease activity even when enzymes are normal. The ANA test may be positive. Electromyography is useful for distinguishing myopathic from neuropathic causes of muscle weakness. Muscle biopsy is indicated in doubtful cases of myositis without the pathognomonic rash.

Treatment

Prednisone in high dosages (1–2 mg/kg/d orally) has been shown to speed recovery. The dosage should be maintained or increased until muscle enzymes have returned to normal. Functional recovery will lag somewhat behind laboratory improvement. With improvement, the dosage may be cut to a level that maintains disease control and normal muscle enzymes. Treatment must be continued for an average of 2 years. Methotrexate, 1 mg/kg/wk, is an effective, steroid-sparing treatment. Intravenous immune globulin or cyclosporine therapy is used in refractory cases. Physical therapy is critical to prevent or allay contractures.

Course & Prognosis

Most children recover and discontinue medications in 1–3 years. Relapses may occur. Functional ability is very good in most patients. Myositis in childhood is not associated with an increased risk of cancer.

POLYARTERITIS NODOSA

Polyarteritis nodosa is a rare disease, but a significant number of cases have been reported in childhood and infancy. No single cause has been found, but evidence of a streptococcal trigger and poorly controlled parvovirus infection have been found in some series.

Pathologically, the disease is a vasculitis of medium-sized arteries with fibrinoid degeneration in the media extending to the intima and adventitia. Neutrophils and eosinophils comprise the inflammatory reaction. Aneurysms may be palpated or seen radiographically. Thrombosis of diseased arteries may cause infarction in many organs. Fibrosis of vessels and surrounding tissues accompanies healing.

Symptoms arise from many organ systems, making diagnosis difficult. Unexplained fever, conjunctivitis, CNS involvement, and cardiac disease are more prominent in children than in adults. Many cases appear as acute myocarditis, and the peripheral neuropathy so common in adults with the disease is unusual in children. Diagnosis depends on biopsy-proved vasculitis or characteristic aneurysms on angiography.

The mortality rate is high, especially with cardiac involvement. Treatment usually consists of prednisone (1–1.5 mg/kg/d orally), immunosuppressants, and intravenous immune globulin, but controlled studies on the efficacy of these therapies are not available.

Frankel SK et al: Vasculitis: Wegener granulomatosis, Churg–Strauss, microscopic polyangiitis, polyarteritis, Takayasu arteritis. *Crit Care Clin* 2002;18:855.

SCLERODERMA

Fortunately, the most common forms of scleroderma in childhood are linear scleroderma and morphea, not systemic sclerosis. The skin disease begins with the appearance of indurated and depigmented patches (morphea) or streaks of skin on an extremity (linear scleroderma). As the linear form progresses over a 2- or 3-year period,

subcutaneous tissue becomes atrophied and contractures develop in affected joints. Physical therapy and treatment with methotrexate or vitamin D analogues may limit extension of the lesions but do not reverse previous damage. It is rare for the limited forms to progress to systemic sclerosis.

In systemic sclerosis, the dermal process is generalized. Raynaud phenomenon is almost invariably present. Arthralgias, esophageal dysfunction, and renal disease are present. Involvement of the lungs and kidneys may lead to rapid demise. The pathogenesis of systemic scleroderma is unknown and there are no effective therapies.

Murray KJ, Laxer RM: Scleroderma in children and adolescents. *Rheum Dis Clin North Am* 2002;28:603.

RAYNAUD PHENOMENON

Raynaud phenomenon is an intermittent vasospastic disorder of fingers and sometimes the toes. As much as 10% of the adult population may have this disorder, and onset in childhood is not uncommon. The classic triphasic presentation is cold-induced pallor, then cyanosis, followed by hyperemia, but incomplete forms are common. In adults older than age 35 years who are ANA-positive, Raynaud phenomenon may be a harbinger of rheumatic disease. This progression is rarely seen in childhood. Evaluation should include a detailed history with review of systems relevant to rheumatic disease and examination for nail-fold capillary abnormalities. In the absence of positive findings, Raynaud phenomenon is likely to be idiopathic.

Treatment involves education about hand warming (eg, using mittens not gloves); the role of stress, which may be a precipitant; and in very symptomatic patients, treatment with calcium channel blockers such as nifedipine during winter months.

Nigrovic PA et al: Raynaud's phenomenon in children: A retrospective review. *Pediatrics* 2003;111:715.

NONRHEUMATIC PAIN SYNDROMES

1. Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy is a painful condition that is frequently confused with arthritis. The prevalence and recognition of the condition appear to be increasing. Severe extremity pain leading to nearly complete loss of function is the hallmark of the condition.

Evidence of autonomic dysfunction is demonstrated by color changes, temperature differences, and dyshidrosis in the affected extremity. Foot involvement is more common than hand involvement. A puffy swelling of the entire hand or foot is common. On examination, cutaneous hyperesthesia is evident to even the slightest touch. Results of laboratory tests are negative. Radiographic findings are normal except for the late development of osteoporosis. Bone scans are helpful and demonstrate either increased or decreased blood supply to the painful extremity.

The cause of this condition is unknown. Unlike adults, children only occasionally have a history of significant physical trauma at disease onset. How autonomic dysfunction causes severe somatic pain is unknown, but the feedback cycle does provide the basis for treatment. In mild cases, a program of rehabilitative physical therapy in combination with desensitization techniques will restore function and relieve pain. Patients with reflex sympathetic dystrophy who are unresponsive to therapy need family counseling and may respond to steroids or ganglionic blocks by local anesthesia. Long-term prognosis is good if recovery is rapid; recurrent episodes imply a less favorable prognosis.

Sherry D: An overview of amplified musculoskeletal pain syndromes. *J Rheumatol* 2000;27:44.

2. Fibromyalgia

Fibromyalgia is a diffuse pain syndrome in which patients experience pain all over their bodies without objective physical findings. Weather changes and fatigue exacerbate symptoms. A sleep disturbance, such as insomnia or prolonged periods of awakening at night, is an almost universal symptom. Patients should be carefully questioned about these symptoms. On examination, patients are normal except for pain during palpation of characteristic trigger points at the insertion of muscles, especially along the neck, spine, and pelvis.

Treatment consists of physical therapy and attention to relieving the sleep disorder. Low-dose antidepressant medication (amitriptyline, 25 mg) taken before sleep may produce a remarkable degree of pain relief. Physical therapy should emphasize a graded rehabilitative approach to stretching and exercise. Analgesics are often ineffective and should be avoided if possible to avoid habituation to narcotic medications.

The prognosis for young patients is unclear, and long-term strategies may be necessary to enable them to cope with the condition.

Schikler KN: Is it juvenile rheumatoid arthritis or fibromyalgia? *Med Clin North Am* 2000;84:967.

Worrel LM et al: Treating fibromyalgia with a brief interdisciplinary program: Initial outcomes and predictors of response. *Mayo Clin Proc* 2001;76:384.

3. Chronic Fatigue Syndrome

Since 1985, chronic fatigue syndrome has become an increasingly common diagnosis. The distinction between this apparent organic fatigue and fatigue associated with emotional causes is not easily made. Criteria have been developed by the National Institutes of Health to assist in classification. The fatigue should have a defined date of onset, and there is a long list of excludable diagnoses. Other clinical manifestations include low-grade fevers, sore throat, painful lymph nodes, and neuropsychiatric problems. Epstein-Barr virus infection does not account for all the patients described. Treatment is symptomatic and somewhat unsatisfactory.

Bell DS et al: Thirteen-year follow-up of children and adolescents with chronic fatigue syndrome. *Pediatrics* 2001;107:994.

Krilov LR, Fisher M: Chronic fatigue syndrome in youth: Maybe not so chronic after all. *Contemp Ped* 2002;19:61.

HYPERMOBILITY SYNDROME

Ligamentous laxity, which previously was thought to occur only in Ehlers-Danlos syndrome or Down syndrome, is now recognized as a common cause of joint pain.

Children are now participating in a wide range of physically demanding sports and activities. Patients with hypermobility present with episodic joint pain and occasionally with swelling that lasts a few days after increased physical activity. Depending on the activity, almost any joint may be affected.

Physical examination may reveal joint swelling and tenderness, but the key to diagnosis is the demonstration of ligamentous laxity. Five criteria have been established: (1) passive opposition of the thumb to the flexor surface of the forearm; (2) passive hyperextension of the fingers so that they are parallel to the extensor surface of the forearm; (3) hyperextension of the elbow; (4) hyperextension of the knee (genu recurvatum); and (5) palms on floor with knees extended. Results of laboratory tests are normal. The pain associated with the syndrome is produced by improper joint alignment caused by laxity that is promoted by the stresses of vigorous exercise.

Treatment consists of a graded conditioning program designed to provide muscular support of the joints involved to compensate for the loose ligaments.

The prognosis is good, provided conditioning before activities is adequate.

NORMAL HEMATOLOGIC VALUES

The normal ranges for peripheral blood counts vary significantly with age. Normal neonates show a relative polycythemia with a hematocrit of 45–65%. The reticulocyte count at birth is relatively high at 2–8%. Within the first few days of life, erythrocyte production decreases, and the levels of hemoglobin and hematocrit fall to a nadir at about 6–8 weeks. During this period, known as physiologic anemia of infancy, normal infants have hemoglobins as low as 10 g/dL and hematocrits as low as 30%. Thereafter, the normal values for hemoglobin and hematocrit gradually increase until adult values are reached after puberty. Premature infants can reach a nadir hemoglobin level of 7–8 g/dL at 8–10 weeks.

Newborns have larger red cells than children and adults, with a mean corpuscular volume (MCV) at birth of more than 94 fL. The MCV subsequently falls to a nadir of 70–84 fL at about age 6 months. Thereafter, the normal MCV increases gradually until it reaches adult values after puberty.

The normal number of white blood cells is higher in infancy and early childhood than later in life. Neutrophils predominate in the differential white count at birth and in the older child. Lymphocytes predominate (up to 80%) between about ages 1 month and 6 years.

Normal values for the platelet count are 150,000–400,000/ μ L and vary little with age.

BONE MARROW FAILURE

Failure of the marrow to produce adequate numbers of circulating blood cells may be congenital or acquired and may cause pancytopenia (aplastic anemia) or involve only one cell line (single cytopenia). Constitutional and acquired aplastic anemias are discussed in this section and the more common single cytopenias in later sections. Bone marrow failure caused by malignancy or other infiltrative disease is discussed in Chapter 28. It is important to remember that many drugs and toxins may affect the marrow and cause single or multiple cytopenias.

Suspicion of bone marrow failure is warranted in children with pancytopenia and in children with single

cytopenias who lack evidence of peripheral red cell, white cell, or platelet destruction. Macrocytosis often accompanies bone marrow failure. Many of the constitutional bone marrow disorders are associated with a variety of congenital anomalies.

CONSTITUTIONAL APLASTIC ANEMIA (Fanconi Anemia)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Progressive pancytopenia.*
- *Macrocytosis.*
- *Multiple congenital anomalies.*
- *Increased chromosome breakage in peripheral blood lymphocytes.*

General Considerations

Fanconi anemia is a syndrome characterized by defective DNA repair that is caused by a variety of genetic mutations. Inheritance is autosomal recessive, and the disease occurs in all ethnic groups. Hematologic manifestations usually begin with thrombocytopenia or neutropenia and subsequently progress over the course of months or years to pancytopenia. Typically the diagnosis is made between ages 2 and 10 years.

Clinical Findings

A. SYMPTOMS AND SIGNS

Symptoms are determined principally by the degree of hematologic abnormality. Thrombocytopenia may cause purpura, petechiae, and bleeding; neutropenia may cause severe or recurrent infections; and anemia may cause weakness, fatigue, and pallor. Congenital anomalies are present in at least 50% of patients. The

most common include abnormal pigmentation of the skin (generalized hyperpigmentation, café au lait or hypopigmented spots), short stature with delicate features, and skeletal malformations (hypoplasia, anomalies, or absence of the thumb and radius). More subtle anomalies include hypoplasia of the thenar eminence or a weak or absent radial pulse. Associated renal anomalies include aplasia, “horseshoe” kidney, and duplication of the collecting system. Other anomalies are microcephaly, microphthalmia, strabismus, ear anomalies, and hypogenitalism.

B. LABORATORY FINDINGS

Thrombocytopenia or leukopenia typically occurs first, followed over the course of months to years by anemia and progression to severe aplastic anemia. Macrocytosis is virtually always present, is usually associated with anisocytosis and an elevation in fetal hemoglobin levels, and is an important diagnostic clue. The bone marrow reveals hypoplasia or aplasia. The diagnosis is confirmed by the demonstration of an increased number of chromosome breaks and rearrangements in peripheral blood lymphocytes. The use of diepoxybutane to stimulate these breaks and rearrangements provides for a sensitive assay that is virtually always positive in children with Fanconi anemia, even before the onset of hematologic abnormalities.

Specific molecular markers/genes called Fanc-A, B, C, and so on are found in different ethnic populations. These markers are identified in research laboratories and are not available as routine clinical tests.

Differential Diagnosis

Because patients with Fanconi anemia frequently present with thrombocytopenia, the disorder must be differentiated from idiopathic thrombocytopenic purpura (ITP) and other more common causes of decreased platelets. In contrast to patients with ITP, those with Fanconi anemia usually exhibit a gradual fall in the platelet count, and counts less than 20,000/ μ L are often accompanied by neutropenia or anemia, along with phenotypical features. Fanconi anemia may also be manifested initially by pancytopenia, and must be differentiated from acquired aplastic anemia and other disorders such as acute leukemia. Examination of the bone marrow and chromosome studies of peripheral blood lymphocytes will usually distinguish between these disorders.

Complications

The most important complications of Fanconi anemia are those related to thrombocytopenia and neutropenia. Endogenous endocrine dysfunction may include

growth hormone deficiency, hypothyroidism, or impaired glucose metabolism. In addition, persons with Fanconi anemia have a significantly increased risk of developing malignancies, especially acute nonlymphocytic leukemia, solid tumors, and myelodysplastic syndromes. Death is usually the result of thrombocytopenic hemorrhage, overwhelming infection, or malignancy.

Treatment

Attentive supportive care is a critical feature of management. Patients with neutropenia who develop fever require prompt evaluation and parenteral broad-spectrum antibiotics. Transfusions are important but should be used judiciously, especially in the management of thrombocytopenia, which frequently becomes refractory to platelet transfusions as a consequence of alloimmunization. Transfusions from family members should be discouraged because of the negative effect on the outcome of bone marrow transplantation. At least 50% of patients with Fanconi anemia respond, albeit incompletely, to oxymetholone, and many recommend institution of androgen therapy before transfusions are needed. However, oxymetholone is associated with hepatotoxicity, hepatic adenomas, and masculinization, which is particularly troublesome for female patients.

Successful bone marrow transplantation cures the aplastic anemia and is an important treatment option for children with Fanconi anemia who have a human leukocyte antigen (HLA)-identical sibling donor. Before transplantation the prospective donor must be screened for Fanconi anemia by testing his or her lymphocytes for chromosome breakage.

Prognosis

Many patients succumb to bleeding, infection, or malignancy in adolescence or early adulthood. The long-term outlook for those undergoing successful bone marrow transplantation is uncertain, particularly with regard to the risk of subsequently developing malignancies.

ACQUIRED APLASTIC ANEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Weakness and pallor.*
- *Petechiae, purpura, and bleeding.*
- *Frequent or severe infections.*
- *Pancytopenia with hypocellular bone marrow.*

General Considerations

Acquired aplastic anemia is characterized by peripheral pancytopenia with a hypocellular bone marrow. Approximately 50% of the cases in childhood are idiopathic. Other cases are secondary to idiosyncratic reactions to drugs such as phenylbutazone, sulfonamides, nonsteroidal anti-inflammatories, and anticonvulsants. Toxic causes include exposure to benzene, insecticides, and heavy metals. Infectious causes include viral hepatitis (usually non-A, non-B, non-C), infectious mononucleosis, and human immunodeficiency virus (HIV). In immunocompromised children, aplastic anemia has been associated with human parvovirus B19. Immune mechanisms of marrow suppression are suspected in most cases.

Clinical Findings

A. SYMPTOMS AND SIGNS

Weakness, fatigue, and pallor result from anemia; petechiae, purpura, and bleeding occur because of thrombocytopenia; and fevers due to generalized or localized infections occur with neutropenia. Hepatosplenomegaly and significant lymphadenopathy are unusual.

B. LABORATORY FINDINGS

Anemia is usually normocytic, with a low reticulocyte count. The white blood cell count is low, with a marked neutropenia. The platelet count is typically below 50,000/ μL and frequently below 20,000/ μL . Bone marrow aspiration and biopsy show hypocellularity, often marked.

Differential Diagnosis

Examination of the bone marrow usually excludes pancytopenia caused by peripheral destruction of blood cells or by infiltrative processes such as acute leukemia, storage diseases, and myelofibrosis. Many of these other conditions are associated with hepatosplenomegaly.

Preleukemic conditions also may present with pancytopenia and hypocellular bone marrows. Cytogenetic analysis of the marrow is helpful, because a clonal abnormality may predict the subsequent development of leukemia. Because some children with Fanconi anemia may not have apparent congenital anomalies, patients with newly diagnosed aplastic anemia should be studied for chromosome breaks and rearrangements in peripheral blood lymphocytes.

Complications

Acquired aplastic anemia is characteristically complicated by infection and hemorrhage; these two complications are the leading causes of death. Other complications are those associated with therapy.

Treatment

Comprehensive supportive care is most important in the management of acute acquired aplastic anemia. Febrile illnesses require prompt evaluation and usually parenteral antibiotics. Red blood cell transfusions alleviate symptoms of anemia. Platelet transfusions may be lifesaving, but they should be used sparingly because many patients eventually develop platelet alloantibodies and become refractory to platelet transfusions.

Bone marrow transplantation is generally considered the treatment of choice for severe aplastic anemia when an HLA-compatible sibling donor is available. Because the likelihood of success with transplantation is influenced adversely by multiple transfusions, HLA typing of family members should be undertaken as soon as the diagnosis of aplastic anemia is made. An increasing number of patients who lack HLA-matched siblings are able to find matched donors through the National Bone Marrow Registry.

The best alternative to bone marrow transplantation from an HLA-matched sibling donor is immunosuppression, usually with antithymocyte globulin (ATG) and cyclosporine. Responses are good. Most patients show hematologic improvement and become transfusion-independent.

Prognosis

Children receiving early bone marrow transplantation from an HLA-identical sibling have a long-term survival rate of greater than 80%. Sustained, complete remissions may be seen in 65–80% of patients receiving immunosuppressive therapy. However, both therapies are associated with an increased risk of myelodysplastic syndromes, acute leukemia, and other malignancies in long-term survivors.

■ ANEMIAS

APPROACH TO THE CHILD WITH ANEMIA

Anemia is a relatively common finding, and identifying the cause is important. Even though anemia in childhood has many causes, the correct diagnosis can usually be established with relatively little laboratory cost.

Frequently the cause is suggested by a careful history. The possibility of nutritional causes should be addressed by inquiry about dietary intake; growth and development; and symptoms of chronic disease, malabsorption, or blood loss. Hemolytic disease may be suggested by a history of jaundice (including neonatal jaundice) or by a family history of anemia, jaundice, gallbladder disease, splenomegaly, or splenectomy. The child's ethnic background may suggest the possibility of certain hemoglobinopathies or of deficiencies of red cell enzymes such as glucose-6-phosphate dehydrogenase (G6PD). The review of systems may reveal clues to a previously unsuspected systemic disease with which anemia may be associated. The patient's age is important because some causes of anemia are age-related. For example, patients with iron deficiency anemia and β -globin disorders present more commonly at ages 6–36 months than at other times in life.

The physical examination may also reveal clues to the cause of anemia. Poor growth may suggest chronic disease or hypothyroidism. Congenital anomalies may be associated with constitutional aplastic anemia (Fanconi anemia) or with congenital hypoplastic anemia (Diamond–Blackfan anemia). Other disorders may be suggested by the findings of petechiae or purpura (leukemia, aplastic anemia, hemolytic–uremic syndrome), jaundice (hemolysis or liver disease), generalized lymphadenopathy (leukemia, juvenile rheumatoid arthritis, HIV infection), splenomegaly (leukemia, sickle cell disease, hereditary spherocytosis, liver disease,

hypersplenism), or evidence of chronic or recurrent infections.

The initial laboratory evaluation of the anemic child consists of a complete blood count (CBC) with differential and platelet count, review of the peripheral blood smear, and a reticulocyte count. The algorithm in Figure 27–1 uses limited laboratory information, together with the history and physical examination, to reach a specific diagnosis or to focus additional laboratory investigations on a limited diagnostic category (eg, microcytic anemia, bone marrow failure, pure red cell aplasia, or hemolytic disease). This diagnostic scheme depends principally on the MCV to determine whether the anemia is microcytic, normocytic, or macrocytic, according to the percentile curves of Dallman and Siimes (Figure 27–2).

The incidence of iron deficiency in the United States has decreased significantly with improvements in infant nutrition. Still, iron deficiency is an important cause of microcytic anemia, especially at ages 6–24 months. A trial of therapeutic iron is appropriate in such children, provided the dietary history is compatible with iron deficiency and the physical examination or CBC count does not suggest an alternative cause for the anemia. If this is not the case or if a trial of therapeutic iron fails to correct the anemia and microcytosis, further laboratory evaluation is warranted.

Another key element of Figure 27–1 is the use of both the reticulocyte count and the peripheral blood smear to determine whether a normocytic or macrocytic anemia is due to hemolysis. Typically hemolytic disease is associated with an elevated reticulocyte count, but some children with chronic hemolysis initially present during a period of virus-induced aplasia when the reticulocyte count is not elevated. Thus review of the peripheral blood smear for evidence of hemolysis (eg, spherocytes, red cell fragmentation, sickle forms) is important in the evaluation of children with normocytic anemias and low reticulocyte counts. When hemolysis is suggested, the correct diagnosis may be suspected by specific abnormalities of red cell morphology or by clues from the history or physical examination. Autoimmune hemolysis is usually excluded by Coombs testing. Review of blood counts and the peripheral blood smears of the mother and father may suggest genetic disorders such as hereditary spherocytosis. Children with normocytic or macrocytic anemias, with relatively low reticulocyte counts and no evidence of hemolysis on the blood smear, usually have anemias caused by inadequate erythropoiesis in the bone marrow. The presence of neutropenia or thrombocytopenia in such children suggests the possibility of aplastic anemia, malignancy, or severe folate/vitamin B₁₂ deficiency, and usually dictates examination of the bone marrow.

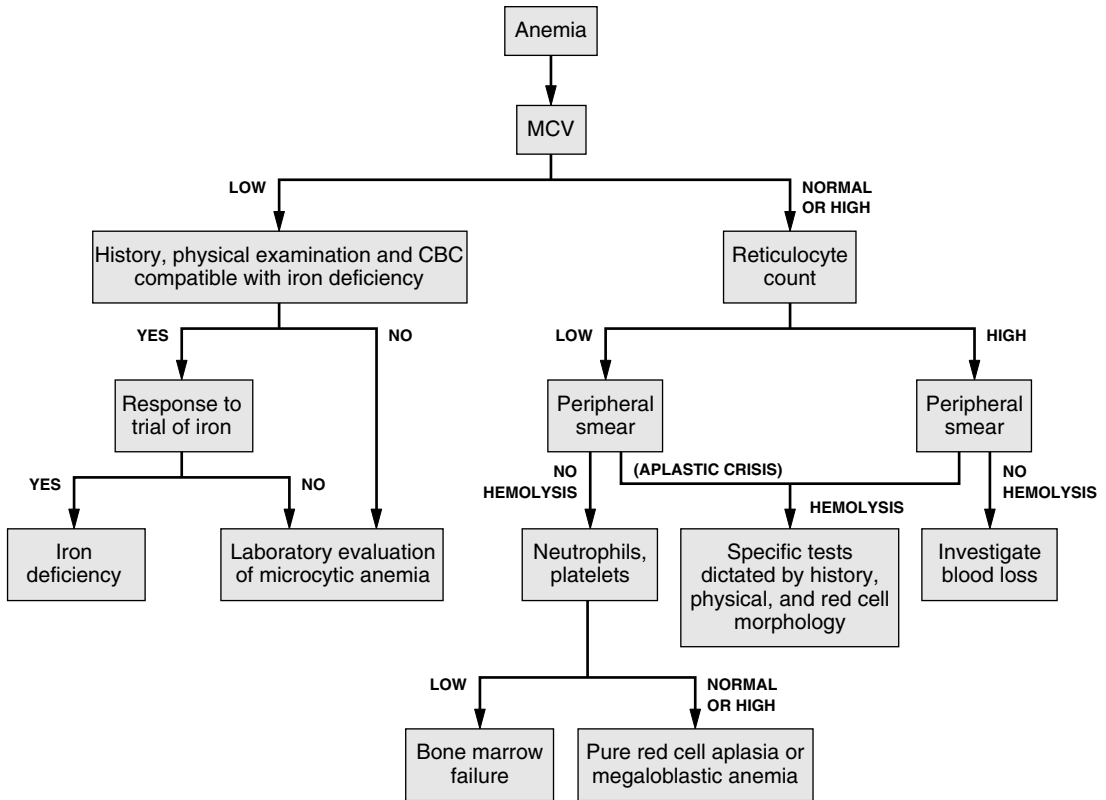

Figure 27–1. Investigation of anemia.

Pure red cell aplasia may be congenital (Diamond–Blackfan anemia), acquired and transient (transient erythroblastopenia of childhood), a manifestation of a systemic disease such as renal disease or hypothyroidism, or due to malnutrition or mild deficiencies of folate or vitamin B₁₂.

Hermiston ML, Mentzer WC: A practical approach to the evaluation of the anemic child. *Pediatr Clin North Am* 2002;49:877 [PMID: 12430617].

PURE RED CELL APLASIA

Infants and children with normocytic or macrocytic anemia, a low reticulocyte count, and normal or elevated numbers of neutrophils and platelets should be suspected of having pure red cell aplasia. Examination of the peripheral blood smear in such cases is important because signs of hemolytic disease suggest chronic hemolysis complicated by an aplastic crisis due to parvovirus infection. Appreciation of this phenomenon is important because chronic hemolytic disease may not

be diagnosed until the anemia is exacerbated by an episode of red cell aplasia that results in a rapidly falling hemoglobin level. In such cases, cardiovascular compromise and congestive heart failure may develop quickly.

1. Congenital Hypoplastic Anemia (Diamond–Blackfan Anemia)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Age: birth to 1 year.
- Macrocytic anemia with reticulocytopenia.
- Bone marrow with erythroid hypoplasia.
- Short stature or congenital anomalies in one third of patients.

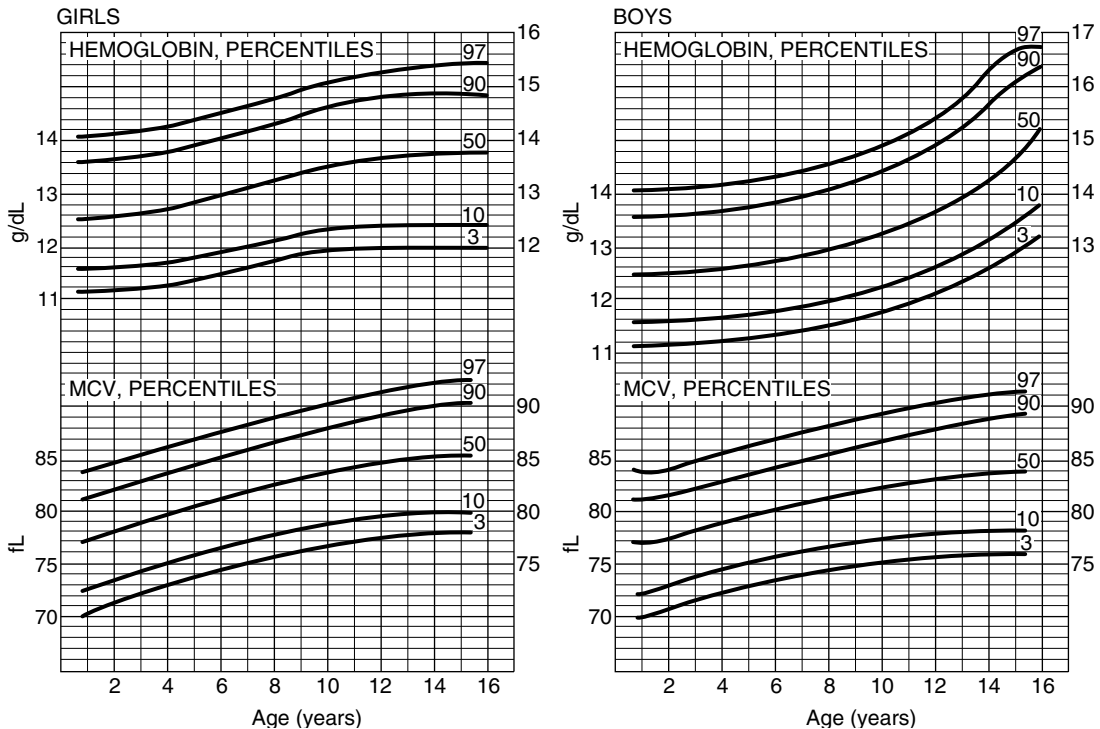

Figure 27-2. Hemoglobin and red cell volume in infancy and childhood. (Reproduced, with permission, from Dallman PR, Siimes MA: Percentile curves for hemoglobin and red cell volume in infancy and childhood. *J Pediatr* 1979;94:26.)

General Considerations

Diamond–Blackfan anemia is a relatively rare cause of anemia that usually presents in infancy or early childhood. Early diagnosis is important because treatment with corticosteroids results in increased erythropoiesis in about two thirds of patients, thus avoiding the difficulties and complications of long-term chronic transfusion therapy. The cause is unclear, and both autosomal dominant and autosomal recessive modes of inheritance have been reported.

Clinical Findings

A. SYMPTOMS AND SIGNS

Signs and symptoms are generally those of chronic anemia, such as pallor; congestive heart failure sometimes follows. Jaundice, splenomegaly, or other evidence of hemolysis is usually absent. Short stature or other congenital anomalies are present in one third of patients. A wide variety of anomalies have been described; those affecting the head, face, and thumbs are the most common.

B. LABORATORY FINDINGS

Diamond–Blackfan anemia is characterized by severe anemia and marked reticulocytopenia. The neutrophil count is usually normal or slightly decreased, and the platelet count is normal or elevated. The bone marrow usually shows a marked decrease in erythroid precursors but is otherwise normal. In older children, fetal hemoglobin levels are usually increased and there is evidence of persistent fetal erythropoiesis, such as the presence of the *i* antigen on erythrocytes. In addition, the level of adenosine deaminase in erythrocytes is elevated.

Differential Diagnosis

The principal differential diagnosis is transient erythroblastopenia of childhood. Children with Diamond–Blackfan anemia generally present at an earlier age, often have macrocytosis, and have evidence of fetal erythropoiesis and an elevated level of red cell adenosine deaminase. In addition, short stature and congenital anomalies, which occur in one third of patients with Diamond–Blackfan anemia, are not associated with

transient erythroblastopenia. Lastly, transient erythroblastopenia of childhood usually resolves within 6–8 weeks of diagnosis, whereas Diamond–Blackfan anemia is generally a lifelong affliction. Other disorders associated with decreased red cell production such as renal failure, hypothyroidism, and the anemia of chronic disease need to be considered.

Treatment

Oral corticosteroids should be initiated as soon as the diagnosis of Diamond–Blackfan anemia is made. Two thirds of patients will respond to prednisone, 2 mg/kg/d, and many of those who respond subsequently tolerate significant tapering of the dose. Patients who are unresponsive to prednisone require chronic red cell transfusion therapy, which inevitably causes transfusion-induced hemosiderosis and the need for chelation with parenteral deferoxamine. Bone marrow transplantation is an alternative therapy that should be considered for transfusion-dependent patients who have HLA-matched siblings. Hematopoietic growth factors have been used in some cases with limited success. Unpredictable, spontaneous remissions occur in up to 20% of patients.

Prognosis

The prognosis for patients responsive to corticosteroids is generally good, particularly if remission is maintained with low doses of alternate-day prednisone. Patients dependent on transfusion are at risk for the complications of hemosiderosis, including death from congestive heart failure, cardiac arrhythmias, or hepatic failure. This remains a significant threat, particularly during adolescence, when compliance with nightly subcutaneous infusions of deferoxamine is often difficult to ensure.

Vlachos A et al: Hematopoietic stem cell transplantation for Diamond–Blackfan anemia: A report from the Diamond–Blackfan Anemia Registry. *Bone Marrow Transplant* 2001;27:381 [PMID: 11313667].

2. Transient Erythroblastopenia of Childhood

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Age: 6 months to 4 years.
- Normocytic anemia with reticulocytopenia.

- Absence of hepatosplenomegaly or lymphadenopathy.
- Erythroid precursors initially absent from bone marrow.

General Considerations

Transient erythroblastopenia of childhood is a relatively common cause of acquired anemia in early childhood. The disorder is suspected when a normocytic anemia is discovered during evaluation of pallor or when a CBC is obtained for another reason. Because the anemia is due to decreased red cell production, and thus develops slowly, the cardiovascular system has time to compensate. Therefore, children with hemoglobin levels as low as 4 or 5 g/dL may look remarkably well. The disorder is thought to be autoimmune in most cases, because IgG from some patients has been shown to suppress erythropoiesis *in vitro*.

Clinical Findings

Pallor is the most common sign, and hepatosplenomegaly and lymphadenopathy are absent. The anemia is normocytic, and the peripheral blood smear shows no evidence of hemolysis. The platelet count is normal or elevated, and the neutrophil count is normal or, in some cases, decreased. Early in the course, no reticulocytes are identified. The Coombs test is negative, and there is no evidence of chronic renal disease, hypothyroidism, or other systemic disorder. Bone marrow examination shows severe erythroid hypoplasia initially; subsequently, erythroid hyperplasia develops along with reticulocytosis, and the anemia resolves.

Differential Diagnosis

Transient erythroblastopenia of childhood must be differentiated from Diamond–Blackfan anemia, particularly in infants younger than age 1 year. In contrast to Diamond–Blackfan anemia, transient erythroblastopenia is not associated with macrocytosis, short stature, or congenital anomalies, or with evidence of fetal erythropoiesis prior to the phase of recovery. Also in contrast to Diamond–Blackfan anemia, transient erythroblastopenia is associated with normal levels of red cell adenosine deaminase. Transient erythroblastopenia of childhood must also be differentiated from chronic disorders associated with decreased red cell production, such as renal failure, hypothyroidism, and other chronic states of infection or inflammation. As with other single cytopenias, the possibility of malignancy (ie, leukemia) should always be considered, particularly

if fever, bone pain, hepatosplenomegaly, or lymphadenopathy is present. In such cases, examination of the bone marrow is generally diagnostic. Confusion may sometimes arise when the anemia of transient erythroblastopenia is first identified during the early phase of recovery when the reticulocyte count is high. In such cases, the disorder may be confused with the anemia of acute blood loss or with hemolytic disease. In contrast to hemolytic disorders, transient erythroblastopenia of childhood is not associated with jaundice or peripheral destruction of red cells.

Treatment & Prognosis

By definition, this is a transient disorder. Some children require red cell transfusions if cardiovascular compromise is present. Resolution of the anemia is heralded by an increase in the reticulocyte count, which generally occurs within 4–8 weeks of diagnosis. In contrast to other autoimmune disorders of childhood (eg, ITP, autoimmune hemolytic anemia), transient erythroblastopenia of childhood is not treated with corticosteroids.

NUTRITIONAL ANEMIAS

1. Iron Deficiency Anemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Pallor and fatigue.*
- *Poor dietary intake of iron (ages 6–24 months).*
- *Chronic blood loss (age > 2 years).*
- *Microcytic hypochromic anemia.*

General Considerations

Long considered the most common cause of anemia in pediatrics, the incidence of iron deficiency has decreased substantially due to improved nutrition and the increased availability of iron-fortified infant formulas and cereals. Thus the current approach to anemia in

childhood must take into consideration a relatively greater likelihood of other causes.

Normal-term infants are born with sufficient iron stores to prevent iron deficiency for the first 4–5 months of life. Thereafter, enough iron needs to be absorbed to keep pace with the needs of rapid growth. For this reason, nutritional iron deficiency is most common between 6 and 24 months of life. A deficiency earlier than age 6 months may occur if iron stores at birth are reduced by prematurity, small birth weight, neonatal anemia, or perinatal blood loss or if there is subsequent iron loss due to hemorrhage. Iron-deficient children older than age 24 months should be evaluated for blood loss.

A significant body of evidence indicates that iron deficiency, in addition to causing anemia, has adverse effects on multiple organ systems. Thus, the importance of identifying and treating iron deficiency extends past the resolution of any symptoms directly attributable to a decreased hemoglobin concentration.

Clinical Findings

A. SYMPTOMS AND SIGNS

Symptoms and signs vary with the severity of the deficiency. Mild iron deficiency is usually asymptomatic. In infants with more severe iron deficiency, pallor, fatigue, irritability, and delayed motor development are common. Children whose iron deficiency is due in part to ingestion of unfortified cow's milk may be fat and flabby, with poor muscle tone. A history of pica is common.

B. LABORATORY FINDINGS

The severity of anemia depends on the degree of iron deficiency, and the hemoglobin level may be as low as 3–4 g/dL in severe cases. Red cells are microcytic and hypochromic, with a low MCV and low mean corpuscular hemoglobin (MCH). The red blood cell distribution width (RDW) is typically elevated, even with mild iron deficiency. The reticulocyte count is usually normal or slightly elevated, but the reticulocyte index or absolute reticulocyte count is decreased. Iron studies show a decreased serum ferritin and a low serum iron, elevated total iron-binding capacity, and decreased transferrin saturation. These laboratory abnormalities are usually present with moderate to severe iron deficiency, but mild cases may be associated with variable laboratory results. The peripheral blood smear shows microcytic, hypochromic red blood cells with anisocytosis, and occasional target, teardrop, and fragmented red cells. Leukocytes are normal, and very often platelet count is increased with normal morphology.

The bone marrow examination is not helpful in the diagnosis of iron deficiency in infants and small chil-

dren because little or no iron is stored as marrow hemosiderin at these ages.

Differential Diagnosis

The differential diagnosis is that of microcytic, hypochromic anemia. The possibility of thalassemia (α -thalassemia, β -thalassemia, hemoglobin E disorders) should be considered, especially in infants of African, Mediterranean, or Asian ethnic background. In contrast to infants with iron deficiency, those with thalassemia generally have an elevated number of erythrocytes (the index of the MCV divided by the red cell number is usually less than 13) and are less likely, in mild cases, to have an elevated RDW. Thalassemias are associated with normal or increased levels of serum iron and ferritin and with normal iron-binding capacity. The hemoglobin electrophoresis in β -thalassemia minor typically shows an elevation of hemoglobin A₂ levels, but coexistent iron deficiency may lower the percentage of hemoglobin A₂ into the normal range. Hemoglobin electrophoresis will also identify children with hemoglobin E, a cause of microcytosis common in Southeast Asians. In contrast, the hemoglobin electrophoresis in α -thalassemia trait is normal. Lead poisoning has also been associated with microcytic anemia, but anemia with lead levels less than 40 mg/dL is often due to coexistent iron deficiency.

The anemia of chronic inflammation or infection is normocytic but in late stages may be microcytic. This anemia is usually suspected because of the presence of a chronic systemic disorder. The level of serum iron is low, but the iron-binding capacity is normal, and the serum ferritin level is elevated. Relatively mild infections, particularly during infancy, may cause transient anemia. As a result, caution should be exercised when the diagnosis of mild iron deficiency is entertained in infants and young children who have had recent viral or bacterial infections. Ideally, screening tests for anemia should not be obtained within 3–4 weeks of such infections.

Treatment

The recommended oral dose of elemental iron is 4–6 mg/kg/d in three divided daily doses. Mild cases may be treated with 3 mg/kg/d given once daily before breakfast. Parenteral administration of iron is rarely necessary. Iron therapy results in an increased reticulocyte count within 3–5 days, which is maximal between 5 and 7 days. The hemoglobin level begins to increase thereafter. The rate of hemoglobin rise is inversely related to the hemoglobin level at diagnosis. In moderate to severe cases, an elevated reticulocyte count 1 week after initiation of therapy confirms the diagnosis and

documents compliance and response to therapy. When iron deficiency is the only cause of anemia, adequate treatment usually results in a resolution of the anemia within 4–6 weeks. Treatment is generally continued for a few additional months to replenish iron stores.

2. Megaloblastic Anemias

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pallor and fatigue.
- Nutritional deficiency or intestinal malabsorption.
- Macrocytic anemia.
- Megaloblastic bone marrow changes.

General Considerations

Megaloblastic anemia is a macrocytic anemia caused by deficiency of cobalamin (vitamin B₁₂), folic acid, or both. Cobalamin deficiency due to dietary insufficiency may occur in infants who are breast-fed by mothers who are strict vegetarians or who have pernicious anemia. Intestinal malabsorption is the usual cause of cobalamin deficiency in pediatrics and occurs with Crohn disease, chronic pancreatitis, bacterial overgrowth of the small bowel, infection with the fish tapeworm (*Diphyllobothrium latum*), or after surgical resection of the terminal ileum. Deficiencies due to inborn errors of metabolism (transcobalamin II deficiency, methylmalonic aciduria) have also been described. Malabsorption of cobalamin due to deficiency of intrinsic factor (pernicious anemia) is rare in childhood.

Folic acid deficiency may be caused by inadequate dietary intake, malabsorption, increased folate requirements, or some combination of the three. Folate deficiency due to dietary deficiency alone is rare but occurs in severely malnourished infants and has been reported in infants fed goat's milk not fortified with folic acid. Folic acid is absorbed in the proximal small bowel, and deficiencies are encountered in malabsorptive syn-

dromes such as celiac disease. Anticonvulsant medications (eg, phenytoin and phenobarbital) and cytotoxic drugs (eg, methotrexate) have also been associated with folate deficiency, caused by interference with folate absorption or metabolism. Finally, folic acid deficiency is more likely to develop in infants and children with increased requirements. This occurs during infancy because of rapid growth and also in children with chronic hemolytic anemia. Premature infants are particularly susceptible to the development of the deficiency because of low body stores of folate.

Clinical Findings

A. SYMPTOMS AND SIGNS

Infants with megaloblastic anemia may show pallor and mild jaundice as a result of ineffective erythropoiesis. Classically, the tongue is smooth and beefy red. Infants with cobalamin deficiency may be irritable and may be poor feeders. Older children with cobalamin deficiency may complain of paresthesias, weakness, or an unsteady gait and may show decreased vibratory sensation and proprioception on neurologic examination.

B. LABORATORY FINDINGS

The laboratory findings of megaloblastic anemia include an elevated MCV and MCH. The peripheral blood smear shows numerous macro-ovalocytes with anisocytosis and poikilocytosis. Neutrophils are large and have hypersegmented nuclei. The white cell and platelet counts are normal with mild deficiencies, but may be decreased in more severe cases. Examination of the bone marrow typically shows erythroid hyperplasia with large erythroid and myeloid precursors. Nuclear maturation is delayed compared with cytoplasmic maturation, and erythropoiesis is ineffective. The serum indirect bilirubin concentration may be slightly elevated.

Children with cobalamin deficiency have a low serum vitamin B₁₂ level, but decreased levels of serum vitamin B₁₂ may also be found in about 30% of patients with folic acid deficiency. The level of red cell folate is a better reflection of folate stores than is the serum folic acid level. Serum levels of metabolic intermediates, methylmalonic acid, and homocysteine may help establish the correct diagnosis. Elevated methylmalonic acid levels are consistent with cobalamin deficiency, whereas elevated levels of homocysteine occur with both cobalamin and folate deficiency.

Differential Diagnosis

Most macrocytic anemias in pediatrics are not megaloblastic. Other causes of an increased MCV include drug therapy (eg, anticonvulsants, anti-HIV nucleoside analogues), congenital heart disease, Down syndrome,

an elevated reticulocyte count (hemolytic anemias), bone marrow failure syndromes (Fanconi anemia, Diamond–Blackfan anemia), liver disease, and hypothyroidism.

Treatment

Treatment of cobalamin deficiency due to inadequate dietary intake is readily accomplished with oral supplementation. Most cases, however, are due to intestinal malabsorption and require parenteral treatment. In severe cases, parenteral therapy may induce life-threatening hypokalemia and require supplemental potassium. Folic acid deficiency is treated effectively with oral folic acid in most cases. Children at risk for the development of folic acid deficiencies, such as premature infants and those with chronic hemolysis, are often given folic acid prophylactically.

ANEMIA OF CHRONIC DISORDERS

Anemia is a common manifestation of many chronic illnesses in children. In some instances, causes may be mixed. For example, children with chronic disorders involving intestinal malabsorption or blood loss may have anemia of chronic inflammation in combination with nutritional deficiencies of iron, folate, or cobalamin. In other settings, the anemia is due to dysfunction of a single organ (eg, renal failure, hypothyroidism), and correction of the underlying abnormality resolves the anemia.

1. Anemia of Chronic Inflammation

Anemia is frequently associated with chronic infections or inflammatory diseases. The anemia is usually mild to moderate in severity, with a hemoglobin level of 8–12 g/dL. In general, the severity of the anemia corresponds to the severity of the underlying disorder, and there may be microcytosis but not hypochromia. The reticulocyte count is low. The anemia is thought to be due to inflammatory cytokines that inhibit erythropoiesis and impair iron release by reticuloendothelial cells. Levels of erythropoietin are relatively low for the severity of the anemia. The serum iron concentration is low, but in contrast to iron deficiency, anemia of

chronic inflammation is not associated with elevated iron-binding capacity and is associated with an elevated serum ferritin level. Treatment consists of correction of the underlying disorder, which, if controlled, generally results in improvement in hemoglobin level.

Hagar W et al: Diseases of iron metabolism. *Pediatr Clin North Am* 2002;49:893 [PMID: 12430618].

2. Anemia of Chronic Renal Failure

Severe normocytic anemia occurs in most forms of renal disease that have progressed to renal insufficiency. Although white cell and platelet production remain normal, the bone marrow shows significant hypoplasia of the erythroid series and the reticulocyte count is low. The principal mechanism is deficiency of erythropoietin, a hormone produced in the kidney, but other factors may contribute to the anemia. In the presence of significant uremia, a component of hemolysis may also be present. In the past, treatment of the anemia of chronic renal failure depended on transfusions of packed red blood cells. However, recombinant human erythropoietin (epoetin alfa) corrects the anemia, and its use has largely eliminated the need for transfusions.

Yorgin PD et al: The clinical efficacy of higher hematocrit levels in children with chronic renal insufficiency and those undergoing dialysis. *Semin Nephrol* 2001;21:451 [PMID: 11559886].

3. Anemia of Hypothyroidism

Some patients with hypothyroidism develop significant anemia. Occasionally, anemia is detected before the diagnosis of the underlying disorder. A decreased growth velocity in an anemic child suggests hypothyroidism. The anemia is usually normocytic or macrocytic, but it is not megaloblastic and hence not due to deficiencies of cobalamin or folate. Replacement therapy with thyroid hormone is usually effective in correcting the anemia.

CONGENITAL HEMOLYTIC ANEMIAS: RED CELL MEMBRANE DEFECTS

The congenital hemolytic anemias are usually divided into three categories: defects of the red cell membrane, hemoglobinopathies, and disorders of red cell metabolism. Hereditary spherocytosis and elliptocytosis are the most common red cell membrane disorders and are described here. The diagnosis is suggested by the peripheral blood smear, which shows characteristic red cell morphology (eg, spherocytes, elliptocytes). These disorders usually have an autosomal dominant inheritance, and the diagnosis may be suggested by a family history. The hemolysis is due to the deleterious effect of the membrane abnormality on red cell deformability. Decreased cell deformability leads to entrapment of the abnormally shaped red cells in the spleen. Many patients have splenomegaly, and splenectomy usually alleviates the hemolysis.

1. Hereditary Spherocytosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Anemia and jaundice.*
- *Splenomegaly.*
- *Positive family history of anemia, jaundice, or gallstones.*
- *Spherocytosis with increased reticulocytes.*
- *Increased osmotic fragility.*
- *Negative direct antiglobulin test (DAT).*

General Considerations

Hereditary spherocytosis is a relatively common inherited hemolytic anemia that occurs in all ethnic groups but is most common in persons of Northern European ancestry, in whom the incidence is about 1:5000. The disorder is a heterogeneous one, marked by variable degrees of anemia, jaundice, and splenomegaly. In some persons, the disorder is mild and there is no anemia because erythroid hyperplasia fully compensates for hemolysis. Severe cases are transfusion-dependent prior to splenectomy. The hallmark of hereditary spherocytosis is the presence of microspherocytes in the peripheral blood. The disease is inherited in an autosomal dominant fashion in about 75% of cases; the remainder is thought to be autosomal recessive or to be caused by new mutations.

Hereditary spherocytosis is usually the result of a partial deficiency of spectrin, an important structural protein of the red cell membrane skeleton. Spectrin deficiency weakens the attachment of the cell membrane to the underlying membrane skeleton and causes the red cell to lose membrane surface area. This process creates spherocytes that are poorly deformable and have a shortened life span because they are trapped in the microcirculation of the spleen and engulfed by splenic macrophages. The extreme heterogeneity of hereditary spherocytosis is related directly to variable degrees of spectrin deficiency. In general, children who inherit spherocytosis in an autosomal dominant fashion have lesser degrees of spectrin deficiency and mild or moderate hemolysis. In contrast, those with nondominant forms of spherocytosis tend to have greater deficiencies of spectrin and a more severe anemia.

Clinical Findings

A. SYMPTOMS AND SIGNS

Hemolysis causes significant neonatal hyperbilirubinemia in 50% of affected children. Splenomegaly subsequently develops in the majority and is often present by age 5 years. Jaundice is variably present and in many patients may be noted only during infection. Patients with significant chronic anemia may complain of pallor, fatigue, or malaise. Intermittent exacerbations of the anemia are caused by increased hemolysis or by aplastic crises and may be associated with severe weakness, fatigue, fever, abdominal pain, or even congestive heart failure.

B. LABORATORY FINDINGS

Most patients have mild chronic hemolysis with hemoglobin levels of 9–12 g/dL. In some cases, the hemolysis is fully compensated and the hemoglobin level is in the normal range. Rare cases of severe disease require frequent transfusions. The anemia is usually normocytic and hyperchromic, and many patients have an elevated MCH concentration. The peripheral blood smear shows numerous microspherocytes and polychromasia. The reticulocyte count is elevated, often higher than might be expected for the degree of anemia. White blood cell and platelet counts are usually normal. The osmotic fragility is increased, particularly after incubation at 37°C for 24 hours. Serum bilirubin usually shows an elevation in the unconjugated fraction. DAT is negative.

Differential Diagnosis

Spherocytes are frequently present in persons with immune hemolysis. Thus, in the newborn, hereditary spherocytosis must be distinguished from hemolytic

disease caused by ABO or other blood type incompatibilities. Older patients with autoimmune hemolytic anemia frequently present with jaundice and splenomegaly and with spherocytes on the peripheral blood smear. The DAT is positive in most cases of immune hemolysis and negative in hereditary spherocytosis. Occasionally, the diagnosis is confused in patients with splenomegaly from other causes, especially when hypersplenism increases red cell destruction and when some spherocytes are noted on the blood smear. In such cases, the true cause of the splenomegaly may be suggested by signs or symptoms of portal hypertension or by laboratory evidence of chronic liver disease. In contrast to children with hereditary spherocytosis, those with hypersplenism typically have some degree of thrombocytopenia or neutropenia.

Complications

Severe jaundice may occur in the neonatal period and, if not controlled by phototherapy, may occasionally require exchange transfusion. Splenectomy is associated with an increased risk of overwhelming bacterial infections, particularly with pneumococci. Gallstones occur in 60–70% of adults who have not undergone splenectomy and may form as early as age 5–10 years.

Treatment

Supportive measures include the administration of folic acid to prevent the development of red cell hypoplasia due to folate deficiency. Acute exacerbations of anemia, due to increased rates of hemolysis or to aplastic crises due to infection with human parvovirus, may be severe enough to require red cell transfusions. Splenectomy is performed in many cases and always results in significant improvement. The procedure increases the survival of the spherocytic red cells and leads to complete correction of the anemia in most cases. Patients with more severe disease may show some degree of hemolysis after splenectomy. Except in unusually severe cases, the procedure should be postponed until the child is at least age 5 years because of the greater risk of postsplenectomy sepsis prior to this age. Alternatively, partial splenectomy may be considered for young children with severe hemolysis. All patients scheduled for splenectomy should be immunized with pneumococcal vaccine prior to the procedure, and some clinicians recommend penicillin prophylaxis afterward. The need for splenectomy in mild cases is somewhat controversial. Splenectomy in the middle childhood years prevents the subsequent development of cholelithiasis and eliminates the need for the activity restrictions recommended for children with splenomegaly. However, these benefits must be weighed against the risks of the

surgical procedure and the subsequent lifelong risk of postsplenectomy sepsis.

Prognosis

Splenectomy eliminates signs and symptoms in all but the most severe cases and reduces the risk of cholelithiasis. The abnormal red cell morphology and increased osmotic fragility persist without clinical consequence.

2. Hereditary Elliptocytosis

Hereditary elliptocytosis is a heterogeneous disorder that ranges in severity from an asymptomatic carrier state with normal red cell morphology to severe hemolytic anemia. Most affected persons have numerous elliptocytes on the peripheral blood smear but mild or no hemolysis. Those with hemolysis have an elevated reticulocyte count and may have jaundice and splenomegaly. These disorders are caused by mutations of red cell membrane skeletal proteins, and most have an autosomal dominant inheritance. Because most patients are asymptomatic, no treatment is indicated. Patients with significant degrees of hemolytic anemia may benefit from folate supplementation or from splenectomy.

Some infants with hereditary elliptocytosis present in the neonatal period with moderate to marked hemolysis and significant hyperbilirubinemia. This disorder has been termed “transient infantile poikilocytosis” because such infants exhibit bizarre erythrocyte morphology with elliptocytes, budding red cells, and small misshapen cells that defy description. The MCV is low, and the anemia may be severe enough to require red cell transfusions. Typically, one parent has hereditary elliptocytosis, usually mild or asymptomatic. The infant’s hemolysis gradually abates during the first year of life, and the erythrocyte morphology subsequently becomes more typical of hereditary elliptocytosis.

CONGENITAL HEMOLYTIC ANEMIAS: HEMOGLOBINOPATHIES

The hemoglobinopathies are an extremely heterogeneous group of congenital disorders that occur in many different ethnic groups. The relatively high frequency of these genetic variants is related to the malaria protection afforded to heterozygous individuals. The hemoglobinopathies are generally classified into two major groups. The first, the thalassemias, are caused by quantitative deficiencies in the production of globin chains. These quantitative defects in globin synthesis cause microcytic and hypochromic anemias. The second group of hemoglobinopathies are those caused by structural abnormalities of globin chains. The most important of these, hemoglobins S, C, and E, are all the result of point mutations and single amino acid substitutions in β -globin. Many, but not all, infants with hemoglobinopathies are identified by routine neonatal screening.

Figure 27–3 shows the normal developmental changes that occur in globin-chain production during gestation and the first year of life. At birth, the predominant hemoglobin is fetal hemoglobin (hemoglobin F), which is composed of two α -globin chains and two γ -globin chains. Subsequently, the production of γ -globin decreases and the production of β -globin increases so that adult hemoglobin (two α chains and two β chains) predominates after 2–4 months. Because α -globin chains are present in both fetal and adult hemoglobin, disorders of α -globin synthesis (α -thalassemia) are clinically manifest in the newborn as well as later in life. In contrast, patients with β -globin disorders such as β -thalassemia and sickle cell disease are generally asymptomatic during the first 3–4 months of age and present clinically after γ -chain production—and therefore fetal hemoglobin levels—have decreased substantially.

1. α -Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- African, Mediterranean, Middle Eastern, Chinese, or Southeast Asian ancestry.
- Microcytic, hypochromic anemia of variable severity.

Figure 27-3. Changes in hemoglobin polypeptide chains during human development. (Reproduced, with permission, from Miller DR, Baehner RL: *Blood Diseases of Infancy and Childhood*, 6th ed. Mosby, 1989.)

- Hemoglobin Bart's detected by neonatal screening.

General Considerations

Most of the α -thalassemia syndromes are the result of deletions of one or more of the α -globin genes on chromosome 16. Normal diploid cells have four α -globin genes; thus the variable severity of the α -thalassemia syndromes is related to the number of gene deletions (Table 27-1). The severity of the α -thalassemia syndromes varies among affected ethnic groups, depending on the genetic abnormalities prevalent in the population. In persons of African ancestry, α -thalassemia is usually caused by the deletion of only one of the two α -globin genes on each chromosome. Thus, in the African population, heterozygous individuals are silent carriers and homozygous individuals have α -tha-

lassemia trait. In Asians, deletions of one or of both α -globin genes on the same chromosome are common. Thus heterozygous individuals are either silent carriers or have α -thalassemia trait, and homozygous individuals or compound heterozygous individuals have α -thalassemia trait, hemoglobin H disease, or hydrops fetalis. Thus the presence of α -thalassemia in a child of Asian ancestry may have important implications for genetic counseling, whereas this is not usually the case in families of African ancestry.

Clinical Findings

The clinical findings depend on the number of α -globin genes deleted. Table 27-1 summarizes the α -thalassemia syndromes.

Persons with three α -globin genes (one-gene deletion) are asymptomatic and have no hematologic abnormalities. Hemoglobin levels and MCV are normal. Hemoglobin electrophoresis in the neonatal period

Table 27-1. The α -thalassemias

Usual Genotypes ^a	α Gene Number	Clinical Features	Hemoglobin Electrophoresis ^b	
			Birth	> 6 mos
$\alpha\alpha/\alpha\alpha$	4	Normal	N	N
$-\alpha/\alpha\alpha$	3	Silent carrier	0-3% Hb Bart's	N
$-/\alpha\alpha$ or $-\alpha/-\alpha$	2	α -thal trait	2-10% Hb Bart's	N
$-/-\alpha$	1	Hb H disease	15-30% Hb Bart's	Hb present
$-/-$	0	Fetal hydrops	> 75% Hb Bart's	-

^a α indicates presence of α -globin gene, - indicates deletion of α -globin gene

^bN = normal results, Hb = hemoglobin, Hb Bart's = γ_4 , Hb H = β_4 .

shows 0–3% Bart's hemoglobin, a variant hemoglobin composed of four γ -globin chains. Hemoglobin electrophoresis after the first few months of life is normal. Thus this condition is usually suspected only in the context of family studies or when a small amount of Bart's hemoglobin is detected by neonatal screening for hemoglobinopathies.

Persons with two α -globin genes (two-gene deletion) are typically asymptomatic. The MCV is usually less than 100 fL at birth. Hematologic studies in older infants and children show a normal or slightly decreased hemoglobin level with a low MCV and a slightly hypochromic blood smear with some target cells. The hemoglobin electrophoresis typically shows 2–10% Bart's hemoglobin in the neonatal period but is normal in older children and adults.

Persons with one α -globin gene (three-gene deletion) have a mild to moderately severe microcytic hemolytic anemia (hemoglobin level of 7–10 g/dL), which may be accompanied by hepatosplenomegaly and some bony abnormalities caused by the expanded medullary space. The reticulocyte count is elevated, and the red cells show marked hypochromia and microcytosis with significant poikilocytosis and some basophilic stippling. Hemoglobin electrophoresis in the neonatal period typically shows 15–30% Bart's hemoglobin. Later in life, hemoglobin H (composed of four β -globin chains) is present. Incubation of red cells with brilliant cresyl blue (hemoglobin H preparation) shows inclusion bodies formed by denatured hemoglobin H.

The deletion of all four α -globin genes causes severe intrauterine anemia and asphyxia and results in hydrops fetalis and fetal demise or neonatal death shortly after delivery. Extreme pallor and massive hepatosplenomegaly are present. Hemoglobin electrophoresis reveals a predominance of Bart's hemoglobin with a complete absence of normal fetal or adult hemoglobin.

Differential Diagnosis

α -Thalassemia trait (two-gene deletion) must be differentiated from other mild microcytic anemias, including iron deficiency and β -thalassemia minor. In contrast to children with iron deficiency, those with α -thalassemia trait show normal or increased levels of ferritin and serum iron. In contrast to children with β -thalassemia minor, those with α -thalassemia trait have a normal hemoglobin electrophoresis after age 4–6 months. Finally, the history of a low MCV (96 fL) at birth or the presence of Bart's hemoglobin on the neonatal hemoglobinopathy screening test suggests α -thalassemia.

Children with hemoglobin H disease may have jaundice and splenomegaly, and the disorder must be differentiated from other hemolytic anemias. The key to the diagnosis is the decreased MCV and the marked

hypochromia on the blood smear. With the exception of β -thalassemia, most other significant hemolytic disorders have a normal or elevated MCV and are not hypochromic. Infants with hydrops fetalis due to severe α -thalassemia must be distinguished from those with hydrops due to other causes of anemia such as isoimmunization.

Complications

The principal complication of α -thalassemia trait is the needless administration of iron, given in the belief that a mild microcytic anemia is due to iron deficiency. Persons with hemoglobin H disease may have intermittent exacerbations of their anemia, which occasionally require blood transfusions. Splenomegaly may exacerbate the anemia and may require splenectomy. Women pregnant with hydropic α -thalassemia fetuses are subject to increased complications of pregnancy, particularly toxemia and postpartum hemorrhage.

Treatment

Persons with α -thalassemia trait require no treatment. Those with hemoglobin H disease should receive supplemental folic acid and avoid the same oxidant drugs that cause hemolysis in persons with G6PD deficiency, because exposure to these drugs may exacerbate their anemia. The anemia may also be exacerbated during periods of infection, and transfusions may be required. Hypersplenism may develop later in childhood and require surgical splenectomy. Genetic counseling and prenatal diagnosis should be offered to families at risk for hydropic fetuses.

Chui DH, Waye JS: Hydrops fetalis caused by α -thalassemia: An emerging health care problem. *Blood* 1998;91:2213 [PMID: 9516118].

Miller ST et al: A fast hemoglobin variant on newborn screening is associated with α -thalassemia trait. *Clin Pediatr* 1997;36:75 [PMID: 9118593].

2. β -Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

β -Thalassemia minor:

- Normal neonatal screening test.
- African, Mediterranean, Middle Eastern, or Asian ancestry.

- *Mild microcytic, hypochromic anemia.*
- *No response to iron therapy.*
- *Elevated level of hemoglobin A₂.*

β-Thalassemia major:

- *Neonatal screening shows hemoglobin F only.*
- *Mediterranean, Middle Eastern, or Asian ancestry.*
- *Severe microcytic, hypochromic anemia with marked hepatosplenomegaly.*

General Considerations

In contrast to the four α -globin genes, only two β -globin genes are present in diploid cells, one on each chromosome 11. Some β -thalassemia genes produce no β -globin chains and are termed β^0 -thalassemia. Other β -globin genes produce some β -globin but in diminished quantities and are termed β^+ -thalassemia. Persons affected by β -thalassemia may be heterozygous or homozygous. Individuals heterozygous for most β -thalassemia genes have β -thalassemia minor. Homozygous individuals have β -thalassemia major (Cooley anemia), a severe transfusion-dependent anemia, or a condition known as thalassemia intermedia, which is more severe than thalassemia minor but is not generally transfusion dependent. β -Thalassemia major is the most common worldwide cause of transfusion-dependent anemia in childhood. In addition, β -thalassemia genes interact with genes for structural β -globin variants such as hemoglobin S and hemoglobin E to cause serious disease in compound heterozygous individuals. These disorders are discussed further in the sections dealing with sickle cell disease and with hemoglobin E disorders.

Clinical Findings

A. SYMPTOMS AND SIGNS

Persons with β -thalassemia minor are usually asymptomatic with a normal physical examination. Those with β -thalassemia major are normal at birth but develop significant anemia during the first year of life. If the disorder is not identified and treated with blood transfusions, such children grow poorly and develop massive hepatosplenomegaly and enlargement of the medullary space with thinning of the bony cortex. The skeletal changes cause characteristic facial deformities (prominent forehead and maxilla) and predispose the child to pathologic fractures.

B. LABORATORY FINDINGS

Children with β -thalassemia minor have normal neonatal screening results but subsequently develop a de-

creased MCV with or without mild anemia. The peripheral blood smear typically shows hypochromia, target cells, and sometimes basophilic stippling. Hemoglobin electrophoresis performed after 6–12 months of age is usually diagnostic when levels of hemoglobin A₂, hemoglobin F, or both are elevated. β -Thalassemia major is often initially suspected when Hb A is absent on neonatal screening. Such infants are hematologically normal at birth but develop severe anemia after the first few months of life. The peripheral blood smear typically shows a severe hypochromic, microcytic anemia with marked anisocytosis and poikilocytosis. Target cells are prominent, and nucleated red blood cells often exceed the number of circulating white blood cells. The hemoglobin level usually falls to 5–6 g/dL or less, and the reticulocyte count is elevated but the reticulocyte index is normal to decreased. Platelet and white blood cell counts may be increased, and the serum bilirubin level is elevated. The bone marrow shows marked erythroid hyperplasia but is rarely needed for diagnosis. Hemoglobin electrophoresis shows only fetal hemoglobin and hemoglobin A₂ in children with homozygous β^0 -thalassemia. Those with β^+ -thalassemia genes make some hemoglobin A but have a marked increase in fetal hemoglobin and hemoglobin A₂ levels. The diagnosis of homozygous β -thalassemia may also be suggested by the finding of β -thalassemia minor in both parents.

Differential Diagnosis

β -Thalassemia minor must be differentiated from other causes of mild microcytic, hypochromic anemias, principally iron deficiency and α -thalassemia. In contrast to patients with iron-deficiency anemia, those with β -thalassemia minor typically have an elevated number of red blood cells, and the index of the MCV divided by the red cell count is under 13. Generally, the finding of an elevated hemoglobin A₂ level is diagnostic; however, the A₂ level is lowered by coexistent iron deficiency, which may lead to some confusion. Thus, in children thought to be iron-deficient, hemoglobin electrophoresis with quantitation of hemoglobin A₂ is sometimes deferred until after a course of iron therapy.

β -Thalassemia major is rarely confused with other disorders. Hemoglobin electrophoresis and family studies readily distinguish it from hemoglobin E- β -thalassemia, which is the other important cause of transfusion-dependent thalassemia.

Complications

The principal complication of β -thalassemia minor is the unnecessary use of iron therapy in a futile attempt to correct the microcytic anemia. Children with β -thalassemia major who are inadequately transfused experi-

ence poor growth and recurrent infections and may have hepatosplenomegaly, thinning of the cortical bone, and pathologic fractures. Without treatment, most children die within the first decade of life. The principal complications of β -thalassemia major in transfused children are hemosiderosis, splenomegaly, and hypersplenism. Transfusional hemosiderosis requires chelation therapy with deferoxamine to prevent cardiac, hepatic, and endocrine dysfunction. Noncompliance with chelation in adolescents and young adults may lead to death from congestive heart failure, cardiac arrhythmias, or hepatic failure. Even with adequate transfusions, many patients develop splenomegaly and some degree of hypersplenism. This may require surgical splenectomy because of the increasing transfusion requirements, but the procedure increases the risk of thrombosis and overwhelming septicemia.

Treatment

β -Thalassemia minor requires no specific therapy but may have important genetic implications for the family. For patients with β -thalassemia major, two approaches to treatment are now available: chronic transfusion with iron chelation and stem cell transplantation. Programs of blood transfusion are generally targeted to maintain a nadir hemoglobin level of 9–10 g/dL. This approach gives increased vigor and well-being, improved growth, and fewer overall complications. However, maintenance of good health currently requires iron chelation with nightly subcutaneous infusion of deferoxamine. Small doses of supplemental ascorbic acid may enhance the efficacy of iron chelation. Newly developed oral iron chelators are under study. Patients who undergo splenectomy to reduce transfusion requirements, and hence iron loading, should receive pneumococcal vaccine prior to the procedure and prophylactic penicillin and urgent treatment of all febrile illness afterward.

Bone marrow or umbilical cord blood transplantation is an important therapeutic option for children with β -thalassemia major who have an HLA-identical sibling donor. The probability of hematologic cure is greater than 90% when transplantation is performed prior to the development of hepatomegaly or portal fibrosis.

3. Sickle Cell Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Neonatal screening test with hemoglobin FS, FSC, or FSA.
- African, Mediterranean, Middle Eastern, Indian, or Caribbean ancestry.
- Anemia, elevated reticulocyte count, jaundice.
- Recurrent episodes of musculoskeletal or abdominal pain.
- Hemoglobin electrophoresis with hemoglobins S and F; hemoglobins S and C; or hemoglobins S, A, and F with S > A.
- Splenomegaly in early childhood with later disappearance.
- High risk of bacterial sepsis.

General Considerations

A high prevalence of sickle hemoglobin is found in persons of central African origin. It also occurs in other ethnic groups in Sicily, Italy, Greece, Turkey, Saudi Arabia, and India. Sickle cell anemia is caused by homozygosity for the sickle gene and is the most common form of sickle cell disease. Other clinically important sickling disorders are compound heterozygous conditions in which the sickle gene interacts with genes for hemoglobin C, D_{Punjab}, O_{Arab}, C_{Harlem}, or β -thalassemia.

Overall, sickle cell disease occurs in about one of every 400 African American infants. Eight percent of African Americans are heterozygous carriers of the sickle gene and are said to have sickle cell trait.

The protean clinical manifestations of sickle hemoglobinopathies can be linked directly or indirectly to the propensity of deoxygenated hemoglobin S to polymerize. Polymerization of sickle hemoglobin distorts erythrocyte morphology, decreases red cell deformability, causes a marked reduction in red cell life span, increases blood viscosity, and predisposes to episodes of vaso-occlusion.

Neonatal screening for sickle hemoglobinopathies is now routine in most of the United States. The identification of affected infants at birth, when combined with follow-up programs of parental education, comprehensive medical care, and prophylactic penicillin, markedly reduces morbidity and mortality in early childhood.

Clinical Findings

A. SYMPTOMS AND SIGNS

These are related to the hemolytic anemia and to tissue ischemia and organ dysfunction caused by vaso-occlusion. Children are normal at birth, and onset of symptoms is unusual before age 3–4 months because high levels of fetal hemoglobin inhibit sickling. A moderately severe hemolytic anemia may be present by age 1 year; causes pallor, fatigue, and jaundice; and predisposes to the development of gallstones during childhood and adolescence. Intense congestion of the spleen with sickled cells may cause splenomegaly in early childhood and results in functional asplenia as early as age 3 months. This places children at great risk for overwhelming infection with encapsulated bacteria, particularly pneumococci. Up to 30% of patients experience one or more episodes of acute splenic sequestration, characterized by sudden enlargement of the spleen with pooling of red cells, acute exacerbation of anemia, and, in severe cases, shock and death. Acute exacerbation of anemia also occurs with aplastic crises, usually caused by infection with human parvovirus, and other viruses.

Recurrent episodes of vaso-occlusion and tissue ischemia cause myriad acute and chronic problems. Dactylitis, or hand-and-foot syndrome, is the most common initial symptom of the disease and occurs in up to 50% of children before age 3 years. Recurrent episodes of ischemic pain, particularly abdominal and musculoskeletal pain, may occur throughout life. Strokes occur in about 8% of children and tend to be recurrent. The acute chest syndrome, characterized by fever, pleuritic chest pain, and acute pulmonary infiltrates with hypoxemia, is caused by pulmonary infection, infarction, or fat embolism from ischemic bone marrow. All tissues are susceptible to damage from vaso-occlusion, and multiple organ dysfunction is common by adulthood. Table 27–2 lists the common manifestations of sickle cell disease in children and adults.

B. LABORATORY FINDINGS

Children with sickle cell anemia (homozygous sickle cell disease) generally show a baseline hemoglobin level of 7–10 g/dL. This value may fall to life-threatening levels at the time of a sequestration or aplastic crisis. The baseline reticulocyte count is elevated markedly. The anemia is usually normocytic or macrocytic, and the peripheral blood smear typically shows the characteristic sickle cells as well as numerous target cells. Patients with sickle β -thalassemia generally have a low MCV and hypochromia as well. Those with sickle β^+ -thalassemia tend to have lesser degrees of hemolysis and anemia. Persons with sickle hemoglobin C disease have fewer sickle forms and more target cells, and the hemo-

globin level may be normal or only slightly decreased because the rate of hemolysis is much less than in sickle cell anemia.

Most infants with sickle hemoglobinopathies born in the United States are now identified by neonatal screening. Results indicative of possible sickle cell disease require prompt confirmation with hemoglobin electrophoresis. Children with sickle cell anemia and with sickle β^0 -thalassemia have only hemoglobins S and F. Persons with sickle β^+ -thalassemia have a preponderance of hemoglobin S with a lesser amount of hemoglobin A. Persons with sickle hemoglobin C disease have equal amounts of hemoglobin S and hemoglobin C. The use of solubility tests to screen for the presence of sickle hemoglobin should be avoided because a negative result is frequently encountered in infants with sickle cell disease, and because a positive result in an older child does not differentiate sickle cell trait from sickle cell disease. Thus hemoglobin electrophoresis is always necessary to accurately identify a sickle disorder.

Differential Diagnosis

Hemoglobin electrophoresis and sometimes hematologic studies of the parents are usually sufficient to con-

firm the correct diagnosis of a sickle cell disorder. Infants whose neonatal screening test shows only hemoglobins F and S occasionally have disorders other than sickle cell anemia or sickle β^0 -thalassemia. The most important of these disorders is a compound heterozygous condition of sickle hemoglobin and pancellular hereditary persistence of fetal hemoglobin. Such children, when older, typically have 30% fetal hemoglobin and 70% hemoglobin S, but they do not have significant anemia nor are they subject to vaso-occlusive episodes.

Complications

Repeated tissue ischemia and infarction causes damage to virtually every organ system. Table 27-2 lists the most important complications. Patients who require multiple transfusions are at risk for transfusional hemosiderosis and the development of red cell alloantibodies.

Treatment

The cornerstone of treatment is enrollment in a program involving patient and family education, comprehensive outpatient care, and appropriate treatment of acute complications. Important to the success of such a program are psychosocial services, blood bank services, and the ready availability of baseline patient information in the setting in which acute illnesses are evaluated and treated. Management of sickle cell anemia and sickle β^0 -thalassemia includes prophylactic penicillin, which should be initiated by age 2 months and continued at least until age 5 years. The routine use of penicillin prophylaxis in sickle hemoglobin C disease and sickle β^+ -thalassemia is controversial. Pneumococcal conjugate and polysaccharide vaccine should be administered to all children who have sickle cell disease. Other routine immunizations, including yearly vaccination against influenza, should be provided. All illnesses associated with fever greater than 38.5°C should be evaluated promptly, bacterial cultures preformed, parenteral broad-spectrum antibiotics administered, and careful inpatient or outpatient observation conducted.

Treatment of painful vaso-occlusive episodes includes the maintenance of adequate hydration (with avoidance of overhydration), correction of acidosis if present, administration of adequate analgesia, maintenance of normal oxygen saturation, and the treatment of any associated infections.

Red cell transfusions play an important role in management. Transfusions are indicated to improve oxygen-carrying capacity during acute exacerbations of anemia, as occurs during episodes of splenic sequestration or aplastic crisis. Red cell transfusions are not indicated for the treatment of chronic steady-state anemia, which is usually well tolerated, or for uncomplicated

episodes of vaso-occlusive pain. Simple or partial exchange transfusion to reduce the percentage of circulating sickle cells is indicated for some severe acute vaso-occlusive events and may be lifesaving. These events include stroke, moderate to severe acute chest syndrome, and acute life-threatening failure of other organs. Transfusions may also be used prior to high-risk procedures such as surgery with general anesthesia and arteriograms with ionic contrast materials. Some patients who develop severe vaso-occlusive complications may benefit from chronic transfusion therapy. The most common indication for this type of transfusion is stroke. Without transfusions, children with stroke have a 70–80% chance of recurrent stroke within a 2-year period. This risk of recurrent neurologic events is reduced markedly by the transfusion therapy.

Successful stem cell transplantation cures sickle cell disease, but to date its use has been limited because of the risks associated with the procedure, the inability to predict in young children the severity of future complications, and the paucity of HLA-identical sibling donors. Daily administration of oral hydroxyurea increases levels of fetal hemoglobin, decreases hemolysis, and reduces by 50% episodes of pain in severely affected adults with sickle cell anemia. The hematologic effects and short-term toxicity of hydroxyurea in children are similar to those in adults. Thus hydroxyurea is being used increasingly for selected children and adolescents who have frequent, severe complications.

Prognosis

Early identification by neonatal screening of infants with sickle cell disease, combined with comprehensive care that includes prophylactic penicillin, has markedly reduced mortality in childhood. Most patients are now expected to live well into adulthood, but they eventually succumb to complications.

4. Sickle Cell Trait

Individuals who are heterozygous for the sickle gene are said to have sickle cell trait. This genetic carrier state occurs in 8% of African Americans and is more common in some areas of Africa and the Middle East. Infants with sickle cell trait are identified by neonatal screening results that show hemoglobins FAS. Accurate identification of older persons with sickle cell trait depends on hemoglobin electrophoresis, which typically shows about 60% hemoglobin A and about 40% hemoglobin S. No anemia or hemolysis is present, and the physical examination is normal. Persons with sickle cell trait are generally healthy, and most experience no illness attributable to the presence of sickle hemoglobin in their red cells. Life expectancy is normal.

Sickle trait erythrocytes are capable of sickling, particularly under conditions of significant hypoxemia, and a number of clinical abnormalities have been linked to this genetic carrier state. Exposure to environmental hypoxia (altitude > 3100 m [10,000 ft] above sea level) may precipitate splenic infarction. However, most persons with sickle cell trait who choose to visit such altitudes for skiing, hiking, or climbing do so without difficulty. Many develop some degree of hyposthenuria, and about 4% experience painless hematuria, usually microscopic but occasionally macroscopic. For the most part, these renal abnormalities are subclinical, and they do not progress to significant renal dysfunction. The incidence of bacteriuria and pyelonephritis may be increased during pregnancy, but overall rates of maternal and infant morbidity and mortality are not affected by the presence of sickle cell trait in the pregnant woman.

An epidemiologic study of army recruits in military basic training found a higher risk of sudden unexplained death following strenuous exertion in recruits with sickle cell trait than in those with normal hemoglobin. This study has raised concerns about exercise and exertion for persons with the trait. However, considerable evidence suggests that exercise is generally safe and that athletic performance is not adversely affected by sickle cell trait. Exercise tolerance is normal, and the incidence of sickle cell trait in black professional football players is similar to that of the general African American population, suggesting no barrier to achievement in such a physically demanding profession. Thus restrictions on athletic competition for children with sickle cell trait are not warranted. Sickle cell trait is most significant for its genetic implications.

5. Hemoglobin C Disorders

Hemoglobin C is detected by neonatal screening. Two percent of African Americans are heterozygous for hemoglobin C and are said to have hemoglobin C trait. Such individuals have no symptoms, anemia, or hemolysis, but the peripheral blood smear may show some target cells. Identification of persons with hemoglobin C trait is important for genetic counseling, particularly with regard to the possibility of sickle hemoglobin C disease in offspring.

Persons with homozygous hemoglobin C have a mild microcytic hemolytic anemia and may develop splenomegaly. The peripheral blood smear shows prominent target cells. As with other hemolytic anemias, complications of homozygous hemoglobin C include gallstones and aplastic crises.

Olson JF et al: Hemoglobin C disease in infancy and childhood. *J Pediatr* 1994;125:745 [PMID: 7965426].

6. Hemoglobin E Disorders

Hemoglobin E is the second most common hemoglobin variant worldwide, with a gene frequency greater than 10% in some areas of Thailand and Cambodia. In Southeast Asia, an estimated 30 million people have hemoglobin E trait. Persons heterozygous for hemoglobin E show hemoglobins FAE by neonatal screening and are asymptomatic and usually not anemic, but they may develop mild microcytosis. Persons homozygous for hemoglobin E are also asymptomatic but may have mild anemia; the peripheral blood smear shows microcytosis and some target cells.

Hemoglobin E is most important because of its interaction with β -thalassemia. Compound heterozygotes for hemoglobin E and β^0 -thalassemia are normal at birth and, like infants with homozygous E, show hemoglobins FE on neonatal screening. Unlike homozygotes, they subsequently develop mild to severe microcytic hypochromic anemia. Such children may exhibit jaundice, hepatosplenomegaly, and poor growth if the disorder is not recognized and treated appropriately. In some cases, the anemia becomes severe enough to require lifelong transfusion therapy. In certain areas of the United States, hemoglobin E- β^0 -thalassemia has

become a more common cause of transfusion-dependent anemia than homozygous β -thalassemia.

Weatherall DJ: Hemoglobin E- β^0 -thalassemia: An increasingly common disease with some diagnostic pitfalls. *J Pediatr* 1998;132:765 [PMID: 9602183].

7. Other Hemoglobinopathies

Hundreds of other human globin-chain variants have been identified and described. Some, such as hemoglobins D and G, are relatively common. Heterozygous individuals, who are frequently identified during the course of neonatal screening programs for hemoglobinopathies, are generally asymptomatic and usually have no anemia or hemolysis. The principal significance of most hemoglobin variants is the potential for disease in compound heterozygous individuals who also inherit a gene for β -thalassemia or sickle hemoglobin. For example, children who are compound heterozygous for hemoglobins S and D_{Punjab} (D_{Los Angeles}) have sickle cell disease.

CONGENITAL HEMOLYTIC ANEMIAS: DISORDERS OF RED CELL METABOLISM

Erythrocytes depend on the anaerobic metabolism of glucose for the maintenance of adenosine triphosphate (ATP) levels sufficient for homeostasis. Glycolysis also produces the 2,3-diphosphoglycerate (2,3-DPG) levels needed to modulate the oxygen affinity of hemoglobin. Glucose metabolism via the hexosemonophosphate shunt is necessary to generate sufficient reduced nicotinamide adenine dinucleotide phosphate (NADPH) and reduced glutathione to protect red cells against oxidant damage. Congenital deficiencies of many glycolytic pathway enzymes have been associated with hemolytic anemias. In general, the morphologic abnormalities present on the peripheral blood smear are nonspecific, and the inheritance of these disorders is autosomal recessive or X-linked. Thus the possibility of a red cell enzyme defect should be considered during the evaluation of a patient with a congenital hemolytic anemia when the peripheral blood smear does not show red cell morphology typical of membrane or hemoglobin defects (eg, spherocytes, sickle forms, target cells), when hemoglobin disorders are excluded by hemoglobin electrophoresis and by isopropanol precipitation tests, and when family studies do not suggest an autosomal domi-

nant disorder. The diagnosis is confirmed by finding a low level of the deficient enzyme.

The two most common disorders of erythrocyte metabolism are G6PD deficiency and pyruvate kinase deficiency.

1. Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- African, Mediterranean, or Asian ancestry.
- Neonatal hyperbilirubinemia.
- Sporadic hemolysis associated with infection or with ingestion of oxidant drugs or fava beans.
- X-linked inheritance.

General Considerations

Deficiency of G6PD is the most common red cell enzyme defect that causes hemolytic anemia. The disorder has X-linked recessive inheritance and occurs with high frequency among persons of African, Mediterranean, and Asian ancestry. Hundreds of different G6PD variants have been characterized. In most instances, the deficiency is due to enzyme instability; thus, older red cells are more deficient than younger ones. The consequence is the inability of erythrocytes to generate sufficient amounts of NADPH to maintain the levels of reduced glutathione necessary to protect the red cells against oxidant stress. Thus most persons with G6PD deficiency do not have a chronic hemolytic anemia but have episodic hemolysis at times of exposure to the oxidant stress of infection or of certain drugs or food substances. The severity of the disorder varies among ethnic groups; G6PD deficiency in persons of African ancestry usually is less severe than in other ethnic groups.

Clinical Findings

A. SYMPTOMS AND SIGNS

Infants with G6PD deficiency may have significant hyperbilirubinemia and may require phototherapy or exchange transfusion to prevent kernicterus. The deficiency is an important cause of neonatal hyperbilirubinemia in infants of Mediterranean or Asian ancestry but less so in infants of African ancestry. Older children with G6PD deficiency are asymptomatic and appear

normal between episodes of hemolysis. Hemolytic episodes are often triggered by infection or by the ingestion of oxidant drugs such as antimalarial compounds and sulfonamide antibiotics (Table 27–3). Ingestion of fava beans may trigger hemolysis in children of Mediterranean or Asian ancestry but usually not in children of African ancestry. Episodes of hemolysis are associated with pallor, jaundice, hemoglobinuria, and sometimes cardiovascular compromise.

B. LABORATORY FINDINGS

The hemoglobin, reticulocyte count, and peripheral blood smear are usually normal in the absence of oxidant stress. Episodes of hemolysis are associated with a variable fall in hemoglobin. “Bite” cells or blister cells may be seen, along with a few spherocytes. Hemoglobinuria is common, and the reticulocyte count increases within a few days. Heinz bodies may be demonstrated with appropriate stains. The diagnosis is confirmed by the finding of reduced levels of G6PD in erythrocytes. Because this enzyme is present in increased quantities in reticulocytes, the test is best performed at a time when the reticulocyte count is normal or near normal.

Complications

Kernicterus is a risk for infants with significant neonatal hyperbilirubinemia. Episodes of acute hemolysis in older children may be life-threatening. Rare G6PD variants are associated with chronic hemolytic anemia; the clinical course of patients with such variants may be complicated by splenomegaly and by the formation of gallstones.

Treatment

The most important treatment issue is avoidance of drugs known to be associated with hemolysis (see Table 27–3). For some patients of Mediterranean, Middle Eastern, or Asian ancestry, the consumption of fava beans must also be avoided. Infections should be

treated promptly and antibiotics given when appropriate. Most episodes of hemolysis are self-limiting, but red cell transfusions may be lifesaving when signs and symptoms indicate cardiovascular compromise.

Seidman DS et al: Role of hemolysis in neonatal jaundice associated with glucose-6-phosphate dehydrogenase deficiency. *J Pediatr* 1995;127:804 [PMID: 7472840].

2. Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is an autosomal recessive disorder observed in all ethnic groups but is most common in northern Europeans. The deficiency is associated with a chronic hemolytic anemia of varying severity. Approximately one third of those affected present in the neonatal period with jaundice and hemolysis that require phototherapy or exchange transfusion. Occasionally, the disorder causes hydrops fetalis and neonatal death. In older children, the hemolysis may require red cell transfusions or be mild enough to go unnoticed for many years. Jaundice and splenomegaly frequently occur in the more severe cases. The diagnosis of pyruvate kinase deficiency is occasionally suggested by the presence of echinocytes on the peripheral blood smear, but these findings may be absent prior to splenectomy. The diagnosis depends on the demonstration of low levels of pyruvate kinase activity in red cells.

Treatment of pyruvate kinase depends on the severity of the hemolysis. Blood transfusions may be required for significant anemia, and splenectomy may be beneficial. The procedure does not cure the disorder but ameliorates the anemia and its symptoms. Characteristically, the reticulocyte count increases and echinocytes become more prevalent after splenectomy, despite the decreased hemolysis and increased hemoglobin level.

Gilsanz F et al: Fetal anaemia due to pyruvate kinase deficiency. *Arch Dis Child* 1993;69:523 [PMID: 8285758].

ACQUIRED HEMOLYTIC ANEMIA

1. Autoimmune Hemolytic Anemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pallor, fatigue, jaundice, and dark urine.
- Splenomegaly common.

- Positive DAT.
- Reticulocytosis and spherocytosis.

General Considerations

Acquired autoimmune hemolytic anemia is rare during the first 4 months of life but is one of the more common causes of acute anemia after the first year. It may arise as an isolated problem or may complicate an infection (hepatitis, upper respiratory tract infections, mononucleosis, cytomegalovirus [CMV] infection); systemic lupus erythematosus and other autoimmune syndromes; immunodeficiency states; or malignancies.

Clinical Findings

A. SYMPTOMS AND SIGNS

The disease usually has an acute onset, manifested by weakness, pallor, dark urine, and fatigue. Jaundice is a prominent finding, and splenomegaly is often present. Some cases are chronic and insidious in onset. Clinical evidence of an underlying disease may be present.

B. LABORATORY FINDINGS

The anemia is normochromic and normocytic and may vary from mild to severe (hemoglobin concentration < 5 g/dL). The reticulocyte count is usually increased but occasionally may be normal or low. Spherocytes and nucleated red cells may be seen on the peripheral blood smear. Although leukocytosis and elevated platelet counts are a common finding, thrombocytopenia occasionally occurs. Other laboratory data consistent with hemolysis are present such as increased indirect and total bilirubin, lactic dehydrogenase, aspartate aminotransferase, and urinary urobilinogen. Intravascular hemolysis is indicated by hemoglobinemia or hemoglobinuria. Examination of bone marrow shows marked erythroid hyperplasia and hemophagocytosis, but is seldom required.

Serologic studies are helpful in defining pathophysiology, planning therapeutic strategies, and assessing prognosis (Table 27–4). In almost all cases, the direct and indirect antiglobulin (DAT and IAT) tests are positive. Further evaluation allows distinction into one of three syndromes. The presence of IgG on the patient's red blood cells, maximal *in vitro* antibody activity at 37°C, and either no antigen specificity or an Rh-like specificity constitute warm autoimmune hemolytic ane-

Table 27–4. Classification of autoimmune hemolytic anemia (AIHA) in children.

Syndrome	Warm AIHA	Cold AIHA	Paroxysmal Cold Hemoglobinuria
Specific antiglobulin test IgG Complement	Strongly positive Negative or mildly positive	Negative Strongly positive	Negative Strongly positive
Temperature at maximal reactivity (<i>in vitro</i>)	37°C	4°C	4°C
Antigen specificity	May be panagglutinin or may have an Rh-like specificity	I or i	P
Other	Positive biphasic hemolysin test
Pathophysiology	Extravascular hemolysis, destruction by the RES (eg, spleen)	Intravascular hemolysis (may have extravascular component)	Intravascular hemolysis (may have extravascular component)
Prognosis	May be more chronic (> 3 months) with significant morbidity and mortality. May be associated with a primary disorder (lupus, immunodeficiency, etc)	Generally acute (< 3 months). Good prognosis: Often associated with infection.	Acute, self-limited. Associated with infection.
Therapy	Respond to RES blockade, including steroids (prednisone, 2 mg/kg/d), IVIG (1 g/kg/d for 2 days), or splenectomy	May not respond to RES blockade. Severe cases may benefit from plasmapheresis.	Usually self-limited. Symptomatic management.

RES = reticuloendothelial system; IVIG = intravenous immune globulin.

mia with extravascular destruction by the reticuloendothelial system. In contrast, the detection of complement alone on red blood cells, optimal reactivity in vitro at 4°C, and I or i antigen specificity are diagnostic of cold autoimmune hemolytic anemia with intravascular hemolysis. Although these are relatively common (~10%) in normal individuals, clinically significant cold antibodies exhibit in vitro reactivity at 30°C or above.

Paroxysmal cold hemoglobinuria usually has a different cause. The laboratory evaluation is identical to cold autoimmune hemolytic anemia except for antigen specificity (P) and the exhibition of in vitro hemolysis. Almost always paroxysmal cold hemoglobinuria is associated with significant infections, such as *Mycoplasma*, Epstein–Barr virus (EBV), and CMV. Warm IgM antibodies are very rare.

Differential Diagnosis

Autoimmune hemolytic anemia must be differentiated from other forms of congenital or acquired hemolytic anemias. The DAT discriminates antibody-mediated hemolysis from other causes, such as hereditary spherocytosis.

Complications

The anemia may be very severe and result in cardiovascular collapse, requiring emergency management. The complications of the underlying disease such as disseminated lupus erythematosus or an immunodeficiency state may be present.

Treatment

Medical management of the underlying disease is important in symptomatic cases. Defining the clinical syndrome provides a useful guide to treatment. Most patients with warm autoimmune hemolytic anemia (in which hemolysis is extravascular) respond to prednisone. After the initial treatment, the dose of corticosteroids may be decreased slowly. Patients may respond to 1 g of intravenous immune globulin (IVIG) per kilogram per day for 2 days, but fewer patients respond to IVIG than to prednisone. Although the rate of remission with splenectomy may be as high as 50%, particularly in warm autoimmune hemolytic anemia, this should be carefully considered in younger patients and withheld until other treatments have been tried. In severe cases unresponsive to more conventional therapy, immunosuppressive agents such as cyclophosphamide, azathioprine, busulfan, and cyclosporine may be tried alone or in combination with corticosteroids. In refrac-

tory cases, recent studies have documented responses to rituximab or bone marrow transplantation.

Patients with cold autoimmune hemolytic anemia and paroxysmal cold hemoglobinuria are less likely to respond to corticosteroids or IVIG. Because these syndromes are most apt to be associated with infections and have an acute, self-limited course, supportive care may be all that is required. Plasma exchange is effective in severe cold autoimmune (IgM) hemolytic anemia and may be helpful in severe cases because the offending antibody has only an intravascular distribution.

Supportive therapy is crucial. Patients with cold-reacting antibodies, particularly paroxysmal cold hemoglobinuria, should be kept in a warm environment. Transfusion may be necessary because of the complications of severe anemia but should be used only when there is no alternative. In most patients, cross-match-compatible blood will not be found, and the least incompatible unit should be identified. Transfusion must be conducted carefully, beginning with a test dose (see Transfusion Medicine section). Identification of the patient's phenotype for minor red cell alloantigens may be helpful in avoiding alloimmunization or in providing appropriate transfusions if alloantibodies arise after initial transfusions. Patients with severe intravascular hemolysis may have associated disseminated intravascular coagulation (DIC), and heparin therapy should be considered in such cases.

Prognosis

The outlook for autoimmune hemolytic anemia in childhood is usually good unless associated diseases are present (eg, congenital immunodeficiency, acquired immunodeficiency syndrome [AIDS], lupus erythematosus), in which case the hemolysis is likely to run a chronic course. In general, children with warm autoimmune hemolytic anemia are at greater risk for more severe and chronic disease with higher morbidity and mortality rates. Hemolysis and positive antiglobulin tests may continue for months or years. Patients with cold autoimmune hemolytic anemia or paroxysmal cold hemoglobinuria are more likely to have acute, self-limited disease (< 3 months). Paroxysmal cold hemoglobinuria is almost always associated with infection (eg, with *Mycoplasma* infection, CMV, EBV).

Zecca M et al: Rituximab for the treatment of refractory autoimmune hemolytic anemia in children. *Blood* 2003;101:3857 [PMID: 12531800].

2. Nonimmune Acquired Hemolytic Anemia

Hepatic disease may alter the lipid composition of the red cell membrane. This usually results in the formation of target cells and is not associated with significant hemolysis. Occasionally, hepatocellular damage is associated with the formation of spur cells and brisk hemolytic anemia. Renal disease may also be associated with significant hemolysis; hemolytic-uremic syndrome is one example. In this disorder, hemolysis is associated with the presence, on the peripheral blood smear, of echinocytes, fragmented red cells, and spherocytes.

A microangiopathic hemolytic anemia with fragmented red cells and some spherocytes may be observed in a number of conditions associated with intravascular coagulation and fibrin deposition within vessels. This occurs with DIC such as may complicate severe infection, but it may also occur when the intravascular coagulation is localized, as with giant cavernous hemangiomas (Kasabach–Merritt syndrome). Fragmented red cells may also be seen with mechanical damage (eg, associated with artificial heart valves).

POLYCYTHEMIA & METHEMOGLOBINEMIA

CONGENITAL ERYTHROCYTOSIS (FAMILIAL POLYCYTHEMIA)

In pediatrics, polycythemia is usually secondary to chronic hypoxemia. However, a number of families with congenital erythrocytosis have been described. The disorder differs from polycythemia vera in that only red blood cells are affected; the white blood cell and platelet counts are normal. It occurs as an autosomal dominant or recessive disorder. There are usually no physical findings except for plethora and splenomegaly. The hemoglobin level may be as high as 27 g/dL. Patients usually have no symptoms other than headache and lethargy. Studies in a number of families have revealed (1) an abnormal hemoglobin with increased oxygen affinity, (2) reduced red cell diphosphoglycerate, (3) autonomous increase in erythropoietin production, or (4) hypersensitivity of erythroid precursors to erythropoietin.

Treatment is not indicated unless symptoms are marked. Phlebotomy is the treatment of choice.

Juvonen E et al: Autosomal dominant erythrocytosis caused by increased sensitivity to erythropoietin. *Blood* 1991;78:3066 [PMID: 1954391].

Sokol L et al: Primary familial polycythemia: A frameshift mutation in the erythropoietin receptor gene and increased sensitivity of erythroid progenitors to erythropoietin. *Blood* 1995;86:15 [PMID: 7795221].

SECONDARY POLYCYTHEMIA

Secondary polycythemia occurs in response to hypoxemia. The most common cause of secondary polycythemia in children is cyanotic congenital heart disease. It also occurs in chronic pulmonary disease such as cystic fibrosis. Persons living at extremely high altitudes, as well as some with methemoglobinemia, develop polycythemia. It has on rare occasions been described without hypoxemia in association with renal tumors, brain tumors, Cushing disease, or hydro-nephrosis.

Polycythemia may occur in the neonatal period; it is particularly exaggerated in infants who are preterm or small for gestational age. In these infants, polycythemia is sometimes associated with other symptoms. It may occur in infants of diabetic mothers, in Down syndrome, and as a complication of congenital adrenal hyperplasia.

Iron deficiency may complicate polycythemia and aggravate the associated hyperviscosity. This complication should always be suspected when the MCV falls below the normal range. Coagulation and bleeding abnormalities, including thrombocytopenia, mild consumption coagulopathy, and elevated fibrinolytic activity, have also been described in severely polycythemic cardiac patients. Bleeding at surgery may be severe.

The ideal treatment of secondary polycythemia is correction of the underlying disorder. When this cannot be done, phlebotomy may be necessary to control symptoms. Iron sufficiency should be maintained. Adequate hydration of the patient and phlebotomy with plasma replacement may be indicated prior to major surgical procedures; these measures prevent the complications of thrombosis and hemorrhage. Isovolumetric exchange transfusion is the treatment of choice in severe cases.

Balcerzak SP, Bromberg PA: Secondary polycythemia. *Semin Hematol* 1975;12:353 [PMID: 1105791].

METHEMOGLOBINEMIA

Methemoglobin is continuously formed at a slow rate by the oxidation of heme iron to the ferric state. Normally, it is enzymatically reduced back to hemoglobin. Methemoglobin is unable to transport oxygen and causes a shift in the dissociation curve of the residual

oxyhemoglobin. Cyanosis is produced with methemoglobin levels of approximately 15% or greater. Levels of methemoglobin increase by several mechanisms.

1. Hemoglobin M

The designation M is given to several abnormal hemoglobins associated with methemoglobinemia. Affected individuals are heterozygous for the gene, which is transmitted as an autosomal dominant disorder. The different types of hemoglobin M result from different amino acid substitutions in α -globin or β -globin. Hemoglobin electrophoresis at the usual pH will not always demonstrate the abnormal hemoglobin, and isoelectric focusing may be needed. The patient has cyanosis but is otherwise usually asymptomatic. Exercise tolerance may be normal, and life expectancy is not affected. This type of methemoglobinemia does not respond to any form of therapy.

Vichinsky EP, Lubin BH: Unstable hemoglobins, hemoglobins with altered oxygen affinity, and M-hemoglobins. *Pediatr Clin North Am* 1980;27:421 [PMID: 7383714].

2. Congenital Methemoglobinemia Due to Enzyme Deficiencies

Congenital methemoglobinemia is caused most frequently by congenital deficiency of the reducing enzyme diaphorase I (coenzyme factor I). It is transmitted as an autosomal recessive trait. Affected patients may have as high as 40% methemoglobin but usually have no symptoms, although a mild compensatory polycythemia may be present. Patients with methemoglobinemia associated with a deficiency of diaphorase I respond readily to treatment with ascorbic acid and methylene blue (see following section), but treatment is not usually indicated.

3. Acquired Methemoglobinemia

A number of compounds activate the oxidation of hemoglobin from the ferrous to the ferric state, forming methemoglobin. These include the nitrites and nitrates (contaminated water), chlorates, and quinones. Drugs in this group are the aniline dyes, sulfonamides, acetanilid, phenacetin, bismuth subnitrate, and potassium chlorate. Poisoning with a drug or chemical containing one of these substances should be suspected in any infant or child who presents with sudden cyanosis. Methemoglobin levels in such cases may be extremely high and can produce anoxia, dyspnea, unconsciousness, circulatory failure, and death. Young infants and newborns are more susceptible to acquired methemoglobinemia because their red cells have difficulty reduc-

ing hemoglobin, probably because their NADH methemoglobin reductase is transiently deficient. Infants with metabolic acidosis from diarrhea and dehydration or other causes may also develop methemoglobinemia.

Patients with the acquired form of methemoglobinemia respond dramatically to methylene blue in a dose of 1–2 mg/kg intravenously. For infants and young children, a smaller dose (1–1.5 mg/kg) is recommended. Ascorbic acid administered orally or intravenously also reduces methemoglobin, but it acts more slowly.

DISORDERS OF LEUKOCYTES

NEUTROPENIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Increased frequency of infections.*
- *Ulceration of oral mucosa and gingivitis.*
- *Normal numbers of red cells and platelets.*

General Considerations

Neutropenia is an absolute neutrophil (granulocyte) count of less than 1500/ μ L in childhood, or below 1000/ μ L between ages 1 week and 2 years. During the first few days of life, an absolute neutrophil count of less than 3500 cells/ μ L may be considered neutropenia. Neutropenia results from absent or defective granulocyte stem cells, ineffective or suppressed myeloid maturation, decreased production of hematopoietic cytokines (eg, granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]), decreased marrow release, increased neutrophil destruction or consumption, or, in pseudoneutropenia, from an increased neutrophil marginating pool (Table 27–5).

The most severe types of congenital neutropenia include reticular dysgenesis (congenital aleukocytosis), Kostmann syndrome (severe neutropenia with matura-

Table 27–5. Classification of neutropenia of childhood.**Congenital neutropenia with stem cell abnormalities**

- Reticular dysgenesis
- Cyclic neutropenia

Congenital neutropenia with abnormalities of committed myeloid progenitor cells

- Neutropenia with immunodeficiency disorders (T cells and B cells)
- Severe congenital neutropenia (Kostmann syndrome)
- Chronic idiopathic neutropenia of childhood
- Myelocathexis with dysmyelopoiesis
- Chédiak–Higashi syndrome
- Shwachman syndrome
- Cartilage-hair hypoplasia
- Dyskeratosis congenita
- Fanconi anemia
- Organic acidemias (eg, propionic, methylmalonic)
- Glycogenosis Ib
- Osteopetrosis

Acquired neutropenias affecting stem cells

- Malignancies (leukemia, lymphoma) and preleukemic disorders
- Drugs or toxic substances
- Ionizing radiation
- Aplastic anemia

Acquired neutropenias affecting committed myeloid progenitors and/or survival of mature neutrophils

- Ineffective granulopoiesis (vitamin B₁₂, folate, and copper deficiency)
- Infection
- Immune (neonatal alloimmune or autoimmune; autoimmune or chronic benign neutropenia of childhood)
- Hypersplenism

tion defect in the marrow progenitor cells), Shwachman syndrome (neutropenia with pancreatic insufficiency), neutropenia with immune deficiency states, cyclic neutropenia, and myelocathexis or dysgranulopoiesis. Genetic mutations for Chédiak–Higashi syndrome and Shwachman syndrome have recently been identified. Neutropenia may also be associated with storage and metabolic diseases and immunodeficiency states. The most common causes of neutropenia are viral infection or drugs resulting in decreased production in the marrow or increased destruction or both. Severe bacterial infections may be associated with neutropenia. Although rare, neonatal alloimmune neutropenia can be severe and associated with increased risk for infection. Autoimmune neutropenia in the mother can result in passive transfer of antibody to and neutropenia in the neonate. Malignancies, osteopetrosis, marrow failure syndromes, and hypersplenism are not usually associated with isolated neutropenia.

Clinical Findings**A. SYMPTOMS AND SIGNS**

Acute severe bacterial or fungal infection is the most significant complication of neutropenia. Although the

risk is increased when the absolute neutrophil count is less than 500/ μ L, the actual susceptibility is variable and depends on the cause of neutropenia, marrow reserves, and other factors. The most common types of infection include septicemia, cellulitis, skin abscesses, pneumonia, and perirectal abscesses. Sinusitis, aphthous ulcers, gingivitis, and periodontal disease also cause significant problems for these patients. In addition to local signs and symptoms, patients may have chills, fever, and malaise. In most cases, the spleen and liver are not enlarged. *Staphylococcus aureus* and gram-negative bacteria are the most common pathogens.

B. LABORATORY FINDINGS

Neutrophils are absent or markedly reduced in the peripheral blood smear. In most forms of neutropenia or agranulocytosis, the monocytes and lymphocytes are normal and the red cells and platelets are not affected. The bone marrow usually shows a normal erythroid series, with adequate megakaryocytes but a marked reduction in the myeloid cells or a significant delay in maturation of this series. Total cellularity may be decreased.

In the evaluation of neutropenia (eg, persistent, intermittent, cyclic), careful attention should be paid to

the duration and pattern of neutropenia, the types of infections and their frequency, and phenotypic abnormalities on physical examination. A careful family history and blood counts from the parents are useful. If an acquired cause, such as viral infection or drug, is not obvious and no other primary disease is present, white blood cell counts, white cell differential, and platelet and reticulocyte counts should be completed once or twice weekly for 4–6 weeks to determine the possibility of cyclic neutropenia. Bone marrow aspiration and biopsy are most important to characterize the morphologic features of myelopoiesis. Measuring the neutrophil counts in response to steroid infusion will document the marrow reserves. Tests for specific causes of neutropenia include measurement of neutrophil antibodies, immunoglobulin levels, antinuclear antibodies, and lymphocyte phenotyping to detect immunodeficiency states. Cultures of bone marrow are important for defining the numbers of stem cells and progenitors committed to the myeloid series or the presence of cytotoxic lymphocytes or humoral inhibitory factors. Cytokine levels in plasma or mononuclear cells can be measured directly. Some neutropenia disorders have abnormal neutrophil function. Recent studies have documented abnormalities in the elastase gene in severe congenital and cyclic neutropenias. Increased apoptosis in marrow precursors or circulating neutrophils has been described in several congenital disorders.

Treatment

Identifiable toxic agents should be eliminated, or associated diseases (eg, infections) treated. Prophylactic antimicrobial therapy is not indicated for afebrile, asymptomatic patients. Recombinant G-CSF and GM-CSF will increase neutrophil counts in most patients. Patients may be started on 3–5 $\mu\text{g}/\text{kg}/\text{d}$ of G-CSF (filgrastim) given subcutaneously or intravenously once a day. Depending on the counts, the dose may be increased or decreased. For patients with congenital neutropenia, the dose should be regulated to keep the absolute neutrophil count less than 10,000/ μL . Some patients maintain adequate counts with G-CSF given 2–3 times/week.

Prognosis

The prognosis varies greatly with the cause and severity of the neutropenia. In severe cases with persistent agranulocytosis, the prognosis is poor in spite of antibiotic therapy; in mild or cyclic forms of neutropenia, symptoms may be minimal and the prognosis for normal life expectancy excellent. Up to 50% of patients with Shwachman syndrome may develop aplastic anemia, myelodysplasia, or leukemia during their lifetime.

Patients with Kostmann syndrome also have a potential for leukemia. Recombinant hematopoietic hormones (ie, G-CSF) increase peripheral counts and decrease infectious complications.

NEUTROPHILIA

Neutrophilia is an increase in the absolute neutrophil count in the peripheral blood to greater than 7500–8500 cells/ μL for infants, children, and adults. To support the increased peripheral count, neutrophils may be mobilized from bone marrow storage or peripheral marginating pools. Neutrophilia occurs acutely in association with bacterial or viral infections, inflammatory diseases (eg, juvenile rheumatoid arthritis, inflammatory bowel disease, Kawasaki disease), surgical or functional asplenia, liver failure, diabetic ketoacidosis, azotemia, congenital disorders of neutrophil function (eg, chronic granulomatous disease and leukocyte adherence deficiency), and hemolysis. Drugs such as corticosteroids, lithium, and epinephrine increase the blood neutrophil count. Corticosteroids cause release of neutrophils from the marrow pool and inhibit egress from capillary beds and postpone apoptotic cell death. Epinephrine causes release of the marginating pool. Acute neutrophilia has been reported after stress such as from electric shock, trauma, burns, surgery, and emotional upset. Tumors involving the bone marrow, such as lymphomas, neuroblastomas, and rhabdomyosarcoma, may be associated with leukocytosis and the presence of immature myeloid cells in the peripheral blood. Infants with Down syndrome have defective regulation of proliferation and maturation of the myeloid series and may develop neutrophilia. At times this process may affect

other cell lines and mimic myeloproliferative disorders or acute leukemia.

The neutrophilias must be distinguished from myeloproliferative disorders such as chronic myelogenous leukemia and juvenile chronic myelogenous leukemia. In general, abnormalities involving other cell lines, the appearance of immature cells on the blood smear, and the presence of hepatosplenomegaly are important differentiating characteristics.

DISORDERS OF NEUTROPHIL FUNCTION

Neutrophils play a key role in host defenses. Circulating in capillary beds, they adhere to the vascular endothelium adjacent to sites of infection and inflammation. Moving between endothelial cells, the neutrophil migrates toward the offending agent. Contact with a microbe that is properly opsonized with complement or antibodies triggers ingestion, a process in which cytoplasmic streaming results in the formation of pseudopods that fuse around the invader, encasing it in a phagosome. During the ingestion phase, the oxidase enzyme system assembles and is activated, taking oxygen from the surrounding medium and reducing it to form toxic oxygen metabolites critical to microbicidal activity. Concurrently, granules from the two main classes (azurophil and specific) fuse and release their contents into the phagolysosome. The concentration of toxic oxygen metabolites (eg, hydrogen peroxide, hypochlorous acid, hydroxyl radical) and other compounds (eg, proteases, cationic proteins, cathepsins, defensins) increases dramatically, resulting in the death and dissolution of the microbe. Complex physiologic and biochemical processes subserve and control these functions. Defects in any of these processes may lead to inadequate cell function and an increased risk of infection.

Classification

Table 27–6 summarizes congenital neutrophil function defects. Recently described is a syndrome of severe neutrophil dysfunction and severe infections associated with a mutation in a GTPase signaling molecule, Rac2. Other congenital or acquired causes of mild to moderate neutrophil dysfunction include metabolic defects (eg, glycogen storage disease, diabetes mellitus, renal disease, hypophosphatemia), viral infections, and certain drugs. Neutrophils from newborn infants have abnormal adherence, chemotaxis, and bactericidal activity. Cells from patients with thermal injury, trauma, and overwhelming infection have defects in cell motility and bactericidal activity similar to those seen in neonates.

Clinical Findings

Recurrent bacterial or fungal infections are the hallmark of neutrophil dysfunction. Although many patients will have infection-free periods, episodes of pneumonia, sinusitis, cellulitis, cutaneous and mucosal infections (including perianal or peritonsillar abscesses), and lymphadenitis are frequent. As with neutropenia, aphthous ulcers of mucous membranes, severe gingivitis, and periodontal disease are also major complications. In general, *S aureus*, along with gram-negative organisms, is commonly isolated from infected sites; other organisms may be specifically associated with a defined neutrophil function defect. In some disorders, fungi account for an increasing number of infections. Deep or generalized infections such as osteomyelitis, liver abscesses, sepsis, meningitis, and necrotic or even gangrenous soft tissue lesions occur in specific syndromes (eg, leukocyte adherence deficiency or chronic granulomatous disease). Patients with severe neutrophil dysfunction may die in childhood from severe infections or associated complications. Table 27–6 summarizes pertinent laboratory findings.

Treatment

The mainstays of management of these disorders remain the anticipation of infections and aggressive attempts to identify the foci and the causative agents. Surgical procedures to achieve these goals may be both diagnostic and therapeutic. Broad-spectrum antibiotics covering the range of possible organisms should be initiated without delay, switching to specific antimicrobial agents when the microbiologic diagnosis is made. When infections are unresponsive or they recur, granulocyte transfusions may be helpful.

Chronic management includes prophylactic antibiotics. Trimethoprim–sulfamethoxazole and other antibiotic compounds enhance the bactericidal activity of neutrophils from patients with chronic granulomatous disease. Some patients with Chédiak–Higashi syndrome improve clinically when given ascorbic acid. Recombinant γ -interferon has been shown to decrease the number and severity of infections in patients with chronic granulomatous disease. Demonstration of this activity with one patient group raises the possibility that cytokines, growth factors, and other biologic response modifiers may be helpful in other conditions in preventing recurrent infections. Bone marrow transplantation has been attempted in most major congenital neutrophil dysfunction syndromes, and reconstitution with normal cells and cell function has been documented. Combining genetic engineering with autologous bone marrow transplantation may provide a future strategy for curing these disorders.

Table 27-6. Classification of congenital neutrophil function deficits.

Disorder	Clinical Manifestations	Functional Defect	Biochemical Defect	Inheritance
Chédiak-Higashi syndrome	Oculocutaneous albinism, photophobia, nystagmus, ataxia. Recurrent infections of skin, respiratory tract, and mucous membranes with gram-positive and gram-negative organisms. Many die during lymphoproliferative phase with hepatomegaly, fever. This may be a viral-associated hemophagocytic syndrome secondary to Epstein-Barr virus infection. Older patients may develop degenerative CNS disease.	Neutropenia. Neutrophils, monocytes, lymphocytes, platelets, and all granule-containing cells have giant granules. Most significant defect is in chemotaxis. Also milder defects in microbicidal activity and degranulation.	Unknown. Alterations in membrane fusion with formation of giant granules. Other biochemical abnormalities in cAMP and cGMP, microtubule assembly.	Autosomal-recessive
Leukocyte adherence deficiency I	Recurrent soft tissue infections, including gingivitis, otitis, mucositis, periodontitis, skin infections. Delayed separation of the cord in newborn and problems with wound healing.	Neutrophilia. Diminished adherence to surfaces, leading to decreased chemotaxis.	Absence or partial deficiency of CD11/CD18 cell surface adhesive glycoproteins.	Autosomal-recessive
Leukocyte adherence deficiency II	Recurrent infections, mental retardation, craniofacial abnormalities, short stature.	Neutrophilia. Deficient "rolling" interaction with endothelial cells. Red cells have Bombay phenotype.	Deficient fucosyl transferase results in deficient sialyl Lewis X antigen, which interacts with P selectin on endothelial cell to establish neutrophil rolling, a prerequisite for adherence and diapedesis.	Autosomal-recessive
Chronic granulomatous disease	Recurrent purulent infections with catalase-positive bacteria and fungi. May involve skin, mucous membranes. Also develop deep infections (lymph nodes, lung, liver, bones) and sepsis	Neutrophilia. Neutrophils demonstrate deficient bactericidal activity but normal chemotaxis and ingestion. Defect in the oxidase enzyme system, resulting in absence or diminished production of oxygen metabolites toxic to microbes.	A number of molecular defects in oxidase components. Absent cytochrome b558 with decreased expression of either (1) or (2): (1) gp91-phox (2) p22-phox Absent p47-phox or p67-phox (cytosolic components).	(1) X-linked (60–65% of cases). (2) Autosomal recessive (< 5% of cases). Autosomal-recessive (30% of cases).
Myeloperoxidase deficiency	Generally healthy. Fungal infections when deficiency associated with systemic diseases (eg, diabetes)	Diminished capacity to enhance hydrogen peroxide-mediated microbicidal activity.	Diminished or absent myeloperoxidase; posttranslational defect in processing protein.	Autosomal-recessive
Specific granule deficiency	Recurrent skin and deep tissue infections.	Decreased chemotaxis and bactericidal activity.	Failure to produce specific granules or their contents during myelopoiesis.	Autosomal-recessive

Prognosis

For mild to moderate defects, anticipation and conservative medical management ensure a reasonable outlook. For severe defects, excessive morbidity and significant mortality still exist. In some diseases, the development of noninfectious complications, such as the lymphoproliferative phase of Chédiak–Higashi syndrome or inflammatory syndromes in chronic granulomatous disease, may influence prognosis.

Ambruso DR et al: Human neutrophil immunodeficiency syndrome is associated with an inhibitory Rac2 mutation. *Proc Natl Acad Sci U S A* 2000;97:4654 [PMID: 10758162].

Etzioni A et al: Brief report: Recurrent severe infections caused by a novel leukocyte adhesion deficiency. *N Engl J Med* 1992;327:1789 [PMID: 1279426].

Kyono W, Coates TD: A practical approach to neutrophil disorders. *Pediatr Clin North Am* 2002;49:929 [PMID: 12430620].

LYMPHOCYTOSIS

From the first week up to the fifth year of life, lymphocytes are the most numerous leukocytes in human blood. The ratio then reverses gradually to reach the adult pattern of neutrophil predominance. An absolute lymphocytosis in childhood is associated with acute or chronic viral infections, pertussis, syphilis, tuberculosis, and hyperthyroidism. Other noninfectious conditions, drugs, and hypersensitivity and serum sickness-like reactions cause lymphocytosis.

Fever, upper respiratory symptoms, gastrointestinal complaints, and rashes are clues in distinguishing infectious from noninfectious causes. The presence of enlarged liver, spleen, or lymph nodes is crucial to the differential diagnosis, which includes acute leukemia and lymphoma. Most cases of infectious mononucleosis are associated with hepatosplenomegaly or adenopathy. The absence of anemia and thrombocytopenia helps to differentiate these disorders. Evaluation of the morphology of lymphocytes on peripheral blood smear is crucial. Infectious causes, particularly infectious mononucleosis, are associated with atypical features in the lymphocytes such as basophilic cytoplasm, vacuoles, finer and less dense chromatin, and an indented nucleus. These features are distinct from the characteristic morphology associated with lymphoblastic leukemia. Lymphocytosis in childhood is most commonly associated with infections and resolves with recovery from the primary disease.

EOSINOPHILIA

Eosinophilia in infants and children is an absolute eosinophil count greater than 300/ μ L. Marrow eosino-

phil production is stimulated by the cytokine interleukin-5. Allergies, particularly eczema, are the most common primary causes of eosinophilia in children. Eosinophilia also occurs in drug reactions, with tumors (Hodgkin and non-Hodgkin lymphomas and brain tumors), and with immunodeficiency and histiocytosis syndromes. Increased eosinophil counts are a prominent feature of many invasive parasitic infections. Gastrointestinal disorders such as chronic hepatitis, ulcerative colitis, Crohn disease, and milk precipitin disease may be associated with eosinophilia. Increased blood eosinophil counts have been identified in several families without association with any specific illness. Rare causes of eosinophilia include the hypereosinophilic syndrome, characterized by counts greater than 1500/ μ L and organ involvement and damage (hepatosplenomegaly, cardiomyopathy, pulmonary fibrosis, and central nervous system injury). This is a disorder of middle-aged adults and is rare in children. Eosinophilic leukemia has been described, but its existence as a distinct entity is controversial.

Eosinophils are sometimes the last type of mature myeloid cell to disappear after marrow ablative chemotherapy. Increased eosinophil counts are associated with graft versus host disease after bone marrow transplantation, and elevations are sometimes documented during rejection episodes in patients who have solid organ grafts.

BLEEDING DISORDERS

Bleeding disorders may occur as a result of (1) quantitative or qualitative abnormalities of platelets, (2) quantitative or qualitative abnormalities in plasma coagulation factors, (3) vascular abnormalities, or (4) accelerated fibrinolysis. The coagulation cascade and fibrinolytic system are shown in Figures 27–4 and 27–5.

For the bleeding patient, obtaining a detailed personal and family history is the most critical aspect of evaluation. The personal history should include bleeding complications associated with dental interventions, surgeries, suture placement and removal, and fractures. A history of mucosal bleeding is suggestive of a platelet disorder, von Willebrand disease, dysfibrinogenemia, or vasculitis. Bleeding into muscles and joints suggests a coagulation protein abnormality. A thorough physical examination should be performed with special attention to the skin, oral and nasal mucosa, liver, spleen, and joints. Excessive bleeding may be due to a congenital or acquired abnormality.

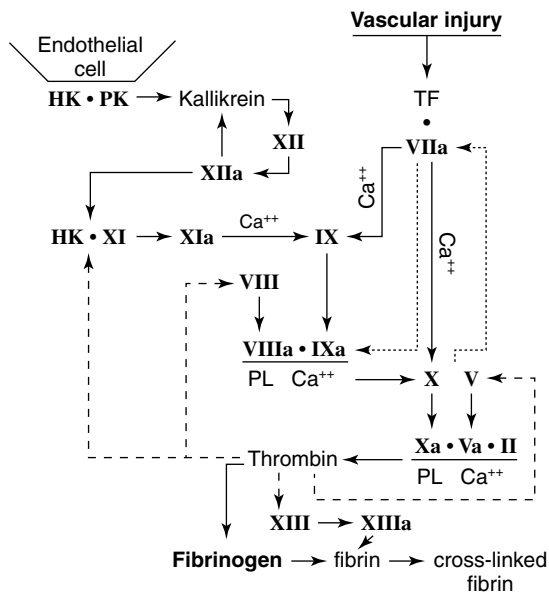

Figure 27-4. The procoagulant system and formation of a fibrin clot. Vascular injury initiates the coagulation process by exposure of tissue factor (TF); the dashed lines indicate thrombin actions in addition to clotting of fibrinogen. The finely dotted lines indicate the feedback activation of the VII-TF complex by Xa and IXa. Abbreviations: HK = high-molecular-weight kininogen; PK = prekallikrein; Ca²⁺ = calcium; PL = phospholipid. (Reproduced, with permission, from Goodnight SH, Hathaway WE [eds]: *Disorders of Hemostasis & Thrombosis: A Clinical Guide*, 2nd ed. McGraw-Hill, 2001.)

Screening tests to investigate patients for possible bleeding disorders should initially include the following:

1. Prothrombin time (PT) to screen for clotting activity of factors VII, X, II, V, and fibrinogen.
2. Activated partial thromboplastin time (aPTT) to screen for clotting activity of the following factors: high-molecular-weight kininogen (HMWK), prekallikrein (PK), XII, XI, IX, VIII, X, V, II, and fibrinogen.
3. Platelet count and size.
4. Functional assessment of vascular, platelet, von Willebrand factor interaction by platelet function analyzer-100 (PFA-100) or bleeding time, to screen for small vessel integrity, platelet function, and von Willebrand disease.

The following may be useful:

1. Thrombin time (TT) to measure the generation of fibrin following conversion of prothrombin to thrombin as well as the antithrombin effect of fibrin-split products or heparin.
2. Fibrinogen level. Additional tests to be performed in hospitalized patients include measurement of fibrin degradation products (FDP) and euglobulin lysis time (ELT), a measure of fibrinolysis.

ABNORMALITIES OF PLATELET NUMBER OR FUNCTION

1. Idiopathic Thrombocytopenic Purpura

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Otherwise healthy child.*
- *Decreased platelet count.*
- *Petechiae, ecchymoses.*

General Considerations

Acute idiopathic thrombocytopenic purpura (ITP) is the most common bleeding disorder of childhood. It occurs most frequently in children age 2–5 years and often follows infection with viruses such as rubella, varicella, measles, parvovirus, influenza, or EBV. Most patients recover spontaneously within a few months. Chronic ITP (> 6 months' duration) occurs in just 10–20% of patients with ITP. The thrombocytopenia results from immune clearance of platelets, which generally have IgM or IgG on their surface. The spleen plays a major role by forming antibodies and by sequestering damaged platelets.

Clinical Findings

A. SYMPTOMS AND SIGNS

Onset of ITP is usually acute, with the appearance of multiple ecchymoses. Petechiae are often present, especially on the lips and buccal mucosa, and epistaxis is common. No other physical findings are usually pre-

sent. Rarely, concurrent infection with EBV or CMV may cause hepatosplenomegaly or lymphadenopathy, simulating acute leukemia.

B. LABORATORY FINDINGS

1. Blood—The platelet count is markedly reduced (usually < 50,000/ μL and often < 10,000/ μL), and platelets frequently are of larger size on peripheral blood smear, suggesting bone marrow response and increased production. The white blood count and differential count are normal. Anemia is not present unless hemorrhage has occurred.

2. Bone marrow—The number of megakaryocytes (which may be larger than normal) is increased. Erythroid and myeloid cellularity is normal.

3. Other laboratory tests—Because the PFA-100 and bleeding time are generally prolonged if the platelet count is less than 40,000/ μL , these tests are not indicated. PTT and PT are normal and also not indicated. Platelet-associated IgG or IgM or both may be demonstrated on the platelets or in the serum.

Differential Diagnosis

Table 27–7 lists common causes of thrombocytopenia. ITP is a diagnosis of exclusion. Bone marrow examination should be performed if the history is atypical, if abnormalities other than purpura and petechiae are present on physical examination, if other cell lines are affected on the CBC, or possibly if corticosteroid therapy is to be administered. Family history or the finding of predominantly giant platelets on the peripheral blood smear should be helpful in determining whether thrombocytopenia is hereditary.

Complications

Severe hemorrhage and bleeding into vital organs are the feared complications of ITP. Intracranial hemorrhage is the most serious but rarely seen complication.

Table 27–7. Common causes of thrombocytopenia.

	Destruction			Decreased Production	
	Antibody-Mediated	Coagulopathy	Other	Congenital	Acquired
Idiopathic thrombocytopenic purpura		Disseminated intravascular coagulopathy	Hemolytic—uremic syndrome	Fanconi anemia	Aplastic anemia
Infection		Sepsis	Thrombotic thrombocytopenic purpura	Wiskott–Aldrich syndrome	Leukemia and other malignancies
Immunologic diseases		Necrotizing enterocolitis	Hypersplenism	Thrombocytopenia with absent radii	Vitamin B ₁₂ and folate deficiencies
		Thrombosis	Respiratory distress syndrome	Metabolic disorders	
		Cavernous hemangioma	Wiskott–Aldrich syndrome	Osteopetrosis	

The most important risk factors for hemorrhage are a platelet count less than 10,000/ μ L and mean platelet volume less than 8 fL.

Treatment

A. GENERAL MEASURES

Most children require no therapy. Treatment should be given for bleeding, not just because the platelet count is low. Aspirin and aspirin-containing drugs should not be administered. Trauma should be avoided. Platelet transfusion should be avoided unless life-threatening bleeding is present and emergent splenectomy is to be pursued, when other therapies are ineffective, or when a procedure such as a craniotomy is necessary.

B. CORTICOSTEROIDS

Patients with significant bleeding (ie, hematuria, hematochezia, epistaxis) or those with a platelet count of less than 10,000/ μ L may benefit from prednisone at 4 mg/kg orally per day for 3–5 days, decreasing to 2 mg/kg/d for a total of 14 days. The dosage is then tapered and stopped. No further prednisone is given regardless of the platelet count unless significant bleeding recurs, at which time prednisone is administered in the smallest dose that will give symptomatic relief (usually 2.5–5 mg twice daily). The patient is then followed up until spontaneous remission occurs or until the patient is a candidate for further therapy.

C. INTRAVENOUS IMMUNE GLOBULIN

As an alternative or adjunct to corticosteroid treatment, IVIG may be given to raise the platelet count in both acute and chronic ITP of childhood. The platelet response to IVIG is comparable to the response to methylprednisolone (30 mg/kg/d for 7 days in acute ITP). IVIG may be effective even when the patient is resistant to corticosteroids; responses are prompt and may last for several weeks. Most patients receive 1 g/kg/d for 1–3 days. IVIG is the treatment of choice for severe, life-threatening bleeding. Platelets may be given simultaneously but are rapidly destroyed. IVIG-associated transient neurologic complications, including headache, nausea, and aseptic meningitis, occur in one third of patients. These symptoms mimic those of intracranial hemorrhage and can necessitate radiologic evaluation of the brain. A transient decrease in neutrophil number may also be seen.

D. RHO(D) IMMUNE GLOBULIN

The intravenous preparation of anti-D immunoglobulin is a polyclonal immunoglobulin that binds to the D antigen on red blood cells, and the coated cells are cleared by the spleen as a result. The antibody-coated platelets are then not phagocytized. The drug is effective

only in Rh-positive patients with a functional spleen. The time required for platelet increase is slightly longer than with steroids or IVIG. However, approximately 80% of children with acute or chronic ITP respond well. Coombs-positive hemolysis may occur transiently with an average hemoglobin concentration decrease of 0.8 g/dL. Severe hemolysis occurs in 5% of treated children. Rho(D) immune globulin is substantially less expensive than IVIG and is administered over just a few minutes.

E. SPLENECTOMY

Most children with chronic ITP have platelet counts greater than 30,000/ μ L. Up to 70% of them recover to a platelet count greater than 100,000/ μ L without therapy within 1 year. For those who do not do so, corticosteroids, IVIG, and Rho(D) immune globulin are treatment options that are usually successful. Splenectomy produces permanent remission in 70–90% but should be considered only after persistence of significant thrombocytopenia for at least 1 year. Preoperative treatment with IVIG or Rho(D) immune globulin is indicated if the platelet count is decreased significantly. If the patient has been receiving corticosteroid therapy, the dose should be appropriately increased during and after surgery. Anticoagulant therapy is not indicated postoperatively, even though the platelet count may rise to 1 million/ μ L. The risk of overwhelming infection is increased after splenectomy, particularly in the young child. Therefore, the procedure should be postponed, if possible, until the child is at least age 5 years. Administration of pneumococcal and *Haemophilus influenzae* b vaccines at least 2 weeks prior to splenectomy is recommended. Meningococcal vaccine is controversial. Penicillin prophylaxis should be started postoperatively and continued for 1–3 years.

Prognosis

Ninety percent of children with ITP will have a spontaneous remission. Features associated with the development of chronic ITP include female sex, age older than 10 years at presentation, a more insidious onset of bruising, and the presence of other autoantibodies. Teens with immune-mediated thrombocytopenia are at higher risk for chronic autoantibody diseases.

2. Thrombocytopenia in the Newborn

Thrombocytopenia is one of the most common causes of purpura in the newborn and should be considered and investigated in any newborn with petechiae or a significant bleeding tendency. A platelet count less than 150,000/ μL establishes a diagnosis of thrombocytopenia. This occurs in approximately 0.9% of unselected neonates. A platelet count less than or equal to 50,000/ μL occurs in 0.1–0.2% of otherwise well neonates. A number of specific entities may be responsible (see Table 27–7); however, one-half of such neonates have alloimmune thrombocytopenia. Infection and intravascular coagulation syndromes are the most common causes of thrombocytopenia in sick full-term newborns and in preterm newborns. In the well-appearing newborn, antibody-mediated thrombocytopenia (alloimmune or maternal autoimmune), viral syndrome, hyperviscosity, and major vessel thrombosis are frequent causes of thrombocytopenia. Management is directed toward alleviation of the specific cause.

Thrombocytopenia Associated with Platelet Alloimmunization

Platelet alloimmunization occurs in one out of approximately 350 pregnancies. Unlike Rh incompatibility, 30–40% of affected neonates are first-born. Thrombocytopenia is progressive over the duration of the gestation and worse in subsequent pregnancies. Alloimmunization occurs when a platelet antigen of the infant differs from that of the mother and when the mother is sensitized by platelets that cross from the fetal to the maternal circulation. In Caucasians, alloimmune thrombocytopenia is most often due to HPA-1a incompatibility. Sensitization of a mother homozygous for human platelet antigen 1b against paternally acquired fetal HPA-1a antigen results in severe fetal thrombocytopenia in 1 in 1200 fetuses. Only 1 in 20 HPA-1a-positive fetuses of HPA-1a-negative mothers develop alloimmunization. The presence of antenatal platelet antibodies on more than one occasion persisting in the third trimester is predictive of severe neonatal thrombocytopenia. A weak or undetectable antibody does not exclude thrombocytopenia. Severe intracranial hemorrhage occurs in 10–30% of affected neonates as early as 20 weeks' gestation. Petechiae or other bleeding manifestations are usually present shortly after birth. The disease is self-limited, and the platelet count normalizes within 4 weeks.

If severe alloimmunization occurs, platelet concentrate from the mother will be more effective than random donor platelets in raising the platelet count. Type-matched platelets from a donor are also effective. IVIG infusions and steroids, which block the reticuloen-

dothelial system, have also been successful in raising the platelet count. If alloimmunization is less severe, observation alone may be all that is required.

Intracranial hemorrhage in a previous child secondary to alloimmune thrombocytopenia is the worst risk factor for severe fetal thrombocytopenia in a subsequent pregnancy. Amniocentesis or chorionic villus sampling to obtain fetal DNA for platelet antigen typing is sometimes performed if the father is heterozygous for HPA-1a. If alloimmunization has occurred with a previous pregnancy, ultrasound examination of the fetal brain to detect hemorrhage should be obtained at 20 weeks' gestation and repeated regularly. Cordocentesis should be performed about 20 weeks' gestation with concentrated, irradiated, filtered, maternal platelets transfused to protect against fetal hemorrhage. If the fetal platelet count is less than 100,000/ μL , IVIG should be administered to the mother weekly. Delivery by elective cesarean section is recommended if the fetal platelet count is less than 50,000/ μL .

Thrombocytopenia Associated with Idiopathic Thrombocytopenic Purpura in the Mother

Infants born to mothers with ITP or antiphospholipid antibodies may develop thrombocytopenia as a result of transfer of IgG antibody from the mother to the infant. Unfortunately, maternal platelet count, maternal antiplatelet antibody levels, and fetal scalp platelet counts are unreliable predictors of bleeding risk. Antenatal administration of prednisone is generally begun once maternal platelet count falls less than 50,000/ μL . IVIG has been administered but is not well-studied.

Most neonates with thrombocytopenia secondary to passive transfer of maternal antibody do not bleed, and thus no specific treatment is indicated. The risk for intracranial hemorrhage is 0.2–2%. If petechiae or puncture wound bleeding ensues, a 1- to 2-week course of oral prednisone, 2 mg/kg/d, may be administered. If the platelet count remains consistently less than 20,000/ μL or if severe hemorrhage is present, IVIG should be given. Platelet transfusions may not be helpful without prior removal of antibody by exchange transfusion. The platelet nadir is usually on the fourth to sixth day of life. Because the antiplatelet IgG may be passed through breast milk, the platelet count should be monitored. For infants with severe thrombocytopenia, full recovery may take 2–4 months.

Neonatal Thrombocytopenia Associated with Infections

Thrombocytopenia is commonly associated with severe generalized infections during the newborn period. Be-

tween 50% and 75% of neonates with bacterial sepsis are thrombocytopenic. Intrauterine infections such as rubella, syphilis, toxoplasmosis, CMV, herpes simplex, enteroviruses, and parvovirus are often associated with thrombocytopenia.

In addition to specific treatment for the underlying disease, platelet transfusions may be indicated in severe cases. Platelet concentrates in doses of 10 mL/kg will raise the platelet count by about 75,000/ μ L.

Thrombocytopenia Associated with Giant Hemangiomas (Kasabach–Merritt Syndrome)

A rare but important cause of thrombocytopenic purpura in the newborn is giant hemangioma. These lesions have a different histologic pattern from classic infantile hemangiomas. They are more appropriately termed “kaposiform hemangioendotheliomas,” or “tufted angiomas.” Platelet sequestration in the lesion results in peripheral depletion of platelets. The bone marrow usually shows megakaryocytic hyperplasia. The thrombocytopenia may be associated with hemolytic anemia and DIC and result in fatal hemorrhage. Treatment is indicated if a serious coagulopathy is present or if the lesion exerts pressure on a vital structure or is cosmetically unacceptable.

Surgery is usually contraindicated because of the risk of hemorrhage. Prednisone therapy has been associated with marked regression. Antiplatelet drugs and pentoxifylline may be helpful. If DIC is present, heparin or aminocaproic acid may be useful. Vascular embolization may be an option. Interferon- α has also been shown to be efficacious, but its use is controversial. When patients have been unresponsive to other treatment, chemotherapy has been given with some efficacy.

3. Disorders of Platelet Function

Platelet function has traditionally been screened by measurement of the bleeding time. If the bleeding time is prolonged, aggregation of platelets with agonists such as adenosine diphosphate, collagen, arachidonic acid, and ristocetin has been studied. Results are compared with those of a normal control subject. A relatively new instrument, the PFA-100, has become available for screening for platelet dysfunction and von Willebrand

disease, and may replace the bleeding time for this purpose. Platelet morphology is assessed with the light microscope and electron microscope.

Platelet dysfunction may be inherited or acquired, but acquired platelet dysfunction is more common. Persons with platelet function defects have skin and mucosal bleeding similar to that occurring in persons with thrombocytopenia. Platelet aggregation and degranulation studies are not uniformly predictive of the severity of clinical symptoms.

Persons with hereditary platelet dysfunction generally have a prolonged bleeding time with normal platelet number and morphology. The inherited disorders are due to defects in platelet–vessel interaction, platelet–platelet interaction, platelet granule defects, signal transduction, thromboxane and arachidonic acid pathway dysfunction, and platelet coagulant–protein interaction.

An example of a platelet–vessel wall dysfunction is Bernard–Soulier syndrome. In this condition the platelets are large and the platelet count slightly decreased. Because the platelets lack or have defective glycoprotein 1b on their surface they cannot adhere to the vessel wall von Willebrand factor (vWF). Glycoproteins V and IX may also be deficient. An example of platelet–platelet dysfunction is Glanzmann thromboasthenia. In this condition glycoprotein IIb–IIIa is deficient or defective so platelets cannot bind to fibrinogen to aggregate. Both conditions are rare and transmitted in an autosomal recessive pattern. Bleeding is treated with platelet concentrates.

Two examples of platelet granule defects are storage pool disease and Quebec platelet disorder. Persons with storage pool disease are missing adenosine dinucleotide phosphate and adenosine trinucleotide phosphate from the dense granules and are usually deficient in dense granules. The dense granules are also deficient in Hermansky–Pudlak, Chédiak–Higashi, and Wiskott–Aldrich syndromes. Deficient α -granules result in the gray platelet syndrome. Quebec platelet disorder is associated with abnormal proteolysis of α -granule proteins, deficiency of platelet α -granule multimerin, and marked impaired aggregation with epinephrine.

Signal transduction defects translate to primary degranulation defects. Platelet dysfunction may also result from abnormalities in the thromboxane and arachidonic acid pathways. Scott syndrome involves a defect in factor Va–Xa interaction on platelets. Platelet dysfunction may occur in persons with Down syndrome.

Acquired disorders of platelet function may occur secondary to uremia, cirrhosis, sepsis, myeloproliferative disorders, acyanotic congenital heart disease, and viral infections. Many pharmacologic agents decrease platelet function. The most common agents are aspirin, nonsteroidal anti-inflammatory agents, and synthetic penicillins.

Treatment

Many individuals with hereditary and acquired platelet function defects will respond to therapy with desmopressin acetate. If this therapy is ineffective, treatment is with random donor platelets as discussed in the transfusion medicine section. Recombinant VIIa has variable efficacy.

Almeida AM et al: The use of recombinant factor VIIa in children with inherited platelet function disorders. *Br J Haematol* 2003;121:477 [PMID: 12716372].

Hayward CP: Inherited platelet disorders. *Curr Opin Hematol* 2003;10:362 [PMID: 12913791].

INHERITED BLEEDING DISORDERS

Table 27–8 lists normal values for coagulation factors. The more common factor deficiencies are discussed in this section. All persons with bleeding disorders should avoid exposure to medications that inhibit platelet function. Participation in contact sports such as football and ice hockey should be considered in the context of the severity of the bleeding disorder.

1. Factor VIII Deficiency (Hemophilia A, Classic Hemophilia)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bruising, bleeding, and hemarthroses.
- Prolonged PTT.
- Reduced factor VIII activity.

General Considerations

Factor VIII activity is reported in units per milliliter, with 1 unit/mL equal to 100% of the factor activity found in 1 mL of normal plasma. The normal range for factor VIII activity is 50–150%. The disease occurs predominantly in males as an X-linked disorder. One third of cases are due to a new mutation. The incidence of factor VIII deficiency is 1:5000 male births.

Clinical Findings

A. SYMPTOMS AND SIGNS

Patients with severe factor VIII deficiency (< 1% circulating factor VIII activity) have frequent spontaneous bleeding episodes involving skin, mucous membranes, joints,

muscles, and viscera. In contrast, patients with mild factor VIII deficiency (5–40% factor VIII activity) bleed only at times of trauma or surgery. Those with moderate factor VIII deficiency (1– < 5% factor VIII activity) have intermediate bleeding manifestations. The most crippling aspect of factor VIII deficiency is the tendency to develop recurrent hemarthroses that incite joint destruction.

B. LABORATORY FINDINGS

Persons with factor VIII deficiency have a prolonged PTT. The bleeding time and PT are usually normal. The diagnosis is confirmed by finding decreased factor VIII activity with normal vWF activity. Cord blood can be assayed accurately to determine factor VIII activity.

In two thirds of families of hemophilic patients, the females are carriers and some are mildly symptomatic. Carriers of hemophilia can be detected by determination of the ratio of factor VIII activity to vWF antigen and by molecular genetic techniques.

Complications

Intracranial hemorrhage is the leading disease-related cause of death among those with hemophilia. Up to 80% of intracranial hemorrhages are not trauma-associated. Hemarthroses begin early in childhood and, if recurrent, result in joint destruction. Large intramuscular hematomas can lead to a compartment syndrome with resultant muscle and nerve death. Each of these complications is more common in persons with severe hemophilia but may be experienced by persons with moderate or mild disease. A serious complication of hemophilia is the development of an acquired circulating antibody to factor VIII after treatment with factor VIII concentrate. Inhibitors or antibodies to factor VIII develop in 15–25% of severe factor VIII-deficient persons. The inhibitor is an antibody that may be amenable to desensitization and immunosuppressive therapy. Factor IX concentrate or activated prothrombin complex concentrates may be of help in stopping hemorrhage. Recombinant factor VIIa concentrate is an alternative.

Therapy-related complications have included infection with HIV and hepatitis B (until about 1985 in the United States) and hepatitis C (removed from most US preparations by 1990). By selecting donors seronegative for these infections and by heat- or chemically treating the factor concentrates to inactivate viruses, the risks of these infections have been eliminated. Safe concentrates are expensive and unobtainable in many parts of the world. Transmission of parvovirus and hepatitis A remains a problem, even with concentrates that have had viral inactivation. Immunization with hepatitis A and hepatitis B vaccines is recommended. Recombinant factor VIII concentrates are available but some contain pooled plasma-derived human albumin.

Treatment

The aim of treatment is to correct the factor VIII activity to normal to prevent or stop bleeding. Some patients with mild factor VIII deficiency may respond to desmopressin; however, most patients require administration of factor VIII concentrates to achieve hemostasis. Factor VIII is available as concentrates from human plasma or as a recombinant protein. The in vivo half-life of factor VIII is generally 8–12 hours. Factor VIII must be prescribed in units rather than vials. Non-life-threatening hemorrhages are treated with about 20–30 units of factor VIII concentrate per kilogram of body weight. This dosage will increase factor VIII activity to 40–60%, respectively. Life-threatening hemorrhage is treated initially with approximately 50 units of factor VIII concentrate per kilogram of body weight, which will increase factor VIII activity by 100%. Subsequent doses are determined according to the situation. The dose given is determined by vial size. Excess factor VIII concentrate should always be infused rather than discarded. Monitoring the factor VIII activity may be warranted, depending on the situation. The majority of moderately to severely affected persons with hemophilia administer factor concentrate intravenously at home to treat routine bleeding episodes.

Hemarthroses are common in persons with hemophilia. Initial therapy is with 20–40 units of factor VIII concentrate per kilogram of body weight, with subsequent doses in accordance with joint status. Prophylaxis with infusions is likely to prevent the development of arthropathy. A prospective study comparing prophylaxis with multiple infusions at the time of an hemarthrosis is ongoing.

Prognosis

When care is coordinated through a hemophilia center where attention is given to the physical, emotional, social, and educational status of the child, the prognosis for good quality of life ensues.

Mannucci PM, Tuddenham EG: The hemophilias: From royal genes to gene therapy. *N Engl J Med* 2001;344:1773 [PMID: 11396445].

2. Factor IX Deficiency (Hemophilia B, Christmas Disease)

The mode of inheritance and clinical manifestations of factor IX deficiency are the same as those of factor VIII deficiency. Factor IX deficiency is 15–20% as prevalent as factor VIII deficiency. As in factor VIII deficiency, factor IX deficiency is associated with prolonged PTT,

but PT and thrombin time are normal. Diagnosis is made by assaying factor IX activity, and severity is determined similarly to factor VIII deficiency.

Factor IX concentrate is the treatment product. Unlike factor VIII, about 50% of the administered dose of human-derived factor IX diffuses into the extravascular space. One unit of human-derived factor IX per kilogram is expected to increase the factor IX level by 1%. Recovery after recombinant factor IX concentrate is more variable. Factor IX has a half-life of 20–22 hours in vivo. Cryoprecipitates and factor VIII concentrates do not contain factor IX and should not be given. Virus-inactivating techniques for factor IX concentrates appear effective in eradicating HIV and hepatitis C. If recombinant factor IX concentrate is administered, strong consideration should be given to measuring a factor IX activity level to assess response because the individual response is highly variable. Only 1–3% of persons with factor IX deficiency form an inhibitor, but those who do may develop anaphylaxis when receiving factor IX concentrate. The prognosis for persons with factor IX deficiency is comparable to those with factor VIII deficiency. Gene therapy trials are ongoing.

Bolton Maggs PH, Pasi KJ: Haemophilias A and B. *Lancet* 2003;361:1801 [PMID: 12781551].

3. Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is a genetic, autosomally transmitted bleeding diathesis of mild to moderate severity. Factor XI deficiency accounts for less than 5% of all hemophilia diseases. Homozygotes generally bleed at surgery or following severe trauma but rarely have spontaneous hemarthroses. In contrast to factor VIII and IX deficiency, factor XI activity is not predictive of risk for bleeding; bleeding may be seen in heterozygous individuals with factor XI activity as high as 60%. The aPTT may be normal. The PFA-100 may be prolonged with ADP and epinephrine or the bleeding time may be prolonged consistent with platelet dysfunction since some affected individuals will be deficient for platelet-associated as well as plasma factor XI. Intervention is usually required only at the time of surgery or trauma. Treatment is with desmopressin or fresh frozen plasma (FFP) to the extent volume expansion is tolerated, and sometimes with platelets. The prognosis for an average life span is excellent.

Bolton-Maggs PH: Factor XI deficiency and its management. *Haemophilia* 2000;6:100 [PMID: 10982275].

4. Other Inherited Bleeding Disorders

Other hereditary single clotting factor deficiencies are rare. Transmission is generally autosomal. Homozygous

individuals with a deficiency or structural abnormality of prothrombin, factor V, factor VII, or factor X have excessive bleeding.

Persons with dysfibrinogenemia (abnormal fibrinogen) are usually asymptomatic but may develop recurrent venous thromboembolic episodes or have a bleeding tendency. Immunologic determinations of fibrinogen are normal, but the thrombin time and PT are often prolonged. Treatment is similar to that outlined for afibrinogenemia.

Afibrinogenemia resembles hemophilia clinically but has an autosomal recessive inheritance. The patients have mucosal bleeding and bleeding from small injuries and develop hematomas, ecchymoses, and hemarthroses. Fatal bleeding from the umbilical cord has been reported. The principal laboratory finding is prolongation of all of the usual clotting tests. Cryoprecipitate generally controls bleeding in persons with fibrinogen abnormalities.

Lak M et al: Bleeding and thrombosis in 55 patients with inherited afibrinogenemia. *Br J Haematol* 1999;107:204 [PMID: 10520042].

VON WILLEBRAND DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Easy bruising and epistaxis from early childhood.*
- *Menorrhagia*
- *Bleeding time usually prolonged; platelet count usually normal.*
- *Reduced activity or abnormal structure of von Willebrand factor.*

General Considerations

Von Willebrand disease and its variants are due to abnormalities of vWF, a plasma protein that forms a multimeric complex in the blood that binds to factor VIII and also is a cofactor for platelet adhesion. Classic von Willebrand disease (type I) involves a partial quantitative deficiency of vWF. Type I comprises 70–80% of all von Willebrand disease. von Willebrand disease type II involves a qualitative abnormality of vWF. Type II disease accounts for less than 10% of von Willebrand disease. Persons with type III disease have virtually complete deficiency of vWF. Von Willebrand disease is the most common inherited bleeding disorder; 1% of

persons are affected, but only 10% of those affected are symptomatic. The disease is usually transmitted as an autosomal dominant trait. Acquired von Willebrand disease may develop in persons with hypothyroidism, Wilms tumor, cardiac disease, renal disease, or systemic lupus erythematosus and in those receiving valproic acid. It is most often due to development of an antibody.

Clinical Findings

A. SYMPTOMS AND SIGNS

A history of increased bruising and excessive epistaxis is usually present. Prolonged bleeding will also occur with lacerations or at surgery. Menorrhagia is often a problem.

B. LABORATORY FINDINGS

The PTT may be prolonged. The PT is normal. A prolonged bleeding and PFA-100 time is usually present because vWF is involved in platelet binding to the blood vessel. Platelet number is decreased in types II and III. Factor VIII and vWF antigen are decreased in types I and III but may be normal in type II von Willebrand disease. vWF activity (ristocetin activity) is decreased in all types. Since vWF levels are dependent on blood type, blood type must be determined. Multimers must be assessed for classification into type.

Treatment

The treatment to prevent or halt bleeding for most persons with von Willebrand disease types I and II is desmopressin acetate, which causes release of vWF from endothelial stores. It may be administered intravenously at a dose of 0.3 µg/kg diluted in at least 20–30 mL of normal saline and given over 20–30 minutes. A threefold to fivefold rise in plasma vWF is expected as it is released from endothelial stores. Efficacy is variable from patient to patient; factor VIII and vWF activity may be measured before and 60 minutes after infusion to assess response. A high-concentration desmopressin nasal spray (150 µg/spray) is an alternative, but the effect varies and response to intravenous desmopressin does not predict response to the nasal preparation. Low-concentration desmopressin spray used to treat enuresis and diabetes insipidus is ineffective. Because stored vWF release is limited, tachyphylaxis often occurs with desmopressin. Children under age 2 years are at increased risk for seizures secondary to desmopressin-induced hyponatremia. If further therapy is indicated, vWF-rich concentrate is recommended.

For persons with some subtypes of type II and all persons with type III disease, treatment is with vWF-enriched concentrate.

Antifibrinolytic drugs (eg, aminocaproic acid) may be useful for control of oral, nasal, or vaginal bleeding. Topical thrombin and fibrin glue may also be of benefit. Menorrhagia may abate with oral contraceptive therapy.

Prognosis

Life expectancy is normal.

Castaman G et al: Von Willebrand's disease in the year 2003: Towards the complete identification of gene defects for correct diagnosis and treatment. *Haematologica* 2003;88:94 [PMID: 12551832].

ACQUIRED BLEEDING DISORDERS

1. Disseminated Intravascular Coagulation (DIC)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Presence of disorder known to trigger disseminated intravascular coagulation.
- Evidence for activation of coagulation (prolonged PTT, PT, or thrombin time; FSP, decreased fibrinogen or platelets).

General Considerations

DIC is an acquired pathologic process characterized by tissue factor activation of the coagulation system. The primary mediator of DIC is interleukin-6. DIC leads to thrombin generation, intravascular fibrin deposition, and platelet consumption. Microthrombi, composed of fibrin and platelets, may produce ischemic tissue damage. The fibrinolytic system is frequently activated secondary to DIC, producing plasmin-mediated destruction of fibrin, fibrinogen, and other clotting factors (V, VIII). Degradation or split products of fibrin–fibrinogen are formed and function as anticoagulants and inhibitors of platelet function. DIC commonly accompanies disorders occurring in critically ill infants and children. Conditions known to trigger DIC include endothelial cell damage (endotoxin, virus), tissue destruction (necrosis, physical injuries), hypoxia (acidosis), ischemic and vascular changes (shock, hemangiomas), and release of tissue procoagulants (cancer, placental disorders).

Clinical Findings

A. SYMPTOMS AND SIGNS

Physical signs of DIC may include (1) diffuse bleeding tendency (hematuria, melena, purpura, petechiae, persistent oozing from needle punctures or other invasive procedures); (2) circulatory collapse, poor skin perfusion, early ischemic changes; and (3) evidence of thrombotic lesions (major vessel thrombosis, gangrene, purpura fulminans).

B. LABORATORY FINDINGS

Tests that are most sensitive, easiest to perform, and best reflect the hemostatic capacity of the patient are the PT, PTT, platelet count, fibrinogen, and a test for fibrin–fibrinogen split products. A test that measures the cross-linked fibrin degradation byproducts called D-dimers may also be helpful in demonstrating activation of both coagulation and fibrinolysis. Often, the PT and PTT are prolonged and the platelet count and fibrinogen level are decreased. Levels of fibrin–fibrinogen split products and D-dimers are elevated. Often the level of physiologic inhibitors of coagulation, especially antithrombin III and protein C, are depressed and thrombosis may ensue.

The abnormalities associated with DIC may vary depending on the triggering event. Patients with infections may have predominantly thrombocytopenia, with only slight prolongation of the PTT and PT and mild elevation of fibrin–fibrinogen split products. Platelets may be consumed in bacterial sepsis without any other evidence of activated coagulation. In contrast, asphyxia may produce significant consumption of fibrinogen and elevated fibrin–fibrinogen split products without depression of platelets.

Differential Diagnosis

Bleeding with liver disease, vitamin K deficiency, or uremia can mimic DIC. Patients with fulminant hepatitis or advanced cirrhosis often have evidence of both decreased production of liver-dependent coagulation factors and increased consumption of platelets and fibrinogen. Generally, factor VII activity is decreased markedly in liver disease compared to mild to moderate decreases in DIC. Factor VIII activity may be normal or even increased in liver disease compared to decreased activity in DIC.

Treatment

A. THERAPY FOR UNDERLYING DISORDER

The most important aspect of therapy is identification and treatment of the triggering event. If the event (eg,

hypoxia, shock, sepsis) can be treated, often no other therapy is needed for the coagulopathy.

B. REPLACEMENT THERAPY

Replacement of depleted coagulation factors and platelets may be necessary in severe DIC. FFP replaces depleted coagulation factors; 10–15 mL/kg will raise clotting factor activities by about 10–15%. Fibrinogen (and factor VIII) can be given as cryoprecipitate also; one bag of cryoprecipitate per 3 kg in infants or one bag of cryoprecipitate per 6 kg in older children will raise the fibrinogen level by 75–100 mg/dL. Platelets are replaced with platelet concentrate; in the neonate, 10 mL of platelet concentrate per kilogram will raise the platelet count by 75,000–100,000/ μ L. In older children, one bag of platelet concentrate per 5–6 kg is the usual dose. An alternative formula is as follows: 1 unit/ m^2 of platelet concentrate will increase the platelet count by about 20,000/ μ L. The minimal hemostatic goals in a bleeding patient are a platelet count greater than 40,000/ μ L, PT of less than 16 seconds, and fibrinogen over 100 mg/dL.

C. ANTICOAGULANT THERAPY

Heparin is often given in hopes of interrupting the clotting process. The rationale for heparin therapy is to allow for more effective replacement therapy while the primary disease is being specifically treated, but there is no controlled trial to show that heparin is beneficial. The most effective and safest method of giving unfractionated heparin is by continuous intravenous administration. A loading dose of 50–100 units/kg is followed by 15–25 units/kg/h by continuous intravenous infusion. Heparin should be administered to achieve a therapeutic level between 0.4 and 0.7 unit/mL. Low-molecular-weight heparin is an alternative therapy that can be given subcutaneously twice a day; the therapeutic range is 0.5–1 unit/mL.

D. SPECIFIC FACTOR CONCENTRATES

Antithrombin concentrate may be of benefit. Protein C concentrate and activated protein C concentrate have been efficacious in the treatment of meningococemia-associated DIC.

2. Liver Disease

The liver is the major synthetic site of prothrombin; fibrinogen; and factors HMWK, V, VII, IX, X, XI, XII, and XIII. It also produces plasminogen and three physiologic anticoagulants, antithrombin III, protein C, and protein S. α_2 -Antiplasmin, which regulates fibrinolysis, is produced in the liver. Deficiency of factor V and the vitamin K-dependent factors (II, VII, IX, and X) is most often a result of decreased hepatic synthesis and is

manifested as PT prolongation. The PTT may also be prolonged. Extravascular loss and increased consumption of clotting factors may contribute to PT and PTT prolongation. The amount of fibrinogen may be decreased, or an abnormal fibrinogen (dysfibrinogen) containing excess sialic acid residues may be synthesized. Dysfibrinogenemia is associated with prolongation of thrombin time and reptilase time. Fibrin–fibrinogen degradation products and D-dimers may be present because of increased fibrinolysis. Thrombocytopenia secondary to hypersplenism and platelet aggregation abnormalities may occur. Treatment consists of replacement with FFP and platelets as needed. If liver disease is associated with fat malabsorption, vitamin K (1–5 mg) should be given. Desmopressin may shorten the bleeding time and PTT in patients with chronic liver disease. Recombinant VIIa also has been shown to be efficacious in advanced liver disease.

3. Vitamin K Deficiency

All newborns have physiologically depressed activity of the vitamin K-dependent factors (II, VII, IX, and X). If vitamin K is not administered at birth, a bleeding diathesis previously called hemorrhagic disease of the newborn, now termed vitamin K deficiency bleeding (VKDB), may develop. One of three patterns is seen:

1. Early VKDB of the newborn occurs within 24 hours of birth and is most often manifested by cephalhematoma, intracranial hemorrhage, or intra-abdominal bleeding. Although occasionally idiopathic, it is most often associated with maternal ingestion of drugs that interfere with vitamin K metabolism (eg, warfarin, phenytoin, isoniazid, rifampin). Early VKDB occurs in 6–12% of neonates born to mothers taking these medications but not receiving vitamin K supplementation. The disorder is often life threatening.
2. Classic VKDB of the newborn occurs at 24 hours to 7 days of age and usually is manifested as gastrointestinal, skin, or mucosal bleeding. Bleeding after circumcision may occur. Although occasionally associated with maternal drug usage, it most often occurs in well babies who do not receive vitamin K at birth and are solely breast-fed.
3. Late VKDB occurs on or after day 8 but rarely beyond age 3 months. Manifestations are intracranial, gastrointestinal, or skin bleeding. Usually it is secondary to chronic diarrhea, malabsorption syndromes, obstructive jaundice, or prolonged antibiotic therapy. It occurs almost exclusively in breast-fed infants.
4. Outside of the newborn period, vitamin K deficiency may occur as a consequence of malabsorp-

tion, fasting, alcoholism, or medications such as antibiotics, coumarins, megadose vitamin E, or salicylates.

The diagnosis of vitamin K deficiency is based on the history, physical examination, and laboratory results. The PT is markedly prolonged. The PTT may be prolonged. The thrombin time does not prolong until late in the course. Platelet counts are normal. The diagnosis is confirmed by a demonstration of noncarboxylated proteins in vitamin K's absence in the plasma and by improvement following treatment with vitamin K. Intravenous or subcutaneous treatment with vitamin K should be given immediately and not withheld awaiting test results. Depending on the severity of bleeding, additional treatment with FFP prothrombin concentrate complex or recombinant VIIa may be indicated.

4. Uremia

Qualitative and quantitative platelet abnormalities are common hemostatic defects. Decreased activity of prothrombin and factors XII, XI, and IX secondary to increased urinary losses can result in prolongation of the PTT. vWF activity may also be decreased. Bleeding occurs in approximately 50% of patients with chronic renal failure. It is most often manifested as purpura, menorrhagia, or gastrointestinal bleeding. Bleeding time is the best predictor of bleeding risk. Bleeding may be managed with infusion of desmopressin, red blood cells, and FFP. Avoiding the development of severe anemia by administering erythropoietin prophylactically decreases the bleeding risk. Recombinant VIIa may be useful in refractory bleeding.

VASCULAR ABNORMALITIES ASSOCIATED WITH BLEEDING

1. Henoch–Schönlein Purpura (see Chapter 22) (Anaphylactoid Purpura)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purpuric cutaneous rash.
- Migratory polyarthritis or polyarthralgias.

- Colicky abdominal pain.
- Nephritis.

General Considerations

Henoch–Schönlein purpura, the most common small vessel vasculitis syndrome in children, occurs primarily in males age 2–7 years. Occurrence is highest in the spring and fall. Two thirds of affected children have a history of upper respiratory infection in the preceding 1–3 weeks.

Henoch–Schönlein purpura is characterized by vasculitis of the small vessels, particularly those of the skin, gastrointestinal tract, and kidney. The most common and earliest symptom is palpable purpura, which results from extravasation of erythrocytes into the tissue surrounding the involved venules. Serum IgA immune complexes are thought to trigger a leukocytoclastic vasculitis. Immune complexes are found in the kidney, intestine, and skin. Suspected though not proved inciting antigens include group A β -hemolytic streptococci and other bacteria, viruses, drugs, foods, and insect bites.

Clinical Findings

A. SYMPTOMS AND SIGNS

The skin rash is often urticarial initially and progresses to a macular–papular appearance, which transforms into a diagnostic symmetrical purpuric rash distributed on the ankles, buttocks, and elbows. Purpuric areas of a few millimeters in diameter are present and may progress to form larger hemorrhages (palpable purpura). Petechial lesions may occur, but most hemorrhages are slightly larger. The rash usually begins on the lower extremities and buttocks, but the entire body may be involved. New lesions can continue to appear for 2–4 weeks. Approximately two thirds of patients develop migratory polyarthralgias or polyarthritis, primarily of the ankles and knees. Edema of the hands, feet, scalp, and periorbital regions may occur. Abdominal colic—due to hemorrhage and edema primarily of the small intestine—occurs in about 50% of those affected. Between 25% and 50% of those affected develop renal involvement, with hematuria, proteinuria, or nephrotic syndrome. Some children develop hypertension. Hematuria alone is never the presenting complaint for Henoch–Schönlein purpura but usually manifests in the second to third week of illness. Renal involvement occurs more commonly in males than in females and in older patients than in younger ones. Testicular torsion may occur. Neurologic symptoms are possible.

B. LABORATORY FINDINGS

The platelet count, platelet function tests, and bleeding time are usually normal, although the platelet count may even be elevated. Blood coagulation studies are normal. Urinalysis frequently reveals hematuria. Proteinuria may also be noted, but casts are uncommon. Stool analysis may be positive for blood even though melena is not observed. The antistreptolysin O (ASO) titer is frequently elevated and the throat culture positive for group A β -hemolytic streptococci. Serum IgA may be elevated.

Differential Diagnosis

Henoch–Schönlein purpura, in contrast with thrombocytopenic purpura, causes a palpable rash and the platelet count is normal. The rash of septicemia (especially meningococemia) may be similar to that of Henoch–Schönlein purpura, although the distribution tends to be more generalized with meningococemia. The possibility of child abuse should be considered in any child presenting with purpura. Other vasculitides should also be considered.

Complications

Intussusception of the small bowel may occur. About 5% of patients develop renal failure as a result of advancing proliferative glomerulonephritis with an associated mortality rate of 3%.

Treatment

Generally, treatment is unwarranted. Corticosteroid therapy may provide symptomatic relief for severe gastrointestinal or joint manifestations but does not alter skin or renal manifestations. Aspirin is useful for the pain associated with arthritis. If culture for group A β -hemolytic streptococci is positive or if the ASO titer is elevated, penicillin should be given in full doses for 10 days.

Prognosis

The prognosis for recovery is generally good, although symptoms frequently (25–50%) recur over a period of several months. In patients who develop renal manifestations, microscopic hematuria may persist for years. Progressive renal failure occurs in less than 5% of patients with Henoch–Schönlein purpura.

Cuttica RJ: Vasculitis in children: A diagnostic challenge. *Curr Probl Pediatr* 1997;27:309 [PMID: 9399074].

2. Other Vascular Disorders

Mild to life-threatening bleeding occurs with some types of Ehlers–Danlos syndrome—the most common collagen disorder (see Chapter 33). The Ehlers–Danlos syndromes are characterized by joint hypermobility, skin extensibility, bowel perforation, and often easy bruising. Despite easy bruising, coagulation abnormalities do not always occur. Reported abnormalities include deficiencies of coagulation factors VIII, IX, XI, and XIII as well as platelet dysfunction. Spontaneous rupture and dissection of aortic aneurysms have been reported in persons with specific types of Ehler–Danlos syndrome.

Beighton P et al: Ehlers–Danlos syndromes: Revised nosology. Villefranche, 1997. *Am J Med Genet* 1998;77:31 [PMID: 9557891].

THROMBOTIC DISORDERS

Thrombotic disorders are uncommon in children but are being recognized with increasing frequency. Multiple risk factors, both inherited and acquired, are usually present in children who develop a thromboembolic event. Conditions commonly associated with thrombosis during childhood are venous access devices and other implanted foreign bodies, malignancy, infection, trauma, collagen–vascular disease, surgery, renal disease, sickle cell anemia, cardiac disease, and immobilization.

Initial evaluation of the child who has a thrombosis must include a family history and definitive imaging study to delineate the type (venous versus arterial) and extent of the thrombosis. Laboratory evaluation is indicated to determine the presence of an underlying congenital or acquired hemostatic abnormality. Consultation with a pediatric hematologist is suggested to guide hemostatic evaluation because the normal ranges for some tests are age-dependent. A deficiency of the anticoagulant proteins, protein C, protein S, or antithrombin III may be congenital or acquired and associated with thrombosis. Activated protein C resistance due to the factor V Leiden mutation is the most common genetic hypercoagulable condition in Caucasians. A mutation in the prothrombin procoagulant protein also predisposes to hypercoagulability in Caucasians. Antiphospholipid antibodies are the most common acquired prothrombotic abnormality. Acquired activated protein C resistance may occur. Asymptomatic children with genetically transmitted prothrombotic risk factors or antiphospholipid antibodies generally do not receive prophylactic anticoagulation therapy. Children with an

acute thrombosis should be treated according to published guidelines specifically designed for children. Heparin is generally administered, although site-directed and systemic administration of a fibrinolytic agent are other treatment options. Following acute therapy, warfarin is generally prescribed. The duration of warfarin therapy is dependent on the risk factors for a recurrent event.

INHERITED DISORDERS

1. Protein C Deficiency

Protein C is a vitamin K-dependent protein that is normally activated by thrombin bound to thrombomodulin and inactivates activated factors V and VIII. In addition, it stimulates fibrinolysis. Two phenotypes of hereditary protein C deficiency exist. Heterozygous individuals with autosomal dominant protein C deficiency typically present with venous thromboembolism as young adults, but the disorder may manifest during childhood. Following a second event, lifelong warfarin therapy should be instituted.

Homozygous or compound heterozygous individuals generally present within the first 12 hours of life with purpura fulminans. Associated findings may include cerebral or retinal thrombosis resulting in blindness. Immediate treatment with FFP every 6–12 hours should be given. Heparin is generally administered simultaneously. Subsequent management requires chronic anticoagulation with warfarin compounds or infusion of protein C concentrate (not yet commercially available in the United States). The long-term outlook is unknown.

2. Protein S Deficiency

Protein S is a cofactor for protein C. Neonates with homozygous protein S deficiency have a course similar to protein C deficiency. Lifelong warfarin therapy is indicated for patients with a recurrent thrombotic event.

3. Antithrombin III Deficiency

Antithrombin III is the most important physiologic inhibitor of thrombin. In addition, it inhibits activated factors IX, X, XI, and XII. Antithrombin III deficiency is transmitted in an autosomal dominant pattern and is associated with venous thromboembolism. Symptoms before puberty are rare.

Availability of antithrombin III concentrate or replacement has been sporadic. Patients with recurrent venous thrombosis are maintained on lifelong warfarin.

4. Factor V Leiden Mutation

An amino acid substitution in the gene coding for factor V results in the production of factor V Leiden, a factor V variant that is resistant to inactivation by activated protein C. About 20% of unselected consecutive Caucasian adults with deep vein thrombosis and 40–60% of Caucasian adults from families with unexplained thrombophilia have been identified with this mutation. Venous thrombosis has been reported in children both heterozygous and homozygous for this mutation. This mutation also predisposes to ischemic stroke. Screening may be performed with an assay for activated protein C resistance. Confirmation is by genetic–molecular analysis.

5. Prothrombin Mutation

The 20210 glutamine to alanine mutation in the prothrombin gene is associated with a three-fold increased risk for venous thrombosis in Caucasians. Testing is by DNA analysis.

6. Other Inherited Disorders

Qualitative abnormalities of fibrinogen (dysfibrinogenemias) are usually inherited in an autosomal dominant manner. Most individuals with dysfibrinogenemia are asymptomatic. Some have problems with bleeding, and others develop venous or arterial thrombosis. This diagnosis is suggested by a prolonged thrombin time with a normal fibrinogen level. Whether dysfunction of the fibrinolytic system plays a role in the development of thrombosis is controversial. Hyperhomocystinemia can be an inherited or an acquired condition and is associated with an increased risk for both arterial and venous thromboses in adults. In children it is a risk factor for ischemic stroke. Elevated lipoprotein(a), a lipoprotein with homology to plasminogen, has been reported as an etiologic agent in childhood thrombosis. Lipoprotein(a) levels are genetically transmitted as an autosomal dominant trait.

ACQUIRED DISORDERS

1. Antiphospholipid Antibodies

The development of antiphospholipid antibodies is the most common acquired blood protein abnormality associated with both venous and arterial thrombosis. Antiphospholipid antibodies include the lupus anticoagulant and the anticardiolipin antibody. The lupus anticoagulant is an immunoglobulin that inhibits *in vitro* phospholipid-dependent coagulation assays such as the aPTT and dilute Russell viper venom time. Anticardiolipin antibodies are detected by ELISA assays.

Both antibodies are associated with thrombosis. Although common in persons with collagen–vascular disorders such as systemic lupus erythematosus, they occur following drug exposure, infection, and lymphoproliferative diseases. They are also present in some well individuals.

Treatment for a thrombosis in a person found to have an antiphospholipid antibody is generally with heparin anticoagulation. Alternatives are local instillation of a fibrinolytic agent or systemic fibrinolysis. Anticoagulation with warfarin should be continued until the antiphospholipid antibody has resolved. The risk for recurrent thrombosis is high if anticoagulation is discontinued prematurely.

■ SPLENIC ABNORMALITIES

SPLENOMEGALY & HYPERSPLENISM

The differential diagnosis of splenomegaly includes the general categories of congestive splenomegaly, chronic infections, leukemia and lymphomas, hemolytic anemias, reticuloendothelioses, and storage diseases (Table 27–9).

Splenomegaly due to any cause may be associated with hypersplenism and the excessive destruction of circulating red cells, white cells, and platelets. The degree of cytopenia is variable and, when mild, requires no specific therapy. In other cases, the thrombocytopenia may cause life-threatening bleeding, particularly when the splenomegaly is secondary to portal hypertension and associated with esophageal varices or the consequence of a storage disease. In such cases, treatment with surgical splenectomy or with splenic embolization may be warranted. Although more commonly associated with acute enlargement, rupture of an enlarged spleen can be seen in more chronic conditions such as Gaucher disease.

Stone DL et al: Life threatening splenic hemorrhage in two patients with Gaucher's disease. *Am J Hematol* 2000;64:140 [PMID: 10814997].

ASPLENIA & SPLENECTOMY

Children who lack normal splenic function are at risk for sepsis, meningitis, and pneumonia due to encapsulated bacteria such as pneumococci and *H influenzae*. Such infections are often fulminant and fatal because of inadequate antibody production and impaired phagocytosis of circulating bacteria.

Congenital asplenia is usually suspected when an infant is born with abnormalities of abdominal viscera and complex cyanotic congenital heart disease. Howell–Jolly bodies are usually present on the peripheral blood smear, and the absence of splenic tissue is confirmed by technetium radionuclide scanning. The prognosis depends on the underlying cardiac lesions, and many children die during the first few months. Prophylactic antibiotics, usually penicillin, and pneumococcal conjugate and polysaccharide vaccines are recommended.

The risk of overwhelming sepsis following surgical splenectomy is related to the child's age and to the underlying disorder. Because the risk is highest when the procedure is performed earlier in life, splenectomy is usually postponed until after age 5 years. The risk of postsplenectomy sepsis is also greater in children with malignancies, thalassemias, and reticuloendothelioses than in children whose splenectomy is performed for ITP, hereditary spherocytosis, or trauma. Prior to splenectomy, children should be immunized against *Pneumococcus*, *H influenzae*, and *Neisseria meningitidis*. Additional management should include penicillin prophylaxis and prompt evaluation for fever 38.8°C or above or signs of severe infection.

Children with sickle cell anemia develop functional asplenia during the first year of life, and overwhelming sepsis is the leading cause of early deaths in this disease. Prophylactic penicillin has been shown to reduce the incidence of sepsis by 84%.

Pickering L; American Academy of Pediatrics: Immunization in special circumstances. *Red Book* 2000;25:66.

■ TRANSFUSION MEDICINE

DONOR SCREENING & BLOOD PROCESSING: RISK MANAGEMENT

Minimizing the risks of transfusion begins by asking the donor questions that will protect the recipient from transmission of infectious agents as well as other risks of

Table 27–9. Causes of chronic splenomegaly in children.

Cause	Associated Clinical Findings	Diagnostic Investigation
Congestive splenomegaly	History of umbilical vein catheter or neonatal omphalitis; signs of portal hypertension (varices, hemorrhoids, dilated abdominal wall veins); pancytopenia, history of hepatitis or jaundice	Complete blood count, platelet count, liver function tests, ultrasonography
Chronic infections	History of exposure to tuberculosis, histoplasmosis, coccidioidomycosis, other fungal disease; chronic sepsis (foreign body in bloodstream); subacute infective endocarditis)	Appropriate cultures and skin tests, ie, blood cultures; PPD, fungal serology and antigen tests; chest film; HIV serology
Infectious mononucleosis	Fever, fatigue, pharyngitis, rash, adenopathy, hepatomegaly	EBV antibody titers
Leukemia, lymphoma, Hodgkin disease	Evidence of systemic involvement with fever, bleeding tendencies, hepatomegaly, and lymphadenopathy; pancytopenia	Blood smear, bone marrow examination, chest film, gallium scan, LDH, uric acid
Hemolytic anemias	Anemia, jaundice; family history of anemia, jaundice, and gallbladder disease in young adults	Reticulocyte count, Coombs' test, blood smear, osmotic fragility test, hemoglobin electrophoresis
Reticuloendothelioses (histiocytosis X)	Chronic otitis media, seborrheic or petechial skin rashes, anemia, infections, lymphadenopathy, hepatomegaly, bone lesions	Skeletal x-rays for bone lesions; biopsy of bone, liver, bone marrow, or lymph node
Storage diseases	Family history of similar disorders, neurologic involvement, evidence of macular degeneration, hepatomegaly	Biopsy of liver or bone marrow in search for storage cells
Splenic cyst	Evidence of other infections (postinfectious cyst) or congenital anomalies; peculiar shape of spleen	Radionuclide scan, ultrasonography
Splenic hemangioma	Other hemangiomas, consumptive coagulopathy	Radionuclide scan, arteriography, platelet count, coagulation screen

PPD = purified protein derivative; EBV = Epstein–Barr virus; LDH = lactic dehydrogenase; HIV = human immunodeficiency virus.

transfusions. In addition, information defining high-risk groups whose behavior increases the possible transmission of AIDS, hepatitis, and other diseases is provided, with the request that persons in these groups not donate blood.

Before blood components can be released for transfusion, donor blood is screened for antibodies to hepatitis B, hepatitis C, HIV-1 and HIV-2, and human T-cell lymphotropic virus (HTLV) I and II; and a serologic test for syphilis is performed. Testing for hepatitis B surface antigen and HIV p24 antigen is also performed. Screening donor blood for viral genome was mandated for HIV and HCV early in 2003. NAT testing for West Nile Virus was begun in 2003. Detection of other viral genomes may be expanded. The aminotransferases may

be measured as surrogate tests for hepatitis (Table 27–10). Positive tests are repeated, and on their confirmation the unit in question is destroyed and the donor placed in a deferral category. Many of the screening tests used are very sensitive and have a high rate of false-positive results. As a result, confirmatory tests have been developed to check the initial screening results and separate the false-positives from the true-positives.

With these techniques, the risk of an infectious complication from blood components has been minimized (see Table 27–10), with the greatest risk being posttransfusion hepatitis (see sections on hepatitis C virus and non-A, non-B, non-C hepatitis in Chapter 21). Autologous donation is recognized by some centers as a safe alternative to homologous blood. Issues of

Table 27–10. Transmission risks of infectious agents for which screening of blood products is routinely performed.

Disease Entity	Transmission	Screening and Processing Procedures	Approximate Risk of Transmission
Syphilis	Low risk that fresh blood drawn during spirochetemia can transmit infection. Organism not able to survive beyond 72 hours during storage at 4°C.	Donor history. RPR or VDRL.	< 1:100,000
Hepatitis A	Units drawn during prodrome could transmit virus. Because of brief viremia during acute phase, absence of asymptomatic carrier phase, and failure to detect transmission in multiple transfused individuals, infection by this agent is unlikely.	Donor history.	1:1,000,000
Hepatitis B	Prolonged viremia during various phases of the disease and asymptomatic carrier state make HBV infection a significant risk of transfusion. Incidence has markedly decreased with screening strategies.	Donor history, education, and self-exclusion. Hepatitis B surface antigen (HBsAg). Surrogate tests for non-A, non-B hepatitis and screen for hepatitis C and retroviruses have helped screen out population at risk for transmitting hepatitis B virus.	1:250,000–1:30,000
Hepatitis C	Over two-thirds of cases of non-A, non-B posttransfusion hepatitis may be due to this agent. The virus has characteristics similar to those of HBV which are responsible for the risk from transfusion. Infection may lead to a significant incidence of cirrhosis and end-stage liver disease.	Donor history. Surrogate tests: ALT and hepatitis B core antibody (anti-HBc), anti-HCV. Nucleic acid testing for viral genome required.	1:1,600,000
Non-A, non-B, non-C hepatitis	Not a specific cause but a classification of agents other than HAV, HBV, HCV, Epstein-Barr virus, and cytomegalovirus, which can cause posttransfusion hepatitis.	Donor history. Surrogate tests: ALT and anti-HBc.	Undefined
Human immunodeficiency virus (HIV-1, HIV-2) infection	Cytotoxic retrovirus spread by sexual contact, parenteral (including transfusion) and vertical routes. Resultant destruction of CD4-positive cells leads to in clinical manifestations of AIDS.	Donor history, education, and self-exclusion. Anti-HIV by EIA, screening test. Western blot confirmatory. P ²⁴ antigen testing. Nucleic acid testing for viral genome required.	1:2,000,000–1:1,500,000
Human T-cell lymphotropic virus I and II (HTLV-I and -II) infection	Retroviruses spread by sexual contact, parenteral (including transfusion) and vertical modes. Over years to decades, infection with HTLV-I may cause lymphoid malignancies or myelopathy.	Donor history. Anti-HTLV-I and -II by enzyme immunoassay screening test. Western blot confirmatory.	1:600,000

ALT = alanine transaminase; HAV, HBV, HCV = hepatitis A virus, hepatitis B virus, hepatitis C virus; HTLV = human T-cell lymphotropic virus; RPR = rapid plasma reagin; VDRL = syphilis test; AIDS = acquired immunodeficiency syndrome.

donor size make the techniques of autologous donation difficult to apply to the pediatric population.

Primary CMV infections are significant complications of blood transfusion in transplant recipients, neonates, and immunodeficient individuals. Transmission of CMV can be avoided by using seronegative donors, apheresis platelet concentrates collected by techniques ensuring low numbers of residual white cells, or red cell or platelet products leukodepleted by filtering (white blood cell counts less than 5 million per packed red cell unit or apheresis platelet concentrate equivalent).

STORAGE & PRESERVATION OF BLOOD & BLOOD COMPONENTS

Whole blood is routinely fractionated into packed red cells, platelets, and FFP or cryoprecipitate for most efficient use of all blood components. The storage conditions and biologic characteristics of the fractions are summarized in Table 27-11. The conditions provide the optimal environment to maintain appropriate recovery, survival, and function and are different for each blood component. For example, red cells undergo dramatic metabolic changes during their 35-day storage, with a decrease in 2,3-DPG during the second week of storage, a decrease in ATP, and a gradual loss of intracellular potassium into the plasma. Fortunately, these changes are reversed readily within hours to days after the red cells are transfused. However, in certain clinical conditions, these effects may define the type of components used. For example, blood less than 7-10 days old would be preferred for exchange transfusion or replacement of red cells in persons with cardiopulmonary disease to ensure adequate oxygen-carrying capacity. However, storage time is not an issue when administering transfusions to those with chronic anemia.

Under certain conditions in which excessive potassium load is a problem, one has the option of using blood less than 10 days old, making packed cells out of an older unit of whole blood, or washing blood stored as packed cells. Regardless of the blood's age, over 70% of the red cells will circulate after transfusion and approximate normal survival in the circulation.

Platelets can be stored at 22°C for a maximum of 5 days. At the extremes of storage, there should be at least a 60% recovery, a survival time that approximates turnover of fresh autologous platelets, and normalization of the bleeding time in proportion to the peak platelet count. Frozen components, red cells, FFP, and cryoprecipitate are outdated at 3 years, 1 year, and 1 year, respectively. Frozen red cells retain the same biochemical and functional characteristics as the day they were frozen. FFP contains 80% or more of all of

the clotting factors of fresh plasma. Factor VIII and fibrinogen are concentrated in cryoprecipitate.

PRETRANSFUSION TESTING

Both the donated blood and the recipient are tested for ABO and Rh(D) antigens and for autoantibodies or alloantibodies. The cross-match is required on any component that contains red cells. In the major cross-match, washed donor red cells are incubated with the serum from the patient, and agglutination is detected and graded. The antiglobulin phase of the test is then performed; Coombs reagent, which will detect the presence of IgG or complement on the surface of the red cells, is added to the mixture, and any possible reaction is evaluated. In the presence of a negative antibody screen in the recipient, a negative antiglobulin phase or immediate spin cross-match test confirms the compatibility of the blood. Further testing is required if the antibody screen or the cross-match is positive, and blood should not be given until the nature of the reactivity is delineated. An incompatible cross-match is evaluated first with a direct antiglobulin or Coombs test to detect IgG or complement on the surfaces of the recipient's red cells. The indirect antiglobulin test is also used to determine the presence of antibodies that will coat or activate complement on the surfaces of normal red cells.

TRANSFUSION PRACTICE

General Rules

Several rules should be observed in administering any blood component:

1. In final preparation of the component, no solutions should be added to the bag or tubing set except for normal saline (0.9% sodium chloride for injection, USP), ABO-compatible plasma, or other specifically approved expanders. Hypotonic solutions cause hemolysis of red cells, and, if these are transfused, a severe reaction will occur.
2. Transfusion products should be protected from contact with any calcium-containing solution (eg, lactated Ringer's); recalcification and reversal of the citrate effect will cause clotting of the blood component.
3. Blood components should not be warmed to a temperature greater than 37°C. If a component is incubated in a water bath, it should be enclosed in a watertight bag to prevent contamination of entry ports.
4. Whenever a blood bag is entered, the sterile integrity of the system is violated, and that unit

Table 27–11. Characteristics of blood and blood components.

Component	Storage Conditions	Composition and Transfusion Characteristics	Indications	Risks and Precautions	Administration
Whole blood	<p>4°C for 35 d. RBC characteristics:</p> <p>Survival: Recovery decreases during storage but is always > 70%. Cells that circulate approximate normal survival.</p> <p>Function: 2,3-DPG levels fall to undetectable after second week of storage. This defect repaired within 24 h of transfusion.</p> <p>Electrolytes: With storage, potassium increases in plasma. This rises to high levels after 2 wk of storage.</p>	<p>Contains RBCs and many plasma compounds of whole blood. Leukocytes and platelets lose activity or viability after a few days under these conditions. Procoagulant clotting factors (particularly VIII and V) deteriorate rapidly during storage. Each unit has about 500 mL volume and Hct 36–40%.</p>	<p>Oxygen carrying capacity (anemia). Volume replacement for blood loss (> 15–20%) or severe shock.</p>	<p>Must be ABO-identical and cross-match-compatible. Infectious diseases. Febrile or hemolytic transfusion reactions. Alloimmunization to red cell, white cell, or platelet antigens.</p>	<p>During acute blood loss, as rapidly as tolerated. In other settings, 2–4 h. 10 mL/kg will raise Hct by 5% and support volume.</p>
Packed red cells	<p>Same as for whole blood. Special rejuvenating solutions allow storage for 42 d.</p>	<p>Contains RBCs; plasma removed in preparation. Status of leukocytes, clotting factors, and platelets same as for whole blood. Hct about 70%, volume 200–250 mL. May request tighter pack to give Hct 80–90%.</p>	<p>Oxygen carrying capacity. Acute trauma or bleeding or situations requiring intensive cardiopulmonary support (Hct < 25–30%). Chronic anemia (Hct < 20%).</p>	<p>Same as for whole blood.</p>	<p>May be given as patient will tolerate based on cardiovascular status over 2–4 hours. Dose of 3 mL packed RBC/kg will raise the Hct by 3%. If cardiovascular status stable, give 10 mL/kg over 2–4 h. If unstable, use smaller volume or do packed RBC exchange.</p>

Washed or filtered red cells	When cells are washed, there is a 24-h outdate. Up to that time, they have the same characteristics as for packed red cells.	Same as for packed red cells	Same as packed red cells. Depending on technique used and extent of reduction of white blood cells, washed red cells may achieve the following: <ul style="list-style-type: none"> • Avoid febrile reactions. • Decrease the transmission of CMV. • Decrease the incidence of alloimmunization to white cell antigens. 	Same as whole blood. Removal of white cells diminishes the risk of febrile reactions. Filtration with high-efficiency white cell filters may decrease rate of alloimmunization to white cell antigens and transmission of CMV.	Same as for packed red cells.
Frozen red cells	Packed red cells frozen in 40% glycerol solution at less than -65°C . Stored 3 years. Retain the same biochemical characteristics, function, and capacity for survival as the day in storage they were frozen; when thawed, 24-h outdate.	Same as for packed red cells.	Same as packed red cells. Useful for avoiding febrile reactions, decreasing transmission of CMV, autologous blood donation, and developing an inventory of rare red cell blood groups.	Same as for whole blood. Risk of CMV transmission is at same level as using seronegative components.	Same as for packed red cells.
Fresh frozen plasma	Plasma from whole blood stored at under -18°C for up to 1 year	Contains > 80% of all procoagulant and anticoagulant plasma proteins	Replacement of plasma procoagulant and anticoagulant plasma proteins. May provide "other" factors, eg, treatment of TTP.	Need not be cross-matched; should be type-compatible. Volume overload, infectious diseases, allergic reactions. Solvent detergent-treated plasma or donor-retested plasma units have decreased risk for viral transmission.	As rapidly as tolerated by patient but not > 4 hours. Dose: 10–15 mL/kg will increase level of all clotting factors by 10–20%.
Cryoprecipitate	Produced by freezing fresh plasma to under -65°C , then allowing to thaw 18 hours at 4°C . After centrifugation, cryoprecipitable proteins are separated. May be stored at under -18°C for up to 1 y.	Contains factor VIII, fibrinogen, and fibronectin at concentrations greater than those of plasma. Also contains factor XIII. VIII > 80 IU/pack, fibrinogen 100–350 mg/pack.	Treatment of acquired or congenital deficiencies of VIII, von Willebrand factor, and fibrinogen. Useful in making biologic glues that contain fibrinogen. Commercial clotting factor concentrates are the treatment of choice for factor VIII deficiency and von Willebrand disease because sterilization procedures further reduce the risk of viral transmission.	Same as for fresh frozen plasma. ABO agglutinogens may also be concentrated and can give positive direct agglutination test if not type-specific	Cryoprecipitate can be given as a rapid infusion. Dose: $\frac{1}{2}$ pack per kg body weight will increase factor VIII level by 80–100% and fibrinogen by 200–250 mg/dL.

(continued)

Table 27–11. Characteristics of blood and blood components. (continued)

Component	Storage Conditions	Composition and Transfusion Characteristics	Indications	Risks and Precautions	Administration
Platelet concentrates from whole blood donation	Separated from platelet-rich plasma and stored with gentle agitation at 22°C for 3–5 d. Containers currently in use are plastic and allow for gas exchange, diffusion of CO ₂ helps keep pH > 6.00, a major factor in keeping platelets viable and functional.	Each unit contains about 5 × 10 ¹⁰ platelets. Survival: Although there may be some loss with storage, 60–70% recovery should be achieved, with stored platelets correcting the bleeding time in proportion to the peak counts reached.	Treatment of thrombocytopenia or platelet function defects.	No cross-match necessary. Should be ABO type-specific. Other risks as for whole blood.	Can be given as rapid transfusion or as defined by cardiovascular status, not more than 4 h. Dose: 10 mL/kg should increase platelet count by at least 50,000/μL.
906 Platelet concentrates by apheresis techniques	Same as random donor units	Platelet content is equivalent to 6–10 units of random donor concentrates. Depending on technique used, these may be relatively free of leukocytes, a product useful in avoiding alloimmunization.	As above, particularly useful in treating patients who have insufficient production in whom alloimmunization is a potential problem.	Same as above.	As above.
Granulocytes	Although they may be stored stationary at 20–24°C, transfuse as soon as possible after collection	Contains at least 1 × 10 ¹⁰ granulocytes but also platelets and red cells. When donors given 10 μg/kg G-CSF subcutaneously and 8 mg decadron orally 12–15 h before collection increases to > 5 × 10 ¹⁰ granulocytes.	Severely neutropenic individuals (< 500/μL) with poor marrow reserves and suspected bacterial or fungal infections not responding to 48–72 h of parenteral antibiotics. Also in patients with neutrophil dysfunction.	Same as for platelets. Pulmonary leukostasis reactions. Severe febrile reactions.	Given in an infusion over 2–4 h. Dose: 1 unit daily for newborns and infants, 1 × 10 ⁹ granulocytes per kg.

CMV = cytomegalovirus; G-CSF = granulocyte colony-stimulating factor; Hct = hematocrit; RBC = red blood cell; TTP = thrombotic thrombocytopenic purpura.

should be discarded within 4 hours if left at room temperature or within 24 hours if the temperature is between 1°C and 4°C.

5. Transfusions of products containing red cells should not exceed 4 hours. Blood components in excess of what can be infused during this time period should be stored in the blood bank until needed.
6. Before transfusion, the blood component should be inspected visually for any unusual characteristics—such as the presence of flocculent material, hemolysis, or clumping of cells—and mixed thoroughly.
7. The unit and the recipient should be identified properly.
8. The administration set includes a standard 170–260 mm clot filter. Under certain clinical circumstances, an additional microaggregate filter may be used to eliminate small aggregates of fibrin, white cells, and platelets that will not be removed by the standard filter.
9. The patient should be observed during the entire transfusion but especially during the first 15 minutes. Any adverse symptoms or signs should be evaluated immediately and reactions to the transfusion reported promptly to the transfusion service.
10. When cross-match-incompatible red cells or whole blood unit(s) must be given to the patient (as with autoimmune hemolytic anemia), a test dose of 10% of the total volume (not to exceed 50 mL) should be administered over 15–20 minutes; the transfusion is then stopped and the patient evaluated for reaction. If no adverse effects are noted, the remainder of the volume can be infused carefully.
11. Blood for exchange transfusion in the newborn period may be cross-matched with either the infant's or the mother's serum. If the exchange is for hemolysis, 500 mL of whole blood stored for less than 7 days will be adequate. If replacement of clotting factors is a key issue, packed red cells (7 days old) reconstituted with FFP may be considered. Based on posttransfusion platelet counts, platelet transfusion may be considered. Other problems to be anticipated are acid–base derangements, hyponatremia, hyperkalemia, hypocalcemia, hypoglycemia, hypothermia, and hypervolemia or hypovolemia.

Choice of Blood Component

Several principles should be considered when deciding on the need for blood transfusion. Indications for blood

or blood components must be well defined, and the patient's medical condition, not just the laboratory results, should be the basis for the decision. Specific deficiencies exhibited by the patient (eg, oxygen-carrying capacity, thrombocytopenia) should be treated with appropriate blood components and the use of whole blood minimized. Information about specific blood components is summarized in Table 27–11.

A. WHOLE BLOOD

Whole blood may be used in patients who require replacement of oxygen-carrying capacity and volume. More specifically, it should be considered when more than 15% of blood volume is lost. Doses vary depending on volume considerations (see Table 27–11). In acute situations, the transfusion may be completed rapidly to support blood volume.

B. PACKED RED CELLS

Packed red cells (which include leukocyte-poor, filtered, or frozen deglycerolized products) prepared from whole blood by centrifugal techniques are the appropriate choice for almost all patients with deficient oxygen-carrying capacity. Exact indications will be defined by the clinical setting, the severity of the anemia, the acuity of the condition, and any other factors affecting oxygen transport.

C. PLATELETS

The decision to transfuse platelets depends on the patient's clinical condition, the status of plasma phase coagulation, the platelet count, the cause of the thrombocytopenia, and the functional capacity of the patient's own platelets. With platelet counts less than 10,000–20,000/ μ L, the risk of severe, spontaneous bleeding is increased markedly, and—in the absence of antibody-mediated thrombocytopenia—transfusion should be considered. Under certain circumstances, especially with platelet dysfunction or treatment that inhibits the procoagulant system, transfusions at higher platelet counts may be necessary.

Transfused platelets are sequestered temporarily in the lungs and spleen before reaching their peak concentrations, 45–60 minutes after transfusion. A significant proportion of the transfused platelets never circulate but remain sequestered in the spleen. This phenomenon results in reduced recovery; only 60–70% of the transfused platelets are accounted for when peripheral platelet count increments are used as a measure of response.

In addition to cessation of bleeding, two variables indicate the effectiveness of platelet transfusions. The first is platelet recovery, as measured by the maximum number of platelets circulating in response to transfusion. The practical measure is the platelet count at

Table 27–12. Adverse events following transfusions.

Event	Pathophysiology	Signs and Symptoms	Management
Acute hemolytic transfusion reaction	Preformed alloantibodies (most commonly to ABO) and occasionally autoantibodies cause rapid intravascular hemolysis of transfused cells with activation of clotting (DIC), activation of inflammatory mediators, and acute renal failure.	Fever, chills, nausea, chest pain, back pain, pain at transfusion site, hypotension, dyspnea, oliguria, dark urine.	The risk of this type of reaction overall is low (1:30,000), but the mortality rate is high (up to 40%). Stop the transfusion; maintain renal output with intravenous fluids and diuretics (furosemide or mannitol); treat DIC with heparin; and institute other appropriate supportive measures.
Delayed hemolytic transfusion reaction	Formation of alloantibodies after transfusion and resultant destruction of transfused red cells, usually by extravascular hemolysis.	Fever, jaundice, anemia. A small percentage may develop chronic hemolysis.	Detection, definition, and documentation (for future transfusions). Supportive care. Risk, 1:2500.
Febrile reactions	Usually caused by leukoagglutinins in recipient cytokines or other biologically active compounds.	Fever. May also involve chills.	Supportive. Consider leukocyte-poor products for future. Risk per transfusion, 1:200.
Allergic reactions	Most causes not identified. In IgA-deficient individuals, reaction occurs as a result of antibodies to IgA.	Itching, hives, occasionally chills and fever. In severe reactions, may see signs of anaphylaxis: dyspnea, pulmonary edema.	Mild to moderate reactions: diphenhydramine. More severe reactions: epinephrine subcutaneously and steroids intravenously. Risk for mild to moderate allergic reactions, 1:1000; severe anaphylactic reactions, 1:150,000.
Transfusion-related acute lung injury	Acute lung injury occurring within 4 h after transfusion. Two sets of factors interact to produce the syndrome. Patient factors: infection, surgery, cytokine therapy. Blood component factors: lipids, antibodies, cytokines. Two groups of factors interact during transfusion to result in lung injury indistinguishable from ARDS.	Tachypnea, dyspnea, hypoxia. Diffuse interstitial markings. Cardiac evaluation normal.	May consider younger products: packed red blood cells \leq 2 weeks, platelets \leq 3 days, washing components to prevent syndrome. Management: supportive care. Risk, 1:2000–1:3000 per transfusion.
Dilutional coagulopathy	Massive blood loss and transfusion with replacement with fluids or blood components and deficient clotting factors.	Bleeding.	Replacement of clotting factors or platelets with appropriate blood components.
Bacterial contamination	Contamination of units results in growth of bacteria or production of clinically significant levels of endotoxin.	Chills, high fever, hypotension, other symptoms of sepsis or endotoxemia.	Stop transfusion; make aggressive attempts to identify organism; provide vigorous supportive medical care including antibiotics
Graft-versus-host disease	Lymphocytes from donor transfused in an immunoincompetent host.	Syndrome can involve a variety of organs, usually skin, liver, gastrointestinal tract, and bone marrow.	Preventive management: irradiation ($>$ 1500 cGy) of cellular blood components transfused to individuals with congenital or acquired immunodeficiency syndromes, intrauterine transfusion, very premature infants, and when donors are relatives of the recipient.

(continued)

Table 27–12. Adverse events following transfusions. (continued)

Event	Pathophysiology	Signs and Symptoms	Management
Iron overload	There is no physiologic mechanism to excrete excess iron. Target organs include liver, heart, and endocrine organs. In patients receiving red cell transfusions over long periods of time, there is an increase in iron burden.	Signs and symptoms of dysfunctional organs affected by the iron.	Chronic administration of iron chelator such as deferoxamine.

DIC = disseminated intravascular coagulation; ARDS = adult respiratory distress syndrome.

1 hour after transfusion. In the absence of immune or drastic nonimmune factors that markedly decrease platelet recovery, one would expect a 7000/ μ L increment for each random donor unit and a 40,000–70,000/ μ L increment for each single-donor apheresis unit in a large child or adolescent. For infants and small children, 10 mL/kg of platelets will increase the platelet count by at least 50,000/ μ L. The second variable is the survival of transfused platelets. Normally, transfused platelets have a half-life of 3–5 days. In the presence of immune or nonimmune destruction, the life span may be shortened to a few days or a few hours. Frequent platelet transfusions may be required to maintain adequate hemostasis.

A particularly troublesome outcome in patients receiving long-term platelet transfusions is the development of a refractory state characterized by poor (< 30%) recovery or no response to platelet transfusion (as measured at 1 hour). Most (70–90%) of these refractory states result from the development of alloantibodies directed against HLA antigens on the platelet. Platelets have class I HLA antigens, and the antibodies are primarily against HLA A or B determinants. A smaller proportion of these alloantibodies (10%) may be directed against platelet-specific alloantigens. The most effective approach to prevent HLA sensitization is to use leukocyte-depleted components (< 5 million leukocytes per unit of packed red cells or per apheresis or 6–10 random donor unit concentrates). For the alloimmunized, refractory patient, the best approach is to provide HLA-matched platelets for transfusion. Reports have suggested that platelet cross-matching procedures using HLA-matched or unmatched donors may be helpful in identifying platelet concentrates most likely to provide an adequate response.

D. FRESH FROZEN PLASMA

The indication for FFP is replacement of plasma coagulation factors in clinical situations in which a deficiency of one or more clotting factors exists and associated

bleeding manifestations are present. In some hereditary factor deficiencies such as factor VIII deficiency or von Willebrand disease, commercially prepared concentrates contain these factors in higher concentrations and, because of viral inactivation, impose less infectious risk and are more appropriate than plasma.

E. CRYOPRECIPITATE

This component may be used for acquired or congenital disorders of hypofibrinogenemia or afibrinogenemia. Although cryoprecipitate is a rich source for factor VIII or vWF, commercial concentrates that contain these factors are more appropriate (see preceding section). The dose given depends on the protein to be replaced. Cryoprecipitate can be given in a rapid transfusion over 30–60 minutes.

F. GRANULOCYTES

With better supportive care over the past 10 years, the need for granulocytes in neutropenic patients with severe bacterial infections has decreased. Indications still remain for severe bacterial infections unresponsive to vigorous medical therapy in either newborns or older children with bone marrow failure, or patients with neutrophil dysfunction. Newer mobilization schemes using G-CSF and steroids in donors result in granulocyte collections with at least 5×10^{10} neutrophils. This may provide a better product for patients requiring granulocyte support.

G. APHERESIS PRODUCTS AND PROCEDURES

Apheresis equipment allows one or more blood components to be collected from a donor while the rest are returned. Apheresis platelet concentrates, which have as many platelets as 6–10 units of platelet concentrates from whole blood donations, are one example; granulocytes another. Apheresis techniques can also be used to collect hematopoietic stem cells that have been mobilized into the blood by cytokines (G-CSF or GM-CSF) given alone or after chemotherapy. These stem cells are

used for autologous bone marrow transplantation. Blood cell separators can be used for the collection of single-source plasma or removal of a blood component that is causing disease. Examples include red cell exchange in sickle cell disease and plasmapheresis in Goodpasture syndrome or in myasthenia gravis.

Adverse Effects

The noninfectious complications of blood transfusions are outlined in Table 27–12. Most complications present a small but significant risk to the recipient.

Each year approximately 150 out of every 1 million children younger than 20 years of age are diagnosed with cancer. For children between the ages of 1 and 20 years, cancer is the fourth leading cause of death, behind unintentional injuries, homicides, and suicides. However, combined-modality therapy, including surgery, chemotherapy, and radiation therapy, has improved survival dramatically, such that the overall 5-year survival rate of pediatric malignancies is now greater than 75%. It is estimated that by the year 2020, one in 600 adults will be a survivor of childhood cancer.

Because pediatric malignancies are rare, cooperative clinical trials have become the mainstay of treatment planning and therapeutic advances. The Children's Oncology Group (COG), representing the amalgamation of four prior pediatric cooperative groups (Children's Cancer Group, Pediatric Oncology Group, Intergroup Rhabdomyosarcoma Study Group, and the National Wilms Tumor Study Group), offers the most current therapeutic options and protocols and strives to answer important treatment questions in a timely manner. A child or adolescent newly diagnosed with cancer should be enrolled in a cooperative clinical trial whenever possible. Because many protocols are associated with significant toxicities, morbidity, and potential mortality, treatment of children with cancer should be supervised by a pediatric oncologist familiar with the hazards of treatment, preferably at a multidisciplinary pediatric cancer center.

Advances in molecular genetics, cell biology, and tumor immunology have contributed to the understanding of pediatric malignancies and their treatment. It is important that biopsy specimens of suspected malignancies be examined by a pathologist familiar with pediatric and adolescent cancers and with the role of ancillary studies. In addition to formalin-fixed tissue, fresh unfixed tissue is essential for metaphase chromosome analysis and electron microscopy. Molecular techniques can sometimes detect an aberrant gene product that is not detectable with routine cytogenetics, ensuring greater diagnostic accuracy and leading to appropriate therapy. The polymerase chain reaction (PCR) also aids in the detection of minimal residual disease. In addition, molecular techniques can determine whether a pathologic process is monoclonal (arising from a single

cell and generally considered malignant) or polyclonal (arising from multiple cells and usually nonmalignant). Diverse rearrangements of the DNA of antigen receptor genes can characterize a benign process, whereas the cells of a lymphoma, for example, have uniform rearrangements.

Molecular techniques have also led to the characterization of oncogenes and tumor suppressor genes in human malignancies. An oncogene is one that causes malignant transformation or deregulated cell growth. For example, the proto-oncogene *c-myc* plays an important role in hematopoietic cell proliferation. It has been recognized at the site of three different translocations in Burkitt lymphomas: $t(8;14)$, $t(8;22)$, and $t(2;8)$. A tumor suppressor gene (antioncogene) constrains cell proliferation; its absence can lead to unchecked cell growth. The retinoblastoma gene is the prototypical tumor suppressor gene. Inactivation of both copies of this gene in a cell leads to tumor formation.

Research in supportive care areas, such as prevention and management of infection, pain, and emesis, has improved the survival and quality of life for children undergoing cancer treatment. Long-term studies of childhood cancer survivors are yielding information that provides a rationale for modifying future treatment regimens to decrease morbidity.

Ries LAG et al: *SEER Cancer Statistics Review, 1975–2000*, http://seer.cancer.gov/csr/1975_2000, 2003.

MAJOR PEDIATRIC NEOPLASTIC DISEASES

ACUTE LYMPHOBLASTIC LEUKEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bone marrow aspirate or biopsy specimen shows more than 25% lymphoblasts.
- Pallor, petechiae, purpura (50%), bone pain (25%).

- *Hepatosplenomegaly (60%), lymphadenopathy (50%).*
- *Single or multiple cytopenias: neutropenia, thrombocytopenia, anemia (99%).*
- *Leukopenia (15%) or leukocytosis (50%), often with lymphoblasts identifiable on blood smear.*
- *Diagnosis confirmed by bone marrow examination.*

General Considerations

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, accounting for about 25% of all cancer diagnoses in patients younger than age 15 years. The worldwide incidence of ALL is about 1:25,000 children per year, including 3000 children per year in the United States. The peak age at onset is 4 years; 85% of patients are diagnosed between ages 2 and 10 years. Before the advent of chemotherapy, this disease was fatal, usually within 3–4 months, with virtually no survivors 1 year after diagnosis.

ALL results from uncontrolled proliferation of immature lymphocytes. Its cause is unknown, and genetic factors may play a role. Leukemia is defined by the presence of more than 25% malignant hematopoietic cells (blasts) on bone marrow aspirate. Leukemic blasts from the majority of cases of childhood ALL have an antigen on the cell surface called the common ALL antigen (CALLA). These blasts derive from B-cell precursors early in their development. Less commonly, lymphoblasts are of T-cell origin or of mature B-cell origin. Over 70% of children receiving aggressive combination chemotherapy and early presymptomatic treatment to the central nervous system (CNS) are now cured of ALL.

Clinical Findings

A. SYMPTOMS AND SIGNS

Presenting complaints of patients with ALL include those related to decreased bone marrow production of red blood cells (RBCs), white blood cells (WBCs), or platelets and to leukemic infiltration of extramedullary (outside bone marrow) sites. Intermittent fevers are common, as a result of either cytokines induced by the leukemia itself or infections secondary to leukopenia. About 25% of patients experience bone pain, especially in the pelvis, vertebral bodies, and legs. Physical examination at diagnosis ranges from virtually normal to highly abnormal. Signs related to bone marrow infiltration by leukemia include pallor, petechiae, and pur-

pura. Hepatomegaly or splenomegaly occurs in over 60% of patients. Lymphadenopathy is common, either localized or generalized to cervical, axillary, and inguinal regions. The testes may be unilaterally or bilaterally enlarged secondary to leukemic infiltration. Superior vena cava syndrome is caused by mediastinal adenopathy compressing the superior vena cava. A prominent venous pattern develops over the upper chest from collateral vein enlargement. The neck may feel full from venous engorgement. The face may appear plethoric, and the periorbital area may be edematous.

A mediastinal mass can cause tachypnea, orthopnea, and respiratory distress. Leukemic infiltration of cranial nerves may cause cranial nerve palsies with mild nuchal rigidity. The optic fundi may show exudates of leukemic infiltration and hemorrhage from thrombocytopenia. Anemia can cause a flow murmur, tachycardia, and, rarely, congestive heart failure. Bone and joint pain may be found on examination, particularly in the pelvis, lower spine, and femurs. Signs of infection may also be present.

B. LABORATORY FINDINGS

A complete blood count (CBC) with differential is the most useful initial test because 95% of patients with ALL have a decrease in at least one cell type (single cytopenia): neutropenia, thrombocytopenia, or anemia. Most patients have decreases in at least two blood cell lines. The WBC count is low or normal ($\leq 10,000/\mu\text{L}$) in 50% of patients, but the differential shows neutropenia (absolute neutrophil count $< 1000/\mu\text{L}$) along with a small percentage of blasts amid normal lymphocytes. In 30% of patients the WBC count is between 10,000 and 50,000/ μL ; in 20% of patients it is over 50,000/ μL , occasionally higher than 300,000/ μL . Blasts are usually readily identifiable on peripheral blood smears from patients with elevated WBC counts. Peripheral blood smears also show abnormalities in RBCs, such as tear drops. Most patients with ALL have decreased platelet counts ($< 150,000/\mu\text{L}$) and decreased hemoglobin ($< 11 \text{ g/dL}$) at diagnosis. Fewer than 1% of patients diagnosed with ALL have entirely normal CBCs and peripheral blood smears but have bone pain that leads to bone marrow examination. Serum chemistries, particularly uric acid and lactate dehydrogenase (LDH), are often elevated at diagnosis as a result of cell breakdown. Serum phosphorus is occasionally elevated at diagnosis as well.

The diagnosis of ALL is made by bone marrow examination, which shows a homogeneous infiltration of leukemic blasts replacing normal marrow elements. The morphology of blasts on bone marrow aspirate can usually distinguish ALL from acute myeloid leukemia (AML). Lymphoblasts are typically small, with cell di-

ameters of approximately two erythrocytes. Lymphoblasts have scant cytoplasm, usually without granules. The nucleus typically contains no nucleoli or one small, indistinct nucleolus. Immunophenotyping of ALL blasts by flow cytometry helps distinguish precursor B-cell ALL from T-cell ALL or AML. Histochemical stains specific for myeloblastic and monoblastic leukemias (myeloperoxidase and nonspecific esterase) distinguish ALL from AML. About 5% of patients present with CNS leukemia, which is defined as a cerebrospinal fluid (CSF) WBC count > 5/μL with blasts present on cytocentrifuged specimen.

C. IMAGING

Chest radiograph may show mediastinal widening or an anterior mediastinal mass and tracheal compression secondary to lymphadenopathy or thymic infiltration, especially in T-cell ALL. Abdominal ultrasound may show kidney enlargement from leukemic infiltration or uric acid nephropathy as well as intra-abdominal adenopathy. Plain radiographs of the long bones and spine may show demineralization, periosteal elevation, growth arrest lines, or compression of vertebral bodies.

Differential Diagnosis

The differential diagnosis, based on the history and physical examination, includes chronic infections by Epstein–Barr virus (EBV) and cytomegalovirus (CMV), causing lymphadenopathy, hepatosplenomegaly, fevers, and anemia. Prominent petechiae and purpura suggest a diagnosis of immune thrombocytopenic purpura (ITP). Significant pallor could be caused by transient erythroblastopenia of childhood (TEC), autoimmune hemolytic anemias, or aplastic anemia. Fevers and joint pains, with or without hepatosplenomegaly and lymphadenopathy, suggest juvenile rheumatoid arthritis (JRA). The diagnosis of leukemia usually becomes straightforward once the CBC reveals multiple cytopenias and leukemic blasts. Serum LDH levels may help distinguish JRA from leukemia. LDH is usually normal in JRA but often elevated in ALL patients presenting with bone pain. An elevated WBC count with lymphocytosis is typical of pertussis; however, in pertussis the lymphocytes are mature, and neutropenia is rarely associated.

Treatment

A. SPECIFIC THERAPY

Intensity of treatment is determined by specific prognostic features present at diagnosis or early in treatment. The majority of patients with ALL are enrolled in clinical trials designed by the Children's Oncology Group (COG) and approved by the National Cancer

Institute (NCI). The first month of therapy consists of induction, at the end of which over 95% of patients exhibit remission on bone marrow aspirates. The drugs most commonly used in induction include oral prednisone or dexamethasone, intravenous vincristine and daunorubicin, intramuscular asparaginase, and intrathecal methotrexate. For T-cell ALL, intravenous cyclophosphamide may be added during induction.

Consolidation is the second phase of treatment, during which intrathecal chemotherapy and sometimes cranial radiation therapy are given to kill lymphoblasts "hiding" in the meninges.

Maintenance therapy includes daily oral mercaptopurine, weekly oral methotrexate, and, often, monthly pulses of intravenous vincristine and oral prednisone or dexamethasone. Intrathecal chemotherapy, either with methotrexate alone or combined with cytarabine and hydrocortisone, is usually given every 2–3 months. Several months of intensive chemotherapy, termed delayed intensification, is generally interposed early within the maintenance chemotherapy phase of treatment.

These drugs have significant potential side effects. Patients need to be monitored closely to prevent drug toxicities and to ensure early treatment of complications. The duration of treatment ranges between 2.2 years for girls and 3.2 years for boys. Treatment for ALL is tailored to prognostic, or risk, groups. A child age 1–9 years with a WBC count under 50,000/μ L at diagnosis and without t(9;22) or t(4;11) is considered to be at "standard risk" and receives less intensive therapy than a "high-risk" patient who has a WBC count at diagnosis over 50,000/μ L or is older than age 10 years. This risk-adapted treatment approach has significantly increased the cure rate among patients with less favorable prognostic features while minimizing treatment-related toxicities in those with favorable features. Bone marrow relapse is usually heralded by an abnormal CBC, either during treatment or for a few years thereafter.

The CNS and testes are sanctuary sites of extramedullary leukemia. Currently, about a third of all ALL relapses are isolated to these sanctuary sites. Systemic chemotherapy does not penetrate these tissues as well as it penetrates other organs. Thus, presymptomatic intrathecal chemotherapy is a critical part of ALL treatment, without which many more relapses would occur in the CNS, with or without bone marrow relapse. The majority of isolated CNS relapses are diagnosed in an asymptomatic child at the time of routine intrathecal injection, when CSF cell count and differential shows an elevated WBC with leukemic blasts. Occasionally, symptoms of CNS relapse develop: headache, nausea and vomiting, irritability, nuchal rigidity, photophobia, and cranial nerve palsies. Previously, up to 15% of boys developed testicular relapse

following completion of chemotherapy. The presentation of testicular relapse is usually unilateral painless testicular enlargement, without a distinct mass. The incidence of testicular relapse has decreased significantly as treatment for ALL has intensified. Routine follow-up of boys both on and off treatment includes physical examination of the testes.

Bone marrow transplantation, now called hematopoietic stem cell transplantation (HSCT), is rarely used as initial treatment for ALL, because most patients are cured with chemotherapy alone. Patients whose blasts contain certain chromosomal abnormalities, such as t(9;22) or hypodiploidy (< 44 chromosomes), and infants with t(4;11) may have a better cure rate with early HSCT from an HLA-DR-matched sibling donor, or perhaps a matched unrelated donor, than with intensive chemotherapy alone. HSCT cures about 50% of patients who relapse, provided that a second remission is achieved with chemotherapy before transplant. Children who relapse more than 1 year after completion of chemotherapy (late relapse) may be cured with intensive chemotherapy without HSCT. A number of new biologic agents, including tyrosine kinase inhibitors and immunotoxins, are currently in various stages of research and development. Some of these therapies may prove relevant for future treatment of poor risk or relapsed ALL.

B. SUPPORTIVE CARE

Tumor lysis syndrome should be anticipated when treatment is started. Alkalinization of urine with intravenous sodium bicarbonate should be undertaken, and the patient should be hydrated and given oral allopurinol. If superior vena caval or superior mediastinal syndrome is present, general anesthesia is contraindicated temporarily. If hyperleukocytosis (WBC count > 100,000/ μ L) is accompanied by hyperviscosity and mental status changes, leukapheresis may be indicated to rapidly reduce the number of circulating blasts and minimize the potential thrombotic or hemorrhagic CNS complications. Severe anemia at diagnosis can usually be corrected with a number of small RBC transfusions and intravenous furosemide. Throughout the course of treatment, all transfused blood and platelet products should be irradiated to prevent graft-versus-host disease from the transfused lymphocytes. Whenever possible, blood products should be leukodepleted to minimize CMV transmission, transfusion reactions, and sensitization to platelets.

During the course of treatment, fever (temperature $\geq 38.3^{\circ}\text{C}$) and neutropenia (absolute neutrophil count < 500/ μ L) require treatment with empiric broad-spectrum antibiotics. Patients receiving ALL treatment must receive prophylaxis against *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*). Trimethoprim-sul-

famethoxazole given twice each day on 2 or 3 consecutive days per week is the drug of choice. Patients non-immune to varicella are at risk for very serious—even fatal—infection. Such patients should receive varicella-zoster immune globulin (VZIG) within 72 hours after exposure and treatment with intravenous acyclovir for active infection.

The treatment of a patient on chemotherapy for ALL is complex because of the infectious complications and potential toxicities of chemotherapy.

Prognosis

Cure rates depend on specific prognostic features present at diagnosis. The two most important features are WBC count and age. Children age 2–9 years whose diagnostic WBC count is less than 50,000/ μ L have a higher rate of cure than other patients. The rapidity of response to induction treatment has prognostic significance as well, reflecting leukemic blast sensitivity to chemotherapy. Patients are categorized as rapid early responders (RER) or slow early responders (SER) based on the percentage of blasts present in bone marrow aspirates within 7–14 days after induction begins. More intensive treatment regimens are given to SERs than RERs to increase their chance of cure. Certain chromosomal abnormalities present in the leukemic blasts at diagnosis influence prognosis. Patients with t(9;22) generally have a very poor chance of cure even with intensive chemotherapy. Likewise, infants with t(4;11) have a poor chance of cure with conventional chemotherapy. In contrast, the 15% of patients whose blasts are hyperdiploid (containing over 50 chromosomes instead of the normal 46) with trisomies of chromosomes 4, 10, and 17 have a greater chance of cure than do children without these trisomies. About 25% of children with ALL have blasts that contain a gene rearrangement between chromosomes 12 and 21, called TEL-AML1, detected by molecular but not by cytogenetic techniques. Children with the TEL-AML1 rearrangement appear to have an excellent prognosis. Techniques based on leukemic blast immunophenotyping or immunoglobulin rearrangements have been developed to detect residual lymphoblasts in bone marrow, called minimal residual disease (MRD), at the end of induction and during remission. In future COG clinical trials, patients with levels of MRD above a certain threshold at the end of remission induction will receive intensified therapy, in an attempt to improve their outcome.

ACUTE MYELOID LEUKEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bone marrow aspirate or biopsy shows 20% or more leukemic blasts.
- Fatigue, bleeding, or infection.
- Adenopathy, hepatosplenomegaly, skin nodules (M4 and M5 subtypes).
- Cytopenias: neutropenia (69%), anemia (44%), thrombocytopenia (33%).

General Considerations

Approximately 500 new cases of acute myeloid leukemia (AML) occur per year in children and adolescents in the United States. Although AML accounts for only 25% of all leukemias in this age group, it is responsible for at least one third of deaths from leukemia in children and teenagers. Congenital conditions associated with an increased risk of AML include Diamond–Blackfan anemia, neurofibromatosis, Down syndrome, Wiskott–Aldrich, Kostmann, and Li–Fraumeni syndromes, as well as chromosomal instability syndromes such as Fanconi anemia. Acquired risk factors include exposure to ionizing radiation, cytotoxic chemotherapeutic agents, and benzenes. However, the vast majority of patients have no identifiable risk factors. Historically, the diagnosis of AML was based almost exclusively on morphology and immunohistochemical staining of the leukemic cells. AML has eight subtypes (M0–M7) according to the French–American–British (FAB) classification (Table 28–1). Immunophenotypic, cytogenetic, and molecular analyses

are increasingly important in confirming the diagnosis of AML and subclassifying it into biologically distinct subtypes that have therapeutic and prognostic implications. Cytogenetic clonal abnormalities occur in 80% of patients with AML and are often predictive of outcome. Recently, the World Health Organization classified AML based on genetic, immunophenotypic, biologic, and clinical features, to more accurately characterize the distinct biologic and clinical behavior of the AML subtypes.

Aggressive induction therapy currently results in a 75–85% complete remission rate. However, long-term survival has improved only modestly to approximately 50%, despite the availability of a number of effective agents, improvements in supportive care, and increasingly intensive therapies.

Clinical and Laboratory Findings

The clinical manifestations of AML commonly include anemia (44%), thrombocytopenia (33%), and neutropenia (69%). Symptoms may be few and innocuous or may be life-threatening. The median hemoglobin value at diagnosis is 7 g/dL, and platelets usually number fewer than 50,000/ μ L. Frequently the absolute neutrophil count is under 1000/ μ L, although the total WBC count is over 100,000/ μ L in 25% of patients at diagnosis.

Hyperleukocytosis may be associated with life-threatening complications. Venous stasis and sludging of blasts in small vessels cause hypoxia, hemorrhage, and infarction, most notably in the lung and CNS. This clinical picture is a medical emergency requiring rapid intervention, such as leukopheresis, to decrease the leukocyte count. CNS leukemia is present in 5–15% of patients at diagnosis, a higher rate of initial involvement than in ALL. Certain subtypes, such as M4 and M5, have a higher likelihood of meningeal infiltration than do other subtypes. Additionally, clinically significant coagulopathy may be present at diagnosis in patients with M3, M4, or M5 subtypes. This problem manifests as bleeding or an abnormal disseminated intravascular coagulation screen and should be at least partially corrected prior to initiation of treatment, which may transiently exacerbate the coagulopathy.

Treatment

A. SPECIFIC THERAPY

AML is less responsive to treatment than ALL and requires more intensive chemotherapy. Toxicities from therapy are common and likely to be life-threatening; therefore, treatment should be undertaken only at a tertiary pediatric oncology center.

Table 28–1. FAB subtypes of acute myeloid leukemia.

FAB Classification	Common Name	Distribution in Childhood (Age)		Cytogenetic Associations	Clinical Features
		< 2 Years	> 2 Years		
M0	Acute myeloid leukemia, minimally differentiated		1%	inv (3q26), t(3;3)	
M1	Acute myeloblastic leukemia without maturation	17%	23%		
M2	Acute myeloblastic leukemia with maturation		26%	t(8;21) t(6;9); rare	Myeloblastomas or chloromas
M3	Acute promyelocytic leukemia		4%	t(15;17); rarely, t(11;17) or (5;17)	Disseminated intravascular coagulation
M4	Acute myelomonoblastic leukemia	30%	24%	11q23, inv 3, t(3;3), t(6;9)	Hyperleukocytosis, CNS involvement, skin and gum infiltration
M4Eo	Acute myelomonoblastic leukemia with abnormal eosinophils			inv16, t(16;16)	
M5	Acute monoblastic leukemia	46%	15%	11q23, t(9;11), t(8;16)	Hyperleukocytosis, CNS involvement, skin and gum infiltration
M6	Erythroleukemia		2%		
M7	Acute megakaryoblastic leukemia	7%	5%	t(1;22)	Down syndrome frequent (< 2 years of age)

FAB = French–American–British classification; CNS = central nervous system.

Current AML protocols rely on intensive administration of anthracyclines, cytarabine, dexamethasone, 6-thioguanine, and etoposide for induction of remission. Studies have shown that intensively timed multiagent induction therapy results in significant improvement in outcome compared with standard timing for non-Down syndrome patients with AML. After remission is obtained those patients who have a matched sibling donor undergo allogeneic hematopoietic stem cell (HSC) transplantation while those patients without an appropriate related donor are treated with additional cycles of aggressive chemotherapy.

The biologic heterogeneity of AML is becoming increasingly important therapeutically. The M3 subtype, associated with t(15;17) demonstrated either cytogenetically or molecularly, is currently treated with all *trans*-retinoic acid (ATRA) in addition to chemotherapy with high-dose cytarabine and daunorubicin. ATRA leads to differentiation of promyelocytic leukemia cells and can induce remission, but cure requires conventional chemotherapy as well. The use of arsenic trioxide has also been investigated in the treatment of this subtype of AML with favorable results.

Another biologically distinct subtype of AML occurs in children with Down syndrome (DS), M7, or megakaryocytic AML.

Using less intensive treatment, remission induction rate and overall survival of these children are dramatically superior to non-DS children with AML. It is important that children with DS receive appropriate treatment specifically designed to be less intensive. Biologic agents are increasingly being studied in the treatment of AML. COG continues to collect data from a recent trial using interleukin-2 to stimulate the immune system against residual leukemia cells. The development and early success of antibody-targeted cytotoxic agents such as gemtuzumab ozogamicin (Mylotarg, a humanized anti-CD33 monoclonal antibody conjugated with calicheamicin) are encouraging in the quest for therapeutic agents that result in higher survival rates.

B. SUPPORTIVE CARE

Tumor lysis syndrome rarely occurs during induction treatment of AML, as opposed to high-risk ALL. Nevertheless, when the diagnostic WBC cell count is greater than 100,000 or significant adenopathy or organomegaly

is present, one should alkalinize urine with intravenous sodium bicarbonate, maintain brisk urine output, and follow potassium, uric acid, and phosphorous lab values closely. Hyperleukocytosis (WBC > 100,000/ μ L) is a medical emergency and, in a symptomatic patient, requires rapid intervention such as leukapheresis to rapidly decrease the number of circulating blasts and thereby decrease hyperviscosity. Delaying transfusion of packed RBCs until the WBC can be decreased to below 100,000/ μ L avoids exacerbating hyperviscosity. It is also important to correct the coagulopathy commonly associated with M3, M4, or M5 subtypes prior to beginning induction chemotherapy. As with the treatment of ALL, all blood products should be irradiated and leukodepleted; pneumocystis prophylaxis must be administered during treatment and for several weeks afterward; and patients not immune to varicella must receive VZIG within 72 hours of exposure and prompt treatment with intravenous acyclovir for active infection.

Onset of fever (temperature $\geq 38.3^{\circ}\text{C}$) or chills associated with neutropenia requires prompt assessment, blood cultures from each lumen of a central venous line, other cultures such as throat or urine as appropriate, and prompt initiation of broad-spectrum intravenous antibiotics. Infections in this population of patients can rapidly become life-threatening. Because of the high incidence of invasive fungal infections, there should be a low threshold for initiating antifungal therapy. Filgrastim (granulocyte-colony-stimulating factor) is commonly used to stimulate granulocyte recovery during the treatment of AML and results in shorter periods of neutropenia and hospitalization. It must be stressed that the supportive care for this group of patients is as important as the leukemia-directed therapy and that this treatment should be carried out only at a tertiary pediatric cancer center.

Prognosis

Published results from various centers show a 50–60% survival rate at 5 years following first remission for those patients that do not have matched sibling HSC donors. Patients with matched sibling donors fare slightly better, with 5-year survival rates of 60–70% after allogeneic HSC transplantation.

As treatment becomes more sophisticated, outcome is increasingly related to the subtype of AML. Currently, AML with t(8;21), t(15;17), or in children with DS has the most favorable prognosis, with 65–75% long-term survival using modern treatments. The least favorable outcome occurs in AML with monosomy 7 or 5, 7q, 5q-, or 11q23 cytogenetic abnormalities.

MYELOPROLIFERATIVE DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Leukocytosis with predominance of immature cells.*
- *Often indolent course.*
- *Fever, bone pain, respiratory symptoms.*
- *Hepatosplenomegaly*

Myeloproliferative diseases in children are relatively rare. They are characterized by ineffective hematopoiesis that results in excessive peripheral blood counts. The three most important types are chronic myelogenous leukemia (CML), which accounts for less than 5% of the childhood leukemias, transient myeloproliferative disorder (TMD) in children with Down syndrome, and juvenile myelomonocytic leukemia (Table 28–2).

1. Chronic Myelogenous Leukemia

General Considerations

CML with translocation of chromosomes 9 and 22 (the Philadelphia chromosome, Ph⁺) is identical to adult Ph⁺ CML. Translocation 9;22 results in the fusion of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The resulting fusion protein is a constitutively active tyrosine kinase that interacts with a variety of effector proteins and allows for deregulated cellular proliferation, decreased adherence of cells to the bone marrow extracellular matrix, and resistance to apoptosis. The disease usually progresses within 3 years to an accelerated phase and then to a blast crisis. It is generally accepted that Ph⁺ cells have an increased sus-

Table 28–2. Comparison of JMML, CML, and TMD

	JMML	CML	TMD
Age at onset	<2 years old	>3 years old	<3 months old
Clinical presentation	Abrupt onset; exzematoid skin rash, marked lymphadenopathy, bleeding tendency, moderate hepatosplenomegaly, fever	Nonspecific constitutional complaints, massive splenomegaly, variable hepatomegaly	DS features, often no or few symptoms; or hepatosplenomegaly, respiratory symptoms
Chromosomal alterations	Monosomy or del (7q) in 20% of patients	t(9;22)	Constitutional trisomy 21, but usually no other abnormality
Laboratory features	Moderate leukocytosis (>10,000/ μ L), thrombocytopenia, monocytosis (>1000/ μ L), elevated fetal hemoglobin, normal to diminished leukocyte alkaline phosphatase, elevated muramidase	Marked leukocytosis (>100,000/ μ L), normal to elevated platelet count, decreased to absent leukocyte alkaline phosphatase, usually normal muramidase	Variable leukocytosis, normal to high platelet count, large platelets, myeloblasts

JMML = juvenile myelomonocytic leukemia; CML = chronic myelogenous leukemia; TMD = transient myeloproliferative disorder; DS = Down syndrome

ceptibility to the acquisition of additional molecular changes that lead to the accelerated and blast phases of disease.

Clinical and Laboratory Findings

Patients with CML may present with nonspecific complaints similar to those of acute leukemia, including bone pain, fever, night sweats, and fatigue. Those patients with a total WBC count of >100,000/ μ L may have symptoms of leukostasis, such as dyspnea, priapism, or neurologic abnormalities. Physical findings may include fever, pallor, ecchymoses, and hepatosplenomegaly. Anemia, thrombocytosis, and leukocytosis are frequent laboratory findings. The peripheral smear is usually diagnostic with a characteristic predominance of myeloid cells in all stages of maturation and relatively few blasts.

Treatment and Prognosis

Historically, hydroxyurea or busulfan has been used to reduce or eliminate Ph⁺ cells. However, HSC transplantation is the only consistently curative intervention. Reported survival rates for patients younger than age 20 years transplanted in the chronic phase from matched related donors are 70–80%. Unrelated stem cell transplants result in survival rates of 50–65%.

The understanding of the molecular mechanisms involved in the pathogenesis of CML has led to the ratio-

nal design of molecularly targeted therapy. Imatinib mesylate (Gleevec) is a tyrosine kinase inhibitor that has had dramatic success in the treatment of CML, with most adults achieving cytogenetic remission. However, some patients are resistant to imatinib, and its role in the long-term management of children with CML awaits further studies.

2. Transient Myeloproliferative Disorder

General Considerations

TMD is unique to patients with trisomy 21 or mosaicism for trisomy 21. It is characterized by uncontrolled proliferation of blasts, usually of megakaryocytic origin, during early infancy and spontaneous resolution. The pathogenesis of this process is not well understood, although mutations in the *GATA1* gene have recently been implicated as initial events.

Although the true incidence is unknown, it is estimated to occur in up to 10% of patients with Down syndrome. Despite the fact that the process usually resolves by 3 months of age, organ infiltration may cause significant morbidity and mortality.

Clinical Findings, Treatment, and Prognosis

Patients can present with hydrops fetalis, pericardial or pleural effusions, or hepatic fibrosis. More frequently,

they are asymptomatic or only minimally ill. Therefore, treatment is primarily supportive. Patients without symptoms are not treated, and those with organ dysfunction receive low doses of chemotherapy or leukopheresis (or both) to reduce peripheral blood blast counts. Although patients with TMD have apparent resolution of the process, approximately 30% go on to develop acute megakaryoblastic leukemia (AML M7) within 3 years.

3. Juvenile Myelomonocytic Leukemia

Clinical and Laboratory Findings

Juvenile myelomonocytic leukemia (JMML), accounts for approximately one third of the myelodysplastic and myeloproliferative disorders in childhood. Patients with neurofibromatosis type 1 (NF-1) are at higher risk of JMML than the general population. It typically occurs in infants and very young children and is occasionally associated with monosomy 7 or a deletion of the long arm of chromosome 7.

Clinical Findings, Treatment, and Prognosis

JMML patients present similarly to those with other hematopoietic malignancies, with lymphadenopathy, hepatosplenomegaly, skin rash, or respiratory symptoms. Patients may have stigmata of NF-1 with neurofibromas or café au lait spots. Laboratory findings include anemia, thrombocytopenia, leukocytosis with monocytosis, and elevated fetal hemoglobin.

The results of chemotherapy for children with JMML have been disappointing, with estimated survival rates of less than 30%. Approximately 40–45% of patients are projected to survive long term using HSC transplantation, although optimizing conditioning regimens and donor selection may improve these results.

BRAIN TUMORS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Classic triad: morning headache, vomiting, and papilledema.*
- *Increasing head circumference, cranial nerve palsies, dysarthria, ataxia, hemiplegia, papilledema, hyperreflexia, macrocephaly, cracked pot sign.*
- *Seizures, personality change, blurred vision, diplopia, weakness, decreased coordination, precocious puberty.*

General Considerations

The classic triad of morning headache, vomiting, and papilledema is present in less than 30% of children at presentation. School failure and personality changes are common in older children. Irritability, failure to thrive, and delayed development are common in very young children with brain tumors. Recent-onset head tilt can result from a posterior fossa tumor.

Brain tumors are the most common solid tumors of childhood, accounting for 1500–2000 new malignancies in children each year in the United States and for 25–30% of all childhood cancers. In general, children with brain tumors have a better prognosis than do adults. Favorable outcome occurs most commonly with low-grade and fully resectable tumors. Unfortunately, cranial irradiation in young children can have significant neuropsychological, intellectual, and endocrinologic sequelae.

Brain tumors in childhood are biologically and histologically heterogeneous, ranging from low-grade localized lesions to high-grade tumors with neuraxis dissemination. High-dose systemic chemotherapy is being used more frequently, especially in young children with high-grade tumors, in an effort to delay, decrease, or completely avoid cranial irradiation. Such intensive treatment may be accompanied by autologous HSCT or peripheral stem cell reconstitution.

The causes of pediatric brain tumors are unknown. The risk of developing astrocytomas is increased in children with neurofibromatosis or tuberous sclerosis. Several studies show that some childhood brain tumors occur in families with increased genetic susceptibility to childhood cancers in general, brain tumors, or leukemia and lymphoma. An excess of seizures has been observed in relatives of children with astrocytoma. Certain pediatric brain tumors such as ependymoma have been linked to polyomavirus, but the exact relationship is unknown. The risk of developing a brain tumor is increased in children who received cranial irradiation for treatment of meningeal leukemia.

Because pediatric brain tumors are rare, they are often misdiagnosed or diagnosed late; most pediatricians see no more than two children with brain tumors during their careers.

Clinical Findings

A. SYMPTOMS AND SIGNS

Clinical findings at presentation vary depending on the child's age and the tumor's location. Children younger than age 2 years more commonly have infratentorial tumors. Children with such tumors usually present with nonspecific symptoms such as vomiting, unsteadiness, lethargy, and irritability. Signs may be surprisingly few or may include macrocephaly, ataxia, hyperreflexia, and cranial nerve palsies. Because the head can expand in young children, papilledema is usually absent. Measuring head circumference and observing gait are essential in evaluating a child for possible brain tumor. Eye findings and apparent visual disturbances such as difficulty tracking can occur in association with optic pathway tumors such as optic glioma. Optic glioma occurring in a young child is often associated with neurofibromatosis.

Older children more commonly have supratentorial tumors, which are associated with headache, visual symptoms, seizures, and focal neurologic deficits. Initial presenting features are often nonspecific. School failure and personality changes are common. Vaguely described visual disturbance is often present, but the child must be directly asked. Headaches are common, but they often will not be predominantly in the morning. The headaches may be confused with migraine.

Older children with infratentorial tumors characteristically present with symptoms and signs of hydrocephalus, which include progressively worsening morning headache and vomiting, gait unsteadiness, double vision, and papilledema. Cerebellar astrocytomas enlarge slowly, and symptoms may worsen over several months. Morning vomiting may be the only symptom of posterior fossa ependymomas, which originate in the

floor of the fourth ventricle near the vomiting center. Children with brainstem tumors may present with facial and extraocular muscle palsies, ataxia, and hemiparesis; hydrocephalus occurs in approximately 25% of these patients at diagnosis.

B. IMAGING AND STAGING

In addition to the tumor biopsy, neuraxis imaging studies are obtained to determine whether dissemination has occurred. It is unusual for brain tumors in children and adolescents to disseminate outside of the CNS.

Magnetic resonance imaging (MRI) has become the preferred diagnostic study for pediatric brain tumors. MRI provides better definition of the tumor and delineates indolent gliomas that may not be seen on computed tomography (CT) scan. In contrast, a CT scan can be done in less than 10 minutes—as opposed to the 30 minutes required for an MRI scan—and is still useful if an urgent diagnostic study is necessary or to detect calcification of a tumor. Both scans are generally done with and without contrast enhancement. Contrast enhances regions where the blood–brain barrier is disrupted. Postoperative scans to document the extent of tumor resection should be obtained within 48 hours after surgery to avoid postsurgical enhancement.

Imaging of the entire neuraxis and CSF cytologic examination should be part of the diagnostic evaluation for patients with tumors such as medulloblastoma, ependymoma, and pineal region tumors. Diagnosis of neuraxis drop metastases (tumor spread along the neuraxis) can be accomplished by gadolinium-enhanced MRI incorporating sagittal and axial views. MRI of the spine should be obtained preoperatively in all children with midline tumors of the fourth ventricle or cerebellum. A CSF sample should be obtained during the diagnostic surgery. Lumbar CSF is preferred over ventricular CSF for cytologic examination. Levels of biomarkers in the blood and CSF, such as human chorionic gonadotropin (HCG) and α -fetoprotein (AFP), may be helpful at diagnosis and in follow-up. HCG and AFP should be obtained from the blood preoperatively for all pineal and suprasellar tumors.

The neurosurgeon should discuss staging and sample collection with an oncologist before surgery in a child newly presenting with a scan suggestive of brain tumor.

C. CLASSIFICATION

About 50% of the common pediatric brain tumors occur above the tentorium and 50% in the posterior fossa. In the very young child, posterior fossa tumors are more common. Most childhood brain tumors can be divided into two categories according to the cell of origin: (1) glial tumors such as astrocytomas and ependymomas or (2) nonglial tumors such as medul-

loblastoma and other primitive neuroectodermal tumors. Some tumors contain both glial and neural elements (eg, ganglioglioma). A group of less common CNS tumors do not fit into either category (ie, craniopharyngiomas, germ cell tumors, choroid plexus tumors, and meningiomas). Low-grade and high-grade tumors are found in most categories. Table 28–3 lists the locations and frequencies of the common pediatric brain tumors.

Astrocytoma is the most common brain tumor of childhood. Most are low-grade tumors found in the posterior fossa with a bland cellular morphology and few or no mitotic figures. Low-grade astrocytomas are in many cases curable by complete surgical excision alone. Chemotherapy is effective in low-grade astrocytomas.

Medulloblastoma and related primitive neuroectodermal tumors are the most common high-grade brain tumors in children. These tumors usually occur in the first decade of life, with a peak incidence between ages 5 and 10 years and a female-to-male ratio of 2.1:1.3. These tumors typically arise in the midline cerebellar vermis, with variable extension into the fourth ventricle. Reports of neuraxis dissemination at diagnosis range from 10% to 46% of patients. Prognostic factors are outlined in Table 28–4.

Brainstem tumors are third in frequency of occurrence in children. They are frequently of astrocytic origin and often are high-grade. Children with tumors that diffusely infiltrate the brainstem and involve primarily the pons have a long-term survival rate of less than 15%. Brainstem tumors that occur above or below the pons and grow in an eccentric or cystic manner

Table 28–3. Location and frequency of common pediatric brain tumors.

Location	Frequency of Occurrence (%)
Hemispheric	37
Low-grade astrocytoma	23
High-grade astrocytoma	11
Other	3
Posterior fossa	49
Medulloblastoma	15
Cerebellar astrocytoma	15
Brainstem glioma	15
Ependymoma	4
Midline	14
Craniopharyngioma	8
Chiasmatal glioma	4
Pineal region tumor	2

Table 28–4. Prognostic factors in children with medulloblastoma.

Factor	Favorable	Unfavorable
Extent of disease	Nondisseminated	Disseminated
Size of primary tumor after surgery	≤ 3 cm (completely resected)	> 3 cm
Histologic features	Undifferentiated	Foci of glial, ependymal, or neuronal differentiation
Age	≥ 4 years	< 4 years

have a somewhat better outcome. Exophytic tumors in this location may be amenable to surgery. Generally, brainstem tumors are treated without a tissue diagnosis.

Other brain tumors such as ependymomas, germ cell tumors, choroid plexus tumors, and craniopharyngiomas are less common, and each is associated with unique diagnostic and therapeutic challenges.

Treatment

A. SUPPORTIVE CARE

Dexamethasone should be started prior to initial surgery (0.5–1 mg/kg initially, then 0.25–0.5 mg/kg/d in four divided doses). Anticonvulsants (usually phenytoin, 4–8 mg/kg/d) should be started if the child has had a seizure or if the surgical approach is likely to induce seizures. Because postoperative treatment of young children with high-grade brain tumors incorporates increasingly more intensive systemic chemotherapy, consideration should also be given to the use of prophylaxis for prevention of oral candidiasis and *Pneumocystis* infection. Dexamethasone and phenytoin potentially reduce the effectiveness of chemotherapy and should be discontinued as soon after surgery as possible.

Optimum care for the pediatric patient with a brain tumor requires a multidisciplinary team including subspecialists in pediatric neurosurgery, neuro-oncology, neurology, endocrinology, neuropsychology, radiation therapy, and rehabilitation medicine, as well as highly specialized nurses, social workers, and staff in physical therapy, occupational therapy, and speech and language science.

B. SPECIFIC THERAPY

The goal of treatment is to eradicate the tumor with the least short- and long-term morbidity. Long-term neuropsychological morbidity becomes an especially im-

portant issue related to deficits caused by the tumor itself and the sequelae of treatment. Meticulous surgical removal of as much tumor as possible is generally the preferred initial approach. Technologic advances in the operating microscope, the ultrasonic tissue aspirator, and the CO₂ laser (which is less commonly used in pediatric brain tumor surgery); the accuracy of computerized stereotactic resection; and the availability of intraoperative monitoring techniques such as evoked potentials and electrocorticography have increased the feasibility and safety of surgical resection of many pediatric brain tumors. Second-look surgery after chemotherapy is increasingly being used when tumors are incompletely resected at initial surgery.

Radiation therapy for pediatric brain tumors is in a state of evolution. For tumors with a high probability of neuraxis dissemination (eg, medulloblastoma), craniospinal radiation is still standard therapy in children older than age 3 years. In others (eg, ependymoma), craniospinal radiation has been abandoned because neuraxis dissemination at first relapse is rare. Approaches to the delivery of radiation to minimize the adverse effects on normal brain tissue are being explored and include stereotactic radiation and the use of three-dimensional treatment planning.

Chemotherapy is effective in treating low-grade and malignant astrocytomas and medulloblastomas. A series of brain tumor protocols for children younger than age 3 years involved administering intensive chemotherapy after tumor resection and delaying or omitting radiation therapy. The results of these trials have generally been disappointing but have taught valuable lessons regarding the varying responses to chemotherapy of different tumor types. Future trials may give shorter courses of more intense chemotherapy followed by conformal radiotherapy. Conformal techniques allow the delivery of radiation to strictly defined fields and may limit side effects.

In older children with malignant glioma, the current approach would be surgical resection of the tumor and combined-modality treatment with irradiation and intensive chemotherapy. In patients with glioblastoma, the use of high-dose chemotherapy and autologous bone marrow or peripheral stem cell reconstitution is being studied. Initial results are promising, but the toxicity of such therapy remains a concern. Surgery is not indicated for diffuse brainstem gliomas. Traditional treatment of these tumors has been local irradiation. Hyperfractionation to increase the dose from the conventional 54 Gy to 72–78 Gy showed no apparent benefit in a recent CCG study. New approaches are needed for this prognostically poor tumor.

The treatment of low-grade astrocytomas is evolving. Increasing numbers of young children are receiving anti-tumor chemotherapeutic agents such as carboplatin and vincristine after incomplete resection of these tumors.

The role of irradiation after subtotal resection even in older children is being questioned. A CCG study is currently evaluating two different chemotherapy regimens in the treatment of progressive low-grade astrocytomas.

Prognosis

Despite improvements in surgery and radiation therapy, the outlook for cure remains poor for children with high-grade glial tumors. For children with high-grade gliomas, an early CCG study showed a 45% progression-free survival rate for children who received radiation therapy and chemotherapy. A follow-up CCG study in which all patients had chemotherapy and radiation therapy showed a 5-year progression-free survival rate of 36%. There is a possibility of effective salvage therapy with high-dose chemotherapy for children who relapse. In addition, the extent of resection appeared to correlate positively with prognosis, with a 3-year progression-free survival rate of 17% for patients receiving biopsy only, 29–32% for patients receiving partial or subtotal resections, and 54% for those receiving 90% resections. Biologic factors that may affect survival are being increasingly recognized. The prognosis for diffuse pontine gliomas remains very poor, with no benefit from high-dose chemotherapy plus radiation versus radiation alone.

The 5- and even 10-year survival rate for low-grade astrocytomas of childhood is 60–90%. However, prognosis depends on both site and grade. A child with a pilocytic astrocytoma of the cerebellum has a considerably better prognosis than a child with a fibrillary astrocytoma of the cerebral cortex. For recurrent or progressive low-grade astrocytoma of childhood, relatively moderate chemotherapy may improve the likelihood of survival.

Conventional craniospinal irradiation for children with low-stage medulloblastoma results in survival rates of 60–90%. Ten-year survival rates are lower (40–60%). Chemotherapy allows a reduction in the craniospinal radiation dose while preserving survival rates for average-risk patients. However, even reduced-dose craniospinal radiation has an adverse effect on intellect, especially in children younger than 7 years of age. Five-year survival rates for high-risk medulloblastoma have been 25–40%, but recent trials suggest a dramatically improved prognosis for patients receiving intensive chemotherapy and radiation. Children with supratentorial primitive neuroectodermal tumors also benefit from the addition of chemotherapy to craniospinal radiation.

Major challenges remain in treating brain tumors in children younger than age 3 years and in treating brainstem gliomas and malignant gliomas. The increasing emphasis is on the quality of life of survivors, not just the survival rate.

LYMPHOMAS AND LYMPHOPROLIFERATIVE DISORDERS

The term “lymphoma” refers to a malignant proliferation of lymphoid cells, usually in association with and arising from lymphoid tissues (ie, lymph nodes, thymus, spleen). In contrast, the term “leukemia” refers to a malignancy arising from the bone marrow, which may include lymphoid cells. Because lymphomas can involve the bone marrow, the distinction between the two can be confusing. The diagnosis of lymphoma is a common one among childhood cancers, accounting for 10–15% of all malignancies. The most common form is Hodgkin disease, which represents nearly half of all cases. The remaining subtypes, referred to collectively as non-Hodgkin lymphoma, are divided into four main groups: lymphoblastic, small non-cleaved-cell, large B-cell, and anaplastic large cell lymphomas.

In contrast to lymphomas, lymphoproliferative disorders (LPDs) are quite rare in the general population. Most are polyclonal, nonmalignant (though often life-threatening) accumulations of lymphocytes that occur when the immune system fails to control virally transformed lymphocytes. However, a malignant monoclonal proliferation can also arise. The transplant-associated LPDs arise in patients immunosuppressed to prevent solid organ or bone marrow transplant rejection. In highly selected populations, including liver and heart transplant patients, these disorders are a significant problem. Spontaneous LPDs occur in immunodeficient individuals and, less commonly, in immunocompetent persons.

1. Hodgkin Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Painless cervical (70–80%) or supraclavicular (25%) adenopathy; mediastinal mass (50%).*

- *Fatigue, anorexia, weight loss, fever, night sweats, pruritus, cough.*

General Considerations

Children with Hodgkin disease have a better response to treatment than do adults, with a 75% overall survival rate at more than 20 years following diagnosis. Although adult therapies are applicable, the management of Hodgkin disease in children younger than age 18 years frequently differs. Because excellent disease control can result from several different therapeutic approaches, selection of staging procedures [radiographic, surgical, or other procedures to determine additional location(s) of disease] and treatment are often based on the potential long-term toxicity associated with the intervention.

Although Hodgkin disease represents 50% of the lymphomas of childhood, only 15% of all cases occur in children age 16 years or younger. Children younger than age 5 years account for 3% of childhood cases, whereas 60% of cases occur in the 10- to 16-year age group. There is a 4:1 male predominance in the first decade. Notably, in underdeveloped countries the age distribution is quite different, with a peak incidence in younger children.

Hodgkin disease is subdivided into four histologic groups, and the distribution in children parallels that of adults: lymphocyte-predominant (10–20%); nodular sclerosing (40–60%) (increases with age); mixed cellularity (20–40%); and lymphocyte-depleted (5–10%). Prognosis is independent of subclassification, with appropriate therapy based on stage (see Staging section).

Clinical Findings

A. SYMPTOMS AND SIGNS

Children with Hodgkin disease usually present with painless cervical adenopathy. The lymph nodes often feel firmer than inflammatory nodes and have a rubbery texture. They may be discrete or matted together and are not fixed to surrounding tissue. The growth rate is variable, and involved nodes may wax and wane in size over weeks to months.

As Hodgkin disease nearly always arises in lymph nodes and spreads to contiguous nodal groups, a detailed examination of all nodal sites is mandatory. Lymphadenopathy is common in children, so the decision to perform biopsy is often difficult or delayed for a prolonged period. Indications for consideration of early lymph node biopsy include lack of identifiable infection in the region drained by the enlarged node, a node

greater than 2 cm in size, supraclavicular adenopathy or abnormal chest radiograph, and lymphadenopathy increasing in size after 2 weeks or failing to resolve within 4–8 weeks.

Constitutional symptoms occur in about one third of children at presentation. Symptoms of fever greater than 38°C, weight loss of 10%, and drenching night sweats are defined by the Ann Arbor staging criteria as B symptoms. The A designation refers to the absence of these symptoms. B symptoms are of prognostic value, and more aggressive therapy is usually required for cure. Generalized pruritus and pain with alcohol ingestion may also occur.

Half of patients have asymptomatic mediastinal disease (adenopathy or anterior mediastinal mass), although symptoms due to compression of vital structures in the thorax may occur. A chest radiograph should be obtained when lymphoma is being considered. The mediastinum must be evaluated thoroughly before any surgical procedure is undertaken to avoid airway obstruction or cardiovascular collapse during anesthesia and possible death. Splenomegaly or hepatomegaly is generally associated with advanced disease.

B. LABORATORY FINDINGS

The CBC is usually normal, although anemia, neutrophilia, eosinophilia, and thrombocytosis may be present. The erythrocyte sedimentation rate and other acute-phase reactants are often elevated and can serve as markers of disease activity. Immunologic abnormalities occur, particularly in cell-mediated immunity, and anergy is common in advanced-stage disease at diagnosis. Autoantibody phenomena such as hemolytic anemia and an idiopathic thrombocytopenic purpura-like picture have been reported.

C. STAGING

Staging of Hodgkin disease determines treatment and prognosis. The most common staging system is the Ann Arbor classification that describes extent of disease by I–IV and symptoms by an A or a B suffix (eg, stage IIIB). A systematic search for thoracic disease includes chest radiography and CT scan. Assessment of abdominal and pelvic disease is usually accomplished by CT scan. Bilateral bone marrow aspirates and biopsies are performed. Technetium bone scanning may show bony involvement and is usually reserved for patients with bone pain, as bone involvement is rare. Gallium scanning defines gallium-avid tumors and is most useful in evaluating residual mediastinal disease at the completion of treatment. Positron emission tomography is increasingly used in the staging and follow-up of patients with Hodgkin disease.

The staging laparotomy in pediatrics is rarely performed because almost all patients are given systemic

chemotherapy rather than radiation. Although excellent disease control with radiation therapy can be achieved in laparotomy-staged children, this option must be weighed against the toxicities of high-dose, extended-field radiation in prepubertal children and the complications of laparotomy, including postsplenectomy sepsis. Reports linking splenectomy with secondary acute myelogenous leukemia following Hodgkin disease therapy are particularly disturbing.

D. PATHOLOGY

The diagnosis of Hodgkin disease requires the presence of the Reed–Sternberg cell or its variants in tissue. When Reed–Sternberg cells are scanty the diagnosis becomes difficult. Reed–Sternberg cells are germinal-center B cells that have undergone malignant transformation. The molecular biology of Reed–Sternberg cell malignant transformation still remains to be elucidated, although it is interesting to note that nearly 20% of these tumors in developed countries are positive for EBV.

Treatment & Prognosis

To achieve long-term disease-free survival while minimizing treatment toxicity, Hodgkin disease is increasingly treated by chemotherapy even in stage I and stage II disease—and less often by radiation therapy.

Several combinations of chemotherapeutic agents are effective, but the most commonly used are MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) and ABVD (adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine). These regimens are non-cross-resistant. When these schedules are alternated, exposure to an individual drug is decreased, and the toxicities associated with cumulative doses are minimized. The combination of cyclophosphamide, cytarabine, and etoposide is also being used increasingly.

Although risk-adapted chemotherapy alone is very effective in achieving cure, radiation continues to play a role in the treatment of childhood Hodgkin disease, because combined-modality therapy may increase the cure rate. The use of radiation therapy at the end of risk-adapted chemotherapy when no residual disease is present appears to improve short-term, event-free survival, but its benefit for long-term survival remains to be demonstrated.

Current treatment gives children with stage I and stage II Hodgkin disease at least a 90% disease-free likelihood of survival 5 years after diagnosis. Because two thirds of all relapses occur within 2 years after diagnosis and because relapse rarely occurs beyond 4 years, 5-year disease-free survival generally equates with cure. In more advanced disease (stage III and stage IV), 5-year

event-free survival rates range from over 60% to 90%. With more patients being long-term survivors of Hodgkin disease, the risk of secondary malignancies, both leukemias and solid tumors, is becoming more apparent. The type of tumor depends on the treatments employed, but the risk is clearly greatest among those who are younger at diagnosis. Therefore, elucidating the optimal treatment strategy that minimizes such risk should be the goal of future studies.

Treatment of relapsed Hodgkin disease is usually successful and involves radiation therapy in combination with chemotherapy. An alternative is autologous or allogeneic hematopoietic stem cell transplant, which may improve survival rates.

2. Non-Hodgkin Lymphoma

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *Cough, dyspnea, orthopnea, swelling of the face, lymphadenopathy, mediastinal mass, pleural effusion.*
- *Abdominal pain, abdominal distention, vomiting, constipation, abdominal mass, ascites, hepatosplenomegaly.*
- *Adenopathy, fevers, neurologic deficit, skin lesions.*

General Considerations

Non-Hodgkin lymphomas (NHLs) are a diverse group of cancers accounting for 5–10% of malignancies in children younger than age 15 years (about 500 new

cases arise per year in the United States). The incidence of NHLs increases with age. Children age 15 years or younger account for only 3% of all cases of NHLs; it is uncommon before age 5 years. There is a male predominance of approximately 3:1. In equatorial Africa, NHLs cause almost 50% of pediatric malignancies.

Children with congenital or acquired immune deficiencies (eg, Wiskott–Aldrich syndrome, severe combined immunodeficiency syndrome, X-linked lymphoproliferative syndrome, HIV infection, immunosuppressive therapy following solid organ or marrow transplantation) have an increased risk of developing NHLs. It has been estimated that their risk is 100–10,000 times that of age-matched control subjects.

However, most children who develop NHL are immunologically normal. Animal models suggest a viral contribution to the pathogenesis of NHL, and there is evidence of viral involvement in human NHL as well. In equatorial Africa, 95% of Burkitt lymphomas contain DNA from the Epstein–Barr virus. But in North America, less than 20% of Burkitt tumors contain the EBV genome. The role of other viruses, such as human herpesviruses 6 and 8, disturbances in host immunologic defenses, chronic immunostimulation, and specific chromosomal rearrangements, is under investigation as potential triggers in the development of NHL.

Unlike adult NHL, virtually all childhood NHLs are rapidly proliferating, high-grade, diffuse malignancies. These tumors exhibit aggressive behavior but are usually very responsive to treatment. Nearly all pediatric NHLs are histologically classified into four main groups: lymphoblastic lymphoma (LL), small non-cleaved-cell lymphoma (Burkitt lymphoma [BL] and Burkitt-like lymphoma [BLL]), large B-cell lymphoma (LBCL), and anaplastic large cell lymphoma (ALCL) (Table 28–5). Malignant lymphoma cells often retain morphologic or immunohistochemical features similar to those of the lymphoid lineage cell from which they are derived. Cell membrane markers determined by immunophenotyping can therefore help clarify the origins of these cancers and serve as an adjunct to histologic classification. Typically, LL is associated with T-cell surface markers, whereas BL and BLL have a B-cell phenotype such as surface immunoglobulins. LBCL seems to arise from cells of the germinal center of lymph nodes and express B-cell markers. ALCL usually has T-cell or null-cell markers.

Recurrent cytogenetic abnormalities can be diagnostic in NHL. Burkitt lymphomas usually carry a translocation involving chromosomes 8 and 14 (or a variant thereof) that juxtaposes a highly active immunoglobulin promoter with the *c-myc* gene. Deregulation of the protein expressed by this gene promotes cellular proliferation. An analogous translocation occurs in LL, in-

Table 28–5. Comparison of pediatric non-Hodgkin lymphomas.

	Lymphoblastic Lymphoma	Small Noncleaved Cell Lymphoma (BL and BLL)	Large B-Cell Lymphoma	Anaplastic Large Cell Lymphoma
Incidence (%)	30–40	35–50	10–15	10–15
Histopathologic features	Indistinguishable from ALL lymphoblasts	Large nucleus with prominent nucleoli surrounded by very basophilic cytoplasm that contains lipid vacuoles	Large cells with cleaved or non-cleaved nuclei	Large pleomorphic cells
Immunophenotype	Immature T cell	B cell	B cell	T cell or null cell
Cytogenetic markers	Translocations involving chromosome 14q11 and chromosome 7; interstitial deletions of chromosome 1	t(8;14), t(8;22), t(2;8)	Many	t(2;5)
Clinical presentation	Intrathoracic tumor, mediastinal mass (50–70%), lymphadenopathy above diaphragm (50–80%)	Intra-abdominal tumor (90%), jaw involvement (10–20% sporadic BL, 70% endemic BL), bone marrow involvement	Abdominal tumor most common; unusual sites: lung, face, brain, bone, testes, muscle	Lymphadenopathy, fever, weight loss, night sweats, extranodal sites including viscera and skin
Treatment	Similar to ALL therapy; 24 mos duration	Intensive administration of alkylating agents and methotrexate; CNS prophylaxis; 3–9 mos duration	Similar to therapy for BL/BLL	Similar to therapy for lymphoblastic lymphoma or BL/BLL

ALL = acute lymphoblastic leukemia; BL = Burkitt lymphoma; BLL = Burkitt-like lymphoma.

volving the T-cell receptor promoter and the *TAL1* gene. Another translocation occurs in ALCL [t(2;5)] that fuses the *NMP* gene (a transcription factor) to the *ALK* gene (a tyrosine kinase), thereby creating a new gene product.

Clinical Findings

A. SYMPTOMS AND SIGNS

Childhood NHLs can arise in any site of lymphoid tissue, including lymph nodes, the Waldeyer ring, Peyer patches, thymus, liver, and spleen. Common extralymphatic sites include bone, bone marrow, CNS, skin, and testes. Signs and symptoms at presentation are determined by the location of lesions and the degree of dissemination. Because NHL usually progresses very rapidly, the duration of symptoms is quite brief, from days to a few weeks. Nevertheless, children present with a limited number of syndromes, most of which correlate with cell type.

Children with LL often present with symptoms of airway compression (cough, dyspnea, orthopnea) or superior vena cava obstruction (facial edema, chemosis, plethora, venous engorgement), which are a result of

mediastinal disease. *These symptoms are a true emergency necessitating rapid diagnosis and treatment.* Pleural or pericardial effusions may further compromise the patient's respiratory and cardiovascular status. CNS and bone marrow involvement are not common at diagnosis. When bone marrow contains more than 25% lymphoblasts, patients are considered to have ALL.

Most patients with BL and BLL present with abdominal disease. Abdominal pain, distention, a right lower quadrant mass, or intussusception in a child older than age 5 years suggests the diagnosis of BL. Bone marrow involvement is common ($\leq 65\%$ of patients). BL is the most rapidly proliferating tumor known and has a high rate of spontaneous cell death as it outgrows its blood supply. Consequently, children presenting with massive abdominal disease frequently have metabolic abnormalities (hyperuricemia, hyperphosphatemia, and hyperkalemia) due to tumor lysis. These abnormalities can be aggravated if tumor infiltration of the kidney, urinary obstruction by tumor, or urate nephropathy interferes with renal function. Although similar histologically, numerous differences exist between cases of BL occurring in endemic areas of equatorial Africa and the sporadic cases of North America (Table 28–6).

Table 28–6. Comparison of endemic and sporadic^a Burkitt lymphoma.

	Endemic	Sporadic
Incidence	10 per 100,000	0.9 per 100,000
Cytogenetics	Chromosome 8 breakpoint upstream of <i>c-myc</i> locus	Chromosome 8 breakpoint within <i>c-myc</i> locus
EBV association	≥ 95%	≤ 20%
Disease sites at presentation	Jaw (58%), abdomen (58%), CNS (19%), orbit (11%), marrow (7%)	Jaw (7%), abdomen (91%), CNS (14%), orbit (1%), marrow (20%)

^aEBV = Epstein–Barr virus; CNS = central nervous system.

Large cell lymphomas are similar clinically to the small non–cleaved-cell lymphomas, although unusual sites of involvement are quite common, particularly with ALCL. Skin lesions, focal neurologic deficits, and pleural or peritoneal effusions without an obvious associated mass are frequently seen.

B. DIAGNOSTIC EVALUATION

Diagnosis is made by biopsy of involved tissue with histology, immunophenotyping, and cytogenetic studies. If mediastinal disease is present, general anesthesia must be avoided if the airway or vena cava is compromised by tumor. In these cases samples of pleural or ascitic fluid, bone marrow, or peripheral nodes obtained under local anesthesia may confirm the diagnosis. Major abdominal surgery and intestinal resection should be avoided in patients with an abdominal mass that is likely to be BL, as the tumor will regress rapidly with the initiation of chemotherapy. Following the diagnosis of NHLs, studies should be obtained to determine the extent of disease. The rapid growth of these tumors and the associated life-threatening complications demand that studies be done expeditiously so that specific therapy is not delayed.

After a thorough physical examination, a CBC, liver and renal function tests, and a biochemical profile (electrolytes, calcium, phosphorus, uric acid) should be obtained. LDH reflects tumor burden and can serve as a marker of disease activity. Imaging studies should include a chest radiograph and chest CT scan if the plain radiographs are abnormal, an abdominal ultrasound or CT scan, and possibly a gallium scan. Bone marrow and CSF examinations are also essential.

Treatment

A. SUPPORTIVE CARE

The management of life-threatening problems at presentation is critical. The most common complications are superior mediastinal syndrome and acute tumor lysis syndrome. Patients with airway compromise require prompt initiation of specific therapy. Because of the risk of general anesthesia in these patients, it is occasionally necessary to initiate steroids or low-dose radiation until the mass is small enough for a biopsy to be undertaken safely. Response to steroids and radiation is usually prompt (12–24 hours).

Tumor lysis syndrome should be anticipated in all patients who have NHL with a large tumor burden. Maintaining a brisk urine output (> 5 mL/kg/h) with intravenous fluids and diuretics is the key to management. Allopurinol will reduce serum uric acid, and alkalization of urine will increase its solubility. Because phosphate precipitates in alkaline urine, alkali administration should be discontinued if hyperphosphatemia occurs. Renal dialysis is occasionally necessary to control metabolic abnormalities. Every attempt should be made to correct or minimize metabolic abnormalities before initiating chemotherapy; however, this period of stabilization should not exceed 24–48 hours.

B. SPECIFIC THERAPY

Systemic chemotherapy is the bulwark of therapy for NHLs. All patients with NHL require intensive intrathecal chemotherapy for CNS prophylaxis. Surgical resection is not indicated unless the entire tumor can be resected safely, which is rare. Partial resection or debulking surgery has no role. Radiation therapy does not improve outcome, so its use is confined to exceptional circumstances.

Therapy for LL is generally based on treatment protocols designed for ALL and involves dose-intensive, multiagent chemotherapy. Moderately high-dose methotrexate is emerging as an important strategy for minimizing induction failures and CNS relapses. The duration of therapy in recent trials has ranged from 11 months to 2 years.

BL and BLL do not respond well to therapy based on ALL protocols. Protocols using alkylating agents and intermediate- to high-dose methotrexate administered intensively but for a relatively short time produce the highest cure rates. LBCL is treated similarly, whereas ALCL has been treated with BL and LL protocols.

Monoclonal antibodies such as rituximab (anti-CD20) allow for more targeted therapy of lymphomas and have been successful in improving outcomes in adults. Studies employing this type of therapy in children are underway in those with refractory or relapsed NHL.

Prognosis

A major predictor of outcome in NHL is the extent of disease at diagnosis. Ninety percent of patients with localized disease can expect long-term, disease-free survival, and patients with extensive disease on both sides of the diaphragm, CNS involvement, or bone marrow involvement in addition to a primary site have a 70–80% failure-free survival rate. Relapses occur early in NHL; patients with LL rarely have recurrences after 30 months from diagnosis, whereas patients with BL and BLL very rarely have recurrences beyond 1 year. Patients who experience relapse may have a chance for cure by autologous or allogeneic HSCT.

3. Lymphoproliferative Disorders

LPDs can be thought of as a part of a continuum with lymphomas. Whereas LPDs represent inappropriate, often polyclonal proliferations of nonmalignant lymphocytes, lymphomas represent the development of malignant clones, sometimes arising from recognized LPDs.

Post-Transplantation Lymphoproliferative Disorders

Post-transplantation lymphoproliferative disorders (PTLDs) arise in patient populations that have received substantial immunosuppressive medications for solid organ or bone marrow transplantation. In these patients, reactivation of latent EBV infection in B cells drives a polyclonal proliferation of these cells that is fatal if not halted. Occasionally a true lymphoma develops, often bearing a chromosomal translocation.

LPDs are an increasingly common and significant complication of transplantation. The incidence of PTLD ranges from approximately 2% to 15% of trans-

plant recipients, depending on the organ transplanted and the immunosuppressive regimen.
